T. R. Clark[1], *M. Carter*[2], *J. Stephenson*[3], *D. M. Costley*[4], *J. Martin*[5], *K. Williams*[6], *L. Browne*[7], *S. Bruck*[8], *L. Davies*[9] *and N. Sweller*[10], *(1)Education & Research, Autism Spectrum Australia (Aspect), Seven Hills, AUSTRALIA, (2)Department of Educational Studies, Macquarie University Special Education Centre, Sydney, Australia, (3)Institute of Early Childhood, Macquarie University Special Education Centre, sydney, Australia, (4)Autism Spectrum Australia (Aspect), Sydney, AUSTRALIA, (5)Internode, Adelaide, Australia, (6)Developmental Medicine, The Royal Children's Hospital, Parkville, VIC, Australia, (7)Macquarie University Special Education Centre, sydney, Australia, (8)Research, Autism Spectrum Australia (Aspect), sydney, Australia, (9)Autism SA, Adelaide, Australia, (10)Department of Psychology, Macquarie University Special Education Centre, Sydney, Australia*

Background: Different approaches to educational service delivery for children with ASD in regular schools are available, based on different conceptual and theoretical underpinnings. Nevertheless, there has been little comparative research examining outcomes and predictors of success under different models. Two approaches to the support of children with ASD in Australian primary schools are the Consultative model used by Autism SA in South Australia (SA) and the Satellite Class model used by Autism Spectrum Australia (Aspect) Aspect in New South Wales (NSW). The Satellite model provides placement into an autism specific class in regular school, with phased transition and support to mainstream when the child is adequately prepared. The Consultative model provides on-demand support in mainstream classes from the point of school entry.
Objectives: The objective of this research was to examine comparative outcomes and predictors of success across the two models of service delivery.
Methods: Â A four-year comparative pragmatic trial of the models was conducted with 85 children. Inclusion criteria for the project were that the child must have a formal diagnosis of Asperger's disorder or autistic disorder (DSM-IV), be functioning within or above the mild range of intellectual disability, be in their first four years of schooling at the project commencement. Data were collected twice yearly. Primary child outcomes identified prior to the commencement of the project related to continuity of placement, social behaviour, school engagement and adjustment. Primary outcomes for school staff and parents related to satisfaction with service delivery and perception of the success of placement. A multilevel model approach to data analysis was taken. Predictors of each outcome variable, including program model, were examined with data structured as rounds (repeated measure), nested within child, and nested within school (i.e., three-levels).
Results: Â Continuity of placement was high in both models. Satellite class transitions were lower than expected with many families electing to remain in satellite classes. With regard to child social skills and school engagement and adjustment, there was no significant difference between the models of service delivery, and the only significant predictor of both was teacher-rated academic competence. Mean level of rated placement success was high in both states across all respondents, typically scoring between 4 and 5 on a 5-point scale. Principal and teacher-rated success of placement was not different between states, and adaptive behaviour at pre-test was a significant predictor of successful outcome for both. Parents in NSW rated school placement in the satellite classes as more successful. Both parent and teacher ratings of success trended down across the study, and children with greater problem behaviours were rated as less successful by both. Both principals and parents rated support as being better in NSW.
Conclusions: Child outcomes were not significantly different but some differences were evident in perceived success of placement and satisfaction with support. Adaptive behaviour at pre-test was a predictor of rated success of placement. While intensity of support differed across the models of support, both included several basic features that are considered best practice in support of children with ASD.

208 **127.208** A Profile on ED Visits in Children Aged 6-12 with Autism Spectrum Disorders

G. Liu[1], *A. Pearl*[2], *K. Moyer*[1], *D. Ba*[1], *L. Kong*[1], *D. Leslie*[3] *and M. Murray*[1], *(1)Penn State College of Medicine, Hershey, PA, (2)Penn State Milton S. Hershey Medical Center, Penn State College of Medicine, Hummesltown, PA, (3)Penn State Milton S. Hershey Medical Center, Penn State College of Medicine, Hershey, PA*

Background: Â Research suggests the utilization of the emergency department by children and adolescents in the general population has steadily increased over the past decade. There is a need to better understand emergency department use by school age children with ASD, as the cost of medical care for children with ASD is greater despite the reported unmet need for service. Past studies have been descriptive in nature, and have outlined the common complaints of ED visits through caregiver-report data and small-scale retrospective chart reviews.
Objectives: Â In this study, we use a large, national healthcare claims database to examine emergency department utilization over nine years (2005 – 2013) in children aged 6 to 12 years with ASD. The goal of this study is to provide an assessment of ED visits as an indicator of the physical and mental health well-being of children with ASD as well as the healthcare service for them.
Methods: Â Using the 2005-2013 MarketScan® Commercial Claims and Encounters database, we identified cohorts of children aged 6-12 who had at least one ED visit during any of those years. We constructed a sub-cohort of children with at least two separate diagnoses of ASD (ICD 9 codes 299.0x and 299.8x) and a sub-cohort of children without ASD. We also broke down the entire cohort into annual cohorts. In each of the annual cohorts as well as in the combined cohort, we described the proportion of patients who visited the ED.
Results: As Figure 1 shows, through the last decade, ED visits among children aged 6-12 with ASD have remained steady with no apparent increase, although slightly higher than non-ASD children of the same age. This was in dramatic contrast to a previous study that showed steady increases in ED visits among adolescents aged 12-21. As shown in Figure 2, we also observed a slight increase in behavioral health-related ED visits among children with ASD, with almost 20% of ED visits being for a behavioral health issue in the most recent years. Multi-variable regression showed that, after adjusting for confounders such as age, gender, census region and type of health insurance plan, children with ASD were 50% more likely to have ED visits compared to children without ASD (adjusted odds ratio [aOR] 1.579, confidence interval [CI] 1.550-1.609). Among other confounders, sex also was significant associated with ED visits, with boys more likely to have ED visits than girls (OR: 1.214, CI: 1.209-1.219).
Conclusions: Our study revealed that the rate of ED visits among children aged 6-12 with ASD was fairly flat between 2005 and 2013, and was only slightly higher than the rate among children without ASD in the same age bracket. On the other hand, we observed a steady increase in ED visits primarily associated with behavioral health conditions, suggesting an ASD-related mental health crisis.

209 **127.209** A Profile on Hospitalization Subsequent to ED Visits in Adolescents with Autism Spectrum Disorders

G. Liu[1], *A. Pearl*[2], *K. Moyer*[1], *L. Kong*[1], *D. Leslie*[1] *and M. Murray*[1], *(1)Penn State College of Medicine, Hershey, PA, (2)Penn State Milton S. Hershey Medical Center, Penn State College of Medicine, Hummesltown, PA*

Background: The prevalence of ASD began to increase dramatically about a decade ago, and now the first wave of these children has approached adolescence and early adulthood. While early diagnosis and intervention have been the focus of the scientific and clinical communities, the population of adolescents with ASD has not received the same attention. Although various ASD-related healthcare services have been designed to better serve this population, it is relatively unknown how well they are being served.
Objectives: In this study, we use a large, national healthcare claims database to compare the healthcare utilization history (in-/out-patient medical records) of adolescents with and without ASD, with a focus on hospitalization due to emergency department visits. The goal of this study is to provide an assessment on patterns of hospitalizations subsequent to ED visits as an indicator of the physical and mental health well-being of adolescents with ASD.
Methods: Using the 2005-2013 MarketScan® Commercial Claims and Encounters database, we identified cohorts of patients who had at least one ED visit during any of those years. We constructed a sub-cohort of children with at least two separate diagnoses of ASD (ICD 9 codes 299.0x and 299.8x) and a sub-cohort of children without ASD. We also broke down the entire cohort into annual cohorts. In each of the annual cohorts as well as in the combined cohort, we described the proportion of patients whose ED visits resulted in subsequent hospitalizations. We also compared the hospital length of stay among ASD vs. non-ASD patients.
Results: Â As observed in Figure 1, a consistently higher proportion of adolescents with ASD had an ED visit leading to hospitalization than adolescents without ASD. In particular, the odds ratio (OR) of admission to hospital after ED among ASD and non-ASD patients was 4.226, with a 95% confidence interval (CI) of 4.047 – 4.412]. Older adolescents (28.22% ASD vs. 8.13% non-ASD for age 18-21; 27.39% ASD vs. 8.15% non-ASD for age 15-17) were more likely to be hospitalized after an ED visit than younger adolescents (22.92% ASD vs. 6.26% non-ASD for age 12-14). While males and females were equally likely to be hospitalized after ED visits among adolescents without ASD (7.61% male vs. 7.69% female), female adolescents with ASD were more likely than males (28.02% vs. 25.13%) to be admitted to the hospital after an ED visit. Adolescents with ASD were also more likely to stay in the hospital longer (average days of hospitalization: 6.38 ± 8.10) than adolescents without ASD (3.97 ± 5.65). Adolescents with ASD were more likely to be hospitalized 3 days or longer (70.76% vs. 51.13) and 7 days or longer (31.55% vs. 15.13%) than adolescents without ASD.
Conclusions: Our study showed a disconcertingly high proportion of adolescents with ASD who had hospitalizations subsequent to emergency department visits over the past decade or so. Furthermore, adolescents with ASD who were hospitalized had longer lengths of stay than adolescents without ASD, suggesting a vulnerability of having physical injuries and/or medical complications, potentially due to an ASD-related mental health crisis.

210 **127.210** Access to Diagnostic and Autism-Related Services in Under-Resourced and Minority Families: Barriers and Enablers for Families and Educational Service Providers

***B. Bronstein**, D. Straiton, M. Pellecchia, H. J. Nuske, E. Reisinger Blanch and D. S. Mandell, University of Pennsylvania, Philadelphia, PA*

Background: Children with ASD from under-resourced and ethnic minority families are diagnosed and enter treatment later than other children (Mandell et al., 2002). Common barriers to accessing care include socioeconomic factors, availability of medical treatment and insurance, and knowledge of child development. Although previous research has reported on potential barriers, it is still unclear which factors *enable* these families to access diagnostic or educational services. Further, little research has examined barriers and enablers related to delays in care for this population using first-hand information gained from qualitative interviews.
Objectives: To identify barriers to care and resources perceived as helpful in obtaining services for underserved minority families in a large city.
Methods: Focus groups (3) and interviews (11) were conducted in a large urban setting to learn about perceived barriers and facilitators to accessing evaluations and autism-specific services. Participants included 28 providers and 24 caregivers of recently diagnosed children with autism from under-resourced communities. Providers were those who worked with families that met the above criteria.
After coders established inter-rater reliability with the master coder (2 consecutive transcripts at $\varkappa$> .60), the qualitative data were analyzed in Dedoose using open coding and then thematic analysis. All transcripts were coded by two independent coders to insure inter-coder reliability.
Results: Several barriers to obtaining an ASD diagnosis as well as autism-related services were identified. Barriers included: (1) poor accessibility for non-native English speakers, (2) stigma related to the diagnosis, (3) absence of knowledge of ASD and the service system, (4) lack of financial resources and transportation, (5) provider's lack of cultural sensitivity, and (6) limited community resources (e.g., availability of local services).
Participants also reported on helpful resources. These included: (1) provider advocacy on behalf of the family, (2) providers taking the role of "students" of the family's culture, (3) providers creating culturally matched videos for parent training, (4) providers initiating parent engagement strategies (e.g., using texting as a mode of communication, including parents in goal development), (5) culture and language matched parent peers to help guide families, and (6) technology for language accessibility.
Conclusions: Caregivers and providers of children with ASD consistently identified similar barriers to accessing care for families from culturally diverse and under-resourced backgrounds. Common barriers such as language specific difficulties, stigma associated with ASD, and accessibility of services often lead to a delay in diagnosis and access to services for minority children with autism. However, participants also identified specific supports or enablers perceived as useful in obtaining a diagnosis or related services, such as, provider advocacy, culturally matched supports, and other language-based accommodations. These findings highlight important considerations for providers working with under-resourced and ethnic minority families and suggest a need for systemic changes in order to facilitate earlier access to an autism diagnosis and services in under-resourced communities.

211 **127.211** Access to Related Services for Students with Autism Spectrum Disorder in a Large School District

***J. Chow**[1], J. Williams[1], W. I. Shih[2] and C. Kasari[2], (1)University of California Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA*

Background: Disparities exist regarding diagnosis and access to services for individuals with Autism Spectrum Disorder (ASD). Students with ASD between the ages of 3 to 21 receive special education services and related services based on the Individuals with Disabilities Education Act (IDEA). Little research has been conducted on access to related services within a school district.
Objectives: RQ (1): Do categories of related services vary by race, gender, grade, and median income for students with ASD in 5th and 8thgrade? RQ (2): As students with ASD transition from 5th to 6th grade and 8th to 9th grade, what changes occur in the categories of related services and whether related services vary by race, gender, and median income?
Methods: Using secondary data analysis from a large urban school district, participants included 1,324 students with ASD in 5th and 8th grades in the 2012-2013 school year who matriculated to 6th and 9th grade, respectively, in the 2013-2014 school year. Twenty related services were recoded into six categories of related services (i.e., Health, Behavioral Support, Motor Skills, Senses, Academic, and Communication). The median income variable was created using student zip code and 2010 census data. Descriptive analyses and binary logistic regressions were conducted to determine if race, gender, grade, and median income served as predictors of whether or not students with ASD in 5th grade and 8thgrade received the categories of the related services. Since most students did not receive a change in the categories of related services (0=no change), regression analyses were not feasible. Instead, descriptive statistics were used to understand the types of changes that occurred as students transitioned from one grade level to the next without the use of the predictor variables.
Results: As hypothesized, median income predicted categories of related services. Median income predicted half of the categories of related services when controlling for gender, grade, and race. Latino and Asian students had lower odds of receiving Academic Support services compared to White students. Females were more likely to receive health services compared to males. Compared to 5th grade students, students in 8th grade were 1.406 times more likely to have an increase in behavioral support service. However, students in 8thgrade were less likely to receive health services compared to 5th grade students. Over 90% of students received no change in related services as they transitioned from one grade level to the next.
Conclusions: The study examined the types of related services students with ASD received as they transitioned from elementary to middle school and from middle to high school and whether disparities exist when accessing related services in school districts. Students received more related services based on family median income. Female students and White students received more services than their counterparts. Students with ASD who transitioned from 5th to 6th grade and 8th to 9th grade received little to no change in related services.

212 **127.212** Advancing Family-Centred Health Care for Autism and Related Conditions through Integrated Research

B. Rappaport[1]*, T. Savion-Lemieux*[2]*, I. Peltekova*[3] *and M. Elsabbagh*[4]*, (1)McGill University, Montreal, QC, Canada, (2)McGill University Health Centre, Montreal, QC, CANADA, (3)McGill University, Montreal, QC, CANADA, (4)McGill University, Montreal, CANADA*

Background: Relative to the large body of research available in autism, translation of evidence into sustainable improvements to care delivery is limited. Among the barriers to translation is that research in autism has traditionally been done in parallel or subsequent to care delivery. Moreover, families who participate in research are not always a representative group of health-services users, thus limiting generalizability of findings into clinical practice. The use of a learning healthcare system approach (e.g., Friedman et al., 2010) is one strategy to accelerate research and its translation of the best available knowledge into population health benefits.
Objectives: We conducted a clinical quality improvement study to identify strategies and tools that can enhance integration of research into routine care in tertiary diagnostic centres in the province of Quebec, Canada. Specifically, we used a qualitative approach to examine facilitators and barriers to capturing clinically valid and standardized phenotypic information derived from diagnostic assessments of children referred for ASD assessments.
Methods: We developed a focus group guide, based on a review and comparison of recommended gold standard local and international practices for routine autism diagnostic assessments (American Academy of Pediatrics, UK National Institute for Health and Care Excellence, and Quebec's College of Physicians/Order of Psychologists). Professionals in five multidisciplinary specialist diagnostic teams were invited to participate in a 90-minute focus group (n=30). Each focus group included 5-7 professionals (e.g., clinical coordinator, psychologist, psychiatrist, developmental pediatrician, speech and/or occupational therapist) from the same care team. Focus group questions prompted information about the team's structure, the routine diagnostic assessment, feedback to families, follow-up with families, and data management.
Results: Overall, we found high consistency between gold standard recommendations and diagnostic team reports of their team's practices. The use of standardized tools was consistently used to assess phenotypic information (e.g., core autism features and developmental skills). In contrast, there was a lack of consistency in measuring psychosocial domains, such as parental knowledge of ASD and parental coping skills. The main barriers to use of standardized tools, reported by clinicians, were limited time and/or resources and linguistic and cultural diversity in the target population. Overall, there was limited systematic capture of clinical data from the diagnostic process into a database. However, two of the care teams had research registries, where a proportion of families seen in their services are enrolled.
Conclusions: We found consistency across diagnostic teams in the constructs guiding assessment of ASD, despite variation in the degree of standardization. Clinical teams do not routinely capture phenotypic data in a systematic way, making it difficult to integrate or utilize clinical phenotypic information into research. Further analysis and follow up activities are now underway to develop strategies and tools to support harmonization of processes and clinical data capture during routine services. This approach is critical as autism research moves to 'Big Data', where the inclusion of representative populations will ultimately help accelerate the integration of research findings into clinical practice. This study demonstrates that further exploration of this area could lead to long-term health system improvement.

213 **127.213** An Assessment of "Empowerment" As a Measure of the Impact of Genetic Results on Families Affected By Autism and Related Neurodevelopmental Conditions

I. Peltekova[1]*, A. Yusuf*[1]*, D. Buhas*[2]*, R. Bruno*[3]*, J. Frei*[4] *and M. Elsabbagh*[5]*, (1)McGill University, Montreal, QC, CANADA, (2)Human Genetics, McGill University, Montreal, QC, Canada, (3)Research Institute of the McGill University Health Centre, Montreal, QC, CANADA, (4)McGill University, Montreal, QC, Canada, (5)McGill University, Montreal, CANADA*

Background: Â Genetic tests are standard of care for children with neurodevelopmental conditions. However, genetic results entail significant complexity. Qualitative studies suggest that genetic results have variable effects on families. However, little has been done to measure the impact of genetic results on families affected by autism and related neurodevelopmental conditions, due to the lack of validated and relevant tools. Recent research in patient reported outcome measures (PROMs) has established the construct of "empowerment" to describe patient benefits from genetic services. It suggests that individuals undergoing genetic counseling have "decisional", "cognitive", and "behavioral" control, "emotional regulation" and "hope". A novel PROM, the Genetic Counseling Outcome Scale (GCOS)-24, has been developed to measure empowerment in genetics. To date, there are no studies that specifically examine empowerment in families affected by neurodevelopmental conditions.
Objectives: Â Our goal is to assess the validity of a novel tool, the GCOS-24, which measures empowerment, in families of children with autism and related neurodevelopmental conditions undergoing genetic testing.
Methods: Â Data were drawn from the ongoing prospective cohort study "ASD Genome to Outcome", assessing genetic results impact on families with autism and related conditions. Parents are invited to the study because their child has been referred for clinical genetic testing, as part of his/her routine evaluation in the context of a neurodevelopmental diagnosis, like autism. In addition to other questionnaires, parents completed the GCOS-24, as well as a measure of parental stress, the Perceived Stress Scale (PSS), and distress, the Distress Thermometer (DT), prior to receiving genetic results for their affected child.
Results: Â Data is available on 28 families: 22 (78.6%) children have autism and 6 (21.4%) have developmental delay or intellectual disability. On average, children were 5.82 (*SD* = 3.31) years of age at entry into the study. Caregiver-reported empowerment, as measured by the GCOS-24, was significantly associated with parent stress, measured using the PSS (r = -0.404, p = 0.033), but not with distress, measured using the DT (r = -0.267, p = 0.169). Empowerment was not moderated by maternal education, family income or the child's diagnosis.
Conclusions: Consistent with findings from other studies assessing empowerment in the context of routine health services, we have validated the use of the GCOS-24 for autism and related neurodevelopmental disorders. However, this measure of "empowerment" was only moderately associated with parental stress, suggesting that the GCOS-24 may also be capturing a unique construct from stress. This is the first study exploring the validity of empowerment as a measure in biomedical research of autism. It offers a methodology for the systematic evaluation of the impact of genetic results on families affected by neurodevelopmental conditions.

214 **127.214** An Examination of Ongoing Case-Based Continuing Education Model for Behavior Analysts

K. O'Connor[1] *and J. K. Randolph*[2]*, (1)MU Thompson Center, Columbia, MO, (2)University of Missouri, Thompson Center for Autism and Neurodevelopmental Disorders, Columbia, MO*

Background:
There is limited research on the methods, social validity and efficacy of continuing education (CE) opportunities provided to behavior analysts. Continuing education is required of behavior analysts to maintain credentials and utilize best-practice. Given the limited data regarding CE preferences of behavior analysts, and potential impact of established CE opportunities, the purpose of this study was to examine the use of a monthly, online, Case-Based CE Model for behavior analysts working with clients with autism.
Objectives:
The objectives of this study were to examine the acceptability and efficacy (behavior analytic knowledge and intervention use), and quality (social validity) of the autism, Case-Based CE Model for behavior analysts. Data regarding: (a) types of CEs utilized, (b) acceptability of types of CEs (c) acceptability of the autism Case-Based CE Model, (d) behavior analytic knowledge (pre/post assessments) and (e) reported use of behavior analytic interventions.
Methods:
The present study is the second phase in the exploration of the Case-Based CE Model. Phase I tested the autism Case-Based CE program (n=13) with behavior analysts completing both pre/post assessments, and social validity. Preliminary results of Phase I led to the expansion of the Case-Based CE Model to examine the acceptance and efficacy of this program.
In the present study, 21 behavior analysts were selected participate in an eight month Case-Based CE Model facilitated by a panel of expert behavior analysts with autism specialty areas. During one hour, monthly online meetings, the host panel facilitated discussion of a participant-presented case, and provided information on advanced behavioral principles. Prior to and following participation in the Case-Based CE Model, participants completed a survey regarding confidence and frequency of use of 80 behavioral interventions, and, perception of the quality and efficacy of current CE opportunities. Participants completed monthly pre/post assessments relating to behavior analytic content presented. Additionally, following each session participants completed a social validity scale regarding their perception of the quality of the session.
Results:
Phase I of the Case-Based CE Model (n=13) demonstrated improvements in behavior analytic knowledge from pre-test to post-test, M= 32.7% increase. Social validity regarding the participation in the Case-Based CE Model was high following each session (5= strongly agree): relevant topic M=4.82, recommendations useful M=4.83, case concerns thoroughly covered M=4.58, addressed needs M=4.91, group participation M=4.76 and effective means to earn CEs M=4.92.
The data collection for Phase II is ongoing, (completion Spring 2017). The pre/post outcomes for content assessment and behavior analytic frequency, as well as an examination of the relationship between participant characteristics (e.g., years of experience, pre-program confidence, attendance) in relation to behavioral intervention use and content assessment outcomes.
Conclusions:
The preliminary result of this study are promising and indicate that the Case-Based CE Model may be effective in increasing participant knowledge and utilization of advanced behavioral principles and is a socially valid means to acquire CE for behavior analysts. The results of this study will generate data regarding the acceptability and efficacy of a Case-Based CE model for behavior analysts that may support future research in this area.

215 **127.215** Associations Between Family Navigation As a Care Coordination Strategy and the Receipt of Intervention Services for Families of Children with ASD within the Autism Speaks Autism Treatment Network.

M. K. Crossman[1,2]*, A. M. Shui*[3]*, D. S. Murray*[4]*, K. Kubicek*[5] *and K. Kuhlthau*[3]*, (1)General Academic Pediatrics, Massachusetts General Hospital, Boston, MA, (2)Harvard Medical School, Boston, MA, (3)Massachusetts General Hospital, Boston, MA, (4)Autism Speaks, Boston, MA, (5)Children's Hospital Los Angeles, Los Angeles, CA*

Background: Increased rates of ASD diagnoses have led to a greater need for medical services, supports and interventions during early childhood and across the life span. The challenges navigating the complex nature of the service system hinders caregivers' ability to receive appropriate and timely services and interventions for their child and family. Family navigation is one model recently utilized to coordinate and increase service access. Research on family navigation as a care coordination strategy for parents of children with ASD has received very little empirical attention.
Objectives: To examine the relationship between caregiver knowledge of a care coordinator (CC) or family navigator (FN) and receipt of behavioral and educational interventions. We hypothesized that caregiver knowledge of the CC or FN would be associated with greater receipt of behavioral and educational interventions after controlling for ASD severity.
Methods: Data on a cross-sectional sample of 564 children who participated in a longitudinal study 3 years after initial enrollment was extracted from the Autism Speaks Autism Treatment Network (ATN) registry. Measures included the total number of behavioral and educational interventions currently received (i.e. speech, OT, PT, behavior therapy, etc.), the child's age at consent, gender, race, ASD severity measured by the Autism Diagnostic Observation Schedule (ADOS), parent education, whether the family maintained any insurance, and caregiver knowledge of a CC or FN (used as a proxy for receiving CC or FN services). Covariates based on both clinical importance and statistical significance were included in the regression model testing the association between number of interventions received and caregiver knowledge of CC or FN.
Results: Results suggest children currently receive 2.88 interventions on average, and only 30% of caregivers reported knowledge of the CC or FN at their ATN site. Results of bivariate tests revealed no significant differences in the number of interventions received based on the child's age at consent, gender, race, ethnicity, or caregiver education. However, the number of interventions received was associated with insurance, ADOS severity score, and knowledge of a care coordinator or family navigator. Multivariable regression analyses showed that knowledge of the CC or FN (β=0.54, SE 0.20, $p < 0.01$ was associated with greater intervention receipt after controlling for ASD severity and insurance.
Conclusions: Â Intervention receipt among families of children with ASD varies by having knowledge of a care coordinator or family navigator, even after controlling for ASD severity and insurance. These results suggest the importance of having a designated individual to guide families as they determine appropriate services for their child and family. Future research is needed to explore whether specific aspects of family navigation predict intervention receipt in addition to other service outcomes, and whether greater service receipt reflects a positive outcome.

216 **127.216** Autism Program Environments Rating Scale (APERS): Psychometric Properties

S. L. Odom[1], *A. W. Cox*[2], *K. Hume*[3], *J. Sideris*[4], *S. Hedges*[5] *and S. Kucharczyk*[6], *(1)University of North Carolina, Chapel Hill, NC, (2)Frank Porter Graham Institute, University of North Carolina - Chapel Hill, Chapel Hill, NC, (3)University of North Carolina, Chapel HIll, Carrboro, NC, (4)Frank Porter Graham Child Development Institute, Chapel Hill, NC, (5)UNC Chapel Hill, Chapel Hill, NC, (6)Curriculum & Instruction, University of Arkansas, Fayetteville, AR*

Background: The increased prevalence of Autism Spectrum Disorders (ASD) has created a need for providing high quality programs for students with ASD in public school settings. Although there have been limited attempts to assess quality of programs for students with ASD, none have provided evidence of the psychometric features of the assessments. In fact, the absence of a reliable and valid standardized assessment of program quality has limited program development efforts and led to litigation challenges from parents of students with ASD. The Autism Program Environment Scale (APERS) was designed to assess the quality of educational programs for students and youth with ASD. The APERS generates a summary quality rating by drawing information from 10 domains, shown in Figure 1.
Objectives: The purpose of this sudy was is to determine the psychometric qualities of the APERS. The research questions addressed are: What is the internal consistency of the APERS? What is the factor structure of the APERS? Is the APERS sensitive to changes across time when a professional development program designed to improve program quality is implemented?
Methods: The APERS is a 60+ items assessment (different number of items for different forms) that employs a 1-5 Likert rating format. Coders base ratings on observations in schools, interviews, and document review. Preschool/elementary and middle school/high school versions of the scale exist. The APERS has been collected in inclusive and noninclusive programs for students with ASD. The current study will draw from two datasets. The first set of data was collected in 76 classes for students with ASD located in 12 states, by staff from the National Professional Development Center on ASD (NPDC). Data were collected at the beginning of the school year and again at the end. The second set of data were collected in 60 high school programs located in three states, by staff from the Center on Secondary Education for Students with ASD (CSESA) only at the beginning of the school year.
Results: To examine internal consistency, Cronbach alphas were calculated. For the NPDC data set, alphas were .95 and .96 for the P/E and M/H forms. For the CSESA data set (M/H form only), alphas were .94 for inclusive programs and .96 for noninclusive programs. An exploratory factor analysis of the NPDC data yield strongest evidence for a one factor solution, which was identified as a measure of quality. This factor model was then applied to the CSESA data in a confirmatory factor analysis and yielded similar results. Also, for the NPDC data, t-tests were conducted for P/E and M/H APERS total mean item rating, indicating significant positive changes across time ($p < .01$ for both, $d = 1.28$ for P/E and $d = 1.10$ for M/H) for schools that had been engaged in a professional development project, indicating sensitivity to program effects across time.
Conclusions: Data from these studies provide evidence that the APERS is a reliable and valid measure of the quality of program environments for students with ASD.

217 **127.217** Back to School: Understanding the Path to Re-Integration for Autistic Children Who Previously Experienced Educational Exclusion

J. L. Brede[1], *A. Remington*[2], *L. Kenny*[2], *K. Warren*[1] *and E. Pellicano*[2], *(1)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, UNITED KINGDOM, (2)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom*

Background:
All children have the right to receive an education and to be included in school, yet young people on the autism spectrum, who are already vulnerable to poor health and social outcomes, are at increased risk of being excluded from so-called inclusive settings. In fact, in England, over a quarter of children and young people on the autism spectrum have been excluded from education at least once. Being excluded from formal education can have drastic consequences, yet little is known about the realities of being excluded from school for autistic children and young people. There is also no research on the most effective ways for teachers to get these children back into school.
Objectives:
The aims of this project were twofold. First, we examined students' experiences in an Inclusive Learning Hub; an educational environment specially designed to increase the opportunities for children with the most complex behaviours to access education. Second, we sought to identify strategies employed by staff to improve students' well-being and re-engagement with school.
Methods:
Nine cognitively able students (8 male, mean age 13.3 years; mean non-verbal reasoning score: 97.5), all with a diagnosis of autism and the majority with a history of demand avoidant behaviour, were seen multiple times over a 6-month period to complete questionnaires and semi-structured interviews. Their parents and 20 members of teaching staff completed a battery of measures examining the students' educational experience and socio-emotional wellbeing and the researchers also observed the young people in situ.
Results:
Young people and their parents gave overwhelmingly negative accounts of their previous school experiences, which meant that these children were unable to engage in and access education and, in most cases, were permanently excluded from school. Unsurprisingly, these events often left the young people highly anxious, lacking in confidence and disaffected by school. Re-integration into school (the 'Hub') was therefore gradual, with staff making extensive efforts to attend to students' mental health needs. Despite often-traumatic educational histories, students' developed a newfound enthusiasm for school and their parents were extremely positive about the gains children had made. The Hub, seemed to provide a safe, secure environment for these young people, with dedicated staff who were highly attuned to the students' individual needs and challenges. Key strategies employed included an individualised student-centred approach avoiding the use of direct demands to reduce levels of stress and anxiety. Young people were also given greater autonomy in controlling their physical environment and daily schedule.
Conclusions:
This project contributes to a better understanding of the educational experience of previously excluded students and, critically, identifies transferable strategies for educators and those supporting these and other students, especially those with a history of demand avoidant behaviour, to ensure their well-being and engagement in learning. Future research needs both to identify the factors that place these children at risk of educational exclusion and to determine the best ways of re-integrating young people into learning environments beyond the safe space of the Hub, ensuring that they are adequately prepared for their future lives.

218 **127.218** Barriers and Facilitators to Accessing and Providing Treatment for Insomnia in Children with Neurodevelopmental Disorders: Parent and Health Care Professional Perspectives

K. Tan-MacNeill[1], *A. Jemcov*[2], *I. M. Smith*[3] *and P. Corkum*[4], *(1)Department of Psychology & Neursocience, Dalhousie University, Halifax, NS, CANADA,*

(2)Department of Psychology & Neuroscience, Dalhousie University, Halifax, NS, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA,

(4)Department of Psychology & Neuroscience; Department of Pediatrics; Department of Psychiatry, Dalhousie University & IWK Health Centre, Halifax, NS, Canada

Background:
Sleep problems are highly prevalent in children with neurodevelopmental disabilities (NDD), such as Autism Spectrum Disorder (ASD), Attention-Deficit/Hyperactivity Disorder (ADHD), Fetal Alcohol Spectrum Disorder (FASD), and Cerebral Palsy (CP), ranging from 50-95%. Behavioural sleep problems, called insomnia, are most common. Treating insomnia is critical, as it has widespread negative effects on both child and family functioning. Although behavioural treatments for sleep problems are recommended, little research exists on parents' and health care professionals' (HCPs) insomnia-related treatment access and service utilization for children with NDD.
Objectives: To identify and explore: 1) barriers and facilitators experienced by parents of children with ASD, ADHD, FASD, and CP related to seeking, access, uptake, and implementation of behavioural treatment for children's insomnia; and 2) barriers and facilitators experienced by HCPs in accessing and providing behavioural insomnia treatment for children with NDDs.
Methods: Using a qualitative online audio/video synchronous focus group and interview design, we recruited Canadian parents of 4- to 12-year-old children with formal diagnoses of ASD, ADHD, FASD, or CP, and the HCPs who work with them (occupational therapists, clinical psychologists, developmental paediatricians, nurses, social workers, physicians, and Board Certified Behaviour Analysts). Data collection is complete for ASD groups (parent n = 20; HCP = 21), and other NDD groups will be completed in fall 2016 (target n = 7 for each of ADHD, FASD, and CP parent and HCP groups), with total anticipated N = 82 (see Table 1 for breakdown). Parents and HCPs participated separately in focus groups, following a semi-structured topic guide focusing on sleep knowledge, access to sleep treatment, and treatment uptake (parents only) or familiarity with and implementation of evidence-based treatment (HCPs only). Perceived acceptability of an online parent-directed behavioural sleep intervention was also assessed. Focus groups/interviews were transcribed and qualitatively analyzed in NVivo using conventional content analysis (coding for key themes). Comprehensive lists of barriers and facilitators were derived from the data and grouped into key theme categories.
Results: The following key themes emerged from parents and HCPs across all four NDDs: 1) Sleep problems and treatment are exceptionally challenging and intensive compared to other problems / treatment due to high impact on family, multifactorial and complex causes, need for individualized treatment, and sleep being but one of many challenges competing for parents' attention. 2) Limited awareness and knowledge about sleep and how to access help for both parents and HCPs. 3) Consistency with routines and perseverance are keys to success. 4) Sleep-related beliefs and attitudes influence parents' treatment seeking and HCPs' willingness to treat.
Conclusions: Â Contradictions were inherent in both HCPs' approach to treatment and parents' perspectives on effectiveness, with both reporting high perceived need for individualization of treatment, yet describing use of similar behavioural strategies across NDD diagnoses. This suggests the appropriateness of a transdiagnostic approach to insomnia treatment, with accommodation for NDD symptoms as needed. Results are informing the modification of an online parent-mediated intervention for sleep problems in neurotypical children,Â *Better Nights, Better DaysÂ* (*BNBD*), into an intervention for children with NDD (*BNBD-NDD*).

219 **127.219** Child Care Center Directors' Knowledge and Perceptions of Early Screening for Developmental Disabilities and Autism Spectrum Disorder (ASD)

J. Page[1], *M. DuBay*[1], *T. Uzonyi*[1] *and E. Crais*[2], *(1)University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background:
Early developmental and ASD screening has many benefits, including earlier diagnosis, access to early intervention (EI), and improved developmental outcomes. To benefit from EI, at-risk children must be identified, typically through screening by a primary healthcare provider, and referred for an evaluation. However, some healthcare providers do not screen for ASD, citing barriers such as lack of time, lack of knowledge, inadequate training, and hesitance to share difficult news with families. Alternatively, child care settings may be another avenue for early screening. Child care providers are in an optimal position to potentially identify at-risk children because they receive training in child development and have ongoing opportunities to monitor child development as well as build rapport with families. While recent studies show that early care professionals can be adept at screening for ASD, research has yet to provide insight as to whether Directors feel comfortable with their providers screening, talking with parents about concerns, or referring families to EI. Given their influence in decision making, examining Director's knowledge, perceptions, and practices around screening for ASD would be an important step in determining whether screening in childcare settings is feasible.
Objectives:
The current study explored Directors' knowledge, perceptions, practices, comfort level, and resources for:

1. recognizing characteristics of developmental disability including ASD,
2. screening for developmental disability and ASD,
3. communicating developmental concerns with parents and referring families to EI, and
4. continuing education in these areas.

Methods:
Twelve semi-structured interviews were conducted with Directors of child care centers serving children birth through age 5, stratified across settings (public, private, home based, faith based). Interviews were recorded, transcribed, checked for accuracy, and coded by the authors, who had established reliability on the codes. Using grounded theory, themes and axial codes (sub-themes within the data) were generated.
Results:
Director's perceptions of their knowledge of recognizing ASD ranged from minimal to moderate with all Directors interested in more training in recognizing signs and symptoms of developmental disabilities and ASD. All Directors expressed that some type of developmental *tracking process* was present at their center, however, none had an ASD screening process, and few formally screened for developmental concerns. All Directors reported feeling very comfortable or somewhat comfortable in communicating developmental concerns with parents, however, knowledge of the referral process to EI varied among Directors.Â A common theme was difficulty when parents disagreed with professionals' concerns.Â Most Directors expressed a need for training in recognizing signs and symptoms of ASD and communicating concerns to parents.
Conclusions:
This study examined the knowledge, perceptions, practices, comfort level and resources of childcare directors in identifying factors that influence formal screening, professional development, and communicating concerns with families. Directors reported that additional training is needed in screening, addressing early signs of ASD, and talking with families. Additional research investigating ASD specific screening in early care settings is warranted and identifying early care professionals' knowledge of screening can help identify gaps in practice.

220 **127.220** Collaborating with Community and Health Care Service Providers: A Community-Based Screening Program for Identifying Toddlers with Autism Spectrum Disorder

M. Couture[1], *A. J. Beaudoin*[2], *M. Gagnon*[1], *C. Gauthier-Boudreault*[1] *and C. St-Cyr*[3], *(1)Universite de Sherbrooke, Sherbrooke, QC, Canada, (2)Université de Sherbrooke, Québec, QC, CANADA, (3)École de réadaptation, Université de Sherbrooke, Sherbrooke, QC, Canada*

Background: Although research has shown that we can identify toddlers with autism spectrum disorder (ASD) in their first two years of life, the mean age of diagnosis in (non-research) clinical context is still around 4 years of age (CDC, 2012). This limits the access to interventions that are most effective when offered before 3 years of age. Knowing that developmental surveillance and targeted screening for ASD could help decrease the mean age at diagnosis, collaboration between community resources and health services should be supported to implement screening program for young children with ASD.
Objectives: To explore the feasibility of a community-based screening program for toddlers (12-30 months old) with ASD and identify contextual components that facilitates or impedes its implementation.
Methods: This prospective collaborative study uses a 3-step procedure to screen toddlers for ASD in the Eastern Townships (Quebec, Canada). Step 1: Parents first completed a one page screening questionnaire depending on the child's age. Step 2: A 30-minute follow-up interview was completed with parents of children who scored at risk of ASD after the first step. Step 3: The research team completed the ADOS-T and the ADI-R with families still considered at risk after the follow-up. Descriptive analyses and predictive value was calculated separately for children aged between 12 and 18 months (group 1) who were screened via the *Infant Toddler Checklist (ITC)* and children aged between 18 and 30 months (group 2) who were screened using the *Modified Checklist for Autism in Toddler – Revised (M-CHAT-R)*.
Results: 690 questionnaires were collected at step 1. Most (67%) of the questionnaires came from the community services or daycare (21%). Of the 690 questionnaires completed, 8.4% (n=58) scored at risk of ASD at step 1, 2.7% (n=15) remained positive at step 2, and 0.44% (n=3) finally scored positive at the third step. Thus, in this study, the positive predictive value of the ITC (group 1) was 0% and 23.07% for the M-CHAT-R (group 2). Information from the clinical setting revealed an increase in children of 3 years old and younger referred to the evaluation clinic for suspicion of ASD in the Eastern Townships between the beginning of the project (8% in 2014) and the time of analysis (33% in 2016).
Conclusions: Based on the result of the pilot project, the community-based screening program should be implemented in the Eastern Townships to continue identifying toddlers at risk of ASD. However, based on the results and recommendations of the AAP Bright Futures guidelines (2016) we proposed to target specifically older toddlers (i.e. 16-30 months) for which the M-CHAT-R can be used. It is important to highlight the collaborations with partners, specifically community services and daycare that were involved in the project. A short training on early markers of ASD might be useful so that they can target children at higher risk and encourage their parents to complete the screening questionnaire.

221 **127.221** Collateral Reports of ASD Symptoms in Adults: A Preliminary Comparison of Caregiver and Clinician Ratings

A. Pearl[1], *M. Murray*[2] *and S. L. Brown*[3], *(1)Penn State Milton S. Hershey Medical Center, Penn State College of Medicine, Hummesltown, PA, (2)Psychiatry, Penn State College of Medicine, Hershey, PA, (3)Penn State College of Medicine, Hershey, PA*

Background: ASD symptoms and psychiatric comorbidities in adults with ASD are notoriously difficult to assess. Recently, versions of the Social Responsiveness Scale, Second Edition (SRS 2) have been normed on adults. The general consensus in assessment is to obtain collateral information from other informants when possible in order to increase the validity of the assessment. However, little is known about the agreement between other-reports of ASD symptoms in adults with ASD on available assessment tools.
Objectives: To explore agreement between self-, caregiver-, and clinician-report of ASD symptoms in adults with ASD.
Methods: Fourteen adults with ASD completed a baseline assessment for a larger project examining the effectiveness of an assessment monitoring system for participants enrolled in the Adult Community Autism Program (ACAP) a state-funded program for adults with ASD. 79% were Caucasian and 93% were male. The mean number of years of education was 12.86 (SD = 1.88) and 43% reported being employed. For all individuals who reported living at home, a parent residing in the household completed the SRS 2; for all individuals who reported living alone, a support staff employed by ACAP who had been working with the participant for at least six months completed the SRS 2.
Results: Participants who lived with at least one parent and had a parent as collateral raters did not differ from participants who lived alone and had ACAP staff as collateral raters on years of education (F = 1.33, *ns*), employment status (50% were employed for wages and the remaining 50% were either unemployed or a student in each group), or race (each group was 86% Caucasian). Only one female was in the entire sample and she reported living alone and therefore had an ACAP staff as a reporter. In regards to ASD symptoms, the self-report of the two groups did not differ on any subscale. Parents rated social cognition symptoms (F = 1.10, *ns*) and restricted and repetitive behaviors (F = 2.09, *ns*) higher than clinicians, while clinicians rated social communication symptoms (F = 1.31, *ns*) as higher. At this time, these were only at trend level significance due to a lack of power. However, by February, 2017 a total of 60 individuals will have enrolled in this pilot project. The preliminary data presented within this submission will be re-run on the full dataset by May, 2017 and it is fully expected that there will be significant differences between parents and clinicians on ratings of ASD symptoms at that time.
Conclusions: The SRS 2 demonstrated a trend toward significant differences between collateral ratings of symptoms of ASD in adults enrolled in a state-funded program for adults with ASD. Caregivers of young adults with ASD rated their children higher on the SRS 2 in terms of social cognitions and restricted and repetitive behaviors than clinicians, while clinicians rated their clients higher on the SRS 2 on social communication in comparison to parents. This suggests that importance of exploring potential differences between patterns of ratings of adults' symptoms of ASD depending on the rater.

222 **127.222** Cost Evaluation of an Early Intervention Program for Children with Autism

***Z. Cidav**, University of Pennsylvania, Philadelphia, PA*

Background: Evidence-based early interventions for children with ASD are intensive and expensive, often consisting of 20-40 hours a week of one-to-one interaction with a skilled therapist and parents who have received considerable training. The course of early intervention can span two or more years, resulting in estimated costs of $40,000 to $80,000. Some payers, including health care insurers and state and local early intervention systems, have balked at these costs, raising concerns about the lack of demonstrated long-term improvements in functioning and cost savings. There is little evidence of economic gains associated with successful early intervention, with which to support resource allocation decisions.
Objectives: The present study will estimate the potential cost-offset of one such early intervention program for children with ASD, the Early Start Denver Model (ESDM) which is a comprehensive, naturalistic, developmental, behavioral intervention for very young children with ASD.
Methods: Data about service use were collected fromÂ the ESDM randomized controlled trial participants for both during the treatment and up to two and a half years post-treatment. These data provide a unique resource with which to evaluate the potential cost-offset of the intervention – that is, the extent to which the intervention reduces subsequent use of other services. These data allow evaluation of the relative cost of service use in two groups: one that received state-of-the-science early intervention and one that received community intervention. We will analyze data from the ESDM randomized controlled trial to determine whether ESDM treatment is associated with reduced health care and education service use and costs overÂ two and a half years immediately following intervention.
Results: N/A. Analysis is ongoing.
Conclusions: Â N/A. Analysis is ongoing.

223 **127.223** Creating Sustainable Systems of Support for Toddlers at Risk for ASD: Caregiver Perceptions and Knowledge Acquisition

***T. Ryan**[1], T. Gaines[2], N. D. Bond[2], E. Chapman[2], S. K. Fuhrmeister[2], E. McCullough[2], M. Costo[2], S. Gillespie[3] and J. L. Stapel-Wax[4], (1)Marcus Autism Center, Suwanee, GA, (2)Marcus Autism Center, Atlanta, GA, (3)Emory University School of Medicine, Atlanta, GA, (4)Emory University School of Medicine, Atl, GA*

Background: According to the National Research Council (2001), early detection and 25 hours per week of active engagement promotes optimal success for young children with autism spectrum disorder (ASD) in kindergarten. Evidence-based practices such as naturalistic and parent-implemented interventions have been identified as "established treatments" for individuals with ASD (Wong et al., 2014; National Standards Project, 2015). Although most research in ASD treatment has focused on clinician-based interventions, there has been increased focus on parent-mediated interventions, as parents are the most community-viable agents of change for children at risk for ASD (U.S. Department of Health & Human Services, U.S. DOE, 2014). However, there remains a scarcity of research on the relationship between parents' ability to provide supports to promote active engagement and their own perceptions of comfort level.
Objectives: This ongoing project aims to increase knowledge of adult-learning strategies, early red flags for ASD, and supports to promote active engagement for toddlers at risk for ASD by improving collaborative coaching proficiencies of early intervention providers (EIPs) across Georgia. This investigation will focus on the relationship between caregivers' self-reported comfort and confidence in providing supports and actual level of supports provided.
Â Methods: This study is tracking the progress of 19 EIPs across Georgia, coached to coach caregivers on increasing active engagement in toddlers at risk for ASD. Coaching of EIPs is conducted in-person quarterly, with all other weekly coaching sessions occurring via technology. Effectiveness of the coach-the-coach model is assessed using SEE-KS™ (Rubin, E. et al., 2014) three-point rating scales to measure caregiver-provided supports.Â SEE-KS™ is a coaching framework based on Universal Design for Learning encompassing the principals of SCERTS® (Prizant et al., 2005).
Â Results: SEE-KS™ and Caregiver Survey values were summarized at pre- and post-coaching time points for families using means and standard deviations. Paired t-tests were employed to gauge the change in each measure for statistical significance. Results from the SEE-KS™ indicate a significant increase from baseline in supports provided by caregivers to foster engagement ($p<0.001$) and to support understanding ($p<0.001$) and expression ($p<0.001$) during the project (see Table 1). No significant changes were seen from baseline in caregiver self-reported comfort and confidence ($p=0.545$) (see Table 1).
Conclusions: Though no significant changes were seen in caregiver comfort before and after coaching, data indicate high caregiver comfort and confidence throughout the coaching process. These data also show that the current coach-the-coach model resulted in significantly increased caregiver-provided supports to promote engagement, understanding, and expression in toddlers at risk for ASD.

224 **127.224** Dbp and CBT – a Professionally Rewarding "Blend" - the Impact of Professional Collaboration on a Vulnerable Underserved Group : Children with Disabilities, Including Those with Autism Spectrum Disorders, Mental Health Challenges, and Their Caregivers

***N. E. Dick**[1,2] and F. E. Felix[3], (1)Paediatrics, North Central Regional Health Authority, Champs Fleur, Trinidad and Tobago, (2)KAIROS Developmental Behavioral Pediatrics, Caribbean Ltd, San Fernando, Trinidad and Tobago, (3)Metanoia CBT, Tacarigua, Trinidad and Tobago*

Background:Â Mental health services are critical and frequently unaddressed, especially within the paediatric population. The World Health Organization identified both developmental disabilities and mental health disorders as significant contributors to the global health burden, especially in middle to low-income and developing countries, of which Trinidad and Tobago occupies the latter category. In the absence of locally-derived statistics, and based on international statistics from developed countries, about 20-30% of children and teenagers experience social and emotional problems that are concerning to their caregivers, with some of these being severe and clinically significant. This quantum is greater in children and adolescents with disabilities, whether simple or complex, especially if they have co-morbid chronic medical conditions. Many children and teens with "dual" mental health and somatic diagnoses, experience symptoms that are unrecognized, undiagnosed, under-diagnosed, or misdiagnosed . As a consequence, these issues remain untreated. There is no known national epidemiologic mechanism for data collection related to these issues, thus making it difficult to include these population niches within national health policy frameworks. This vulnerable population represents a major gap in our national public health system, with fragmented and/or unavailable services being the norm. Caregivers of children and adolescents with complex chronic medical issues, autism spectrum disorders, neurodevelopmental and/or behavioral issues experience higher levels of negative psychosocial stressors and have greater levels of maladaptive coping mechanisms than parents of healthy, typically developing children and teenagers. Children and adolescents with autism, are known to experience higher rates of anxiety, learning disabilities, sensory challenges and dietary atypia, which often go unrecognized.
Objectives: To develop, audit and systematically improve a collaborative and integrated model of service delivery between a volunteer mental health clinician (Cognitive Behavioural Psychotherapist) and a physician (Developmental Behavioural Paediatrician). To provide Specialist Paediatric care, Sub-specialty Developmental Behavioral consultation/support, Paediatric Psychopharmacotherapy (medication management), and Psychotherapeutic support for both child and caregiver as well as care coordination are offered by this, despite an overwhelming, persistent lack of time; and professional and material resources.
Methods: Case selection occurs from the socioeconomically, ethnically and geographically diverse clientele of a public health sector, sub-specialty paediatric ambulatory service. Clinical evaluation, case-conferencing and existing clinical evidence informs management plans, to the limit of material and human resources. Where necessary, cross-referrals are made to other disciplines e.g. Psychiatry, Occupational Therapy and to other governmental agencies, e.g. Ministry of Education.
Results: This professional synergy, despite its occurrence in a resource-poor environment, includes improvements in the insight of the child/teen and/or their caregiver(s) to their own challenges, self-monitoring (where applicable), coordinated medical, pharmacologic and mental health management; as well as application of well-known evidence-based strategies to enhance positive behaviours, to augment coping skills; personal and family resilience in chronic conditions.
Conclusions: Multidisciplinary, integrated models of care, have proven synergistic and more efficacious in the management of comorbid developmental disabilities, medical and psychiatric problems. There is potential to expand this type of service, to include other related disciplines to provide more effective service to this vulnerable niche of our paediatric population nationwide.

225 **127.225** Detection of Autism Spectrum Disorders in Children Aged 4-6 Years By Municipal Maternal and Child Health Physicians: An Educational Intervention Study

*M. Neukerk[1], **M. van 't Hof**[1,2], J. T. Bailly[1], H. W. Hoek[2,3] and W. A. Ester[1,2], (1)Sarr Expert Centre for Autism, Lucertis Child and Adolescence Psychiatry, Rotterdam, Netherlands, (2)Parnassia Psychiatric Institute, The Hague, Netherlands, (3)Department of Psychiatry, University Medical Center Groningen, University of Groningen, Groningen, Netherlands*

Background: The transition into primary school at age 4 can be challenging for children with autism spectrum disorders (ASD). Due to the new demands that are made to children in this period, their limitations in social functioning and school achievements may manifest and appear faster. Detection of possible ASD signals takes mainly place by parents, teachers and during obligatory municipal maternal and child health centre visits in The Netherlands.
Physicians of municipal maternal and child health centres have limited education and instruments to detect ASD. Further education on detecting ASD is needed to optimally equip these doctors for this task. Most research aims to increase the early detection of ASD in children aged 0-3 years and shows positive results. However, there is a lack of research on educational interventions to detect ASD in children aged 4-6 years by municipal maternal and child health physicians.
Objectives: To explore the effect of the online educational intervention: *Detection of ASD in children aged 4-6 years for municipal maternal and child health physicians.* This intervention is developed within the project "Reach-Aut Academic Centre for Autism; Transitions in education", and will be available throughout The Netherlands.
Methods: Ninety-seven participants were invited to participate in the study and consisted of three sessions of each, one and a half hour duration. The sessions were offered through an online interactive classroom. The focus and content has been developed with three groups of stakeholders; autism scientists, clinical practitioners and parents of children with ASD. Outcomes consisted of: 1) knowledge about ASD: signals, early detection, communication with parents and referrals, 2) number of ASD related referrals, 3) attitude towards the mentally ill (CAMI), 4) perceived competency about ASD knowledge and detection skills, and 5) satisfaction about the educational intervention.
Results: Forty-two physicians (95.2 % female, mean age = 41.3 years, SD = 12.5) completed the intervention up till now. Participants scored on the ASD knowledge test (scored 1-10) 6,6 at start and 7,4 after the educational intervention ($p<0.01$). The perceived competence increased significantly regarding ASD knowledge, recognising signs of ASD, communicating ASD features towards parents and referring towards the proper healthcare. Physicians scored on the CAMI above average on Benevolence (M = 3.80, SD = 0.35) and Community Mental Health Ideology (M = 3.84, SD = 0.43), and below average on Authoritarianism (M = 2.16, SD = 0.35) and Social Restrictiveness (M = 2.13, SD = 0.43). Physicians rated the educational intervention with an average grade of 7.9.
Conclusions: The educational intervention *Detection of ASD in children aged 4-6 Years for municipal maternal and child health physicians* seems to be effective in increasing knowledge about ASD and perceived competence. Municipal maternal and child health physicians have in general a positive attitude towards the mentally ill. At IMFAR 2017 we will present updated results that include the complete group of participants (N=91).

226 **127.226** Early Diagnosis of ASD in Toddlers: Models to Improve Access and Wait Times

***R. Choueiri**[1] and J. F. Lemay[2], (1)University of Massachusetts Memorial Children's Medical Center, North Worcester, MA, (2)Pediatrics, University of Calgary, Calgary, AB, Canada*

Background: Early and intensive intervention can improve outcomes in ASD. Currently in the US, early diagnosis of ASD and access to services are delayed by long wait times. We report and discuss the results of successful ASD Assessment Processes in two different diagnostic and tertiary centers; both use a two-level ASD screening model and evaluation algorithm using the RITA-T (Rapid Interactive Screening for Autism in Toddlers) for toddlers under 39 months of age
Objectives: Improve early detection of autism with a two level screening test using the MCHAT R/F as a Level 1 and the RITA-T as an interactive Level 2 screening test, in two different diagnostic centers.
Methods: This two screening model was piloted in two different centers: a) In Calgary, with a waitlist >12 months for children under 39 months of age, a Quality Improvement Project was commenced in 2013 aimed at creating an efficient, sustainable and evidence-based ASD diagnostic process. Toddlers were initially screened by the MCHAT and the RITA-T. Three groups were created (low, moderate and high risk) depending on RITA-T and MCHAT scores. Diagnostic evaluation was completed on each group. b) In Worcester, MA, this process tested the two-level screening model completed by Early Intervention (EI) providers, and linking EI and diagnostic center for improved early screening, identification, communication and wait times. Early Intervention providers in the largest program in the Worcester area were trained with the RITA-T and on the MCHAT R/F. They screened all their toddlers already enrolled with the MCHAT and completed the RITA-T on those with a positive score and on a sample of 20 toddlers with an initial positive MCHAT but a final negative result. Toddlers were then referred for diagnostic evaluation.
Results: A) In the Calgary Group: wait improved (<28 days), evaluation processes streamlined, and validation of this process was confirmed by parents. A total of 176 toddlers were evaluated with this model. The statistical and descriptive data of the RITA-T in this model are currently being analyzed. b)-In Worcester, the study is ongoing currently; so far 90 toddlers were evaluated. Of those 75 had an ASD diagnosis. The RITA-T preliminary properties in this setting show sensitivity 0.9 and specificity of 0.85 and a positive predictive value of 0.9. Early Intervention providers relate improved communication with diagnosticians and better early detection skills and wait time to be seen is within 2 months Conclusions: A two level ASD screening model that integrates the MCHAT R/F and the RITA-T improves early detection, wait times and communication in tertiary and diagnostic centers and improves communication between Early Intervention providers and diagnosticians.

227 **127.227** Early Intervention Staff Views on Supporting Evidence Based Practice

D. Trembath[1], *R. Sulek*[2], *J. M. Paynter*[3], *K. Simpson*[4] *and D. Keen*[5], *(1)Menzies Health Institute, Griffith University, AUSTRALIA, (2)Menzies Health Institute Queensland, Griffith University, Australia, (3)School of Applied Psychology, Griffith University, Southport, Australia, (4)Griffith University, Mt Gravatt, Australia, (5)Griffith University, Mt Gravatt, AUSTRALIA*

Background: While a range of evidence-based interventions are available to children on the autism spectrum and their families, applying these within an evidence-based practice (EBP) framework in community-based early intervention (EI) settings remains challenging. Common barriers to EBP identified through previous research include a lack of staff training, time, and workplace resources, as well as incongruences between interventions developed in research environments and clinical realities in community settings. Unfortunately, few studies have examined strategies for supporting EBP, and rarely have EI staff been consulted regarding their views on how to support their own practice, thus jeopardising the ecological and social validity of strategies developed.
Objectives: Our aim in this study was to examine EI staff views on supporting their engagement in EBP in order to identify ecologically and socially valid strategies for doing so.
Methods: We conducted a qualitative study involving five focus groups involving 29 professional (e.g., speech pathologists, teachers), paraprofessional (e.g., childcare workers), and managerial staff who worked in a community-based EI service to explore their views. The service provides a comprehensive program delivered by a multidisciplinary team to approximately 200 children per annum across multiple sites. Audio recordings were transcribed verbatim and analysed using thematic analysis.
Results: Â Two central themes, comprising six categories, emerged to account for the participants' views. *Initiative and Effort* (theme 1) accounted for the range of creative strategies staff had developed and adopted to support their use of EBP. These included methods aimed at rapidly transferring core skills to new untrained staff and ensuring clear communication between team members working inconsistent shifts to ensure continuity of care. Staff also expressed the need for *A better way* (theme 2) involving organisation-wide strategies with direct applicability for supporting staff in their use of evidence-based intervention strategies with fidelity when working in the classroom with children.
Conclusions: Â The findings demonstrate that EI staff are ideally positioned to play a key role in developing ecologically and socially valid strategies to support their engagement in EBP. In particular, the findings highlight the importance of organisational-wide models for supporting EBP, with a focus on peer-to-peer mentoring. Clinical and research implications, particularly those pertaining to the translation of research to practice in community settings, will be presented with reference to the themes and illustrated with participants' comments.

228 **127.228** Early Support Program for Autism: Bridging the Gap Between Diagnosis and Treatment

J. R. Hurts[1], *C. Ardel*[2], *G. G. Baldi*[3], *S. Colamarino*[4], *A. Y. Hardan*[2] *and G. W. Gengoux*[2], *(1)PGSP-Stanford Psy.D. Consortium, Palo Alto, CA, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)Children's Health Council, Palo Alto, CA, (4)John and Marcia Goldman Foundation, San Francisco, CA*

Background: Autism Spectrum Disorder (ASD) is a lifelong condition that affects approximately 1 in 68 children and impacts many aspects of child and family life. The weeks after diagnosis can be particularly overwhelming, especially with the burden of navigating numerous treatment recommendations and diverse service systems. Many providers have lengthy waitlists, which can be frustrating for families who have been told that early intervention is critical for long lasting improvement.
Objectives: This presentation describes the Early Support Program for Autism (ESPA), an innovative community support program aimed at bridging the gap between diagnosis and treatment by providing supportive services at no cost to families after diagnosis.
Methods: ESPA is a collaboration between a large academic medical center and a local mental health agency. The primary components of the program include Clinical Care Coordination and Parent Education. The Clinical Care Coordination service is designed to help families navigate educational and healthcare systems, find relevant resources, and connect with community providers. Coordinators work with the family through an initial appointment and follow up contact as needed to provide guidance in accessing treatments and resources. The Parent Education service involves four sessions to introduce developmentally-based strategies to help parents to more effectively play and interact with their children. Sessions are offered in individual format either in-person or video conference.
Results: A total of 1100 families have accessed the program over the past three years, hearing about ESPA from other families, service providers, online, parent support groups, and flyers posted in the community. The majority of program participants (89.5%) live in the San Francisco Bay Area where the program is located, although families from surrounding areas, other states, and other countries have also reached out for support. A majority of the children (66%) are between the ages of 18 months to 7 years and most parents call within a few weeks of ASD diagnosis. However, ages of participants have ranged from 5 months to 65 years and families have connected with the program at all stages in the diagnostic process. Our analysis found that most often families request information related to accessing 1) behavior, speech, and occupational therapy through insurance, 2) special education services through the public school system, and 3) regional center services. Families have also requested lists of providers, opportunities to participate in research, information about parent support groups, and opportunities for children to connect socially with peers. Anonymous surveys of parent satisfaction indicate services were rated as excellent (86% for clinical care coordination and 98% for parent education).
Conclusions: With lengthy waitlists for diagnosis and treatment, many families are frustrated by the delay in accessing early intervention services. ESPA provides an innovative delivery model for parents to receive critical support navigating service systems as well as education to strengthen the parent-child relationship. Further research on programs such as this one will provide important insights into how providers can minimize stress and foster empowerment in the period immediately following ASD diagnosis.

229 **127.229** Educating Health Care Professionals about ASD through an Online Learning Module

P. Burnham Riosa[1]*, A. Greenblatt*[2] *and B. Muskat*[3]*, (1)Centre for Applied Disability Studies, Brock University, St. Catharines, ON, Canada, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)Hospital for Sick Children, Toronto, ON, CANADA*

Background: The rate of associated medical conditions among youth with ASD is high, at a prevalence of approximately 40 to 60% (Coury, 2010; Kielinen et al., 2004; Liptak et al., 2006). Because of the complex presentation of ASD and other possible health needs, this patient population is likely to come into contact with various health care professionals. During hospital visits in particular, youth with ASD may require a host of specialized supports in order to deliver medical services safely, and to optimize care experiences and outcomes. Currently, there is a limited understanding of how to best support this patient population. Health care professionals (HCPs) have reported feeling ill prepared to provide appropriate care and support for patients with ASD.
Objectives: Research has shown that families face many unique hospital challenges; many HCPs and other hospital staff are not well prepared to care for youth with ASD and want ASD-specific training (Muskat et al., 2015). Therefore, the main objectives of this project were to: (1) develop and implement an online training module for hospital staff about ASD and (2) evaluate hospital staff's perceived utility of the online module.
Methods: The online module was a pilot project developed by professionals with clinical and research expertise in ASD in collaboration with the educational technology department at the hospital. Hospital staff were notified about the module through email (departmental listservs) and a notice on the hospital website. Following participation in the 10-minute module, learner feedback was solicited though a series of open- and closed-ended questions.
Results: Eighty-five participants completed the module (nurses: *n* = 28; physicians: *n* = 4; allied health professionals: *n* = 43, other: *n* = 12). Majority of participants answered the subsequent evaluation questions; however; there were some missing responses. All participants (*n* = 80/80; 5 did not complete this question) perceived the module to be easy to complete. Majority of participants (67%, *n* = 56/84) had prior ASD-focused education/training and many (64%, *n* = 41/64) had experience working with 20 or more children with ASD. Even with a sample of hospital staff that had ASD-specific experience and training, 66% (*n* = 53/80) reported that they learned something new and 85% (*n* = 69/81) reported that the module information would be helpful in their daily work. Approximately 89% (*n* = 70/79) of participants said that they would recommend it to their colleagues. Open-ended feedback was examined and revealed that participants were interested in receiving additional ASD online module training opportunities. Topics of interest included: funding issues faced by parents, hands-on behaviour management strategies, assessment and intervention strategies, summaries of current treatments and other ASD-related research, in-hospital resources, guidance for practical issues (e.g., medication adherence), guest speaker presentations, and ASD training geared specifically for protection services staff.
Conclusions: The results from this pilot evaluation have important practice implications for HCPs and other hospital staff who encounter and care for patients with ASD and their families. Next steps for this online module will be discussed.

230 **127.230** Embedded Behavioral-Health Services for Children with ASD in Pediatric Primary Care: Feasibility and Resident Training

A. Dubin[1]*, T. Foster*[1]*, Z. Warren*[2] *and J. F. Hine*[3]*, (1)Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt University, Nashville, TN, (3)Dept of Pediatrics, Vanderbilt University Medical Center, Nashville, TN*

Background: Â Prior research suggests that behavioral health problems are diagnosed earlier and better managed when behavioral health providers are integrated within primary care settings (Chomienne et al., 2011) and that physicians report satisfaction regarding the ability to refer patients to behavioral health providers for rapid assessment and intervention (Clatney et al., 2008). Similar results were obtained when examining ASD-specific behavioral services in a pediatric primary care practice (Herrington et al., 2016). However, little research has examined similar outcomes among physicians in *training*(i.e., medical residents). Medical residents report low comfort levels regarding ASD (Broder-Finger et al., 2014), and investigations are lacking regarding residents' satisfaction and learning associated with working alongside behavioral health providers to treat patients with ASD.
Objectives: Â The current study aimed to extend previous research by (1) collecting additional information about the feasibility and outcomes associated with incorporating ASD-specific assessment and brief intervention services in a primary care clinic and (2) surveying residents who work alongside a behavioral health provider about their training experiences, perceived comfort in working with individuals with ASD, and further training needs.
Methods: A psychology provider was physically embedded in a resident primary care clinic associated with an academic medical center one day per week. The provider was available solely for providing follow-up for ASD-related concerns (e.g., failed screenings, diagnostic referrals, behavioral consultation). Data about referral types, show rates, and latency to consultation and diagnosis were used to assess feasibility and impact. In addition, medical residents were asked to complete surveys comprised of 1-5 point Likert items examining their perceptions of the benefits of the embedded psychologist; comfort level in screening, diagnosing, providing recommendations, and managing behaviors of children with ASD during appointments; and training needs. Residents' training experiences, familiarity, and comfort level specific to ASD also were compared with those related to commonly encountered medical diagnoses (e.g., diabetes).
Results: Â Preliminary data show the integrated behavioral health provider within the resident pediatric primary care clinic was able to see 75 children referred due to concerns for ASD over ten months; 33 of these children (44%) were diagnosed with ASD. It was possible to make a diagnosis within the initial consult session for 67% of the children; further testing was required for the remaining children. The latency to evaluation and diagnosis for referred children was less than two months, compared with a minimum of 6-7 months for specialty clinic assessment. Similarly, the median age at diagnosis (34 months) was considerably lower than the national average of approximately 50 months. Updated clinical data and additional data regarding resident's perceived comfort and training needs associated with working with patients with ASD will be provided in detail.
Conclusions: This study extends support for the value of embedding behavioral health services for children with ASD within pediatric primary care settings.

231 **127.231** Environmental Enrichment Therapy for Autism: Outcomes with Increased Access

M. Leon[1]*, E. Aronoff*[2] *and R. Hillyer*[3]*, (1)UC Irvine, University of California, Irvine, Irvine, CA, (2)Mendability, American Fork, UT, (3)Mendability, LLC, American Fork, UT*

Background: While there are several behavioral therapies available for ASD treatment, these programs are inaccessible to many, are often costly, are typically less effective as patients age, are not reliably effective, and may address a narrow range of symptoms. A treatment that successfully addresses the limitations of current therapies therefore would be of great value. Two randomized clinical trials have shown that environmental enrichment can ameliorate the symptoms of ASD, but there was no evidence that this approach could ameliorate such symptoms under real-world circumstances.
Objectives: We therefore determined whether providing environmental enrichment via an online system could improve ASD symptoms.
Methods: 1,002 individuals, 1-18 years old were given daily environmental enrichment by their parents, guided by an online system, and assisted by occupational therapists, who communicated via phone or email. The parents were asked to assess the symptoms of their child with a comprehensive questionnaire every two weeks for 7 months and the therapy could be regularly customized by a computer algorithm, based on the specific needs of the child.
Results: An intention-to-treat analysis showed significant gains for a wide range of symptoms that included: learning, memory, anxiety, attention, motor skills, eating, sleeping, sensory processing, self-awareness, communication, social skills, mood, and core autism behaviors. The children of compliant caregivers had greater improvement in their symptoms than children of non-compliant parents. The treatment was effective across a wide age range and across all levels of initial symptom severity. There also was equal progress for males and females.
Conclusions: Environmental enrichment in the form of Sensory Enrichment Therapy, delivered via an online system, appears to be an effective, low-cost, accessible means of treating ASD symptoms.

232 **127.232** Evaluating Process and Impact of an Autism Intervention Training Program (AITP) for Professionals in India.

K. Sengupta[1]*, C. Patil*[2] *and D. Scheelen*[3]*, (1)Ummeed Child Development Center, Mumbai, Maharashtra, India, (2)Ummeed Child Development Center, Mumbai, India, (3)Independent Consultant, Medford, OR*

Background: Low & Middle Income Countries (LMIC) like India lack professionals trained specifically for delivery of services to children with ASD. The few existing programs for training parents and non-specialist professionals often address discrete skills like social communication, challenging behaviors etc. There is an urgent need to create transdisciplinary resources trained to address comprehensive challenges associated with ASD across childhood and adolescence, using evidence-based practices.
Objectives: To evaluate the process and early impact of a training program in autism intervention (AITP), piloted by a not-for-profit organization in Mumbai, India for in-service multidisciplinary professionals.
Methods: A 6-month certificate program was piloted at Ummeed in Mumbai, India in 2016 to train in-service professionals in intervention approaches in children with ASD. Informed by the existing evidence base, practice wisdom, community feedback and a formal needs assessment survey, the curriculum was planned to provide participants knowledge and skills in assessment, goal planning, intervention techniques, special issues in autism and engaging families in care for children (1-12 years old) with ASD. The modular course provided information through lectures, practical experiences and on-job supervision via Skype. 12 in-service professionals, with work experience ranging from 2-25 years, representing 12 organizations, from 7 cities across India, including occupational, speech & physiotherapists, psychologists and special educators participated in the pilot.
The training program was evaluated using Kirkpatrick's Evaluation criteria. Reaction and knowledge were measured via pre-post questionnaires, video samples of work and case presentations. A qualitative approach was used to evaluate therapist perception of change in attitude & behavior and overall impact. Following a constructivist-interpretivist paradigm, in-depth interviews were conducted with 11 participants, transcribed, manually coded and analysed for content.
Results: Participants were motivated to participate due to their inability to see progress in children with ASD using existing skill sets and a desire to learn more. All participants found the AITP content relevant, useful across settings and culturally applicable. They greatly appreciated the value of post training supervision, with non-judgmental, supportive supervisor attitude and peer support. Participants endorsed the value of being taught different approaches to intervention and family centered care.
Participants in early stages of their career described increase in number of children with ASD they work with and improvement in ability to identify red-flags of ASD in undiagnosed children, engagement with families, coordination of care and overall self-efficacy. More experienced participants in positions of responsibility within organizations additionally influenced change in prevalent practices in organizations and trained co-workers, parents and teachers in schools. Parent organizations of 2 participants, catering to children with cerebral palsy in Kolkata and Chennai, started services for children with ASD post their participation in AITP.
Conclusions: This study demonstrates how local clinical and training expertise can be utilized effectively to create a structured yet broad, culturally appropriate training program in Autism intervention for in-service professionals that harnesses and builds on their existing skills. While long term impact needs to be evaluated, current findings can potentially inform development of similar training programs across other LMICs, thereby addressing the needs of multiple stakeholders in the community.

233 **127.233** Evaluation of Multiple Iterations of Government Funded Applied Behaviour Analysis Services for Children and Youth with ASD

K. Dobranowski[1] *and M. Lloyd*[2]*, (1)Faculty of Health Sciences, University of Ontario Institute of Technology, Oshawa, ON, Canada, (2)University of Ontario Institute of Technology, Oshawa, ON, CANADA*

Background: Â The Durham Region Applied Behaviour Analysis (ABA) based-services and supports is a government funded program for children and youth with Autism Spectrum Disorder (ASD). When parents enrol their children in the program and provide written confirmation of ASD diagnosis they are placed on a waitlist; when children are discharged from the program parents are given the option to put their child back on the waitlist. Goals for the service are discussed with parents and accordingly individual service plans are developed. As a result, this program has seen children receive 1, 2 or even 3 rounds of ABA based-services since 2011.
Objectives: As part of an overall program evaluation we sought to understand the needs of the children who have received more than one round of service, and the outcomes of the service (i.e. goals achieved).
Methods: Â Data from de-identified ABA clients was extracted from the treatment centre's health information management system for services delivered from September 1, 2011 to March 31, 2016. The data for each round of service was cleaned, sorted and analyzed according to age, sex, area of concern (i.e. communication, behaviour, social and activities of daily living) and outcome of program. The outcome of the program is determined by assessing the service plan and implementing a goal achievement scale to determine if children achieved or did not achieve their goals in the allotted time.
Results: The ABA program saw 1044 individual children and youth over 5 years, of which 71.0% received one round of service, 26.0% received two rounds, and 3.1% received three rounds equalling over 1300 delivered service plans. The average age of children and youth with: one round of service was 8.5 years, with two rounds was 7.7 years, and with three rounds was 6.4 years. There were 266 children and youth who received two rounds of service, and 77.8% achieved their goals. Approximately half (51.1%, n=135) of these children received services for the same area of concern in both rounds (mostly for communication) and 79.2% whose 2nd service was in the same area of concern achieved their goals; the other half (48.9%, n=129) changed their area of concern for their second round of service and 71.3% achieved their goals. Within individuals with two rounds of service, 64% of females switched their area of concern while 46% of males did. There were 32 children and youth who received three rounds of service, and 66.7% achieved their goals. 53.1% of these children received three rounds of service for the same area of concern (majority were for communication) for all three rounds and 46.8% of children or youth changed their area of concerns and 73.3% achieved all of their goals.
Conclusions: It is unclear why children and youth are staying within the same area of concern in each round of service given the high rate of goal achievement. Future research should examine why families return to the area of concern (e.g. was there a regression or is it a new goal in that area of concern).

234 **127.234** Experiences of College Students with Autism Spectrum Disorder: A Focus Group Study

J. Kaboski[1]*,* ***J. M. Olivieri***[2]*, E. A. DeLucia*[1]*, K. Tang*[1]*, M. B. White*[3] *and A. R. Sinko*[3]*, (1)University of Notre Dame, South Bend, IN, (2)Saint Mary's College, Notre Dame, IN, (3)University of Notre Dame, Notre Dame, IN*

Background: Current evidence suggests that individuals with Autism Spectrum Disorder (ASD) have more difficulty obtaining a college education than their typically developing (TD) peers (e.g., Getzel, 2008; Jorgensen et al., 2009). The U.S. Department of Education states that 35% of students with ASD who entered college completed a degree within 6 years, as opposed to 51% of TD adults (Sanford et al., 2011). It is well documented that college students with ASD may struggle with both social and organizational aspects of the college experience (White, Ollendick & Bray, 2011). However, few focus groups, interview-style studies, or case studies have been conducted to analyze the difficulties that ASD students face in college, particularly with regard to students who have attended four-year colleges.
Objectives: The primary goal of this study was to better understand the experiences of students with ASD as they navigate their enrollment in a four-year college. Questions asked were on the subject of: (1) academia, (2) socializing, and (3) available resources. This focus group was designed to evaluate the successes and gaps in four-year colleges at providing adequate support for ASD students in order to succeed.
Methods: Â Five young adults were recruited based on their self report of having received some ASD-related diagnosis at some point in their lives (including DSM-IV-TR diagnoses of Asperger syndrome and PDD-NOS) and attended at least 1 semester of four-year college. Participants came to our laboratory for two focus group sessions one week apart. Each session was two hours long and was facilitated by a licensed clinical social worker who specializes in working with college students with ASD. The investigators provided the facilitator with prompts and questions as a foundation of issues to discuss. Sessions were recorded, transcribed, and analyzed for common themes and experiences among the participants.
Results: Â The participants' conversations during the focus group were transcribed to analyze common themes among students with ASD in upper level educational institutions. Participants identified academic difficulties regarding time management, long term papers or other long-term assignments, as well as a preference to work independently rather than in groups. Multiple participants also reported feeling confused when trying to understand and interpret a professor's lecture or instructions for an assignment, and participants often did not fully understand the process of obtaining accommodations through Disability Services. Participants recommended that incoming students with ASD contact the Disabilities Services at their college before attending in order to understand the services available to them before classes begin. With regard to social aspects of college, participants reported difficulties meeting other students in classes, and perceiving their peers not comprehending or understanding their needs. In particular, participants who had roommates often reported difficulty sharing living quarters with them.
Conclusions: These results highlight common experiences among several college students with ASD who all attended different four-year colleges. They suggest a need for further evidence-based academic and social supports for college students with ASD.

235 **127.235** Exploring Differences in Autism Spectrum Disorder Symptomology By Racial/Ethnic and Socio-Economic Status

S. F. Vejnoska[1]*, K. S. Dickson*[2]*, S. R. Rieth*[3]*, J. Suhrheinrich*[4] *and A. C. Stahmer*[5]*, (1)UC Davis MIND Institute, Sacramento, CA, (2)Child and Adolescent Services Research Center, San Diego, CA, (3)San Diego State University, San Diego, CA, (4)University of California, San Diego, La Jolla, CA, (5)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA*

Background:
Despite the identification of effective treatments, parents face many barriers obtaining recommended services for children with autism spectrum disorder (ASD; Benevides, Carretta, & Lane, 2016; Mandell et al., 2010). Minority and economically disadvantaged groups may experience particular difficulties receiving services. Studies examining disparities find that children from ethnic and racial minorities are diagnosed with ASD later than their White peers (Mandell et al., 2009), and suggest that Hispanic children with milder forms of ASD may be under-diagnosed (Chaidez, Hansen, & Hertz-Picciotto, 2012; Jo et al., 2015). Children living in higher socioeconomic status (SES) families are diagnosed earlier than those in lower SES families (Fountain, King, & Bearman, 2011). Minority children also begin receiving ASD specific services later than White peers (Magaña & Smith, 2013; Mandell et al., 2009) and Latino children receive fewer ASD specific services (Magaña et al., 2013).
Previous data were typically drawn from large national or statewide datasets designed to analyze the general degree of disparity across racial/ethnic and SES groups. This project seeks to limit some sources of variability by examining differences in characteristics of students served under the autism educational category in Southern California. Limiting the sample to one region likely removes discrepancies in diagnostic and treatment service quality and availability across regions and states that may be contributing to disparities identified in larger examinations.
Objectives:
To examine the symptomology of a diverse sample of public school students served under the educational category of autism to examine possible differences related to race/ethnicity or maternal education in (1) intellectual functioning, (2) ASD symptom severity, and (3) adaptive behavior.
Methods:
Participants included 279 students served under the autism educational category, living in a large, ethnically diverse area. Standardized measures of student cognitive level, ASD symptoms, and adaptive behavior were collected. Maternal education level and student race/ethnicity was collected via a demographics survey completed by parents. One-way analyses of variance (ANOVA) tests assessed mean differences observed on all measures across maternal education and student race/ethnicity. A factorial two-way ANOVA tested the interaction between maternal education and student ethnicity. Appropriate post-hoc analyses were conducted using Tukey's Honest Significant Difference method.
Results:
Results demonstrated a significant relation for maternal education level with both cognitive scores and ASD severity. Students from lower educated mothers had lower cognitive scores and more severe autism symptoms than those from higher educated mothers. A significant interaction between maternal education level and race/ethnicity on cognitive scores indicated that higher maternal education levels were associated with higher cognitive scores for White and Non-Hispanic/Latino-Other students compared to Hispanic or Latino students.
Conclusions:
These findings suggest a potential disparity in the identification of students with ASD due to maternal education level, with children from lower resource families requiring higher symptomology for identification under the autism educational category. Implications and limitations will be discussed along with future research needs to improve access to quality care for students from low resource families.

236 **127.236** Exploring the Service Needs of Families and Children with ASD: Understanding Service Type, Insurance Status, and Outcome Indicators.

K. Casagrande *and B. Ingersoll, Michigan State University, East Lansing, MI*

Background: Families of children with ASD utilize a greater number of services than families of children with other special healthcare needs. However, they also report more unmet needs. This is especially true for family services, such as parent-training and respite care. Differences in service access are further influenced by family socioeconomic status (SES) and insurance status. Some research suggests that families in the Medicaid system receive more services than those covered by private insurance, while others argue that this may be due to inefficient service delivery. Reported services are also affected by different service indicators, such as cost, satisfaction, or number of visits. This combination of differences makes it difficult to understand the service needs of this population.
Objectives: We aim to better understand service needs of families of children with ASD through exploratory analysis focusing on: 1) service types, 2) insurance status, and 3) service outcome indicators.
Methods: Parents of children with ASD (n=249; mean=9.7 years old) completed a demographic questionnaire and a modified version of the Services Inventory. Modifications were made based on common service needs of families and children with ASD, as well as recommendations from parents and professionals. Special attention was given to ensure that the content would be clear to low-income families receiving services within the Medicaid system. Parents were asked to indicate whether they receive, need, or do not need each of 28 common intervention, ancillary, and family support services. Service adequacy was measured as the ratio of total services received to the total number of services needed and received. Parents also indicated satisfaction with each service they receive and how they pay for their child's services (i.e., private insurance, Medicaid, or out-of-pocket).
Results: Â The relationship between all service use variables was high, indicating that parents' perceptions of service adequacy were consistent with more objective measures. Families reported receiving 8 different services on average. This represented 44% of needed common intervention services, 55% of needed ancillary services, and 37% of needed family support services, indicating unequal distribution of needs. There were also differences based on SES. Higher SES families reported greater service adequacy than lower SES families ($p<.001$, $d=.51$). Furthermore, families with private insurance actually reported higher service adequacy ($p=.002$, $d=.43$) compared to families of children with Medicaid. Across service types, privately insured families received more common interventions ($p<.001$, $d=.58$) and ancillary services ($p=.042$, $d=.30$) than Medicaid families, but there were no differences in family support services ($p=.282$, $d=.16$).
Conclusions: Despite recent changes in insurance legislation, families of children with ASD continue to face high levels of unmet needs, which are intensified by lower SES. In contrast to previous research, we found that privately insured families reported better service outcomes; however, many families reported mixed insurance status. Family-support services emerged as a primary area of unmet needs that was equal among privately insured and Medicaid families. Results suggest that overall improvements need to be made in family support services, as well as efforts to improve service access among lower SES families.

237 **127.237** Five-Year Program Evaluation of a Government Funded Applied Behaviour Analysis Program

M. Lloyd *and K. Dobranowski, Faculty of Health Sciences, University of Ontario Institute of Technology, Oshawa, ON, Canada*

Background: Â Since September 2011, the Durham Region, in Ontario, Canada has been providing customized Applied Behavioural Analysis (ABA) services and supports to children and youth with Autism Spectrum Disorder (ASD) and their families. This program is available for children and youth with ASD up to their 18th birthday. This government funded ABA program is designed to be short-term and intensive (i.e. between 2 to 4 hours per week and 2 to 6 months). The clinicians, in consultation with the parents, develop goals for each child upon entry and create a unique service plan to help the child achieve these goals (using goal achievement scaling).
Objectives: Â The objective is to describe the program evaluation results of Durham's ABA-based services examining who has received the services according to age, sex, area of concern (i.e. behaviour management/emotional regulation, communication, social/interpersonal, or daily living skills.), and the outcome of service plan (goals achieved).
Methods: De-identified data on ABA clients housed in a health information management system were extracted for services delivered between September 1, 2011, and March 31, 2016. The data was cleaned, sorted, and relevant variables were selected for coding and analysis.
Results:
The ABA program administered 1373 service plans in 5 years to 1044 individual children (once a round of service is complete, parents can place their child back on the waitlist to receive another round of service); 82% were male, 18% were female, and the average age was 8 years old. The largest number of service users were between the ages of 6-10 (42.5%) followed by 0-5 year olds (31.9%). The most common area of concern for service users was communication skills (37.5%), followed by behaviour skills (28.8%), social skills and activities of daily living (27.2% and 6.5% respectively). Children aged 6-10 and 11-14 were most likely to receive services for behaviour (38.8% and 40.7% respectively), and communication was the most common area of concern for children aged 0-5 (70.3%), whereas youth aged 15-17 were most likely to receive services for social skills (45.5%). 82% of the clients achieved their goals. By area of concern, those who received services for communication were the most likely to achieve their goals (87.5%). Those age 0-5 were the most likely to achieve their goals (88.6%) and those aged 15-18 were the most likely to not achieve their goals (23.6%). The percent of males and females who achieved their goals was similar across the age groups, ranging from 77-90%, except for females in the 15-18 age range, where only 55.6% achieved their goals. Among those who did not achieve their goals, the majority (20.0%) cancelled their sessions and had difficulty fulfilling their plan (19.0%).
Conclusions: In its first 5 years, the Durham ABA-based services and supports for children and youth with ASD has demonstrated to be effective at facilitating the achievement of the goals established by the families. It is critical to understand why children and their families have difficulty with their service plans in order to best support these families.

238 **127.238** How Does Transitioning to a Mainstream 'Satellite' Class Affect the Learning, Social and Emotional Functioning of Special School Pupils on the Autism Spectrum?g of Special School Pupils on the Autism Spectrum?

A. Croydon[1]*, A. Remington*[2]*, L. Kenny*[2]*, H. White*[1] *and E. Pellicano*[2]*, (1)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, UCL Institute of Education, University College London, London, United Kingdom, (2)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom*

Background:
In line with international efforts to promote inclusive education, current legislation in England places a duty on local authorities to ensure that a child or young person with a special educational need or disability (SEND), including autism, is educated within a mainstream setting. The often-significant learning and behavioural needs of autistic children and young people, however, can seem to make it particularly challenging to include these children effectively within regular, mainstream schools and to obtain appropriate educational provision compared with children with other SEN. One solution may be the 'satellite' model of education where special school pupils with autism are relocated to mainstream schools but remain in separate ('satellite') classes, receiving the tailored curriculum and specialist teaching of the originating school, with access to the social and learning opportunities of a mainstream placement. There is, however, remarkably little research on the impact of transition to such satellite classes.
Objectives:
This study therefore sought to understand the impact of transitioning from an autism-specific special school to two satellite classrooms – one in a mainstream primary and another in a mainstream secondary school on the learning, social and emotional functioning of a group of young autistic people with additional intellectual disabilities and varying degrees of communicative competence.
Methods:
The current study focussed on one example of the satellite model, recently implemented by the local education authority in the London borough of Tower Hamlets, which houses a diverse ethnic population, with high levels of child poverty and special educational needs, and where many families do not have English as a home language. Questionnaires and interviews with autistic students (n = 10; 1 girl), their parents and teachers examined the academic, social, emotional and behavioural development of transitioning students and were completed twice within the space of one year – immediately before and 12 months after transition.
Results:
Overall, the young people, their parents and their teachers were extremely positive about their satellite placements and identified encouraging outcomes in terms of students' learning, behaviour and social awareness. There was considerable agreement between teachers, parents and children that fewer behavioural issues in the satellite classes were a key benefit of the transition, enabling children and young people to 'raise their game' in terms of their learning and their own behaviour. Although the satellite students and their families did not appear to be fully integrated into the life of host mainstream schools, families considered inclusion in the satellite classes as a positive outcome in itself, and some perceived a greater sense of social inclusion and acceptance for their children.
Conclusions:
This research offers unique insight into the experience of transitioning from special school to satellite classrooms in a mainstream setting, from the viewpoint of the young people, their parents and teachers. The findings highlight the benefits and also the challenges of the process and of the satellite class model itself – a potentially promising model for educating children and young people in England.

239 **127.239** ICF-CY Domains of Importance for Parents of Young Children with Autism Considering Treatment Outcomes and Quality of Life: Family-Centered Beyond Professional-Child Intervention.

***K. Strauss**, A. Delle Fratte and L. Fava, Association for Treatment and Research in Autism and Related Conditions, Umbrella Autism, Rome, Italy*

Background:
Early Intensive Behavior Interventions (EIBI) that foster Parent Inclusion distinguish in the professional's role to support the family to identify challenges to participation, and to instruct in ways that built child and family capacity. The International Classification of Functioning, Disability and Health - Children and Youth version (ICF-CY) framework support professionals consideration of parental perspectives on children's Activities, Participation and Environmental Factors associated with EIBI.
Objectives:
This action research from Italy sought to (1) employ ICF terminology in categorizing the concerns and goals regarding EIBI based on a preliminary autism core set, (2) develop an extended schedule of the instrument to assess severity-related parent treatment priorities, (3) to document the association to perceived family Quality of Life, and (4) to assess the rate of agreement in treatment priorities based on child skill performance between parents and professionals.
Methods:
Through an action research process, 20 parents of preschoolers with autism spectrum disorders who received EIBi intervention with active Parent Inclusion provided ratings of parent Quality of Life (WHOQOL-BREF, WHOQOL group, 1998), child functioning (ICF-CY developmental code sets and autism-specific ICF-CY components, Castro et al., 2013; Boelte et al., 2016), and assigned each a measure of treatment priority. Each ICF-CY profile was analyzed by two clinicians, a neuropsychologist and a clinical supervisor, and clinically chosen treatment priorities assigned. A total of 130 ICF-CY categories were included. For analysis categories relevant in at least 30% of the cases were retained and reported as follows.
Results:
The resulting schedule retained N=69 items of parent concerns were distributed mainly across ICF-CY Activity and Participation (44 items), less across Body Functions (29 items) and Environmental Factors, (5 items). Parental concern and treatment priority varied with the content of unit analyzed with parents focussing mainly on psychosocial and communication functions. In addition parents demand high support priorities in managing health and social service systems and policies. In choosing treatment priorities parents apply a deficit-based selection approach coherently with high priorities where child's abilities are lacking. Clinicians priority interrater agreement was high (kappa range .07 to .08), while parent - clinician interrater agreement was small to moderate (kappa range .04 to .06). A quadratic relation was found for child performance and clinician treatment priorities. Clinicians apply a strength - based approach to priority selection were basic skills are present and a deficit-based approach in major deficit areas that are defined teaching barriers (such as imitation, attention). Family Quality of Life was negatively impacted by poor child performance in communication, major life areas and handling demands , as well as lacking services that meet the child's needs.
Conclusions:
The results indicate that (a) a functional perspective added to diagnostic indicators may inform intervention practices, and (b) environmental factors such as the professional-family rapport impact family Quality of Life and thus intervention outcome. We found that parents follow a need-based logic in treatment expectations, whereas professional treatment planning mainly incorporates a strengths-based logic following the notion of proximal development.

240 **127.240** Impact of Household Income and Urbanicity on School Services

***B. L. Baer**[1], A. R. Marvin[2], P. H. Lipkin[3] and J. K. Law[1], (1)Interactive Autism Network, Baltimore, MD, (2)Kennedy Krieger Institute, Baltimore, MD, (3)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD*

Background: Access to an appropriate educational setting is a priority for families of children with autism spectrum disorder (ASD).
Objectives: (1) To determine how school type, school services, and suspension rates for children with ASD are associated with household income and urbanicity (as determined by surrounding population density). (2) To determine whether emotional, academic, and special needs of children with ASD are being met in the school system by household income and urbanicity.
Methods: Â Parent participants in the Interactive Autism Network (IAN)— a large, validated and verified, internet-mediated parent-report research registry—completed the School Service Questionnaire (SSQ) on their child(ren) with ASD. The SSQ asks questions regarding special services, school placement, suspension and drop-out rates, and satisfaction with school services. Data from the IAN registry regarding participants' household income and urbanicity (using the 2013 NCHS Urban-Rural Classification Scheme for Counties) were also included in the analysis.
Results: Parents of 1774 children with ASD (79.9% male) completed an online survey on school services as part of a series of baseline questionnaires for the Interactive Autism Network (IAN). The data revealed that urbanicity (urban, suburban, small-medium metro, rural) was significantly related to use of certain special services such as behavior therapy ($X^2(3)=9.12$, $p=0.028$), assistive technology ($X^2(3)=13.68$, $p=0.003$), applied behavior analysis ($X^2(3)=14.34$, $p=0.002$), and social skills training groups ($X^2(3)=13.37$, $p=0.004$). Each of these services was more common in suburban areas compared to urban, small-medium metropolitan, and rural areas. Household income was also significantly related to the use of social skills training groups: families in the third and fourth income quartiles were more likely to use this service ($X^2(3)=9.85$, $p=0.02$). School placement was significantly affected by urbanicity ($X^2(12)=39.34$, $p<0.001$), with home school and public school being more common in rural settings, and private/non-public, specialized private, and specialized public being more common in urban settings (see table 1). In terms of income, 69.2% of children in all household income quartiles were in the public school system. However, there were significant differences by income quartile ($X^2(12)=55.12$, $p<0.001$) as to where the remaining children attended (see table 2). Higher suspension rates were significantly associated with smaller urbanicity settings ($X^2(3)=13.286$, $p=0.004$), but suspension rates did not significantly differ by household income. Lastly, parents' satisfaction with school services meeting their child's emotional, academic, and special needs significantly differed by household income, with higher income quartiles having generally higher rates of satisfaction. Parent satisfaction, however, did not differ by urbanicity.
Conclusions: There are discrepancies in the use of special services, school placement, suspension rates, and level of satisfaction with school services based on urbanicity and household income. These findings point to the need for better educational access for children with ASD who come from less-resourced settings.

241 **127.241** Improving Diagnostic Capacity for Autism Spectrum Disorder in a Developing Country: A Model Public/Non-Governmental Organization (NGO) Partnership Program

P. Bahadursingh[1], *J. S. Ramcharan*[2], *N. E. Dick*[3] *and R. Teelucksingh*[4], *(1)South West Regional Health Authority, San Fernando, Trinidad and Tobago, (2)Child Health, University of the West Indies, Mt Hope, Trinidad and Tobago, (3)Paediatrics, North Central Regional Health Authority, Champs Fleur, Trinidad and Tobago, (4)Rotary Club of Port Spain West, Port of Spain, Trinidad and Tobago*

Background:
Accurate identification and treatment of autism spectrum disorder is considered a critical public health challenge even in well-resourced communities. In a developing country, the ability to actualise better services is further limited by resource challenges regarding funding, management support, political support, infrastructure constraints, and the limits of human resources. While clinical practice recommendations for identification/diagnosis of ASD support the use of structured/standardized tools, these tools and supportive training opportunities for use are often lacking with limited financial support available across resource strained public health systems. The current project utilized external funding support from a NGO to train professionals within the public health system to utilize standard tools for screening and diagnosis of autism.
Objectives:
We studied the impact of a NGO sponsored training in altering practice within the public health system for physicians, psychologists and therapists.
Methods:
In April 2015, a local Rotary Club, a Child Health Department of a tertiary institution, a Community Paediatric team in a Regional Health Authority (RHA) and the Training Department of the RHA came together to host training in specialised tools used for screening and diagnosis of Autism (Screening Test for Autism in Toddlers, STAT, Autism Diagnostic Observation Schedule-2, ADOS-2). In parallel a steering committee comprising all stakeholders was formed to discuss impact, use, and future directions. The project funded by the Rotary Club sponsored formal ADOS-2 and STAT training by a certified trainer from an external U.S. based university. The Training department of the RHA and the Rotary club worked together to oversee the administration of the project. The training was carried out in a public teaching hospital. Professionals trained included doctors, psychologists and therapists.
Results:
23 professionals comprising 2 child psychiatry and 2 child development services within the public health service received ADOS-2 training. 42 professionals representing all 5 RHAs received STAT training. In the year following training, some 42 ADOS-2 assessments and 75 STAT assessments of young children were conducted within the public health system with 3 out of 5 represented regional health authorities (RHA) incorporating use. In addition, the NGO investment led to an additional joint partnership supporting provider training in an evidenced-based parent training program. Subsequently, within the calendar year following training 60% of RHAs held parent training sessions for local families.
Conclusions:
In keeping with the United Nations mandate for upgrading services for Autism this Public/NGO partnership has served to bolster our capacity in a developing country. Given the constraints, financial and otherwise, this type of partnership may the way forward in developing countries. While the partnership has bolstered capacity and spurred additional collaborations, further supports and strategies beyond just provision of training and instruments is necessary to achieve wide-scale systems change and improvements in care within developing countries.

242 **127.242** Increasing Use of M-CHAT-R/Follow-up in Pediatric Care through Clinician Participation in a Maintenance of Certification Quality Improvement Project

L. Stewart[1], *R. Sturner*[2] *and B. Howard*[2], *(1)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Center for Promotion of Child Development through Primary Care, Baltimore, MD*

Background: Â The American Academy of Pediatrics recommends that all children be screened for Autism Spectrum Disorder (ASD) at ages 18 and 24 months using valid tools. Screening for ASD is critical for earlier identification and intervention to improve outcomes, yet routine screening is not uniformly implemented. Many practice-level barriers prevent the efficient and timely use of recommended ASD screens such as the Modified Checklist for Autism in Toddlers-Revised with the required Follow-up Interview (M-CHAT-R/F). These barriers to screening are often the target of Quality Improvement (QI) projects in pediatric care. Part 4 of the American Board of Pediatrics (ABP) required physician Maintenance of Certification (MOC-4) program—Improving Professional Practice—aims to increase physician knowledge of quality improvement methods and engagement in QI projects to improve care. One accredited MOC-4 program offered through the Center for Promotion of Child Development through Primary Care targets barriers to routine ASD screening among physicians using the affiliated web-based platform CHADIS, which supports developmental screening, clinical decision making, and patient engagement in pediatric care.
Objectives: Compare 6-month baseline average M-CHAT-R/F screening rates to 6-month post-MOC QI project rates to assess influence of physician participation in an MOC project on improving ASD screening.
Methods: All physicians enrolled in this MOC QI project completed a 10 minute online educational module on autism screening, diagnosis, and intervention. Physicians also met with coaches monthly for one hour to identify barriers to screening in his/her practice and plan QI activities to overcome them using the Plan-Do-Study-Act framework. Coaches reviewed run charts tracking the impact of QI activities on ASD screening rates with physicians. To assess practice-level impact of MOC-related QI activities, the number of M-CHAT-R/Fs completed using the CHADIS system was examined for the 6 months prior compared to the 6 months following MOC enrollment.
Results: MOC participation and M-CHAT-R/F screening data was analyzed from 138 clinicians representing 47 practices ranging from solo practitioner to multi-physician hospital settings across the U.S. On average, these physicians reported 24 years of clinical experience. Before MOC participation, 71% reported routinely screening for ASD at ages 18 and 24 months. Many barriers to appropriate use of the M-CHAT-R/F were identified, including inefficient office workflows, failure to administer follow-up interviews for all positive screens, and limited task-sharing and communication between clinical support and administrative staff. In the 6 months prior to MOC enrollment, an average of 21 M-CHATS-R/Fs were completed per month across practices. After MOC enrollment, the average number of M-CHAT-R/Fs completed in the CHADIS system increased to 30 per month, a 43% increase. Percent change in screening between baseline and follow up was positive among all enrolled practices and ranged from 12% to 180% increases in screening after implementing the Plan-Do-Study-Act QI framework and tailored improvement activities.
Conclusions: Physician participation in the MOC-4 quality improvement project offered through CHADIS increased rates of M-CHAT-R/F use across a 6-month period. Future projects engaging physicians in quality improvement at the practice level should be considered to reduce barriers to implementing routine ASD screening in pediatric care.

243 **127.243** Initial Efficacy of Primary Care Stepping Stones Positive Parenting Program on Reducing Risk of Dysfunctional Parental Discipline of Children Newly Diagnosed with Autism Spectrum Disorder

S. E. McMillin[1]*, M. W. Bultas*[2]*, K. J. Pierce*[2]*, T. M. White*[2] *and D. Zand*[3]*, (1)Saint Louis University, Saint Louis, MO, (2)Saint Louis University, St. Louis, MO, (3)Saint Louis University, St Louis, MO*

Background: Dysfunctional parental discipline practices have been implicated in the development and maintenance of disruptive externalizing behaviors by young children. Parents of children with autism spectrum disorder (ASD) commonly experience more disruptive behaviors from their children compared to parents of children without disabilities. Primary Care Stepping Stones Positive Parenting Program (SS-Triple P), a personalized, parent-mediated intervention that targets disruptive behaviors in their children newly diagnosed with ASD through the promotion of positive parenting practices.
Objectives: To investigate whether participation in a brief, one-to-one parenting intervention designed to target discrete problem behaviors impacted the disciplinary styles of parents of children newly diagnosed with ASD.
Methods: A two-group, pre- and post-test, open trial design with random assignment to intervention (N=12) versus wait list control (WLC, N=9) was administered. Patients were recruited from an urban Midwestern Autism Speaks-Autism Treatment Network diagnostic clinic and surrounding community. Child inclusion criteria included receiving a DSM-V ASD diagnosis in the past year from a physician or psychologist, age between 2 and 12 years, and demonstrating moderate to severe behavior problems (Eyberg Intensity T-Score>60). Parental discipline was measured using the Parenting Scale (PS), by Arnold, O'Leary, Wolff and Acker (1993) (α=0.86). This 30-item questionnaire measures dysfunctional discipline styles in parents by asking about the probability with which the parent uses particular discipline strategies. All 30 items are scored on a 7 point Likert scale, with low scores indicating good parental discipline and high scores indicating dysfunctional parental discipline. The Parenting Scale yields a Total score and three factors: Laxness (permissive, inconsistent discipline); Over-reactivity (harsh, emotional, authoritarian discipline and irritability); and Hostility (use of verbal or physical force).
Results: Â Parents who received 4 weeks of Stepping Stones Primary Care Triple P had a PS Total Score that on average was significantly lower than the PS Total Score of parents who had not yet received Triple P: $F(2, 19) = 8.33$, $p < .01$; Wilk's $\Lambda = 10.709$, partial $\eta 2 = .31$. In addition, parents who received 4 weeks of Triple P had significantly lower measures ofÂ Over-reactivityÂ than the parents who had not yet received Triple P: $F(2, 19) = 4.95$, $p < .05$; Wilk's $\Lambda = 0.793$, partial $\eta 2 = .21$. No other subscale produced statistically significant findings.
Conclusions: Â Initial results from this pilot study show that a brief, parent-mediated intervention for parents of children with ASD can bolster functional parental discipline styles and help parents avoid and reduce dysfunctional parental discipline styles. Specifically, parents who participated in the Triple P intervention were less likely to report using harsh, irritable, or authoritarian discipline compared to parents who had yet to receive the Triple P intervention. Because harsh discipline can exacerbate child behavior problems and because children with ASD commonly display some externalizing behaviors, interventions which bolster and reinforce good parental discipline strategies are important for families with children with ASD. Primary Care Stepping Stones Triple P is a brief (4 session) intervention that can improve parental discipline and be used long after treatment is complete.

244 **127.244** Interdisciplinary Team Evaluation: A Cost and Time Effective Method for the Clinical Assessment of Autism Spectrum Disorder

J. Gerdts[1]*, J. Mancini*[2] *and R. Bernier*[3]*, (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Seattle Children's Autism Center, Seattle, WA, (3)University of Washington Autism Center, Seattle, WA*

Background: Diagnostic evaluations for autism spectrum disorder (ASD) follow a range of processes that can be lengthy and contribute to long wait times for an evaluation. Focusing on essential features of diagnostic evaluations may create a more streamlined process at diagnostic centers, thereby alleviating wait times. At the Seattle Children's Autism Center (SCAC), we developed an interdisciplinary team evaluation model with two providers of different disciplines, allowing two patients to be evaluated in a single day (Figures 1 and 2). We previously reported commensurate family satisfaction and ASD diagnostic rates across three evaluation models: Team evaluation, Psychology only, and Physician only (Gerdts, et al., 2016). However, differences in actual reimbursement rates and billing times have been unexamined.
Objectives: To compare reimbursement rates and billed hours in Team evaluations versus more traditional ASD diagnostic evaluation methods.
Methods: Sixty-one patients who completed diagnostic evaluations at the SCAC were randomly selected to examine actual reimbursement amounts and billed time for full diagnostic evaluations (excluding an initial triage appointment). Patients were evenly distributed across evaluation types (n=18 for Team, n=21 for Psychologist, and n=22 for Physician). Fifty-three percent of patients had Medicaid and 47% had a commercial insurance plan, with no differences in insurance types across evaluation types (p=.94). Billed hours were determined by summing the time implied by the billing codes associated with the diagnostic evaluation. Net clinic hourly income for evaluations was estimated by calculating the difference between hourly reimbursement rates and average hourly salary rates for provider types at SCAC in the various evaluation tracks.
Results: Given the large discrepancy between Medicaid and commercial insurance reimbursement rates for evaluation, (t(59)=-6.57, p<.001), insurance type was entered as a covariate in analyses of variance. After controlling for insurance type, there were no significant differences in reimbursement rates across diagnostic tracks (p=.59). However, there were large differences in billed time, F(2, 58)=28.35, p<.001 with Teams billing significantly fewer hours than Psychologists only and significantly more than Physicians (Mean=4.5, 6.2, 3.0 hours, respectively for Team, Psychologist, and Physician tracks, p<.005). After controlling for insurance type, there were significant differences in hourly net income across diagnostic tracks, F(2,57)=29.39, p<.001, with highest clinic income for the Physician track (Mean net income=$142.49 per hour), followed by Teams (Mean=$92.37), followed by Psychologists (Mean=$24.30).
Conclusions: ASD Interdisciplinary Team Evaluations appear to be an efficient method for completing ASD diagnostic evaluations while still incorporating gold standard diagnostic tools (e.g., ADOS-2, caregiver interview), without detriment to family satisfaction and while maintaining consistency in diagnostic rates (as reported previously, Gerdts, et al., 2016). Team evaluations result in significantly fewer billed hours (nearly 2 hours less) than a traditional psychology-only evaluation, and generate more income relative to average provider salary when taking actual reimbursement rates into account.Â In ASD diagnostic centers employing a variety of providers, team evaluations focusing on ruling-in/ruling-out ASD may be an efficient and cost-effective method for conducting ASD diagnostic evaluations, likely beneficial in decreasing wait times thus expediting family's access to services that are often contingent on an ASD diagnosis.

245 **127.245** Living up to the Ethical Obligation to Secure the Rights of Individuals with Autism in Developing Countries

M. Indargiri[1]*, F. Crawford*[2] *and H. J. Bursztajn*[3]*, (1)clinical language sciences, university of reading, reading, United Kingdom, (2)WHEELOCK COLLEGE, BOSTON, MA, (3)harvard medical school, cambridge, MA*

Background:
Following World War II the United Nations Assembly, backed by 47 nations, enshrined key aspirations such as dignity, equality, freedom and respect in the Universal Declaration of Human Rights to, at a minimum, guard "against tyranny and oppression" (p. 71, Section 217 A, para.3). Since then, more than 70 treaties, including the Convention on the Rights of Persons with Disabilities (United Nations, 2006), have been signed to further secure these inalienable rights for "vulnerable" populations. Yet, according to a 2011 report by the World Health Organization these basic provisions continue to elude most of the world's 1 billion people with disabilities (most of who live in the developing world). Their progress is continually hindered by attitudinal, financial, and/or physical barriers in key social institutions.
Objectives:
The purpose of this conference discussion is to engage an interdisciplinary audience to contemplate the following question: What would it take for developed countries to share their expertise and resources with key constituencies in developing countries in order to positively impact the outcomes of children with autism?
Methods:
The impetus for this question stems from a service learning work experience in one resource limited country, Barbados that lead the authors to lead a series of workshops for parents of children with autism . These parents sought the knowledge, the expertise and key understandings about how to direct the inner lives of their children, and if they to have been provided adequate resources and training, would be able to do much more on behalf of the children and families with autism.
Results: N/A
Conclusions:
The authors hope that the question they pose for discussion would generate ideas for collaborating to both develop studies and outreach programs aimed at assisting parents and educators of children with autism in less resource-rich countries where access to well-established therapies and resources are scarce !

246 **127.246** Measuring Person Centred Outcomes for Autistic Adults in Receipt of Social Care – Lessons and Results from a Nationwide Study.

I. Dale[1]*, C. N. Hughes*[2]*, T. Humphrey*[3]*, H. Judge*[2]*, C. De Oliveira Ormrod*[4]*, C. Povey*[5] *and J. Rowland*[2]*, (1)The National Autistic Society, Sheffield, England, United Kingdom, (2)The National Autistic Society, London, United Kingdom, (3)University of East London, London, United Kingdom, (4)University of Manchester, Manchester, United Kingdom, (5)The National Autistic Society, London, UNITED KINGDOM*

Background: Many autistic adults receive social care (human services). This care is often publicly funded. Autistic adults and their families have a right to expect the care to lead to positive outcomes. The evidence base for how most effectively to provide this support is poor. Hence suitable outcome measures are needed. Previous attempts at measuring outcomes for autistic people have largely been based on the subjective views of researchers, or lengthy questionnaires which many autistic people have difficulty completing. Barriers to establishing outcome measures include: the costs and burdens which measurement processes impose on services and the people they support; the varying priorities of autistic people, and the importance of not imposing social norms on them; the varying levels of intellectual disability among autistic people and the forms of communication which they employ; and the range of stakeholders' expectations (autistic people, their families, commissioners of services, regulatory bodies, policy makers, service staff).
Objectives: This study was conducted by a leading nationwide charity for autistic people and their families. The study's objectives were (1) To consult each stakeholder group on the outcomes most of interest (2) To review existing approaches and their suitability for adults in receipt of social care (3) To test existing and new approaches in a cross-section of service settings.
Methods: The study comprised an international literature review of outcomes for autistic people; a nationwide review of existing approaches within the charity and among other autism charities and social care providers; focus groups and interviews with autistic people, families, social care staff and managers; a nationwide survey of 6,000 autistic people and their families; pilot fieldwork in a cross-section of service settings using questionnaires and observational methods; testing of recording systems; use of independent researchers; and analysis of administrative data held by the charity. The study received approval from the research ethics committee of an external publicly funded body.
Results: No single outcome measure was found that addresses all stakeholders' expectations. Safety, quality of family life, achievement of meaningful goals, reduced support needs, and societal benefits collectively go some way to meeting their evidence needs. No existing instruments or approaches were found that proved workable on a large scale in a social care setting. In particular multi-dimensional Quality of Life measures, even if adapted for people with an intellectual disability, have some use in goal setting but are too broad and abstract for use with many autistic people. Autistic people may also find them patronising or intrusive.
Conclusions: An effective outcomes framework for adult social care for autistic people should comprise a range of measures, primarily tailored to the individual and also if possible addressing other stakeholders' priorities. Although goal setting should be person centred, standard outcome measures which can be aggregated are preferable for benchmarking and evaluation. A mixture of observation, administrative data and fieldwork is needed. Outcome measures should not only be reliable and valid but also fulfil more practical and autism specific criteria such as being low burden, person centred, and flexible.

247 **127.247** Measuring the Social Return on Investment from Progression Support for Autistic Adults – Lessons and Results from Case Studies.

I. Dale[1], *C. Povey*[2] *and S. Peters*[3], *(1)The National Autistic Society, Sheffield, England, United Kingdom, (2)The National Autistic Society, London, UNITED KINGDOM, (3)The National Autistic Society, Bristol, United Kingdom*

Background: Autism is a lifelong condition experienced by a significant and possibly increasing proportion of the population. The direct financial cost of supporting autistic people and their families is significant. Outcomes for autistic people in adulthood are on average worse than for the rest of the population. Hence the wider economic and social benefits to society of providing support which leads to improved outcomes are also likely to be significant. Applying a Social Return On Investment (SROI) approach to interventions for autistic adults is a potentially informative way of understanding the balance of costs and benefits to society.
Objectives: The project's objectives are to assess (1) the applicability of SROI concepts to services for autistic adults (2) identification of autism specific issues necessitating modification of the SROI approach (3) the practicality of collecting longitudinal SROI data in a frontline service setting (4) the value and insights which the autistic adults, service managers, commissioners and other stakeholders derived from the resultant SROI estimates.
Methods: This project takes place within three geographically separate services operated by a leading nationwide autism charity. Each service was chosen because its focus is to support autistic adults in achieving progression towards a life course goal – for example successful transition into adulthood, or progression towards sustained, unsupported employment. A review of SROI approaches in government and the third sector was undertaken. A longitudinal dataset of service fees was constructed to quantify financial costs and identify individuals with apparently changing support needs. With individuals' consent, input data and contextual information was collected via interviews and case notes.
Results: Autism professionals, autistic people and their families generally agreed with the validity and relevance of the SROI approach. When case studies are completed, feedback will be sought from stakeholders on the insights they bring. Significant changes over time in individuals' service fees were less common than expected, suggesting that achievement of life course goals is rare, though further investigation may identify other factors that explain this finding. Autistic adults in receipt of these services often had a poor employment history, accessed health and social care frequently, andÂ some wereÂ in contact with the criminal justice system. This suggests there is high potential SROI which can be realised if services prove effective for at least some individuals up to a 'break even' point which the project will attempt to estimate.
Conclusions: The SROI approach appears to be applicable to services for autistic adults and of value to stakeholders. There are some challenges including the difficulty autistic people may have with recall or intrusive questioning; the often slow and uneven progress achieved towards outcomes; and the complexity of SROI calculations for untrained service managers. These challenges can potentially be overcome if a professional analyst is engaged, processes are co-produced with autistic people, and periodic data collection is built into the support planning and reviewing process.

248 **127.248** Mixed Method Feedback on the Integration of Parent Engagement Strategies into an Evidence-Based Parent Coaching Intervention for Young Children at Risk for ASD

R. Haine-Schlagel[1,2], *K. S. Dickson*[1], *S. R. Rieth*[1,2], *L. Brookman-Frazee*[1,3] *and A. C. Stahmer*[1,4], *(1)Child and Adolescent Services Research Center, San Diego, CA, (2)San Diego State University, San Diego, CA, (3)University of California, San Diego, La Jolla, CA, (4)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA*

Background: Parent meditated interventions have numerous positive effects on child/family outcomes and can provide intensive, daily intervention (Burrell & Borrego, 2012). These interventions require active parent engagement (service initiation, attendance, and participation; e.g., Haine-Schlagel & Walsh, 2015). Studies have suggested that specific provider approaches, such as parent-professional collaboration and problem solving, can facilitate parent engagement (Brookman-Frazee, 2004; Burrell, 2013). Little is known about how child-focused providers will perceive training specific to parent engagement, in particular as part of an evidence-based parent coaching intervention for children with ASD.
Objectives: The current study used mixed qualitative and quantitative methods to characterize provider perspectives on parent engagement strategies that were integrated into training on an evidence-based parent coaching intervention for young children at risk for ASD (Project ImPACT for Toddlers or PI for T; Ingersoll & Dvortscak, 2010). The engagement strategies, referred to as Alliance, Collaboration, and Empowerment (ACEs), were adapted from a toolkit initially designed for child mental health services (Haine-Schlagel et al., 2016)
Methods: Agencies serving toddlers with ASD were invited to participate. The first 15 agencies to respond identified an agency leader to learn PI for T and become an agency trainer (AT). Training was delivered over 12 weeks and included two sessions focused exclusively on ACEs. After an additional three months utilizing PI for T independently, ATs received a feedback survey (responses on five-point scale; 1=strongly disagree and 5=strongly agree) and were invited to participate in an interview by someone not involved in training. The survey and interview guide included several questions specifically about ACEs, which are the focus of this study. Data presented are from the first eight ATs to complete both the survey and interview. ATs were 87.5% female. Modal age range was 36-40; 25% were Hispanic/Latino. Average years of experience was 9.5 (range 4-28); 25% had a PhD and 75% had an MA/MS. Data collection is ongoing and will be completed by the end of 2016.
Results: Quantitative survey data and qualitative interview data were examined using complementarity (i.e., quantitative provides breadth/qualitative provides depth; Palinkas et al., 2011). Quantitative data were analyzed using descriptives in SPSS; qualitative data are preliminary and currently being analyzed using a Rapid Assessment Process (Beebe, 2001).
Quantitative data (across 3 items) indicate that ATs felt ACEs training was valuable (M=4.125; SD=.711; range 3-5), which was consistent with a complementary qualitative theme that providers found ACEs useful in helping parents and providers work together and found the training materials useful in learning to implement ACEs. Survey results (1 item) also indicated that ATs used ACEs with other families they serve (M=4.375; SD=.518; range 4-5), which was consistent with a complementary theme indicating that ATs used ACEs with other families and planned to train other providers to use ACEs.
Conclusions: Both quantitative and qualitative data indicate that early intervention service providers consider training on parent engagement strategies to be useful and generalizable in their practice. Future research can examine whether parent engagement strategies used by providers improve both parent engagement and child outcomes.

249 **127.249** Mobile-Health to Enhance Parent-Mediated Intervention for Children with Autism Spectrum Disorder in Vietnam: Process of Development and Lessons Learnt

H. S. Vu[1], *S. Rodger*[2], *H. Hoang*[3] *and M. Tran*[3], *(1)Center for Creative Initiatives in Health and Population, Hanoi, Vietnam, (2)University of Queensland, Brisbane, AUSTRALIA, (3)Center for Creative Initatives in Health and Population, Hanoi, Viet Nam*

Background:
There is some evidence for the effectiveness of parent-mediated intervention model, in which parents can learn the necessary skills to deliver therapies for their children. This is particularly important in settings where there is a dearth of qualified early childhood interventionists and allied health therapists such as in low and middle-income countries. With the fast development of the internet and mobile phone uptake, using m-health to improve parents' knowledge and skills is considered as having the potential to bridge the disparity of services.
Objectives:
This presentation will present the process of developing a web-based platform (a365.vn, and responsive to mobile devices) to support Vietnamese parents to undertake early intervention for their children at home, as well as lessons learnt from piloting this model.
Methods:
Data for this presentation came from project reports, back-end data of web-based platform, interviews with parents during users testing, monitoring and evaluation, and reflections within research team.
Results:
With financial support from Grand Challenges Canada, a365.vn has been developed and improved through several steps (formative research, user's testing, content development) and with the involvement of professionals from different disciplines and especially parents (end-users). A365 provides key strategies for parents to do intervention with their children, modeling videos to support parents to teach their children specific skills, and short questionnaires for parents monitoring progress of their children. By end of September 2016, forty one modeling videos have been made available for parents to use with a log-in account and password protection; 425 care givers from 47 provinces (out of 63 provinces in Vietnam) used a365 for intervention, especially a number of users from locations where limited services are available for children with ASD. Parents considered this web-based platform as a good resource to build their capacity in teaching their children, and enhance their children skills and ability. However, a number of parents did not consider themselves capable of providing intervention and found some challenges when use a365. They also expressed their needs of having more modeling videos, instruction, and coaching.
Conclusions:
M-health is potential for increasing access to services for children with ASD. It is an evolutional process and requires strong engagement of end-users and multi-disciplinary collaboration in order to be a friendly and effective product for users. Coaching and motivating parents is important.

250 **127.250** Multidisciplinary Evaluation for ASD in a Clinical Setting

R. Sidhu *and C. Hall, Marcus Autism Center, Atlanta, GA*

Background:
Best practice guidelines for autism assessment call for a comprehensive evaluation including the following components: parent interview, review of relevant records, cognitive/developmental assessment, direct play observation, adaptive assessment, and comprehensive medical examination (National Standards Project, 2015). As an autism specialty clinic, we have followed these guidelines in our diagnostic protocol; however historically the medical evaluation occurred only after the autism diagnosis had already been made by a psychologist. There are many problems with this approach. By delaying the medical evaluation to the end of the diagnostic process, important medical information will not be incorporated into the diagnostic formulation. Neurological disorders that better account for the developmental concerns, e.g. cerebral palsy, or medical conditions that preclude a diagnosis of ASD, e.g. profound visual or hearing impairment, will be missed. When medical conditions are not taken into proper consideration, inappropriate behavioral assessments are utilized and underlying diagnoses are conceptualized incorrectly.
Objectives:
The objective of our current initiative is to meet best practice guidelines through an integrated multidisciplinary approach, which includes incorporating medical and behavioral assessment findings in the conceptualization of each child's diagnosis.
Methods:
In the new diagnostic model, patients are first seen by a medical provider (child neurologist, developmental-behavioral pediatrician, child psychiatrist, or pediatric nurse practitioner) who conducts a parent interview, reviews medical records and performs a physical examination.Â When significant red flags for autism are present and medical/neurological conditions do not account for the developmental delay, children are referred on to a psychologist for a comprehensive evaluation of behavioral symptoms. After psychological testing is completed, the physician/nurse practitioner(NP) and psychologist confer to conceptualize the case and determine diagnosis, followed by a joint feedback session with the family.
Results:
Multidisciplinary evaluations were rolled out as a pilot in our clinic in May 2016. Patients participating in this pilot identified as White (58%), Black/African American (32%), Asian (5%) and Other (9%), and 59% had Medicaid as their primary insurance. A total of 85 patients received a diagnostic interview with a physician/NP. Of these, 38% were not referred on for additional testing (ASD ruled out for 18%, and clear ASD already established for 20%). 15% of the patients had significant medical conditions (e.g. congenital CMV, agenesis of corpus callosum, sensorineural hearing loss, complex congenital heart disease). Of the children who were referred on for comprehensive psychological assessment, 72% met criteria for ASD.
Conclusions:
Autism spectrum disorders can be very challenging to diagnose, particularly in young children, as other neurodevelopmental disabilities can have similar presentations. An autism diagnostic assessment requires a comprehensive evaluation, ideally in a multidisciplinary setting. Both medical and behavioral assessments should be thoughtfully integrated to inform diagnostic formulation. Experts from different fields who are well trained in ASD assessment should work collaboratively to establish a diagnosis of autism in order to develop more comprehensive care plans that take all aspects of the child's profile into consideration. Future plans for multidisciplinary diagnostic assessment involve expansion of expertise to include professionals in speech language pathology, nutrition, and clinical genetics.

251 **127.251** Multimodal Study Using Geospatial Mapping and Survey Analysis to Determine Disparities in Access to Care for Children with ASD

C. R. Shoff[1]*, R. Gott*[2]*, J. Gehricke*[3] *and M. Dillon*[4]*, (1)Lindenwood University, St. Charles, MO, (2)Saint Louis University, Clayton, MO, (3)University of California, Irvine, Santa Ana, CA, (4)The Center for Autism & Neurodevelopmental Disorders, Santa Ana, CA*

Background: Among individuals with Autism Spectrum Disorders (ASD), disparities in access to healthcare have been linked to low socioeconomic status, racial and ethnic minorities, and residence in rural and under-resourced areas. However, little is known about the specific barriers individuals with ASD face in accessing care and the impact of specific geographic locations. The Autism Treatment Network (ATN) is a multisite network of 14 North American academic medical centers that specialize in the diagnosis and treatment of individuals with ASD. The purpose of this multimodal study was to examine how social determinants of health impact access to care across ATN sites.
Objectives: The main goals of the study were to (1) identify underserved individuals in ATN sites' geographically defined catchment areas and determine whether or not they are receiving care at the site (2) identify how each ATN site is meeting the needs of underserved populations, and (3) highlight areas where sites need to increase outreach to individuals.
Methods: The multimodal study included a site-level survey with clinicians and a more detailed catchment area and service area analysis. The 34 items site level survey assessed the local, clinical, and patient characteristics of each of the 14 ATN sites to identify underserved populations and barriers to healthcare delivery. Building on part one, the second part of the study used geospatial mapping software (ArcGIS), to analyze whether sites are serving individuals at risk for not accessing healthcare services within their hospital's defined catchment area. U.S. Census data and Area Deprivation Index (ADI) scores were used to identify zip codes with underserved individuals. After analyzing the data from 12 ATN sites we identified the percentage of high needs individuals within the catchment area and within the service area.
Results: Several barriers to reaching/serving the underserved in ATN communities were identified via the survey. The most frequently cited perceived barriers to reaching/serving the underserved included socio-economic status (42.9%), geographical distance (42%), caregivers' education (35.7) and knowledge (28.5%), as well as transportation limitations (28.5%). Across all ATN sites, the percentage of individuals with an Area Deprivation Index greater than 100 (considered high-needs) in the hospital's defined catchment areas (geographic area where patient population are drawn) was 55.6% and service areas (actual patients who access ATN centers) are 44.5%. The difference between the percentages of high needs individuals in the catchment area and those in the service area ranged from 3.4% to 118.9%. Some sites serve a greater percentage of high needs individuals than those in their catchment area, while other sites are not reaching a large proportion of high-needs individuals.
Conclusions: The survey revealed considerable variability among ATN sites in the demographic characteristics of patients and barriers to accessing care. Geospatial mapping using zip codes is an objective way for autism centers to identify geographical areas where they need to outreach to high needs patients. The catchment and service area analysis revealed areas where ATN sites could focus outreach efforts.

252 **127.252** Predictors of Behavioral Health Treatment Continuation and Adherence in Children with Autism Spectrum Disorders

M. N. Davignon[1]*, N. Shankute*[2]*, M. L. Massolo*[3]*, C. Yoshida*[3] *and L. A. Croen*[3]*, (1)Kaiser Roseville Medical Center, Roseville, CA, (2)Kaiser Permanente Division of Research, Berkeley, CA, (3)Kaiser Permanente Division of Research, Oakland, CA*

Background: Behavioral Health Treatments (BHT) based on the principles of Applied Behavioral Analysis (ABA) can improve many of the core difficulties in autism spectrum disorders (ASD) including social deficits and restricted, repetitive behaviors. While ABA-based treatments are commonly recommended for children with ASD, little is known about how many families continue treatment once they start, nor about characteristics that predict adherence to and continuation of recommended treatment.
Objectives: To identify factors that are associated with continuation of and adherence to BHT in a large, diverse population of insured patients with ASD.
Methods: This cross-sectional study included 226 Kaiser Permanente Northern California members aged 2-18 years old with ASD referred for BHT between February and May 2014. Patients had to receive at least 2 consecutive weeks of billed BHT during the study period to be included. We conducted analyses to explore the associations between socio-demographic factors (child sex, race/ethnicity, age at referral to BHT, type of health insurance, copay amount, maternal age at referral to BHT, maternal and paternal education) and clinical factors (medical complexity, psychiatric medication use, receipt of additional therapies) and the binary outcomes of interest: continuing treatment for at least 12 months and treatment adherence (receipt of >=80% of the authorized treatment hours).
Results: Median age at referral to BHT was 6.0 years (40% < 5 years, 15% 12+ years). The majority of patients were male (83%), and had employer or self-funded insurance (95%), $20 copay or less (78%), mother >30 years of age (91%), and mother (78%) and father (73%) with undergraduate or post-graduate education; race ethnicity was mixed (36% white, 22% Hispanic, 29% Asian, 14% Black/Other). Among patients who initiated BHT, 69% (N=155) continued treatment for at least 12 months. Patients who continued vs those who discontinued BHT were similar with respect to sex, race/ ethnicity, insurance coverage type, medical complexity, and receipt of other treatments including psychiatric medication and rehabilitative services. Patients who continued treatment had a significantly younger median age at referral for BHT (6.0 years vs 7.3 years, p=0.04), were less likely to have psychiatric comorbidities (19% vs 41%, p<0.01) or genetic syndromes (4% vs 16%, p<0.01), had a shorter interval between treatment authorization and treatment initiation (p=0.05), and were more likely to receive >10 hours/ week of BHT (48% vs 14%, P<0.01) than patients who discontinued treatment. Only 15% of patients who initiated treatment adhered to treatment recommendations. Younger age at referral for BHT (p=0.049) and receipt of >10 hours/ week of BHT (76% vs 38%, p<0.01) were significantly associated with adherence to treatment.
Conclusions: Nearly one third of patients discontinued treatment within the first 12 months of starting and only 15% of families were able to adhere to their child's recommended treatment regimen. Our findings suggest that children who are older, who have psychiatric comorbidities or genetic syndromes, who take longer to initiate treatment, or receive less than 10 hours/ week of BHT are most likely to struggle with continuation of and adherence to treatment, and may need additional attention.

253 **127.253** Predictors of School Satisfaction in Parents of Children with Autism Spectrum Disorder

B. L. Ncube[1]*, M. Charles*[2]*, A. Perry*[3] *and J. A. Weiss*[4]*, (1)York University, York, ON, CANADA, (2)York University, Toronto, ON, Canada, (3)Psychology, York University, Toronto, ON, CANADA, (4)York University, Toronto, ON, CANADA*

Background: Â Children with developmental disabilities (DD), including autism spectrum disorder (ASD) and intellectual disability (ID), are entitled to public schooling with appropriate supports (Brown & Percy, 2007). However, little Canadian research has examined parents' satisfaction (or frustration) with the services their children receive in the school system. Research suggests that parents of children with ASD are more likely to report difficulty accessing appropriate services for their child and report more dissatisfaction with their child's care than parents of children with other DD (Vohra et al., 2014). Further, research on individuals with DD, with and without ASD, generally focuses on individuals with milder impairment while children with severe DD are often excluded.
Objectives: Â The present study (1) compared school satisfaction between parents of children with DD, with and without ASD, and parents of typically developing (TD) children; and (2) examined factors that may be predictive of school satisfaction in parents of children with ASD.
Methods: This study is part of the larger GO4KIDDS project (Great Outcomes for Kids Impacted by Severe Developmental Disabilities) looking at the health, well-being, and social inclusion of children with severe DD. Parents of 417 children with severe DD, with and without ASD, and 210 TD children completed online or paper surveys. Groups were similar in age (4 to 20 years) and sex (69% male). Analysis for Question 2 was conducted with a subsample of the ASD group who had completed additional survey questions (n = 107; M_{age} = 10.51; 87% male).
Results: Question 1. Results of an independent t-test revealed that the overall level of school satisfaction (rated on a 5-point scale) in the DD group (N= 398, M= 3.31, SD= 1.19) was significantly lower than that of the TD group (N= 210, M= 3.92, SD= .84), t(558)= 7.34, p<.001, Cohen's d=.59. However, within the DD group, there were no differences in school satisfaction between parents of children with ASD and parents of children with other DD.
Question 2. For the ASD group only, a hierarchical multiple regression was conducted with the mean of a 9-item measure of school satisfaction as the dependent variable. Parent Positive Outlook was entered at Step 1 to control for the potential effect of parent optimism and method variance. Child variables (e.g., adaptive skills and maladaptive behaviour) were entered at Step 2, parent variables (e.g., parent mental health) at Step 3, contextual variables (e.g., SES) at Step 4, and school services (e.g., SLP) and type of school placement (e.g., special education class) at Step 5. The final model accounted for 23.5% of the variance in school satisfaction, with significant coefficients for child's Adaptive Behaviour and Parent Positive Outlook. Further analyses regarding different types of school programs will also be included on the poster, as well as illustrative parent comments.
Conclusions: Results of this study have implications for school-based interventions for children with ASD, particularly those who have limited adaptive skills. These results also point to the need for better communication with, and support for, parents.

254 **127.254** Quality of Life Assessment for Adults with ASD (QLAA)

A. El-Nageh*, 2672562259, JFCS of Greater Philadelphia, Philadelphia, PA*

Background: Â Service providers working with adults diagnosed with ASD need a reliable standardized QoL instrument to effectively and comprehensively address needs and assist those they serve. In the absence of such a tool, the assessment is often limited with results based on a particular provider's area of specialty. This limitation can lead to an incomplete assessment that includes recommendations for a specific component(s) of one's needs, rather than one than address the full breadth of one's needs. JFCS sought funding from Autism Speaks, and in December 2014 was awarded a $25,000 Family Services Community Grant to fund the development of an appropriate Qol instrument for adults with ASD. JFCS completed the project and developed the Quality of Life Assessment for Adults with ASD (QLAA) in December 2015.
Objectives: Â In order to assess an individual's quality of life, the following components must be assessed: physical well-being, psychological well-being, social well-being, independence, education, and employment. By measuring overall quality of life, as well as scoring each of these domains, direct care workers may identify the individual's needs, and develop individualized and meaningful treatment plans.Â The QLAA includes the six mentioned domains of quality of life, and the values, goals, aspirations and current life circumstances of the adult completing the QLAA. The QLAA may be used by social service providers working with adults diagnosed with ASD.Â These professionals may utilize the QLAA in the following ways:

- To determine client needs during the initial assessment
- When reviewing needs and progress
- To inform strategy to match unmet needs to available services
- To evaluate service appropriateness
- To evaluate the effectiveness of interventions

Methods: A literature review on QoL and existing measurements was completed. A multidisciplinary focus group was hosted with professionals working with adults with ASD. Interviews were conducted with adults diagnosed with ASD as well. The adults were asked to define QoL, list and describe the factors that impact QoL, and provide suggestions and recommendations about the implementation of a QoL instrument. Transcriptions of the interviews and focus group were reviewed as well as existing QoL tools, and re-occurring concepts were identified to generate the primary items included in the QLAA.Â The QLAA was piloted with 23 participants. 11 participants completed the QLAA a second time, and 8 participants identified 2 individuals who knew the participant well to complete the QLAA by proxy.
Results: Participants' Overall Score: Employed Avg= 148 (Range: 45-180); Unemployed Avg= 129 (Range: 45-168).Â Common responses to "what is important to you?": Social support, employment, hobbies, health, community engagement and independence.
Conclusions: Â (1)Â 3 items were revised based on participants' feedback; (2) When comparing the proxy scores to the participants' scores, results indicated that individuals who know the adult well may be a reliable source in determining his/her qol, which is useful if the tool cannot be administered directly with the adult due to communication impairments; (3) Due to the small sample size of this study, the QLAA must be used with a large sample to further assess its validity.

-

255 **127.255** Racial Disparity in Mental Healthcare Services Access and Utilization Among Children with ASD in the US

W. Zeleke[1]*, T. L. Hughes*[2] *and N. Drozda*[2]*, (1)Duquesne University, Gibssonia, PA, (2)Duquesne University, Pittsburgh, PA*

Background: Researchers indicate that mental healthcare disparities are apparent among minority children with Autism Spectrum Disorder (ASD) (Mandell, et al., 2009). Disparities in the access and use of health and mental health care services are particularly alarming in the context of children and adolescents with ASD. Poor access to and underuse of health and mental healthcare services, especially among youth, can result in an exacerbation of the current condition as well as the onset of additional and related conditions, which end up being more costly and harmful from a public health standpoint (Parish et al., 2011). Minority children with ASD are at particularly high risk of not receiving adequate and appropriate mental healthcare services. However, this issue has received scant attention as evidenced by the very limited number of research studies about it.
Objectives:
The purpose of this study is to examine the mental healthcare disparities in terms of racial and/or ethnic differences between minority children with ASD and White children with ASD.Â Specifically, we aim to investigate the types and levels of services minorities children with ASD are using and examine the risk and protective factors that exist for children with ASD from ethnic and racial minority families, which affect accessing and utilizing health care and education services.
Methods:
Using data from the 2011 Survey of Pathway to Diagnosis and Services ("Path Way") (N=1725; White= 1368, Minority=347), we conducted bivariate and multivariate logistic regression to examine the differences between minority and White children with ASD in accessing and utilizing mental healthcare services. "Pathway" is a nationally representative survey about children, 6-17 years, who were identified by the 2009/10 National Survey of Children with Special Health Care Needs (NS-CSHCN). The data set takes a close look at the current and past use of clinical treatments, interventions, and healthcare services.
Results:
We found minority children with ASD received less behavioral intervention or modification services and less cognitive–based therapy compared to their White counterparts. However, differences related to specific services such as sensory-integration therapy, occupational therapy, physical therapy, social skills training, other social skills training, and speech and language therapy in school and other settings were found to be insignificant. Additionally, the data analysis yielded some significant differences between White and minority children with ASD in regard to working with healthcare providers. Minority families tended to work with audiologists and developmental pediatricians more often than Whites and minorities tended to work with neurologists and psychiatrists less frequently compared to their White counter parts.
Conclusions:
The results of this study indicate that the type and quality services that children with ASD from minority populations receive need improvement. In addition to the need for assertive policy to support the availability of behavioral and cognitive-based therapy, future research needs to explore effective disparity-reduction strategies that promote both the amount and quality of services children with ASD from minority households receive.

256 **127.256** Racial and Ethnic Differences in the Utilization of Emergency Departments for Transition Age Young Adults with ASD Only and ASD with ID

H. J. Carretta[1]*, T. W. Benevides*[2] *and K. Y. Graves*[3]*, (1)Florida State University College of Medicine, Tallahassee, FL, (2)Thomas Jefferson University, Philadelphia, PA, (3)Behavioral Sciences and Social Medicine, Florida State University College of Medicine, Tallahassee, FL*

Background:
Racial and ethnic differences in emergency department (ED) utilization are well known in the literature for typical young adults. Less is known about differences among those with autism (ASD) with or without intellectual disability (ID). In particular, little is known about ASD and ID young adults covered by Medicare. Persons less than 65 covered by Medicare have met criteria for a disability designation by the Social Security Administration. This may indicate a greater severity of disability. Furthermore, adults with ASD/ID often encounter difficulty finding appropriate providers and are more likely to have injuries and comorbidities that necessitate visits to the ED.
Objectives: This presentation will describe racial/ethnic differences in ED utilization among young adult Medicare beneficiaries aged 18-25 years with ASD and no intellectual disability (ASD-only) as compared to beneficiaries with ASD and ID (ASD+ID).
Methods:
We conducted a retrospective analysis of existing national Centers for Medicare and Medicaid (CMS) claims Limited Data Sets (LDS) for 2008-2010. ASD and ID cases were identified by searching all claims types (Inpatient "IP", Outpatient "OUT", Hospice, Carrier, Skilled Nursing and Home Health) for ASD beneficiaries (ICD-9 diagnosis codes 299.xx) and diagnosis codes 317.xx, 318.xx or 319.xx as ID. Claims associated with ED utilization for treat and release (T&R) ED events were identified in the Outpatient File using Revenue Center Codes "0450", "0451", "0452", "0456", and "0459" and the Patient Discharge Status Code. ED events admitted to the same hospital were identified using the Admit Source Code in the IP file.Â This study combined the two types of ED visits for analysis. Zero inflated negative binomial (ZINB) regression models were conducted separately for 2008, 2009 & 2010 and included binary indicators for ASD+ID versus ASD-only, sex, age group (23-25 vs. 18-22), ACG Concurrent Risk Score and Medicaid buy-in months. Minority status was identified as any Hispanic or racial minorities not listed as white: black, Asian, north American native, & Hispanic. The relationship between group status and minority status for ED visits is examined with an interaction term in the ZINB model.
Results:
Only results for 2008 are presented here due to space limitations. All 3 years will be presented at the conference. The ASD-only group was composed of 25.6% racial/ethnic minorities and the ASD+ID group was 33.9% minority.
Table 1 Demographic characteristics.
Table 2 displays the ZINB model for number of ED visits during 2008. The ASD+ID group had 17% more ED encounters. Minorities as a group appear to use 28% fewer ED visits. Examining Minority Status by ASD+ID and ASD-only separately reveals that the ASD+ID-Minority subjects used 30% more ED visits per year than the ASD-only-white group.
Conclusions:
Minorities appear to use fewer ED service when examined as a group. ASD+ID-Minorities use 30% more ED services as compared with ASD-only-white subjects. Additional research is needed to determine whether choice is the primary driver of ED utilization in this population or whether other factors like case severity, comorbidities and provider availability are driving the increased ED utilization.

257 **127.257** Reducing Behavioral Crisis Emergency Room Visits through a Novel Care Model: Behavioral & Developmental Neuropsychiatry (BDNP) Care Continuum

C. A. Erickson[1], *L. K. Wink*[1], *L. A. Terhune*[2], *R. Sorensen*[1], *J. Imhoff*[1], *K. C. Dominick*[3], *E. Pedapati*[4], *A. K. Hill*[1], *M. Sorter*[1] *and S. Benton*[1], *(1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Division of Psychiatry, Cincinnati Children's Hospital Medical Center, CINCINNATI, OH, (4)INSAR Cincinnati Children's Hospital Medical Center, Anderson, OH*

Background: The Behavioral & Developmental Neuropsychiatry (BDNP) care continuum group at Cincinnati Children's Hospital in the Division of Psychiatry frequently serves patients with ASD and significant irritability marked by physical aggression, self-injury, and severe tantrums. High patient acuity and limited outpatient care resources contribute to high emergency room (ER) visit rates when in crisis in this population. The BDNP care continuum has 3 mechanisms to reduce ER visits for behavioral crises in the highest acuity patients: 1) Outpatient nurse care management; 2) Mental Health Specialist support in outpatient clinic to enhance outpatient visit safety thus promoting adherence to outpatient care; 3) An across the continuum effort to direct admit patients (bypassing an ER visit) to our BDNP inpatient unit when admission is deemed necessary.
Objectives: The key objective of this study was to assess the rates of ER visits for behavior pre- and post-enhanced continuum care efforts in the first 30 patients served in our ASD/MI care continuum. The *specific aim* was to determine if enhanced outpatient management was associated with reduced ER visit rates. The *key secondary aim*was to determine any potential cost savings associated with findings from our primary aim.
Methods: We gathered data from the first 30 patients with ASD/MI enrolled in our enhanced BDNP care continuum.Â Requirement for enrollment in this enhanced level of care included a history of severe self-injury and/or aggression and a clinical global impressions severity (CGI-S) score of 5 "very ill" or greater. This data review project was approved by the CCHMC IRB. Data was extracted from EPIC charting looking at ER visits for behavioral reasons for each of the first 30 patients enrolled in the enhanced BDNP care continuum. Our primary outcome is a comparison of the number of ER visits for behavioral reasons on an annualized basis prior to and after the implementation of enhanced BDNP care for each patient assessed.
Results: Each patient showed a reduction in ER visits per year due to behavioral crisis. All patients met diagnostic criteria for intellectual disability, autism spectrum disorder, and intermittent explosive disorder. A statistically significant mean reduction in annualized ER visits for behavioral crisis was noted (See Figure 1; change from a mean 1.7 +/- 0.9 ER visits per year pre-intervention versus 0.3 +/- 0.4 visits per year post-intervention; $p<0.0001$). For this patient cohort followed, an estimate ER visit cost savings of $92,405 per year was calculated.
Conclusions: This report is consistent with reduced ER visits for behavioral concerns post enhanced BDNP care initiation. Future Directions include, but are not limited to, the following: 1) Assess for potential patient and family quality of life change with initiation of this treatment approach; 2) Assess for injury reduction associated with enhanced care initiation; 3) Assess the ability to expand and develop the model to meet a growing need for such services. We hope to expand this work to a broader group of patients in the future in need of these services.

258 **127.258** Right Kids, Right Time, Right Services: Translating Research to Practice in Early Detection of Developmental Challenges in Early Childhood Education Settings

B. Mozolic-Staunton[1], *J. Barbaro*[2], *M. Donelly*[3] *and J. Yoxall*[3], *(1)Southern Cross University, Casuarina, NSW, Australia, (2)Olga Tennison Autism Research Centre, School of Psychology & Public Health, La Trobe University, Melbourne, Australia, (3)Health and Human Sciences, Southern Cross University, Bilinga, Australia*

Background: Valid and reliable tools have recently been developed to accurately detect early signs of autism spectrum disorder (ASD) and other developmental challenges in children as young as 12 months of age. Translation of research findings to practice and policy through routine implementation of evidenced-based tools in the community, particularly early childhood education and care childcare settings is limited and a two year delay for young children with early signs of ASD in accessing diagnostic assessment and early intervention persists in many communities.
Objectives: The study aimed to compare the effectiveness of current practice of developmental surveillance (PEDS; broadband open questions completed by parents) with the Social Attention and Communication Surveillance system (SACS-R; targeted checklist of key markers for ASD and developmental delay at multiple age points completed by educators or nurses) in both health and early childhood education settings in the early detection of ASD.
Methods: A comparison of results of developmental surveillance using PEDS and SACS-R was conducted in two separate prospective, longitudinal cohort studies to establish reliability and validity of developmental surveillance procedures across health and education settings, urban and regional locations and sample across a range of demographic conditions.
Results: This study established that the interrater reliability of early childhood educators in administering the SACS-R is similar to nurses and is very high (k = 0.909). Reliance on parent report alone via PEDS, as is current practice in many communities, has the potential to miss nearly half of children (48.2%) undergoing developmental monitoring. Sensitivity, specificity, positve and negative predictive values of SACS and PEDS are reported based on comprehensive developmental assessment and Autism Diagnostic Observation Schedule- 2nd edition (ADOS-2) for children referred from the health or early childhood education system (n=305).
Conclusions: Â Highly likely cases of ASD or significant developmental challenges in this study would have gone undetected if SACS-R was not used during a child's visit to a health check or in their childcare setting. Results support the implementation of the SACS-R across health and education settings as a reliable and valid method of early detection of children with ASD and informs policy and practice in the childcare sector which presents an ideal opportunity for ongoing developmental surveillance and appropriate, timely referral of young children to essential early intervention supports.

259 **127.259** Role of Care Coordination in Improving Access to Services for Newly Diagnosed Children

***C. Rhodes**, K. M. Stiles and C. Hall, Marcus Autism Center, Atlanta, GA*

Background:
Difficulty accessing appropriate services and supports are major concerns of families and stakeholders in the post-diagnosis period. While early diagnosis of autism is essential, it is also imperative that young children begin receiving appropriate intervention and services following diagnosis without delay. In order to address challenges faced by families during this period and ensure smooth transition to necessary supports an innovative model of care coordination services was introduced. In recent years care coordination services have in received increased recognition as an important tool in achieving optimal health and wellness outcomes for vulnerable populations (APA Policy statement 2014) and as a key service for children with ASD (Doehring 2013).
Objectives:
The present study examines the utility of care coordination strategies to support families as they learn to navigate complex systems. More specifically, we looked at how our model of care coordination service provision provided immediately post-diagnosis impacted families in our clinic.
Methods: Â The study took place in a large autism specialty center that serves an ethnically diverse and often economically disadvantaged population. In 2013, as part of a larger effort to improve the quality of clinic services, we began offering care coordination to all families on the day of diagnosis. Working collaboratively with the diagnostic team, the care coordination team developed comprehensive personalized packets of ASD resources and provider information unique to each child and family's needs based on the team's clinical recommendations. In addition to the take-home packet, each family met with a care coordinator who is then available to assist the family on an on-going basis. Beginning in 2016, satisfaction surveys were sent to all families receiving care coordination services post-diagnosis (n=462) with a response rate of 12% (n=55).
Results:
Survey responses indicated a high degree of satisfaction with services provided (94%). At the same time, 94.4% expressed satisfaction with meeting the care coordinator on the day of diagnosis. In describing what aspects of the program were most helpful, families ranked in order: (1)"receiving autism-related information resources"; (2)"time to ask questions"; (3)"information on community providers"; and (4)"emotional support"; however, the majority of families indicated "all of the above" as most helpful. In response to whether resources provided helped families connect with services, 76% responded in the affirmative. In addition, nearly all (98%) indicated intention for future contact with their care coordinator.
Conclusions:
Survey results were overwhelmingly positive and confirmed our thinking that meeting with a care coordinator immediately post-diagnosis was beneficial. A repeated comment from families was that they appreciated receiving a resource packet and having someone to explain the information to them. While families rated individual aspects of the materials and services provided positively, the majority of respondents expressed most satisfaction with the combination of all four aspects of the program. The high level of satisfaction, in combination with the majority of respondents stating intent to continue contact with their care coordinator suggests the model may be a valuable addition to clinical service array.

260 **127.260** Services and Care for Adults with Autism Spectrum Disorder in the European Union: A Multi-Site Assessment By the Asdeu Consortium

***D. E. Schendel**[1], C. Kloster Warberg[2], S. Cramer[2], L. Poustka[3], R. Diehm[4], G. Iskrov[5], R. Stefanov[6], L. Bouvet[7], B. Roge[8], A. Staines[9], M. R. Sweeney[10], A. M. Boilson[11], T. Leósdóttir[12], E. Saemundsen[13], F. Muratori[14], I. K. Moilanen[15], M. Gissler[16], T. Parviainen[17], P. Tani[18], R. Kawa[19], A. M. Vicente[20], C. Rasga[21], M. Posada[27], (1)Aarhus University, Aarhus, DENMARK, (2)Aarhus University, Aarhus, Denmark, (3)Clinic for Child and Adolescent Psychiatry, Medical University Vienna, Vienna, Austria, (4)Clinic for Child and Adolescent Psychiatry, Medical University of Vienna, Wien, Austria, (5)Bulgarian Association for Promotion of Education and Science (BAPES), Plovdiv, Bulgaria, (6)Institute for rare diseases, Bulgarian Association for Promotion of Education and Science (BAPES), Plovdiv, Bulgaria, (7)University Toulouse 2, Toulouse, France, (8)Université de Toulouse 2 Jean Jaurès, Toulouse, FRANCE, (9)Dublin City University, Dublin, IRELAND, (10)School of Nursing and Human Sciences, Dublin City University, Dublin, Ireland, (11)Dublin City University, Dublin 9, IRELAND, (12)(State Diagnostic and Counselling Centre, Kópavogur, Iceland, (13)State Diagnostic and Counseling Center, Kopavogur, ICELAND, (14)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, (15)University of Oulu, Oulu, FINLAND, (16)University and University Hospital of Oulu, Oulu, Finland, (17)The Finnish Association for Autism and Asperger's Syndrome, Helsinki, Finland, (18)University of Helsinki, Helsinki, Finland, (19)University of Warsaw, Warsaw, Poland, (20)Instituto Nacional Saude Doutor Ricardo Jorge, Lisbon, PORTUGAL, (21)Instituto Nacional de Saúde Doutor Ricardo Jorge (INSA), Lisbon, Portugal, (22)"Victor Babes" National Institute of Pathology, Bucharest, Romania, (23)Centre for Autism, The National Autistic Society, London, United Kingdom, (24)The National Autistic Society, London, UNITED KINGDOM, (25)University of Salamanca, Salamanca, Spain, (26)Carlos III National Health Institute, Madrid, SPAIN, (27)Carlos III Health Institute, Madrid, SPAIN*

Background: In the wake of dramatic increases in autism spectrum disorder (ASD) diagnosed in children we now see an unprecedented increase in persons with ASD entering adolescence and young adulthood. In comparison with research in children, however, the research base focusing on ASD in adulthood is underdeveloped. There is relatively little research knowledge regarding autistic adult services and care or the readiness of communities to provide adult services for persons with ASD.
Objectives: Create a framework for improving services and care for autistic adults in the European Union (EU) through improved understanding of current care practices, gaps in care provision, opportunities for care improvement and local models of adult care as part of the Autism Spectrum Disorder in the European Union (ASDEU) consortium comprised of 20 partners in 14 EU states.
Methods: The 5 adult services focus areas are approaches to services and treatment, management of comorbidity, access to diagnosis and post-diagnostic support, transitions during adult life, and autistic elder care. Study methods include 1) site-specific literature and key informant searches regarding local organization of services and local services policies and recommendations for autistic adults in each participating country; 2) on-line surveys of knowledge, experiences and opinions of experts, adult service providers, autistic adults, and carers of autistic adults regarding local current care practices, perceived service gaps, examples of local best practices, and suggestions for improving existing care strategies. Survey questions were derived from 'external referents of care', i.e., published adult services and care recommendations, and survey answer choices were designed to gauge how closely the respondent believes the local situation 'fits' the recommendations.
Results: Local literature and informant searches yielded complex views of variation in services organization across EU states at the national, regional, and municipal levels for the public and private sectors. The number and geographic distribution of autism-specific organizations providing services is highly diverse across countries, but with geographic clustering in major urban areas and capital cities. There is considerable variation in the public-private sector balance in services provision both between AND within countries. The private sector appears to be the core knowledge and competence base in adult services and in many countries is the main provider of autism-specific adult services. Even within countries, however, there may be significant inequalities in the public and private coverage among different regions and the level of development and specialization of the services offered by private organizations may be limited. The study is ongoing, with results from the on-line surveys to come.
Conclusions: Even in its preliminary stages, the investigation thus far has yielded an overarching view on the state of services for autistic adults and elders in the EU, a state which appears to rest on the balance between public and private sector contributions. Preliminary results from the on-line survey to be presented will illustrate the concordance between published autistic adult services recommendations and real-world experiences across the EU. Final study results will support EU policy makers and service providers on strategies for autistic adult services.

261 **127.261** Supporting Educational Personnel to Train Their Staff in ASD: A Pilot Study

J. Salt *and K. Johnsen, HAVE Dreams, Park Ridge, IL*

Background:
Teachers, paraprofessionals and related service personnel who work in special education rarely receive specialized training in autism. This pilot study evaluated a new Training Academy to support existing school personnel to train their own staff. Participants attended the Training Academy as a supportive, collaborative cohort. The cohort received training materials and in-vivo practice sessions, prior to delivery of each training. Participants were required to provide their own school staff with 3 trainings: ASD for a general audience; ASD specific to paraprofessionals; ASD specific to speech, social work and O.T.
Objectives: This study investigated the effectiveness of the Academy model to increase education professionals competence in delivering training to their staff. The study addressed:
(i) educator change in competence of training skills gained across the training period
(ii) the relationship of educators self-efficacy to outcome
(iii) the relationship of educator self-efficacy to professional experience prior to training
Methods:
Participating educators (n= 15) who attended the Academy completed a structured questionnaire pre and post training.
The questionnaire emphasized key aspects of training competencies. Three sections described a training scenario related to (i) general ASD knowledge, (ii) paraprofessional competencies (iii) related services competencies. The final questionnaire had 12 questions; maximum score, 72.
In addition, the participants completed the ASSET, a self-report measure to assess self efficacy in ASD specific skills (Ruble et al.,2013).
Results:
i) T-test revealed that there was a significant ($p<.01$) increase in competence scores pre and post training academy for each type of training provided (general ASD, paraprofessional, related services).
ii) ASSET scores were divided by the mean to create high and low self efficacy groups. To compare group performance pre and post training, scores were entered into a repeated measures multivariate analysis of variance, with time (pre, post) as the within subjects repeated measure and group (high, low SE) as the between factor. There was no significant group by time interaction effects.
iii) To determine the effect of prior experience on educator self-efficacy, data was entered in a logistic regression model with group membership (high and low self-efficacy) as the dependent variable, and lifetime number of ASD students, educational level, and years teaching as covariates. There were no significant effects of professional experience predicting self-efficacy group membership.
Conclusions:
These results indicate the effectiveness of our training program. By attending the training, educators increased their confidence in their ability to train the autism curriculum to their staff. Educators in both the low and high self-efficacy groups increased their training competence scores over the training period. Furthermore, educators' self-efficacy for training competencies appeared to have little relationship to their prior professional experience, experience with autism or their educational level. This has important implications for training educational professionals. Even professionals who have many years experience, or who have taught many students with ASD, can increase their own training competence by attending an intensive training. The sample size is small and results must be interpreted with caution. The Training Academy is now being provided to professionals in a second cohort.

262 **127.262** The Complex Road to ASD Interventions: Parents' and Providers' Views of Barriers and Facilitators

M. L. Massolo[1]*, M. N. Davignon*[2]*, A. E. Richards*[1]*, C. Yoshida*[1] *and L. A. Croen*[1]*, (1)Kaiser Permanente Division of Research, Oakland, CA, (2)Kaiser Roseville Medical Center, Roseville, CA*

Background: As a result of autism insurance mandates, health plans in many States are required to cover the cost of ASD behavioral health treatments (BHT). While there is a growing body of research evaluating the effectiveness of BHT, little is known about what helps or hinders participation in recommended BHT services.
Objectives: To identify factors that influence parent participation in and compliance with recommended BHT services for their child with ASD.
Methods: We conducted interviews (N=84) with parents and clinical providers of children with ASD referred for BHT by Kaiser Permanente. We used a non-probabilistic purposive sampling approach to capture the range of race/ethnic groups among patients (13 white, 10 Asian, 6 Hispanic, 3 African-American, 8 Other) and their experiences with BHT treatment (child never started (N=10), child started but discontinued (N=8), child currently receiving (N=22). The provider group included KP clinicians (16 pediatricians and psychologists, 11 case managers) and non-KP BHT providers (17 ABA interventionists and supervisors). Three interviewers trained in qualitative methods developed guides and conducted all interviews. Areas explored with parents included acceptability of care, attitudes and beliefs about autism, language and literacy, involvement in care, education/income, stigma, family functioning, and specific experiences with the treatment process. Questions to providers about their experiences with the services and with their patients completed the picture. Interviews, in person or by telephone, ranged from 30 minutes to 2 hours.
Results: Many parents expressed confusion and difficulty navigating a complex system to access BHT. Obstacles to initiating or continuing BHT included financial burden, gaps in care coordination, deficient quality of care, and other effects of treatment such as the financial impact of the number of hours recommended, and the invasion of privacy resulting from in-home therapy. Immigrant families encountered additional obstacles including language, cultural, and literacy barriers, and lack of culturally competent support. Many KP providers echoed the parents' frustration with the system, which they perceived as overloaded, unwieldy, lacking high quality interventionists, and too restrictive for case managers. From the point of view of BHT providers, barriers to families initiating and continuing BHT services include lack of capacity of BHT providers to keep up with the number of referred children, family difficulties with choosing or committing to a vendor, vendor difficulties establishing contact and scheduling visits with families, turnover in intervention teams, and the practice of assembling teams for each child, rather than having permanent, full time staff onboard. There is a shared perception among some parents and providers that business interests trump the care of individuals. Possible solutions suggested by parents, KP clinicians and BHT providers included improved education and training for parents and providers, active case management, improved care coordination, availability of translated materials, interpreters trained in ASD, culturally competent providers, and introduction of patient navigators.
Conclusions: The interviews provided insights about the experiences of an ethnically diverse group of ASD families referred to BHT services. Many barriers were experienced by both families and providers. Overcoming them is necessary in order to reap the benefits of BHT.

263 **127.263** The Conditions and Characteristics of Adult Supplemental Security Income Recipients with Autism

K. A. Anderson[1], *J. Hemmeter*[2], *J. Rast*[3], *A. Roux*[3], *P. Shattuck*[3] *and C. Sosnowy*[3], *(1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Office of Research, Demonstration, and Employment Support, Social Security Administration, Baltimore, MD, (3)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Â Achieving economic security and independence is an everyday challenge for many adults with Autism Spectrum Disorder (ASD), who often have high rates of unemployment, earn low wages, and have high medical costs. Several studies of young adults with ASD have found low household income to be inversely related to several key outcomes including employment, independent living, and access to services. The federally-administered Supplemental Security Income (SSI) program provides income support to alleviate some of the adverse effects of poverty for people with disabilities. In 2014 alone, 8.3 million people received SSI benefits in the United States at an annual cost of $55 billion. Despite its pivotal importance, however, virtually nothing is known about the population of adult SSI recipients with autism.
Objectives: Â We used a mix of Social Security Administration (SSA) program data and SSA's National Beneficiary Survey to generate national point-estimates of the conditions and characteristics of adult SSI recipients with autism.
Methods: Â We described the characteristics, employment status and benefits of adults with a primary or secondary impairment of ASD who received SSI in December, 2014. To report aggregate data of SSI receipt over a 14-year period, we examined the population of adults with ASD who received at least one SSI payment during *any month* in FFY 2001 through 2014.
Results: Â Roughly 129,500 adults with ASD received SSI for at least one month in 2014, a 740% increase since 2001. Among them, nearly 37,050 people also had intellectual disability (ID) as a listed impairment. Roughly 85,330 adults with ASD and no reported ID received SSI in December 2014. Seventy-three percent of these recipients were between the ages of 18 and 25 years, and 81% were male. Around 79% were living in their own household or alone and 19% lived in someone else's household receiving support and maintenance. Sixteen percent were employed in December 2014 with an average earned income of $194/month. The 2014 annual SSI payment amount varied: roughly 46% received the maximum annual SSI payment amount of $8,652, 39% received between $4,326 and $8,651, and 15% received less than $4,325.
Conclusions: This study is an important first step in building an accurate description of the population of SSI recipients with autism. Further research is needed to improve our understanding of how adults with autism access and maintain SSI benefits, how service needs change across the life span, and how SSI benefits relate to later health and economic well-being.

264 **127.264** The Costs and Benefits of Employing an Adult on the Autism Spectrum

M. Scott[1,2], *A. Jacob*[2], *D. Hendrie*[3], *R. Parsons*[4], *S. J. Girdler*[2,5], *T. Falkmer*[1,2] *and M. Falkmer*[2,5], *(1)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (2)School of Occupational Therapy and Social Work, Curtin University, Perth, Australia, (3)School of Public Health, Curtin University, Perth, Australia, (4)School of Pharmacy, Curtin University, Perth, Australia, (5)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Brisbane, Australia*

Background: Comparatively few adults on autism spectrum participate in the competitive workforce. In Australia, the labour force participation rate for adults on the autism spectrum is 42% in comparison to 53% of all individuals with disabilities, and 83% for individuals without disabilities. While once employed adults on the autism spectrum have the opportunity to demonstrate their strengths, low employment rates suggest many factors are influencing their employability. One factor may include employers' assumptions that hiring individuals with a disability will incur higher costs due to additional work training, supervision and modifications. Research has examined the benefits and costs of employing adults on the autism spectrum from the perspective of the employee, taxpayer and society, but few studies have considered the employer perspective.
Objectives: This study examined the costs and benefits of employing adults on the autism spectrum, from the perspective of employers.
Methods: An online survey of 59 employers employing adults on the autism spectrum in open employment was conducted. Employers were asked to compare employees *with* and *without* autism on the basis of job similarity.
Results: Compared with employees *without* autism, employees on the autism spectrum demonstrated increased attention to detail (55% vs 19%), a higher work ethic (71% vs 30%) and consistently produced work of superior quality (41% vs 26%). Challenges associated with employing adults on the autism spectrum included following instructions (14% vs 4%), being flexible (28% vs 8%) and perseverating on work tasks (16% vs 8%). While the mean hourly wage for employees on the autism spectrum was lower ($21.84/hour), compared to their co-workers' wage ($23.49/hour), this study found no significant differences between employees *with* and *without* autism with regard to weekly supervision costs, weekly costs to the employers and costs related to workplace training and modifications. Additional benefits of employing an adult on the autism spectrum included increased autism awareness in 59% of workplaces, and in 55% of workplaces promoting a culture of inclusion. More than 60% of employers reported that they would recommend employing an adult on the autism spectrum to a business associate, with very few responding that they would not.
Conclusions: Employing an adult on the autism spectrum provided many benefits to employers and their organisations without incurring additional costs over and above that associated with any new employee. The results also showed that employing adults on the autism spectrum contributed to new and innovative ideas and can have a positive impact on workplace culture and attitudes, but highlighted the need for support for employers through autism awareness and education in the workplace.

265 **127.265** The Effect of Familial Status on the Attainment and Funding of Services in Children with ASD

L. Nichols[1]*, R. K. Ramsey*[1]*, M. Khowaja*[1]*, L. B. Adamson*[1] *and D. L. Robins*[2]*, (1)Georgia State University, Atlanta, GA, (2)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Single parents of children with autism spectrum disorder (ASD) report elevated levels of stress related to child care and work responsibilities (Johnson & Simpson, 2013). Additionally, parents face high costs for ASD-related intervention services (Tregnago & Cheak-Samora, 2006). As such, un-partnered parents may have more difficulty obtaining intervention services for their child due to high stress and financial burden. Moreover, familial status may affect funding options or services utilized.
Objectives: Â The goal of the current study was to examine how marital status relates to access to intervention services and public vs. private funding for services in families with a child with ASD.
Methods: Â Participants included families of 116 children diagnosed with ASD after screening positive on the Modified Checklist for Autism in Toddlers (-Revised), with Follow-UpÂ (M-CHAT(-R)/F) during 18- and 24-month visits at pediatricians' offices in metro-Atlanta. Families also attended a re-evaluation between 3-4 years of age *(M_{age}*=48.47 months*, SD*=12.32*)*, and provided information about intervention participation and funding of each service received since diagnosis (state/school funded vs. any use of private insurance/pay). Interventions included: speech-language, occupational, physical, developmental, sensory-integration, and behavioral therapies, as well as special education, special (pre)schools, and Babies Can't Wait early intervention program. Complementary therapies that did not fit these categories were coded into a separate "Other" category. The number of services, type of services, and source of funding for each intervention were examined in relation to family structure (partnered vs. non-partnered).
Results: Overall, 90.2% of children with partnered parents and 87.0% of children with non-partnered parents got some type of intervention service, which was not a significant difference, X^2(1, *N*=115)=.209, *p*=.45. However, children with partnered parents (*M*=3.09, *SD*=1.77) received more types of services than children with non-partnered parents (*M*=2.30, *SD*=1.49, *t(*113)=1.98, *p*=.034). In particular, children with partnered parents (31.5%) are more likely to use complementary interventions (i.e., "Other") than children with non-partnered parents (4.3%, X^2(1, *N*=115)=7.05, *p*=.005). No significant difference across any other intervention type was found. There also was no significant difference between familial status and use of public funding for services for most types of interventions, with the exception of pre-school; more non-partnered parents (86.7%) paid for pre-school with public funding than partnered parents (53.7%, X^2(1, *N*=82)=5.53, *p*=.021).
Conclusions: Â The majority of families received at least one type of intervention service regardless of marital status, suggesting that single-parent households are not at a large disadvantage. However, one-parent households received fewer *types* of interventions compared to two-parent households. Specifically, children with partnered parents received more nonconventional therapies (i.e. "Other"), such as music therapy and hippotherapy, which is consistent with Hall's (2012) finding that partnered parents are more likely to utilize complementary/alternative therapies. This suggests single parents may lack resources to enroll their children in alternative services. Future research on the efficacy of specific types and number of interventions is needed to further understand whether children with partnered parents are making greater gains due to increased access to more types of intervention services.

266 **127.266** Therapist Adaptations to a Package of Evidence-Based Strategies for Children with Autism Spectrum Disorder

M. Dyson[1]*, C. Chlebowski*[2] *and L. Brookman-Frazee*[3]*, (1)University of California San Diego, San Diego, CA, (2)University of California, San Diego, San Diego, CA, (3)University of California, San Diego, La Jolla, CA*

Background: There is growing evidence that it is common for therapists to adapt evidence-based practices (EBP) protocols when implementing in routine mental health (MH) settings. Less is known, however, about the types, rationale, and implications of these adaptations on clinical and implementation outcomes (Wiltsey-Stirman, et al. 2015).
Objectives: This mixed-methods study examined the types and reasons therapists adapted AIM HI ("An Individualized Mental Health Intervention for ASD"), a package of evidence-based strategies designed for children with autism spectrum disorder served in publically-funded MH settings.
Methods: Quantitative (Therapist Adaptations to Practice Questionnaire (TAPQ)) and qualitative data (semi-structured interviews) were collected as part of a randomized effectiveness trial of AIM HI in which MH programs were randomized to immediate AIM HI training/implementation or wait-list control/routine care observation condition. TAPQ and semi-structured interviews were completed with a subgroup of therapists (n=51) from 14 MH programs following 6 months of AIM HI training/consultation. Emergent themes from qualitative data were used to complement and expand findings from the TAPQ characterizing the types of adaptations therapists report. .
Results: On the TAPQ, 95% of therapists reported that they made some adaptations to AIM HI, and the most common *types* of adaptations included: (1) integrating components of other treatments in the delivery of AIM HI (35% of therapists); (2) lengthening the pacing of an AIM HI protocol step (33%); (3) modifying the terminology or language/wording when describing AIM HI concepts/components (30%); and (4) involving other individuals (e.g., teachers) in the treatment process (26%). Less common adaptations included: (1) shortening the pacing of protocol steps (11%); (2) adjusting the order of the protocol steps (4%); (3) skipping protocol components (3%). The following were the most common *reasons* for adaptations: (1) *intervention-client fit*, including accommodating the child (48%) and caregivers' (48%) clinical functioning or needs and increasing caregiver involvement in treatment (49%); and (2) *intervention-provider fit*, including consistency with the therapists' previous clinical practice/style (28%). Preliminary themes from the qualitative interviews confirmed and expanded upon the most common adaptations and reasons for these adaptations. For example, therapists indicated that they often modified the AIM HI terminology to make concepts easier to understand for a range of caregiver characteristics (e.g., monolingual Spanish-speaking caregivers, those with lower education or literacy levels, and those with their own mental health/developmental challenges).
Conclusions: Results suggest that most therapists made adaptations to the AIM HI protocol. It is encouraging that adaptations were consistent with the AIM HI protocol, with the primary intent of enhancing the intervention to fit with therapeutic style and to address clients'/caregivers' needs and functioning. These findings suggest that therapists are able to implement fidelity-consistent adaptations to the AIM HI protocol and provide insight into potential areas in which therapists would benefit from targeted training on how to systematically adapt the AIM HI protocol.

267 **127.267** Understanding General Practitioners' Knowledge, Attitudes and Experiences in the Recognition and Management of Individuals on the Autism Spectrum

S. Unigwe[1], *L. Kenny*[2], *C. Buckley*[3], *A. Remington*[4], *L. Crane*[5] *and E. Pellicano*[2], *(1)Royal College of General Practitioners, London, United Kingdom, (2)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom, (3)The Royal College of General Practitioners UK, London, UNITED KINGDOM, (4)Centre for Research in Autism & Education, UCL, London, United Kingdom, (5)Goldsmiths, University of London, London, UNITED KINGDOM*

Background:
In many countries, the general practitioner (GP) or primary care physician plays a key role in the identification and management of children, young people and adults on the autism spectrum. In the United Kingdom (UK), they are often the first port of call for those seeking assistance for a suspected autism diagnosis. However, changing definitions of autism, the substantial heterogeneity both between and within individuals, and the prevalence of co-occurring conditions in many autistic children and adults all present serious difficulties to non-specialist clinicians. Indeed parents of autistic children, and autistic individuals themselves, often report dissatisfaction with their healthcare experiences, especially regarding the diagnostic process.
Objectives:
In the UK, there have been recent calls for increased autism training for GPs and other frontline professionals, yet there is a paucity of research on what GPs currently know about autism and how confident they feel in making clinical decisions for their patients. We therefore conducted the first study to our knowledge to determine GPs' level of existing autism knowledge and experience, and their perceived confidence in working with autistic patients.
Methods:
An online survey was sent to registered GPs based in the UK. The survey collected responses on participants' (1) background, training and experience as a GP, (2) a 22-item knowledge of autism questionnaire and (3) a 14-item self-efficacy scale targeting GPs' confidence in their abilities around the diagnosis and management of autism, and (4) an open question eliciting participants' experiences on working with autism.
Results:
304 participants completed all three parts of the survey, with 91% indicating that in the past year they had been approached by at least 1 patient about a suspected autism diagnosis, with the majority (78%) being approached by up to 5 people. GPs generally scored highly on the knowledge of autism scale (mean=19.4 out of 22) – despite 40% reporting never having received formal training about autism. Nevertheless, participants reported remarkably limited confidence in their abilities to identify and manage their autistic patients, with many citing a number of barriers including unclear referral pathways and limited local support services. Perceived self-efficacy was also significantly associated with personal experience of autism and the amount of autism training received.
Conclusions:
GPs' confidence may well play a role in their decisions to refer – or not to refer – children or adults for further diagnostic assessment for autism. Efforts to enhance perceived self-efficacy are therefore much needed. Our findings suggest that initiatives targeted towards training on autism and greater clarity around referral pathways for diagnosis of autism should be key priorities in order to improve both GPs' confidence in caring for their autistic patients and autistic people's experiences with GPs. In England, local clinical commissioning groups (CCGs) are best served to assist GPs in ensuring that they can reliably detect the condition and make appropriate provisions for support.

268 **127.268** Use and Perceived Evidence-Base of Autism Spectrum Disorder Interventions By Allied Health Practitioners

J. M. Paynter[1], *D. Trembath*[2], *R. Sulek*[3] *and D. Keen*[4], *(1)School of Applied Psychology, Griffith University, Southport, Australia, (2)Menzies Health Institute, Griffith University, AUSTRALIA, (3)Menzies Health Institute Queensland, Griffith University, Australia, (4)Griffith University, Mt Gravatt, AUSTRALIA*

Background: Recent reviews of the research have identified empirically-supported interventions for people with Autism Spectrum Disorders (ASD) (e.g., National Autism Centre, 2015; Wong et al., 2015). However, a research to practice gap is widely acknowledged (e.g., Cook, Cook, & Landrum, 2013) with continued use of interventions classified as unsupported (e.g., sensory integration), ineffective (e.g., facilitated communication), and/or harmful (e.g., chelation) reported by parents (e.g., Carlon, Stephenson, & Carter, 2014) and professionals (e.g., Kadar et al., 2012). Little is known about why specific practices are used by allied health professionals in the community, including their knowledge of the evidence base for their chosen practices, and what factors hinder or facilitate the use of empirically-supported treatments. This information is vital for bridging the research to practice gap and improving ASD intervention outcomes.
Objectives: We aimed to explore reported levels of use of intervention strategies and their perceived evidence-base, and the impact of organisational culture, attitudes, and demographic variables on use of ASD interventions.
Methods: Â Participants included 140 allied health staff (speech pathologists, occupational therapists, psychologists, and behaviour analysts) from across Australia who reported working with people with ASD. They completed an online survey that included measures of demographics, the Organisational Culture Questionnaire (Russell et al., 2010); the Evidence-based Attitudes Scales (Aarons, 2004), and the Intervention Practices Scale (Paynter & Keen, 2015). In addition, participants were asked to rate the level of empirical support for each practice.
Results: Â Participants reported greater use of empirically-supported than emerging or unsupported practices. Participants' use of empirically-supported, emerging, and unsupported practices was linked to the level of evidence of each category perceived by participants. This included greater use of unsupported practices by those rating them as having a stronger evidence base. Although participants generally rated unsupported practices correctly and more rarely used these practices, a significant minority reported continued use of unsupported and potentially harmful practices such as facilitated communication and reported beliefs that such practices were empirically-supported. Those who reported using more unsupported practices also reported greater openness to using a range of strategies and trended toward being more likely to use strategies if they personally appealed to them on the evidence-based attitudes scale. Greater use of empirically supported interventions showed a trend towards lower negative attitudes towards evidence-based practice. No significant links to organisational culture were found.
Conclusions: This study adds to our understanding of the intervention practices used with people with ASD by allied health professionals. It also highlights the continued challenge of translating research to practice in ASD, in particular in terms of debunking misinformation about the effectiveness of strategies shown in research to be ineffective, an area that has to date received little attention. Future research using direct observation could extend this research through investigating the fidelity of implementation of practices and consistency with self-report. Such research would provide valuable insight into the strengths and needs of practitioners and would assist in developing strategies to support knowledge translation to allied health practitioners in the community.

269 **127.269** Using Technology to Support Early Intervention Providers to Build Capacity in Families of Toddlers at Risk for Autism Spectrum Disorder

M. Costo[1], *S. K. Fuhrmeister*[1], *N. D. Bond*[1], *E. Chapman*[1], *E. McCullough*[1], *T. Gaines*[1], *S. Gillespie*[2] *and J. L. Stapel-Wax*[3], *(1)Marcus Autism Center, Atlanta, GA, (2)Emory University School of Medicine, Atlanta, GA, (3)Emory University School of Medicine, Atl, GA*

Background:
Caregivers are the most community-viable agents of change in providing necessary supports and services for very young children (12-24 months) at risk for ASD. Yet, research shows that the early intervention system is ill-prepared in the specific skills and methods needed to effectively collaborate with and coach caregivers (Friedman & Woods, 2012). In addition, personnel shortages in the early intervention system (Cason, Behl, & Ringwalt, 2012) have resulted in reduced quality and duration of services for families, particularly those living in rural areas (Hallam et al., 2009). Therefore, more innovative methods for providing support and coaching to Early Intervention Providers (EIPs) is necessary to ensure development of knowledge and skills and translation into practice (Bransford et al., 2000). However, there is a paucity of research on the effectiveness of coach-the-coach models supporting EIPs with the use of technology.
Objectives:
This ongoing project aims to improve collaborative coaching proficiencies of EIPs across Georgia via implementation of a coach-the-coach model focused on increasing knowledge of adult-learning strategies, early red flags for ASD, and supports to build family capacity to promote active engagement for toddlers at risk for ASD. The project utilizes innovative, mobile coaching technology to create a community-viable system for reaching families.
Methods:
This study is tracking the progress of 19 EIPs across Georgia, including underserved rural areas, coached to coach caregivers on increasing active engagement in toddlers at risk for ASD. Each EIP is coached over the course of a year, with most coaching sessions occurring via technology. Effectiveness of the coach-the-coach model is assessed using the SEE-KS™ (Rubin, E. et al., 2014) three-point rating scales. SEE-KS™ is a coaching framework based on Universal Design for Learning encompassing the principals of SCERTS® (Prizant et al., 2005).
Results:
SEE-KS™ subscales (Fostering Engagement, Presenting Information, and Allowing Child Expression) were generated by averaging corresponding items on the SEE-KS™ measure for each family at a baseline and follow-up time point per yearly quarter. Restricting the analysis to the first two quarters, mixed effects linear growth models were employed to determine if SEE-KS subscales significantly changed both within quarters and at baseline across quarters. Results show a significant change from baseline to follow-up within each quarter across all subdomains (all $p<0.05$) (See Table 1) and baseline for quarter 2 being higher than baseline at quarter 1 across all subdomains, though not significantly. The overall trends over time are all highly significant ($p<0.001$) which indicates a significant provider improvement over time (See Figure 1).
Conclusions:
These data indicate that the current coach-the-coach model resulted in caregivers providing increased supports to promote engagement, understanding, and expression in toddlers at risk for ASD. Through the use of innovative technology within the coach-the-coach model, EIPs were able to build caregiver capacity to implement supports and empower caregivers to utilize evidence-based supports. And though insignificant, the increasing baseline scores between quarter 1 and quarter 2 show that the EIPs are generalizing these skills from one family to the next.

270 **127.270** Variables Associated with Services Sought By Caregivers of Individuals with Autism Spectrum Disorder

S. J. Lee[1], *A. Wainer*[2], *L. Soorya*[1], *L. Fogg*[1], *L. Kraus*[3] *and J. W. Lee*[1], *(1)Rush University Medical Center, Chicago, IL, (2)Rush University Medical Center, Oak Park, IL, (3)rush University Medical Center, Chicago, IL*

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder commonly seen with language impairment, intellectual disability, medical conditions, and psychiatric disorders. Currently, a myriad of treatment options are available, reflecting the phenotypic heterogeneity within ASD. Treatment barriers in ASD are well established in literature and access to services can be impacted by patient, family, provider, and policy-level factors. Another important factor for optimal treatment may include treatment choices made by families caring for individuals with ASD.
Objectives: To explore potential child and familial demographics associated with treatments sought by families caring for individuals with ASD.
Methods: Parents of individuals with ASD completed online survey questions related to services sought. The services were categorized under four service groups: Educational, Mental Health (MH), Medical Services (MED), and Complementary and Alternative Medicine (CAM). Data were analyzed using IBM Statistical Package for the Social Sciences 20.0 (SPSS). Descriptive information was obtained by computing frequency statistics for the sample to gather basic demographic information and number of services of sought. Chi-square tests were used to measure differences in services sought by individual characteristics including gender, diagnosis, and race, as well as family characteristics such as family income, insurance, parental education, and parental employment.
Results: On average, families sought approximately 8 services. Significant differences in the number of services sought were seen in diagnosis, race, and parental employment. Individuals with ASD and comorbid psychiatric conditions sought more services than ASD alone. Asians sought the least number of services and Caucasians sought the most number of services. Lastly, families with employed parent(s) sought more services compared to families with unemployed parent(s). The type of services sought by families varied by child gender, diagnosis, race, parental employment status, and having private insurance. Caregivers of male individuals with ASD sought Educational and Medical services at a higher rate relative to females. Individuals with comorbid psychiatric conditions sought more Educational, MH, and MED services than ASD alone. Asians were least likely to seek MH services while Caucasians were most likely. For medical services, African-Americans sought more MED services. Families with employed parent(s) sought more Educational, MH, MED, and CAM than families with unemployed parent(s). Lastly, having private insurance increased the rate of Educational, MH, and MED services seeking behavior.
Conclusions: Results suggest diagnosis, race, and parental employment may influence the number of services sought by families caring for individuals with ASD. Furthermore, the type of services sought may be differentiated by gender, diagnosis, race, parental employment status, and having private insurance. Overall, there seems to be significant variability in treatment choice and utilization among families caring for individuals with ASD. Little is known on how families decide on which services to use, but is likely a complicated process with many factors influencing their decisions. Our findings suggest culture-specific variability in service seeking behavior, and a role for culturally sensitive diagnostic and educational programs in minority communities to reduce disparities and improving awareness about ASD-related treatment.

271 **127.271** What Autism Spectrum Disorder Services Do Families Want? : Results of a Brief Quality Improvement Survey in a Hospital-Based Outpatient Clinic

*J. Palilla[1], E. Bernabe[2] and **L. Dewey**[3], (1)Nemours Alfred I. duPont Hospital for Children, Wilmington, DE, (2)Nemours/AIDHC, West Chester, PA, (3)Nemours, Wilmington, DE*

Background: Research consistently demonstrates that children with Autism Spectrum Disorder (ASD) require intervention to support their cognitive, language, social, and educational development (Reichow & Volkmar, 2010). Additionally, the quality and quantity of services available for children with ASD (Dawson, 2008) has continued to increase. However, caregiver satisfaction regarding their access to services and participation in services has remained moderately low (Brookman-Frazee et al., 2007). Thus, to improve caregiver satisfaction with services, increase family participation, and plan for future program development, better understanding of caregiver feedback regarding desired treatment services and possible barriers to participation in services is needed.
Objectives: Although there are a wide variety of interventions available for children with ASD, minimal research has investigated which of the various treatment services caregivers are most interested in having their child participate in through an outpatient setting. Thus, the aims of the study were to: 1) assess the types of services that caregivers reported an interest in; 2) assess caregiver-reported barriers to participating in services; and 3) assess caregiver awareness of the services available at an outpatient clinic.
Methods: Following participation in either an evaluation or a treatment session with one of two specific ASD providers in an outpatient clinic, caregivers of children diagnosed with ASD (n = 28) completed a questionnaire developed by the clinicians that assessed caregiver interest in, barriers to, and awareness of various treatment services available in the outpatient clinic. Demographic information was also gathered via the questionnaire.
Results: Demographic information indicated that the majority of children with ASD were male (M=26, F=2). The average age of the child with ASD was 7 (age range 2-15 years). While the majority of caregivers reported an interest in receiving behavior management treatment services (64.29%) and participation in social skills groups (60.71%), nearly half of the caregivers (46.43%) also expressed interest in additional written materials about ASD (see Table 1). Regarding barriers to services offered, time of day, childcare, and concern services will not meet the needs of the child were of similar difficulty (21-28%) for caregivers (see Table 1). Regarding awareness of services offered, the majority of caregivers reported being aware of the following services: Behavior Management (82.1%) and Evaluations (78.5%). However, less than half of the caregivers reported an awareness of the following services offered: parent training, parent support, medication management, cognitive behavior therapy (CBT), and speech services.
Conclusions: The preliminary results of this study suggest that there are cost-effective ways, such as providing increased written materials and education by the outpatient provider, to assist families with accessing desired services and stresses the importance of increasing caregiver awareness of available services. These results will guide program development to ensure that written materials and visibility of services offered are prioritized by the outpatient clinic to meet the needs of caregivers.

272 **127.272** Young Adults on the Autism Spectrum: Lost in the Services Maze

***C. M. Anderson** and C. L. Butt, Interprofessional Health Studies, Towson University, Towson, MD*

Background: National surveys suggest many young adults with autism spectrum disorder (ASD) are left without adequate services once they leave high school. However, little is known about what actually transpires as families try to access services for their adult children with ASD.
Objectives: To explore experiences of young adults with ASD and their families related to availability, quality, and appropriateness of services post high school.
Methods: Qualitative interviews addressing post high school experiences were conducted with 35 parents and 14 young adults with ASD. Interviews were transcribed; material relating to publicly funded services was segregated, then coded using a grounded theory approach.
Results: Three major themes emerged from families' narratives: *Information and Access*, *Program and Staff Issues*, and *Young Adult Characteristics and Fit*. ***Information and Access:*** Families were often bewildered by the overwhelming array of adult services. High schools did not always guide families through this labyrinth. Young adults had first to qualify for services and then be accepted by a service-providing agency. Those who had severe behaviors (e.g. aggression, elopement) had trouble finding a willing provider, while those who were more cognitively able rarely qualified. Youth who graduated from high school with typical peers faced a major gap. A young man with ASD: *"I was at home for like three years because we couldn't find anywhere for me to go….Â I graduated at 17..., and a lot of the agencies nowadays -- you have to be 21."* ***Program and Staff Issues:*** Programs, which varied greatly in quality, had seldom been designed with ASD in mind. They were generally underfunded; low pay, high turnover, and a lack of ASD-related knowledge among staff were common. Formal goals frequently went unmet, and there was little accountability. A mother: *"I called a meeting and I was like… 'You are supposedly getting money to provide services for my son…. I come and find he is standing in the rain for 20 minutes because you have him on some inappropriate assignment, no support, and nothing that is really helping him to get a job.'"* ***Young Adult Characteristics and Fit:*** Young people with ASD and their parents struggled to characterize where they were on the spectrum and what this meant with regard to needed services. Parents of those with intellectual disability feared little thought was being given to future potential, while parents of the cognitively able were distressed that little help was offered to address ASD-specific challenges. Co-occurring medical or mental health concerns complicated matters for individuals across the spectrum. The mother of a daughter with a high IQ and psychiatric issues: *"I reach out to the Developmental Disabilities Administration, to these people, to those people… she doesn't fit the box. She's not mentally ill enough, she's not disabled enough."*
Conclusions: Young adults with ASD and their families bear a substantial burden as a result of lacking or inappropriate services. A better understanding of gaps and issues confronting families, and how these differ according to young adult characteristics, may inform efforts to improve policies and practices.

273 **127.273** Cross-Cultural Family Perspectives on Early Detection of ASD

A. Evans[1], *A. Delehanty*[2], *R. R. Grinker*[3], *S. Mazzatenta*[2], *J. Brown Speights*[4], *T. Walton-Walker*[2], *I. Davis*[5], *G. Ranger-Murdock*[6], *J. Boucher*[7] *and A. M. Wetherby*[2], *(1)National Black Church Initiative, Washington, DC, (2)Florida State University Autism Institute, Tallahassee, FL, (3)George Washington University, Washington, DC, (4)Florida State University College of Medicine, Tallahassee, FL, (5)Florida State University, Tallahassee, FL, (6)Cornell University, Ithaca, NY, (7)CADB, Ossining, NY*

Background: Although early social communication delays may be observable by 18-24 months, most children are not diagnosed with autism spectrum disorder (ASD) until 4-5 years of age. Children from minority or underserved backgrounds are identified 1-2 years later restricting access to early intervention. African American children are frequently misdiagnosed with other neurodevelopmental or emotional behavioral disorders and are underrepresented in intervention research (Hilton et al., 2010; Mandell et al., 2005; 2007). Among Latino children, healthcare professionals may be unable to conduct screening in the family's native language, and they encounter a lack of accessible specialists (Magaña et al., 2015; Zuckerman et al., 2013). Families from minority backgrounds may experience limited resources, socioeconomic variables, varying family interpretation of symptoms related to cross-cultural norms, and lack of trust and partnership with health professionals (Burkett et al., 2015; Grinker et al., 2011). The AAP recommends prioritizing research addressing health disparities in timely access to diagnostic and treatment (Cheng et al., 2010).
Objectives: To describe qualitative research findings from focus groups with diverse families implemented to identify challenges and barriers to early detection and access to care for toddlers under 24 months.
Methods: The research team contacted agencies serving young children and faith-based organizations through the National Black Church Initiative (NBCI). Focus groups were conducted in urban regions of Florida, Georgia, Pennsylvania, and New York. Separate groups were held for parents, grandparents, and parents of children at-risk for developmental delay. There were 105 participants in 8 focus groups; 70% black, 30% white, and 15% Hispanic. Driven by a grounded theory approach, researchers analyzed transcripts of audio-recordings to identify emergent thematic patterns. Multiple sites and diverse stakeholder viewpoints allowed for increased dimensions of variation and saturation of themes. Four members of the research team belonged to minority backgrounds represented in the sample, and verified that inferences were grounded in the data.
Results: Seven cross-cultural perspectives emerged for in-depth inquiry: 1) historical inequalities impact trust, prompting caregivers to view extended family as first-tier medical authority; 2) assumptions made based upon race, ethnicity, home language, and gender result in lack of a distinct call to action when toddlers show signs of ASD and communication delays; 3) people who speak languages other than English may expect children to have delays; 4) cultural beliefs and judgments of mainstream medical services, and need to keep diagnosis and treatment from extended family; 5) desire that others recognize child's worth and value in the presence of their disability, 6) role of spirituality to understand and cope with child's disability and the church as a place safe from stigma; and 7) increased role of supportive extended family members may serve as protective shield and help interventions fit family lifestyle.
Conclusions: Professionals should be aware of personal biases that may create obstacles for underserved families. To facilitate family engagement and connections to resources, professionals should consider ASD through each family's cultural lens, utilize evidence-based family-centered practices such as motivational interviewing, understand environmental stressors, and support caregivers' advocacy competencies (Ennis-Cole et al., 2013; Ingoldsby, 2010).

274 **127.274** Physicians' Perspectives on Early Screening and Diagnosis of ASD: Challenges and Solutions in Diverse Communities

R. Turchi[1], *J. Brown Speights*[2], *A. Delehanty*[3], *S. Mazzatenta*[3], *L. Orsini*[1], *E. Kaiser*[4], *J. L. Stapel-Wax*[5], *D. L. Robins*[6], *S. Dufek*[7] *and A. M. Wetherby*[3], *(1)Drexel University, Philadelphia, PA, (2)Florida State University College of Medicine, Tallahassee, FL, (3)Florida State University Autism Institute, Tallahassee, FL, (4)Marcus Autism Center, Atlanta, GA, (5)Emory University School of Medicine, Atl, GA, (6)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (7)Weill Cornell Medical College, White Plains, NY*

Background: The AAP recommends developmental surveillance at all pediatric visits and ASD-specific screening at 18 and 24 months (Johnson et al., 2007). Surveys of healthcare professionals suggest tremendous variability in the rates at which clinicians follow these guidelines (Dosreis & Weiner, 2006; King et al., 2010; Pierce et al., 2011; Self, Parham, & Rajagopalan, 2015). Barriers to implementation of universal screening include integrating screening into work flow, time constraints, electronic health records, and training needs (Crais et al, 2014; King et al., 2010). There is a need for research further illuminating the challenges faced by physicians and other healthcare providers in low- and high-resource settings and solutions to increasing accurate screening, diagnosis, and referral to early intervention.
Objectives: To present qualitative research findings from focus groups with physicians from diverse metropolitan areas across the U.S., designed to 1) identify barriers to early detection and access to early intervention for children under 24 months, and 2) develop strategies to increase physicians' confidence in identifying early signs of ASD, communicating with families, and accessing early intervention services in underserved communities.
Methods: Five focus groups with 45 primary care physicians and nurse practitioners were conducted in diverse regions of Florida, Georgia, and Pennsylvania. Driven by an iterative, grounded theory approach, researchers analyzed transcripts from audio-recordings using inductive coding. The use of multiple sites and diverse stakeholder viewpoints allowed for increased dimensions of variation and for saturation of themes. Physicians on the research team verified themes were grounded in the data, inferences were accurate, and that researcher bias did not interfere with interpretation.
Results: Illustrative quotes were drawn from diverse topics surrounding four major themes: 1) physician-perceived practical and psychological/motivational family challenges to accessing resources and services, including lack of medical follow-up, time constraints, and reimbursement issues; 2) efficient, effective tools for screening and assessment of ASD, including the utility of current tools, difficulty evaluating ASD in the primary care setting, and a perceived lack of reliable tools that would simplify diagnosis in the absence of available biomarkers, 3) the role of the primary care physicians in ASD screening and diagnosis, including confusion related to responsibilities of pediatricians and specialists who may be serving a population of varying cultural backgrounds; and finally, 4) strategies for building trust—the need to express empathy and offer hope to families, addressing parents' questions about causality, vaccination, and complementary and alternative medicine to treat ASD, and concern about parents/caregivers switching physicians when ASD is mentioned.
Conclusions: Topics for further inquiry include physicians' suggestions for refinement, including family navigation, continuity of care, a process-oriented approach to diagnosis of ASD, policy improvements, a team-centered medical home, a variety of media for reaching families, and the need for widespread physician training on ASD.

275 **127.275** Engaging Community Service Providers to Improve Earlier Autism Screening and Detection

J. L. Stapel-Wax[1], *E. Kaiser*[2], *L. Orsini*[3], *S. Mazzatenta*[4], *K. Traub*[5], *M. Costo*[2], *T. Gaines*[2], *D. L. Robins*[6], *S. Dufek*[7], *G. Ranger-Murdock*[8], *J. Boucher*[9], *C. J. Newschaffer*[6], *A. Klin*[10], *C. Lord*[11] *and A. M. Wetherby*[4], *(1)Emory University School of Medicine, Atl, GA, (2)Marcus Autism Center, Atlanta, GA, (3)PA Chapter of the American Academy of Pediatrics, Media, PA, (4)Florida State University Autism Institute, Tallahassee, FL, (5)AJ Drexel Autism Institute, Philadelphia, PA, (6)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (7)Weill Cornell Medical College, White Plains, NY, (8)Cornell University, Ithaca, NY, (9)CADB, Ossining, NY, (10)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA, (11)Psychiatry, Weill Cornell Medical College, White Plains, NY*

Background: It is important to build the capacity of community service providers to recognize the early signs of ASD in order to connect children to early intervention services to have the greatest impact on child and family outcomes. Community Based Participatory Research (CBPR) is used increasingly to address health issues and disparities for children by focusing on social, structural, and physical environmental inequities through active involvement of stakeholders, organizations, and researchers throughout the research process (Israel et al., 2001). CBPR can be used to address challenges to translational research including limited external validity, poor community trust in research, and lack of sustainability of practice change in community settings (Dankwa-Mullan et al., 2014).
Objectives: To utilize CBPR to engage community service systems in a new web-based professional development course and screening portal for social-communication delays and early signs of autism.
Methods: Community service providers (CSPs) from primary care practices, social services, and early learning centers were recruited to participate in this ongoing research. CSPs were invited to Autism Navigator for Primary Care, a web-based professional development course on the early signs of autism using video footage to rapidly build the capacity for early detection and understand how to share screening results with families. CSPs were provided with a tablet computer containing an interactive web platform with an automated screening tool linked to family resources on development and autism. Barriers to screening experienced by CSPs were identified through weekly communication that tapered to monthly over time. Feedback from CSPs was used to improve the screening process and potential access to care.
Results: To date, 158 CSPs have been recruited from 4 states in this multisite project, 121 from primary care and 37 from social service agencies; 138 CSPs have completed the coursework and screened 1,513 children by 18 months of age. It is anticipated that the number of CSPs and children screened will double in the next 6 months. Demographic information will be provided about CSPs in each service system. Barriers to screening experienced by CSPs and solutions to help CSPs incorporate practice change into their busy workflow will be reported. The most common barriers encountered include time to complete the course, understanding technology, and time to implement universal screening when many tasks must be completed during well-child visits. Strategies to address these barriers include contacting providers via e-mail and phone calls, weekly email blasts to highlight course content, improve user friendliness of portal, developing a briefer version of the course, meeting to troubleshoot problems, offering technical assistance, setting formal training dates and setting completion goals, promoting structured provider communication and partnership with other agencies, identifying staff members willing to engage family in screening while waiting for appointments, and enabling families to complete screening at home.
Conclusions: These findings will have important implications for bridging the research-to-practice gap and lowering the reachable age of early detection of ASD. Screening by different community service systems provides the opportunity to study strategies to address health disparities in access to early screening, diagnosis, and care.

276 **127.276** Using Tailored E-Mail Messages about Social Communication Milestones and Autism Spectrum Disorder to Engage Professionals in Autism Navigator® for Primary Care

A. Delehanty[1], *J. Warrick-Imrisek*[2], *N. D. Rich-Wiseman*[3], *D. Jones-Ellis*[1], *S. Barnes*[1], *C. North*[1] *and A. M. Wetherby*[1], *(1)Florida State University Autism Institute, Tallahassee, FL, (2)Florida State University College of Medicine, Tallahassee, FL, (3)Florida State University College of Medicine, Bedford, MA*

Background: The AAP and other professional organizations maintain a strong commitment to screening all children for autism spectrum disorder (ASD) at 18-24 months; yet, a recent USPTF report found inconclusive evidence to support universal screening in primary care prior to parents' expression of concerns. Pediatric healthcare professionals and families may be familiar with infants' motor milestones, but less aware of early social communication milestones and red flags for ASD.Â Bridging this research-to-practice gap is more critical than ever, and important steps include training professionals about screening, diagnosis, and evidence-based treatment.Â Researchers have investigated the utility of academic detailing, or educational outreach through professional development, to encourage physicians to change screening and referral processes (Honigfield, Chandhok, & Spiegelman, 2011; Soumerai & Avorn, 1990). Engagement with course material may be enhanced through the use of web-based tools. There is a need for research on the effectiveness of media message framing in encouraging professionals to complete coursework and change their screening and referral practices.
Objectives: The purpose of this study was: 1) to examine the responses of professionals enrolled in Autism Navigator® for Primary Care who received tailored e-mail messages about early social communication milestones and ASD; and 2) to characterize participants' perceptions of the messages.
Methods: Engaging weekly e-mail messages were developed through extensive efforts of an interdisciplinary team of autism researchers and specialists in marketing and public relations, user interface, and graphic design (Figure 1). Messages were framed to encourage course completion and utilization of a parent portal with automated screening linked to family resources. Participants were randomly assigned to one of two conditions based on e-mail message type. Gain-framed message highlighted the benefits of screening and awareness of early social communication milestones. Loss-framed e-mails stressed the risks or costs of not being aware and not screening (Tversky & Kahneman, 1981). Website analytics were used as a metric to examine relations between click-through rates and course activity. Participants were invited to respond to a brief, online survey to explore their perceptions of the messages.
Results: Data collection is ongoing. The mean open rate for messages to date is 36%. The click-through rate was 16% for gain-framed and 15% for loss-framed messages. In the 5 weeks since the email campaign began, there has been a 54% increase in course activity completion. Professionals varied in their perceptions of messages and offered suggestions for refinement.
Conclusions: E-mail engagement was higher than rates reported in the education and training industry, where average open and click-through rates hover between 16-22% and 3-6%, respectively (Chaffey, 2016; Constant Contact, 2016). Receiving informative messages about ASD and social communication delays was associated with upward trends in users' activity in a professional development course. This study demonstrates how media messaging and data analytics can be used to monitor and engage distance learners in course utilization and completion. These findings will inform further academic detailing efforts, and add to research on web-based tools and strategies for tailoring messages that encourage professionals to translate new knowledge into practice.Â

277 **127.277** Employing Process Maps to Identify Provider- and Site-Variation in Screening for Autism Spectrum Disorder

T. I. Mackie[1]*, C. Tan*[2]*, J. Benneyan*[3]*, R. C. Sheldrick*[4] *and M. Sridhar*[5]*, (1)Institute for Health, Health Care Policy and Aging Research, School of Public Health, Rutgers University, New Brunswick, NJ, (2)Brandeis University, Waltham, MA, (3)Northeastern University, Boston, MA, (4)Tufts Medical Center, Boston, MA, (5)Robert Wood Johnson Medical School, Rutgers University, New Brunswick, NJ*

Background: Â Challenges in moving scientific evidence into practice and policy are well-documented in the identification and treatment of autism spectrum disorder (ASD), especially for historically underserved communities. One factor thought to contribute to this translational lag is the time it requires to move a traditional research program from investigation of efficacy to effectiveness to implementation. To expedite the traditional research program, health services researchers are increasingly employing effectiveness-implementation hybrid designs that take a dual focus *a priori*on effectiveness and implementation. Blending these approaches into a single design is hypothesized to improve "clinical utility" of the study for practicing clinicians and decision makers.Â We demonstrate the value of a multi-method qualitative study that employed process maps- a systems-level visualization of the process logic and flow- to investigate fidelity and process efficiency of a three-stage screening process.
Objectives: We present how the use of multiple qualitative methods informed the development, validation, and application of process maps, with implications for improvements in fidelity and process efficiency of the intervention protocol.
Methods: We employ multiple qualitative methods to assess fidelity and process efficiency in the protocol for a three-stage ASD screening process. To improve the validity of process maps, we utilized respondent triangulation through inclusion of multiple samples, specifically: (1) research staff who developed and supported intervention approach (n=10), and (2) EI service providers who administered the two stage screening (n=21). All participants were asked to develop a process map of the screening process from point of initiation until time of completion. For trainers, we then conducted two concurrent focus groups to develop independent process maps and a subsequent member-checking focus to reconcile differences and validate findings. For EI providers, process maps were created during semi-structured interviews. Once collected, we individually analyzed trainer and EI provider process maps, coded, and summarized themes regarding protocol adaptation and provider variation.
Results: Â Comparing process maps of research staff and EI providers revealed considerable variation in adaptations made to the multi-stage screening protocol. For example, while the process maps generated by research staff illustrated initiation of the process to be when screening tools were distributed to providers, the process maps from EI providers demonstrate multiple non-scripted criteria to initiate or deter the process, including (1) whether the EI service provider, other clinical team members, or parents expressed concerns for ASD, (2) assessment of parental readiness to discuss ASD, and (3) assessment of family's service delivery needs and priorities. After initiation of the screening process, maps also revealed variation in how providers present ASD concerns indicated by the screening tools and the extent to which they expedited the process for further evaluation or relied on the family to move the process to subsequent screening stages.
Conclusions: Our findings suggest considerable adaptation occurred to intervention protocol, but systematic investigation of adaptations provides opportunity for protocol enhancement and training. Results reported above, for example, calls for additional EI service provider training in a shared decision-making process that encourages meaningful family engagement while minimizing delays to diagnosis during this critical developmental period.

278 **127.278** Pathways to Autism Spectrum Disorder Diagnosis through a Multi-Stage Screening Process

E. Frenette[1]*, N. A. Hoch*[1]*, J. D. Vera Jones*[1]*, T. I. Mackie*[2] *and C. Tan*[3]*, (1)University of Massachusetts Boston, Boston, MA, (2)Institute for Health, Health Care Policy and Aging Research, School of Public Health, Rutgers University, New Brunswick, NJ, (3)Brandeis University, Waltham, MA*

Background: For Autism Spectrum Disorder (ASD), evidence suggests that early screening improves detection rates. Our team implemented a multi-stage screening protocol for ASD in Early Intervention settings based on the “clinical reasoning model.”Â According to this protocol, referral decisions were based on screening results and the expressed clinical concern from parents or Early Interventionists. That is, children were promoted to successive stages if screening results were positive or clinical concern was reported subsequent to screening.
Objectives: Â To assess the utility of *a posteriori*concern-based referrals for ASD within Early Intervention settings and conduct a basic cost/benefit analysis of this multi-stage screening process.
Methods: Â 1022 children between the ages of 14-33 months participated in a case finding process for ASD involving stage 1: parent-report questionnaires, stage 2: structured observations, and stage 3: full diagnostic assessments. Quantitative methods were used to assess the effectiveness of different diagnostic pathways. Qualitative interviews of providers (N=20) were conducted to understand factors that influence their decision making processes.
Results: Among children with positive screening results, parents and/or Early Interventionists were concerned 64% of the time. The most efficient pathway to diagnosis was a positive screening score at stage 1 along with reported concern [5.6 assessment hours/diagnosis]. The least efficient pathways were those in which there were positive screening scores but no reported concerns [11 assessment hours/diagnosis]. Notably, pathways in which the stage 1 screening was negative but there was at least some reported concern fell in the middle [7.5 assessment hours/diagnosis]. Qualitative results suggest EI interventionists employed dynamic and distinct strategies to move families through the three-stage screening process when clinical concerns, whether the parents or their own, are present.
Conclusions: Results demonstrate the value of allowing referrals based on clinical concern subsequent to screening. Although, it is unclear the degree to which screening results influenced these concerns (concerns were coded after stage 1 screening results and are therefore not independent). Results also highlight that Early Interventionists find value in screening that go beyond the psychometrics of the binary result to include instruments' ability to enhance conversations and to collect clinically meaningful information about observed behavior within natural settings. These data show how important screening is and how crucial it is that we do not solely rely on parent concern in drawing conclusions about the value of ASD screening. If screening does not occur until parents are concerned, opportunities will be missed to diagnose children and therefore limit their chance to receive high intensity services at a younger age.

Oral Session -
134 - Welcome Address & Sponsor Update
8:45 AM - 9:00 AM - Yerba Buena 8-9

8:45 Welcome Address & Sponsor Update

Keynote Address
135 - Engaging Autism: Interventions for Improving Social Communication Outcomes
9:00 AM - 10:00 AM - Yerba Buena 8-9

Speaker: C. Kasari, University of California, Los Angeles, Los Angeles, CA

Early interventions for children with ASD have resulted in greater numbers of children entering mainstream settings, and fewer children entering school as minimally verbal. While we have several effective behavioral interventions, heterogeneity in response to treatment remains a significant challenge. Our approach to addressing heterogeneity and response to treatment has been 1) the development of targeted and modular interventions that address core areas of impairment in children with ASD, and 2) methodologies that address response to intervention with the goal of personalizing treatment. This talk will describe our work in applying targeted interventions for improving social communication outcomes across a range of developmental ages, delivered in authentic community settings, and mediated through multiple individuals. Underserved, and under-represented groups of children will be highlighted, including minimally verbal school aged children, and girls, as well as methods for systematically adapting interventions based on child response. To further the goal of personalized treatment, future challenges center on greater specification of the active ingredients of interventions, and individual differences in predicting response to treatments.

9:00 Engaging Autism: Interventions for Improving Social Communication Outcomes

***C. Kasari**, University of California, Los Angeles, Los Angeles, CA*

Early interventions for children with ASD have resulted in greater numbers of children entering mainstream settings, and fewer children entering school as minimally verbal. While we have several effective behavioral interventions, heterogeneity in response to treatment remains a significant challenge. Our approach to addressing heterogeneity and response to treatment has been 1) the development of targeted and modular interventions that address core areas of impairment in children with ASD, and 2) methodologies that address response to intervention with the goal of personalizing treatment. 1 **136.001** A Researchkit App with Automatic Detection of Facial Affect and Social Behaviors from Videos of Children with Autism

***J. Hashemi**[1], K. Campbell[2], S. Espinosa[1], S. Marsan[3], Q. Qiu[1], M. Tepper[1], K. Carpenter[3], J. Schaich Borg[1], G. Dawson[3], R. Bloomfield[1], H. Egger[4] and G. Sapiro[1],*

(1)Duke University, Durham, NC, (2)Duke Center for Autism and Brain Development, Durham, NC, (3)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (4)Child and Adolescent Psychiatry, NYU Langone Medical Center, New York, NY

Background: The gold standard for Autism Spectrum Disorder (ASD) screening involves parental reports of child behaviors. Few screening methods are scalable and incorporate objective data. Wide use of mobile devices that can both display and collect text and video data provides an opportunity for testing new screening methods that are feasible beyond the clinical setting. Naturalistic observation can now be quantified with computer vision techniques and could have applications in detecting subtle behavioral abnormalities.
Objectives: To create and test a self-contained mobile application that allows for remote collection of ASD-specific questionnaire data, observational video data of a child reacting to various video stimuli while in his/her natural environment, and automatic coding of observational video data.
Methods: The ResearchKit app *Autism&Beyond* was developed and launched as a study with informed consent and IRB oversight. The app incorporates demographic questionnaires and a digital version of the full Modified Checklist for Autism in Toddlers (M-CHAT-R/F) including follow-up questions. In addition, three short video stimuli (bubbles, rhymes and toys, and a bunny) as well as a mirror stimulus are presented to elicit affective and social responses. Using the front facing camera on the mobile device, video of the child is recorded during stimulus presentation and saved at 640 by 480 resolution and at 15 frames per second. Developed computer vision algorithms automatically detect and track multiple facial landmarks including points around the eyes, nose, and mouth. From the tracked facial landmark locations, multiple characteristics are gathered including head position, head orientation, facial affect classification, and blink rate. Responses to stimuli were analyzed separately to determine whether stimuli differentially elicit child behavior.
Results: Over six months of data collection, 878 subjects met the inclusion criteria (at date of abstract submission we have registered over 2,000 consent forms, over 5,000 video recordings, and over 8,000 completed surveys and questionnaires). Of these, 152 children 1-6 years old with parent-reported Autism diagnosis and/or high risk M-CHAT score uploaded video data through the mobile application. The child's face was detected on average during 84-92% of the video stimulus, with the most face detection in the rhymes stimulus. Computer vision algorithms classified positive affect during a mean of 22-31% of the total time, with the most positive affect detected during the mirror stimulus. Using head position, social referencing occurredÂ for 12-42% of subjects throughout the various stimuli, with greatest probability of social referencing observed during the Mirror stimulus.
Conclusions: We developed and deployed a mobile application to gather ASD-specific questionnaire and video data in naturalistic settings. From the video data we were able to automatically score affective and social responses of a child during various video stimuli. Application of computer vision to facial expression analysis could lead to new behavioral imaging methods for detecting subtle neurologic processes relating to attention and emotional expression, and may be useful for early Autism screening and monitoring.

2 **136.002** A Smartphone Application to Measure Response to Name in Everyday Environments

R. P. Thomas[1], *L. A. Wang*[1], *J. Miller*[2], *J. W. Pennington*[2], *S. Hassan*[2], *A. Grasmeder*[2], *J. Swanick*[2], *N. Minyanou*[1] *and J. Miller*[3], *(1)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Department of Biomedical and Health Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Â Reduced response to name is a hallmark feature of Autism Spectrum Disorder (ASD) but our current methods of identifying it are not very sensitive. Measurement of response to name is often qualitative, relying on the child's performance during an in-person evaluation (ADOS) or a yes/no response on parent questionnaires (M-CHAT). Measured as a quantitative variable, or as a *rate*of responding rather than a dichotomous summary judgment, response to name may be both a more sensitive indicator of ASD and a potential moderator of response to treatment.
Objectives: Â The objective of the study was to develop a smartphone application to record children's response to name in everyday environments.Â We examined fidelity, accuracy of parent ratings, and user experience.
Methods: Â Parents of children between the ages of 18-48 months participated in the study. Children could be typically developing, or have ASD or another developmental concern. Parents downloaded the app onto their smartphone and were asked to complete 3 sessions. The app included a built-in tutorial; otherwise no instructions were provided. The tutorial displayed illustrations and text guiding parents to stand 3-5 feet behind the child, call the child's name once, and then press Yes or No to rate whether the child responded. Within each session, the app prompted up to 3 name call trials in case the child did not respond right away. After 3 sessions, we provided feedback to the parent about fidelity. Then parents were asked to record up to 30 additional sessions over the course of one week. Sessions were automatically uploaded to our database, with both a video file and time-stamped text file of parent ratings. After completing all sessions, parents completed online questionnaires about user experience and satisfaction.
Results: Â So far, 4 families have begun participation, and 17 more have expressed interest (study goal is 30 families). We currently have 16 pre-feedback trials and 135 post-feedback trials. Two raters viewed each video recording and text file to establish parent fidelity (the parent's ability to administer the trial correctly) and accuracy (of child response ratings). Inter-rater agreement was 100% for fidelity and 98% for accuracy. Across participants' first three sessions, parent fidelity averaged 78% (range 50%-100%). Two families needed feedback to say the child's name only once, and not to shout the child's name. Across post-feedback trials, parent fidelity averaged 89% (range=77%-97%).Â Parent accuracy for rating their child's response was 97% (range=95%-100%).Â Parent survey responses indicated parents "strongly agreed" the app was easy to use, that it measured a meaningful behavior, and that they would recommend the app to a friend.
Conclusions: Â The app appears easy for parents to use correctly, though instructions do need to highlight calling the child's name only once and not shouting the child's name. Ongoing data collection will allow us to also develop formulas for calculating a child's rate of responding, which can then be examined across children with ASD, other delays, and typical development.

3 **136.003** A Mobile Video Game for Studying Social and Nonsocial Executive Functions in Children with ASD

B. Li[1], *Y. A. Ahn*[2], *M. Kim*[3], *M. Mademtzi*[4], *S. A. A. Chang*[5], *E. Barney*[6], *C. Foster*[4], *M. Best*[5] *and F. Shic*[3], *(1)Seattle Children's Research Institute, Seattle, WA, (2)Seattle Children's, Seattle, WA, (3)Center for Child Health, Behavior and Development, Seattle Children's, Seattle, WA, (4)Yale Child Study Center, New Haven, CT, (5)Yale University, New Haven, CT, (6)Child Study Center, Yale University, New Haven, CT*

Background: Deficits in executive functioning skills (EFS) is a characteristic for autism spectrum disorder (ASD). Clinicians often use traditional behavioral assessment (e.g. Wisconsin card sorting task) to test children's EFS, but these resources are not easily accessible for children living in undeveloped areas. Digitalized games have the potential to be a supplementary tool in increasing the accessibility of EFS assessments.
Objectives: To (1) design a well-controlled mobile technology game that can assess and potentially improve EFS in children with autism,using social and nonsocial conditions that test EFS; (2) To conduct a proof of concept usability test of the game.
Methods: We designed a tablet video game with three tasks: set shifting, working memory, and inhibitory control tasks. The program selects either social and nonsocial stimuli as targets for each session of the task, and each session has two social blocks and two nonsocial blocks (randomly counterbalanced). Similar to the Wisconsin card sorting task, our shifting task shows four images on the screen for each trial, and users have to guess which image is the correct answer.he underlying unspoken rule (happy face, angry face, red fractal, or blue fractal) changes for every ten trials.Â The working memory task shows objects for 10 seconds for participants to memorize, and then they have 45 seconds to choose all the right answers.The difficulty of the task depends on the participants' performance. For inhibitory task, users are asked to click as many pictures as possible on the screen, but are required to stop touching the screen when a "stop sign" or "angry face" pop out. The stop signal appears 5 times in each session. The appearance time and appearance length of the "stop (signal)" are pseudo-randomized and counterbalanced.Â Users' touches are recorded for post-hoc analysis.
Results: A supervised 6-year-old child with autism played all three tasks in 8.5 minutes. Throughout the experiment, the child touched the targets for a total of 74 times. In the shifting game, the child answered 17 out of 40 questions within the 2 minute time limit. He learned the first hidden rule and gave correct answers for the first 9 questions but failed to learn the new rule afterwards and got half of the questions wrong. In the inhibitory game, the child touched 44 targets in total and four of those occurred during the inhibitory stage. Of the four, three occurred during the social trials. In the memory game, the child spent an average of 1.99 seconds finding the memorized images during the two nonsocial trials. However during the two social trials, the child could not remember the correct target before reaching the time limit of 45 seconds.
Conclusions: This video game could be useful for examining discrepancies between socially-oriented and non-socially oriented executive function ability in children with ASD. In the future, we will collect more data from TD children, children with ASD, and TD adults. We will analyze and compare playing patterns, performance, and verbalization of each participant.

4 **136.004** Novel and Surprising Touchscreen Game Elements Can Motivate Spontaneous Communication from Children with Autism

***A. M. Alcorn**, UCL Institute of Education, University College London, Centre for Research in Autism and Education (CRAE), London, United Kingdom*

Background: A core characteristic of autism is difficulty with social communication and interaction, particularly initiating new communications. This research uses touch-screen computer games as a means to motivate practice of spontaneous initiations. The current games deliberately try create situations that children will perceive as subjectively novel or surprising (i.e. *discrepant,* differing from their current knowledge and expectations), and that are "worth communicating about" to others. In a previous project (the ECHOES virtual environment), autistic children were observed to frequently and spontaneously initiate about events of this type. ECHOES deliberately included novelty (e.g. new digital objects), however, software errors also caused *unintentional* surprises, such as the character making "mistakes" in an activity he had previously demonstrated correctly. The new designs *deliberately* alter a game environment and introduce new elements, trying to re-create and extend the type of spontaneous initiations fortuitously present in ECHOES.
Objectives: Evaluate a new set of games to determine whether deliberate inclusion of novel and surprising elements can motivate spontaneous, positive initiations about game content, similar to the interactions seen in ECHOES.
Methods: Three new games were developed, based on the simple, exploratory, cause-and-effect play in the original ECHOES environment. In one, children sorted apples by colour; two centred on growing flowers or carrots by shaking a magic cloud. Each game had a "baseline" and a "discrepant" version. After the baseline versions were familiar to children (session 1), additional objects and properties were introduced to create "discrepant" versions, with novel and surprising elements (sessions 2-3). Surprises included altered object appearances, sound effects, and timings between events. A character also made occasional "mistakes" with his actions and utterances. These things were predicted to interest children and pose opportunities for them to spontaneously initiate communication. A proof-of-concept scale school study in the UK (10 autistic children age 5-11 years, 2 female, phrase language use) evaluated the new games' effectiveness at motivating communication with an adult social partner. Children played the games individually, over 3 short sessions (mean 48 minutes total play /child).
Results: In 580 min of gameplay video, there were 409 spontaneous initiations to the adult researcher or game character, related to discrepancies (range 11-79 initiations, mean= 40.9/child). In an additional 241 instances, children reacted to discrepancies in a non-socially-directed way. 46% of these initiations were about game elements *deliberately* included to create discrepant (novel or surprising) situtations. Children also initiated about "non-designed" discrepancies: genuine system errors, and subjectively perceived changes or differences. Across all children, there were very few instances of negative affect. The games appeared both motivating, and emotionally manageable.
Conclusions: The current strategy of including novel and surprising game elements appears to have been successful in motivating spontaneous social communication for a diverse group of autistic children. It merits further investigation with a wider age/ability range, and with other types of technology. These findings are an early step towards determining whether this strategy may contribute to a future technology-based intervention for autism, capable of changing children's initiation behaviour outside of a game context.

5 **136.005** Using Positional Tracking to Monitor Gaze in VR - Pilot Study

***L. A. Hart**[1], R. A. Oien[2], E. Velasquez[3], Q. Wang[4], M. Mademtzi[5], F. R. Volkmar[6] and F. Shic[7], (1)Yale School of Medicine, New Haven, CT, (2)The Arctic University of Norway, Tromso, NORWAY, (3)Full Sail University, Orange County, FL, (4)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Yale Child Study Center, New Haven, CT, (6)Child Study Center, Yale School of Medicine, New Haven, CT, (7)Seattle Children's Research Institute, Seattle, WA*

Background: The use of video as a tool to facilitate learning and skill development has undergone numerous iterations within this field and others, and its application has expanded to include eye-tracking and assessment to name only a few examples. More recently, 360 degree video has begun to enter the realm of mainstream media, in part as an accompaniment to the advent of virtual reality headsets (HMDs) as an affordable consumer product. In addition to their potential benefits to ecological validity (Cummings, Bailenson, & Fidler, 2012), the sophisticated positional tracking systems possessed by most commercial HMDs represents an opportunity to leverage this feature as an alternative measure of visual attention within VR environments. Evidence from both eye-tracking (Wang et al., 2015) and earlier work with HMDs (Jarrold et al., 2013) suggests that visual attention can be beneficially altered through interactive training and prompts. While currently limited to positional tracking, HMDs' stereoscopic 360° environments and real-time positional data makes them a viable and affordable candidate platform for interventions and assessments that would benefit from the ability to track visual attention.
Objectives: The first phase was conducted to 1) assess participants' level of comfort during extended use of HMDs, and 2) evaluate gaze as a measure of visual attention. Phase 2's primary goal: use these findings to inform the design of a background VR environment capable of 1) automatic data recording, 2) displaying playlists of 360° videos, and 3) providing a framework for custom stimuli setup.
Methods: Â Phase 1 consisted of 4 participants with a neurodevelopmental disorder(s) including ASD - both verbal and nonverbal (ages 6 to 18), and 2 TD participants (ages 5 to 11). Each participant watched five 360° videos varied across dimensions of social and physical intensity on an oculus DK2. Visual attention was defined as the central 25°s of the visible 100° FoV (Field of View) in the DK2. Questions and observations concerning comfort and overall enjoyment were recorded by a confederate. For phase 2, our initial approach was translated and modified within Unity, a popular game development platform.
Results: Â On average, participants spent 14 minutes and 21 seconds wearing the DK2, and responded positively during the session and to questions post-viewing. Notably, none of the participants with ASD paused or removed the headset, and only one TD participant briefly removed their headset during the "physical intense" 360° video (a rollercoaster ride). Results from the attention measure generally align with previous findings in the literature. Translation to Unity allowed for automatic data recording through a combination of Unity's Raycasting API and tagged "detection zones" for stimuli. Advantages included the removal of added time spent on data collection after setup and greater overall flexibility.
Conclusions: Â The initial evaluation of commercial HMDs for tracking attention and potential usability in applications and research targeting individuals with ASD is encouraging, however, further investigation is needed before concerns over sensory sensitivities are fully resolved. While the second phase of the project is still in development, progress and results from ongoing recruitment will be reported.

6 **136.006** Child-Directed Play-Based Identification of Sensory Preferences: A Report on the Sensory Toy Box Experience with ASD and TD Children

S. Valencia[1]*, M. Mademtzi*[1]*, P. E. Ventola*[1]*, K. Chawarska*[2] *and F. Shic*[3]*, (1)Yale Child Study Center, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Seattle Children's Research Institute, Seattle, WA*

Background: Sensory preferences of children with Autism Spectrum Disorder (ASD) are often unique from their peers, and it can be challenging to identify learning interfaces that promote engagement. The autonomous collection of data during a child's naturalistic play has the potential to provide unique insights into how children interact and engage with different sensory feedback modes. We developed and evaluated the Sensory Toy Box (Valencia, 2016), a device that can be activated in 9 different ways (through a button press, texture touch and/or placement of objects). The device logs each activation and provides different types of feedback in response such as sounds and light.
Objectives: 1) To enable direct identification of sensory preferences through a child-oriented play approach and 2) examine engagement within the different sensory feedback modes among typically developing (TD) and ASD groups.
Methods: We evaluated engagement and preferred activation and feedback modalities during 5-minute individual free play sessions with the Sensory Toy Box in a group of toddlers (M_{Age} =22.5 months, *SD* =7.9 months, TD *n* =3, ASD *n* =2) and school-aged children (M_{Age} =63.3 months, *SD* =20.1 months, TD *n* =2, ASD *n* =4). We used the Sensory Profile 2 (SP2) parent questionnaire to gather sensory profile information for reference. We collected data autonomously with the device and video-coded (ICC>=0.94) the interactions.
Results: Within our sample, children with ASD had higher engagement with the device (*M* =75.7% of time engaged, *SD* =17.5, *n* =6) than TD (*M* =50.5% engaged, *SD* =18.1, *n* =5), t (9) =2.45; p=0.038. When considering each age group separately, a significant difference was found only in the toddler group: ASD (*M* =81.6% engaged, *SD* =7.6, *n* =2) and TD (*M* =38.8% engaged, *SD* =6.3, *n* =3), p=0.0061. However, there was no significant difference among the group of school-aged children, ASD (*MÂ* =74.3% engaged, *SDÂ* =21.7, *nÂ* =4); TD (*MÂ* =68.1% engaged, *SDÂ* =14.3, *n* = 2), p>0.05. Children with ASD, both toddler and school-aged children groups, exhibited higher number of total activations in the visual feedback mode than the TD group. There was only a significant difference in the group of school-aged children for ASD (*M* =35, *SD* =9.8, *n* = 4) and TD (*MÂ* =5, *SDÂ* =4.2, *n* =2) groups, p =0.01. There was a significant correlation, between ASD diagnosis and engagement time (*rÂ* =0.63, *p* =0.037). Within the ASD group, number of activations during the auditory feedback mode were correlated with their SP2 auditory processing scores (*r* =0.60, *pÂ* =0.05) for both age groups. Participants with "Much more than others" auditory processing SP2 scores, performed 62% of their total activations during the auditory modality. No significant correlations were found for activations performed during the visual feedback mode and SP2 visual processing scores in both age groups.
Conclusions: In this work we have developed an initial prototype of an interactive technological tool to assist in the evaluation of sensory preferences in children with ASD. This preliminary study motivates further investigation in quantifiable measures of preferences and behaviors through child-directed play interactions with tangible toys.

7 **136.007** Evaluating the Effectiveness of a PRT Community-Based Autism Parent Coaching Program Using LENA

M. Stolte[1]*, V. R. Smith*[1] *and C. Labonte*[2]*, (1)Educational Psychology, University of Alberta, Edmonton, AB, CANADA, (2)Department of Educational Psychology, University of Alberta, Edmonton, AB, Canada*

Background: The gap between research and practice is wide despite increased awareness of the need to adopt evidence-based practices (EBP). A key component of effective ASD early intervention is parent coaching. Through partnership with community providers, real world implementation of parent coaching EBP's can be evaluated. Additionally, new technologies may help bridge the gap in community practice by simplifying feedback. Parent coaching in pivotal response treatment [PRT] (Koegel et al., 2006) is an EBP currently under dissemination in Western Canada. This study extends pilot work on using the Language Environmental Analysis System (LENA), a new technology, to provide feedback on a PRT parent coaching model in community practice (Stolte & Smith, in submission).
Objectives:

1. To provide an updated description of a community based pivotal response training (PRT) parent coaching model and extend previous findings
2. To evaluate the effectiveness of the model on child, parent and parent-child interactional communication patterns using the LENA
3. To evaluate the use of LENA as a new technology to measure program effectiveness in a real world setting

Methods: Using a non-concurrent multiple-baseline single-subject research design matched with new digital language processor technology (i.e., LENA), a community-based PRT parent coaching model was evaluated for pre-schoolers with ASD. Three parent-child dyads participated in a 5 week coaching model, 2 hours per week, producing 46 independent recordings. Using LENA Advanced Data Extraction (ADEX) software, baseline, intervention and follow-up data were evaluated on child, adult, conversational turns, and ratio of child initiated conversational turns. Detailed child and parent information, PRT fidelity, content validity, and functional relationships between coaching condition and communication patterns are appraised including video analysis and standardized communication measures.
Results: A program description and detailed parent and child information was obtained. Demonstration of PRT learning improved for all parents though only one parent met full fidelity. A functional relationship between adult language and coaching condition was identified for 2 of the 3 dyads. Functional relationships between conversational turns and coaching condition were inconsistent due to high variability, though 1 child improved in vocalizations over time. Visual analysis of 33,648 LENA communication blocks suggest child and adult initiations improved for 1 dyad, but was not replicated. Extracted LENA data on controlled conditions yielded distinct communication patterns across participants.
Conclusions: This PRT parent coaching model holds promise for community practice. By using new technology paired with single subject design methodology, detailed communication information and functional relationships could be evaluated over time. Extending previous findings, LENA analysis indicated replication of a functional relationship between coaching condition and adult word count for 2 of 3 dyads. All parents demonstrated improvement in PRT though fidelity was inconsistent. Extracted ADEX analysis also indicated distinct parent-child communication patterns between dyads. This study demonstrates the importance of evaluating EBP in community settings and how new technologies, such as LENA, can support this objective.

8 **136.008** An Automated Telehealth System for Long-Term Monitoring of Meltdowns in Children with Autism Spectrum Disorder: Epxautism.

***J. R. Feltes**, M. Pan, S. Zhang, R. Talkin, N. Zhao, R. Chen and N. Marrus, Washington University School of Medicine in Saint Louis, Saint Louis, MO*

Background: Â For patients with autism spectrum disorder, wait times often exceed three months for scheduling specialty clinic visits. Moreover, current attempts to ascertain data on longitudinal behavior patterns in autistic patients during this interim rely primarily on retrospective interviews or questionnaires, which suffer greatly from recall bias. The lack of accurate and effective monitoring of clinically relevant behaviors such as meltdowns can lead to less than optimal care provided to the patient. We have created an automated text-message-based intervention to bridge these temporal gaps in care, giving providers data and automatically triaged alerts on patients' behaviors between visits.
Objectives: Â To monitor patients with autism through a novel telemedicine system which facilitates early detection of exacerbation of problem behaviors, providing a tool for healthcare providers to improve treatment recommendations and medication titration.
Methods: Â EpxAutism sends daily/weekly messages to parents of children with autism asking about quantity and duration of meltdowns, instances of aggression/disruption/self-injurious behavior during meltdowns, and whether there is a known antecedent to meltdowns. The system synthesizes data received through text responses for each patient, triages patients into one of three risk categories based on their change in behaviors, and sends alerts to providers upon recognizing significant upward deviations in recorded problem behaviors.
Results: We achieved an 85% overall response rate to messages through an initial phase of pilot study involving 6 enrolled patients. Each patient has a diagnosis of autism spectrum disorder. Duration of enrollment spans from 18 days to 110 days. Response rate has not decreased significantly for patients enrolled for more than 100 days.
Conclusions: We present EpxAutism, a novel, cost-effective monitoring system for behaviors of children with autism between clinic visits. Prompt reporting both reduces recall bias as compared to paper surveys/retrospective questionnaires and allows providers in this study to remotely alter subjects' plan of care. Data suggest that our intervention is a promising method of tracking meltdowns and problem behavior in patients with autism, allowing physicians to more precisely treat patients and also be alerted more promptly about ongoing behavioral problems. Results from our pilot warrant further study in a larger population, which is ongoing.

9 **136.009** Distance Mentoring Model for Autism Assessments in the Indian Himalayas

***S. Nagesh**, Latika Roy Foundation, Dehradun, India*

Background:
Reductions in under five mortality rates has shifted global program and policy focus to lives that thrive and live with or without disability in most parts of the world. In the Indian Himalayas, identification and assessment of developmental disabilities in young children poses a huge challenge, and intervention therefore remains a far dream. With no developmental pediatricians in Uttarakhand, the Himalayan state of India, the program uses expertise from a qualified early development expert based in a high income country to train, support and supervise a team of local professionals in the field of Autism, for assessment and intervention.
Objectives: The model provides expert supervision and support in the local language and maximizes use of limited resources of time, money and personnel. The model depends on a strong mentorship capacity, committed time by professionals to assess, record, share and seek guidance, and deep relationship building which in turn strengthens the support between the family and the team.
Methods:
The program began with on site training on the use of new tools for autism diagnosis (ADOS and ADIR). The module initiated with training to build the knowledge base and was followed by multiple hands-on sessions on the use of assessment tools with families whose children were suspected to have autism. Multiple sessions with close supportive supervision were followed by the local professional teams conducted the assessments independently. The assessments reports were emailed to the consultant and video recordings were uploaded on the Internet using strict privacy settings. The local team received immediate feedback and timely support with diagnoses and intervention plans for the child and the family. Technical assistance also involved access to web resources, and training for parent groups. The consultant and the local team meet face to face twice a year to develop further insights, review complex cases, facilitate parent meetings, and training in advanced modules.
Results:
In six months, the team assessed, diagnosed and provided intervention support to fifty children with autism. The model did not need funding and provided on-site training support using new assessment tools and distance support to validate assessments and diagnoses thereafter to a team of local professionals for children with autism. Children and families receive the benefit of best practice interventions and specialist inputs that would otherwise not be available for them. While we understand the pivotal role technology plays in this program, we cannot undermine the value of on-site visits and face-to-face meetings.
Conclusions:
Though the technology is not complex, for local professionals to learn and use the video camera, email, whatsapp and youtube are innovations in their own right. This model can be adapted and applied to settings where there is a need for training and support. The distance-mentoring model can supplement the more traditional model of site based service delivery and support. The foundation is aiming to scale the model for children with cerebral palsy and Down syndrome.

10 **136.010** Data Collection and Token Management System for Group-Based Therapy

R. Jakobovits[1,2]*, R. C. Bocirnea*[2]*, B. Aaronson*[1] *and A. Estes*[3]*, (1)University of Washington, Seattle, WA, (2)Experiad Solutions, Honolulu, HI, (3)University of Washington Autism Center, Seattle, WA*

Background: Motivity is a cloud-based software system for data collection and therapy management that is being developed with grants from the National Institute of Mental Health. Motivity is unique in its ability to support group-based therapy with multiple observers using mobile devices to collect data simultaneously on large groups of individuals, providing real-time data visualization to all users, updating instantly when new data is collected. The Motivity prototype was tested at the University of Washington Apex Summer Camp for 5 weeks. Apex is an evidence-based program serving over 90 children each summer that utilizes a naturalistic day camp environment and structured recreational activities to teach behavioral and social skills. Therapy is conducted by 40 trained interventionists. Over 25 different behaviors are tracked continuously throughout the day to monitor progress and develop individualized goals. The program includes a reward system in which children earn points for appropriate behavior, such as helping peers and staying on task, and lose points for behaviors targeted for decrease, such as interruption and teasing.Â At the end of each day, children redeem points for prizes.
Objectives: Â The Motivity prototype was deployed to Apex with the goal of evaluating the real-time feedback capabilities and scalability of the system to support large group therapy and school-based interventions.
Methods: Prior to deployment of Motivity, Apex data collection was entirely paper-based and was extremely tedious and time-consuming for Apex staff, involving over 150 hours per week of staff labor to tally up points and enter data for analysis and point tracking.Â For the field test, the paper system was completely replaced by the Motivity prototype on iPads and Kindle Fire devices.Â The camp director (BA) used Motivity's Knowledge Authoring Interface (KAS) to model the Apex scoring system and measures in Motivity. To support groups, a Group Teach interface was added to Motivity in the form of a scrollable grid, with each column representing one child. Staff were trained for 1 hour on the use of Motivity prior to camp. Children were divided into 8 groups of 12 children each; each group had 4-5 staff members facilitating group therapy with 2-3 mobile devices (iPads and Kindle Fires) per group.
Results: The Motivity model and navigational structure fully supported the Apex behavior tracking and token economy requirements. After five weeks of use, **over 150,000 behaviors were recorded**. Apex staff reported high satisfaction with the system, including usability, performance, and functionality.
Conclusions: The camp director reported that Motivity saved each staff member over 4 hours of manual labor per week, and allowed much quicker evaluation of student progress, clinical responsiveness, and ability to provide comprehensive information to parents. For example, counselors were able to monitor behavioral changes in response to a medical adjustment and share definitive data with the family and primary care providers immediately. Motivity allowed interventionists to provide a level of clinical support that would not have been possible using the original paper methods.

11 **136.011** Healthier Me: An App to Promote Health, Nutrition and Safety for Children with ASD

J. Harris[1] *and A. P. Robertiello*[2]*, (1)Children's Specialized Hospital, Mountainside, NJ, (2)Autism, Children's Specialized Hospital, Mountainside, NJ*

Background:
Behavioral and cognitive challenges experienced by people with ASD may impact personal hygiene, nutrition, fitness, health maintenance, and safety. Neglect of personal and oral hygiene, nutrition, and exercise may lead to infection, tooth decay and periodontal disease, obesity, hypertension, coronary disease, and other adverse health conditions. Indeed, the CDC reports that obesity is 50% more common among teens with developmental disabilities including ASD. In addition, behavioral and cognitive challenges associated with ASD may impact safety practices, leading to unintentional injury of self or others or loss of life. The Interactive Autism Network notes that approximately half of children with ASD over the age of four attempt to elope from a safe environment. More than one third of children with autism who wander or elope have significant challenges communicating their name, address, or phone number. This represents a significant public health concern among youth with ASD.
Objectives:
Aim 1: Develop technology to track, educate, and reinforce behaviors which promote health, good hygiene, nutrition, and safety forÂ youth with ASD
*Aim 2:*Examine experiences of users of the technology developed in Aim 1.
Methods:
Interviews were conducted with families, service providers, and other professionals in the field of ASD to determine needs, approach, and content to address daily hygiene, healthy eating, fitness, and safety concerns. Based on this primary input, a mobile app, “Healthier Me”, was developed, tied to delivery of personalized reinforcers with ability to track related behaviors and provide user-directed education. Healthier MeÂ was developedÂ to track hygiene habits; reinforce healthy food choices, drinking sufficient water, and avoidance of foods specified as allergic; track activities and time spent being physically active; and offer information about eachÂ “healthier” activity. Specific educational information related to safety and health maintenance is also provided on the app. People with ASD and/or their caregivers were recruited to download the app. Qualitative interviews were then conducted regarding the user experience.
Results:
Data derived from qualitative interviews will be reviewed in an iterative manner to develop common themes related to engagement and utility of the app.
Conclusions:
The creation of the “Healthier Me” app is an innovative approach to meeting an unmet need – helping youth with autism learn and practice safe and healthy activities as a regular part of their lives. It can be used in multiple environments by the person with ASD and/or their various care providers to encourage good health, nutrition, fitness, and safety. User experience will provide pilot information regarding initial response to the app among stakeholders. Subsequent research will focus on both short-term and long-term effects of the use of the “Healthier Me” app on health status, personal hygiene, and safe behaviors of youth with ASD.

12 **136.012** Can Computer-Assisted Training of Prerequisite Motor Skills Help Enable Communication in People with Autism?

M. K. Belmonte[1]*, E. J. Weisblatt*[2]*, A. Rybicki*[3] *and P. Karanth*[4]*, (1)Com DEALL Trust, Bangalore, INDIA, (2)Department of Psychology, University of Cambridge, Cambridge, UNITED KINGDOM, (3)Division of Psychology, Nottingham Trent University, Nottingham, United Kingdom, (4)The Com DEALL Trust, Bangalore, 560043, INDIA*

Background: Our and others' research indicates that in fully a third of people with autism who lack communicative speech, the communication deficit may actually be a deficit in motor skills necessary to move the mouth and the vocal tract. These individuals have difficulties in fine, gross and especially oral motor skills, and a disparity between impaired expressive language and relatively intact receptive language. Within this motor-impaired subgroup specifically, training in visuomotor skills prerequisite to effective communication may provide a 'back door' to developing social communication, via a route other than speech.
Objectives: Given the labour-intensive nature of communication therapy in general, we therefore are interested in testing a computer-assisted, caregiver-mediated training programme for motor communicative skills, and contrasting learning effects between a motor-impaired autistic subgroup defined by impaired fine and especially oral motor skills and disparity between impaired expressive and more intact receptive language.
Methods: Point OutWords (http://www.AutismCollaborative.org/PointOutWords/), free, tablet-based software designed and tested in collaboration with autistic clients and their communication therapists in India and England, and deployed worldwide, exploits the autistic fascination with parts and details to motivate attention to learning manual motor and oral motor skills essential for communication. Autistic clients practise pointing and dragging objects, then pointing at sequences of letters on a keyboard, and if and when able, speaking the syllables represented by these letters. Users and their parents or guardians can opt into network-based collection of data on motor interactions with Point OutWords, from which are derived several internal measures of baseline and change in visuomotor targeting error, touch force, and any anticipatory movements of the device by the caregiver. These measures of motor skills development internal to the software are complemented by external, standardised tests of motor and communicative development administered to children (Mullen Scales of Early Learning: Fine Motor, Receptive Language, Expressive Language) and parents (Movement Assessment Battery for Children (MABC-2) Checklist), Social Responsiveness Scale (SRS-2), Parenting Stress Index (PSI-4), Vineland Adaptive Behavior Scales II); these are analysed by a 2x2 (motor-impaired or motor-intact subgroup, Point OutWords treatment or iPad exposure control condition) repeated-measures analysis of variance, and also by Bayes factors as data are accumulated.
Results: Â Pilot results indicate an increase in pointing and dragging accuracy in all internal measures $p < 0.05$). Current results show no significant effect of treatment or of subgroup; Bayes factors indicate neither conclusive evidence for or against any effects. Data acquisition continues, and updated results will be presented.
Conclusions: Â Caregiver-mediated, computer-assisted therapies targeting prerequisite motor skills – and the Point OutWords therapy in particular – may or may not be an effective complement to traditional therapies that more directly address autistic social communicative deficits. Further exploration is warranted and is being implemented. Point OutWords is at least a useful demonstrator of the potential for a task-sharing approach to autism therapy that involves caregivers and avoids the need for additional clinical staff time.

13 **136.013** Matrix Training on a Mobile Application to Enhance Language Learning and Generalization in Minimally-Verbal Autism

O. Wendt[1]*, R. Nigam*[2] *and K. Warner*[1]*, (1)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN, (2)Department of Communication Disorders, Governors State University, University Park, IL*

Background: A “delay in, or total lack of, the development of spoken language” characterizes minimally-verbal individuals with autism. Many learn to communicate through alternative means such as tablets and mobile technology. However, utterances on these devices are often very limited; learners do not surpass single-word responses for requesting and labeling, and vocabulary repertoires are small. Matrix training is a language intervention to systematically build up vocabulary and teach longer word combinations to produce more complex utterances. In this generative approach to instruction, words are arranged in a matrix format so that some multiword phrases are taught and others develop without direct instruction. Specifically, linguistic elements (e.g., nouns, verbs, etc.) are presented in systematic combination matrices, which are arranged to induce generalized rule-like behavior, a particular difficulty in autism.
Objectives: A mobile application, SPEAKmore!, was developed to carry out matrix training on a tablet device (see Figure 1). This study aimed to answer:

1. Does language training with SPEAKmore! facilitate production of action-object combinations on a tablet device? This was accomplished by measuring the percentage of correct target forms in intervention probes.
2. Do newly learned skills generalize to untrained action-object combinations. This was achieved by taking generalization probes during the intervention phase assessing performance on combinations that were never taught before.

Methods: An experimental single subject design, that is a multiple probe design (Horner & Baer, 1978), was used across sets of action-object combinations with generalization probes of untrained combinations. This design is currently implemented with five participants, who are between 8-12 years old, have an official diagnosis of severe autism according to CARS-2 and ADOS-2 scores, qualify as minimally verbal by having no more than 10 spoken words, and communicate primarily on a tablet. These students were taught action-object combinations on a 6x6 matrix with SPEAKmore!. From the total pool of 36 possible symbol combinations, the researcher created four different sets of three symbol combinations each that were actively taught. The remaining 24 combinations were tested for generalization effects.
Results: Preliminary results are available for two of the five participants. Figure 2 shows participants’ performance measured as the percentage of correct symbol combinations. Both participants demonstrate a similar pattern of successful acquisition of symbol combinations during the intervention condition and subsequent generalization to untrained stimuli. Within three intervention sessions, both participants reached over 80% correct and their performance remained at this level. Performance on generalization increased steadily for both over the course of intervention. Effect sizes as measured by the Non-overlap of all Pairs Index indicate a medium-strong effect for participant 1 and a strong effect for participant 2.
Conclusions: Results suggest that matrix training through a mobile application may be a promising approach to teach new vocabulary and enhance the complexity of utterances for tablet communicators with severe autism. To further investigate the robustness of this technology intervention, findings need to be replicated using (a) different language targets (e.g., agent-action, adjective-object combinations), and (b) expansions from two-term to three-term semantic relations (e.g., agent-action-object).

14 **136.014** Integrating User Analytics into Mobile Applications for Speech and Language Treatment in Autism

*M. G. Zentner[1] and **O. Wendt**[2], (1)Information Technology at Purdue (ITaP), Purdue University, SPEAK MODalities, LLC, West Lafayette, IN, (2)Purdue University, West Lafayette, IN*

Background: Today it is common for Internet-based businesses to collect data regarding customer behavior and exploiting such behavior to expand their business. However, more introspectively such companies also seek to use these data to understand their effectiveness in serving their customers. In fact, the translation of research efforts in autism technology almost demands these same types of user analytics as rationale for those who would invest in and seek to promote the commercial enterprises that are essential for the translation of such research into practice. Specifically, translation necessitates the confluence of at least 4 key elements i) a societal recognition of a problem, ii) a common understanding of the economics involved in addressing the problem, iii) proof that delivery of a solution to the problem is accepted in the marketplace, and iv) protectable intellectual property that allows an enterprise to recover the costs of translating the research into practice in the market.
Objectives: The objectives are to address the double bottom line problem: how to translate research into practice in a manner that is economically feasible and that simultaneously provides societal benefit. The former activity is addressed by assessing the societal value of delivering more effective mobile technology solutions to the autism population, while the latter focuses on measuring the degree to which this activity has the potential for impact.
Methods: Â Autism tools created for today’s popular tablet architectures (e.g. iOS, Android) can be fitted with common usage analytics collection tools (e.g., Google Analytics) as a first order usage information collection mechanism. We will illustrate this scenario using an application for augmentative and alternative communication (AAC) training in minimally-verbal autism: The SPEAKall!® application has been instrumented with Google analytics to measure communication activities performed by the population using SPEAKall!. This instrumentation allows the collection of usage patterns from a large population of AAC users, which is distinct from the assessment of individual effectiveness in and immediately after therapy delivery sessions. While collecting such usage patterns does not suffice as evidence for the effectiveness of a therapeutic approach, it does demonstrate the market acceptance and employment of an approach in practice, and is a completely objective measure of mobile technology usage intensity.
Results: Preliminary results indicate the SPEAKall! application was downloaded by 9,223 users over a 6-months period; 12,810 therapy sessions took place with an average length of 11min. A bi-modal weekly therapy pattern emerged. Most users composed 2-word utterances, more than half proceeded to 5-word sentences. Google Analytics also revealed most frequently used interface features and motor patterns for accessing app content. Further data analyses will examine vocabulary growth by studying the degree to which users create new symbol vocabulary. Finally, we will also present a study of geographical user spread.
Conclusions: App analytics technology can be a meaningful way to assess and justify implementation of mobile technologies in autism treatment. It generates an additional strand of evidence for technology solutions beyond traditional efficacy data from behavioral or neurophysiological investigations.

15 **136.015** My Hospital Story - a Hospital Narrative App

***K. Blakeslee**[1], C. Wilkinson[2], K. Diezel[3], C. Mauras[2], N. Goodman[2], S. Al Ayubi[4], N. Gujral[3] and B. Resner[5], (1)Autism Spectrum Center, Boston Children's Hospital, Boston, MA, (2)Developmental Medicine Center, Boston Children's Hospital, Boston, MA, (3)Boston Children's Hospital, Boston, MA, (4)Innovation & Digital Health Accelerator, Boston Children's Hospital, Boston, MA, (5)Hospital IQ, Newton, MA*

Background: Â *My Hospital Story*is a mobile web app designed to prepare children and their families for medical visits and procedures at Boston Children's Hospital (BCH). Hospital narratives use images of children and developmentally appropriate text to prepare children and families for medical experiences. Hospitals in particular can cause stress for families and children with autism due to sensory concerns, communication challenges, and the unpredictability of the environment. Fears about these stressors and the hospital environment can often lead to medical needs not being met.
Objectives: Â The *My Hospital Story*app is a digital version of hospital narratives designed to improve the patient and family experience by preparing and supporting children and families when they come into the hospital. The goals of the app include lowering patient and parent anxiety about the hospital setting, increasing patient coping with visits and procedures through prior preparation, and removing barriers to care.
Methods: Â Before their visit to the hospital, children and caregivers can use the app to view step-by-step photos of their upcoming clinic visit, surgery, or procedure. Each photo is accompanied by text illustrating what is happening from the child's perspective as well as the hospital environment. The app allows users to enter their child's name and gender so that pictures and text are personalized.
Results: Â At this time we have 13 stories available on the app spanning 6 departments (Developmental Medicine, Psychiatry, Neurology, Surgery, Audiology, and Phlebotomy) in our hospital. Currently, the app is being used in a pilot study to help prepare families for audiology visits.
Conclusions: Â This project has been a collaborative effort between the Autism Spectrum Center, Child Life Services, and the Innovation and Digital Health Accelerator at Boston Children's Hospital. The mobile app has several advantages over paper versions. It is accessible at all times, it is easily edited and updated, and lastly it provides an attractive interface to share and communicate these hospital narratives to children. Future versions hope to include additional features, such as automated audio readings of the text, translation into multiple languages, and the ability to customize stories with personal photos.

16 **136.016** A Usability Evaluation of a Driver Training Application for Teens with Autism Spectrum Disorder

M. A. Monahan[1]*, J. O. Brooks*[2]*, C. Jenkins*[3] *and J. Seeaner*[4]*, (1)Driver Rehabilitation Institute, Santa Rosa, CA, (2)DriveSafety, Inc., Greenville, SC, (3)Clemson University, Greenville, SC, (4)CU-ICAR, Greenville, SC*

Background: Â Learner and licensed drivers with autism spectrum disorder (ASD) make more driving errors than their peers without ASD. Yet there is a lack of driver training tools specifically designed for the learning preferences of individuals with ASD.
Objectives: Â The objective is to design a driving training tool that incorporates learning preferences for individuals with ASD while adhering to usability principles (e.g., ease of learning and user satisfaction).
Methods: Â A usability evaluation was conducted with four rounds of subjects, alternating between neuro-typical teens and teens with ASD. Each round of subjects tested the Drive Focus™ application (app) prototype. Subjects' comments about the app were collected using a "think aloud" method while observations of their interaction with the app were recorded. A human factors psychologist and an occupational therapist reviewed the comments and observations and decided whether to and how to resolve problems based on usability principles and four learning preference themes. Next, the app was refined and the entire process was repeated again until four rounds of subjects had tested the App.
Results: The number of comments/observations decreased within groups; subjects without ASD 245 (n=5) to 225 (n=8) while subjects with ASD: 125 (n=6) to 32 (n=5). The number of changes made to the app in support of learning preferences included themes of concrete language (55 changes), structure and predictability (41changes), visual information (21 changes), and generalization (8 changes).
Conclusions: The total number of changes declined between the initial and final session for each of the participant groups (subjects without ASD and subjects with ASD) suggesting that the iterative process of the usability evaluation was helpful in improving the app. The decline in comments and observations was most notable among the ASD groups suggesting that the application of learning preference themes was particularly useful.

17 **136.017** Jemime, a Serious Game to Teach Emotional Facial Expressiveness for Individuals with Autism Spectrum Disorders.

S. Hun-Billiaut[1,2]*, S. Serret*[1,2,3]*, J. Bourgeois*[1]*, P. Foulon*[4]*, D. Cohen*[5,6]*, C. Grossard*[5,6]*, O. Grynszpan*[6]*, F. Askenazy*[1,3]*, A. Dapogny*[6]*, S. Dubuisson*[6]*, L. Chen*[7] *and K. Bailly*[6]*, (1)Cognition-Behaviour-Technology (CoBTeK), EA 7276, University of Nice Sophia Antipolis, Nice, France, (2)Autism Resource Center, Lenval Foundation, Nice, France, (3)University Department of Child and Adolescent Psychiatry, Children's Hospitals of Nice CHU-Lenval, Nice, France, (4)Genious group, Colombes, France, (5)Department of Child and Adolescent Psychiatry, AP-HP Groupe Hospitalier Pitié-Salpêtrière, PARIS, France, (6)CNRS UMR 7222, Institute of Intelligent Systems and Robotics, University Pierre et Marie Curie, PARIS, France, (7)Liris laboratory UMR CNRS 5205, Ecole Centrale of Lyon, Ecully, France*

Background: Poor social cognition is a core problem in Autism Spectrum Disorders (ASD). Individuals with ASD have difficulties in emotional processing (recognition and analysis of social situations) as well as in emotional production, with a reduced emotional facial expressiveness. Some remediation programs using the support of new technologies have been developed to train people with ASD to produce emotions. However, none of them are based on a production of social situations with imitative models as avatars.
Objectives: The objective of the JEMImE project is to develop a specific game, in which people with ASD are first trained to imitate emotional expressions displayed by an avatar and then taught to produce emotional facial expressions in social scenes.
Methods: Players with ASD are asked to produce emotional expressions (facial and vocal) of joy, anger or sadness. Two technical innovations have been introduced. Firstly, the software performs a real-time analysis of the emotional production of the players. Secondly, an automatic evaluation is performed by anÂ innovative algorithm implemented in the software, comparing the players' productions with those of typically developing children (6-12 years) contained in an inbuilt emotional expression database.
Results: Â The game is composed of two phases, both using the technical innovations (real-time automatic detection and automatic evaluation). The first phase aims toteach players how to produce joy, anger or sadness using games based on 1) imitation and 2) production on request, within or without social situations (Fig 1). Thus, the software is able to detect each emotion produced in real-time, and to give a feedback to the player about the quality of the emotion. The second phase, using a 3D virtual environment, aims to train spontaneous emotional productions, depending on the social context. Indeed, the progression through the social scenes presented to the player depends on the quality of the emotional productions performed by the player, and changes if the production is not relevant for the current scene. In this phase, the software detects each produced emotion and gives a feedback about the accuracy of the emotional expression according to the context.
Conclusions: In summary, JEMImE software offers a personalized training for the production of emotional expressions in patients with ASD. Future research should investigate the efficiency of the algorithm for the training of the production of emotions in players with ASD. The JEMImE game is expected to benefit ASD individuals, their families and care-givers by offering them an easily accessible and amusing tool to train emotional expressiveness.

18 **136.018** Rethink: Leveraging Technologyto Disseminate Evidence-Based Interventions

P. Wright*, Rethink New, Pittsburgh, PA*

Background: Â There are dozens of established, effective interventions for individuals with Autism Spectrum DisorderÂ (ASD) (Wong et al, 2015) However these evidence-based practices are difficult to implement in community based settings such as schools (Stahmer et al, 2015; Suhreinrich, 2013). Access to effective intervention is even more difficult for children of poverty and for those in rural settings (Elder, Brasher & Alexander, 2016). Public educators require significant training and time to learn to deliver evidence-based practices (Stahmer et al, 2015). There are more than 400,000 FTE paraprofessionals engaged in the education of special education students (U.S. Department of Education, 2010). The vast majority of special education paraprofessionals, 97%, report providing one-to-one instruction to students with disabilities (Carter, O'Rourke, Sisco, & Pelsue, 2009). Unfortunately, many paraprofessionals do not receive adequate training to meet the high demands of this profession (However, Ghere and York-Barr (2007).Â Video modeling has been determined to be an effective method to support educators in learning to implement evidence-based practices (Catania & Reed, 2009; Moore & Fisher, 2007).
Objectives: Does access to Rethink's video models of evidence-based practices increase the ability of paraprofessional educators improve instructional practices and their ability to deliver evidence-based instruction to students with ASD?
Methods: Â A pre-post survey was conducted for content knowledge and application of the evidence-based practices for the paraprofessionals. Social validity wasÂ assessed regarding the utilization of the video models for adult learning with paraprofessionals. Supporting classroom teachers completed a pre-post measure regarding paraprofessional performance in the classroom and also participated in a social validity assessment.
Results: Â Paraprofessionals participating in the project demonstrated increased knowledge of evidence-based practices on the post assessment. Social validity measures reported that the practices were effective in changing instructional behavior in the classroom and that the method of professional development was acceptable for adult learners. Supporting classroom teachers reported that paraprofessionals were more effective in their delivery of instruction and that the utilization of the short video models is an effective method of providing professional development to paraprofessionals.
Conclusions: It is imperative that evidence-based practices move out of the research institutions and into the applied setting of schools and classrooms. Paraprofessionals deliver instruction to learners with ASD, yet they do not receive adequate training. A cost-effective, efficient method of training paraprofessionals may include the use of on-demand video-models. This study demonstrates how one commercially available technology product can be utilized to improve instruction delivered by paraprofessionals in public school classrooms.

19 **136.019** Autism Focused Intervention Resources and Materials (AFIRM): Supporting Teachers Use of Ebps

A. Sam[1]*, A. W. Cox*[2]*, S. L. Odom*[3]*, A. Zembo*[4] *and V. Waters*[4]*, (1)Frank Porter Graham Child Development Institute, Carrboro, NC, (2)Frank Porter Graham Institute, University of North Carolina - Chapel Hill, Chapel Hill, NC, (3)University of North Carolina, Chapel Hill, NC, (4)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background:
There is a national need for preparing teachers and other educational staff to implement evidence-based practices (EBP) with students with ASD. A report from the National Professional Development Center on Autism Spectrum Disorder (NPDC) details 27 evidence-based practices, supported by research, that are effective for individuals with ASD (Wong et al., 2014). However, selecting and implementing EBP for individuals with ASD poses challenges for practitioners in special education and related fields. The US Department of Education recently funded a new, e-learning resource, AFIRM (http://afirm.fpg.unc.edu/), for 2 years. AFIRM is developing online, self-paced learning modules on these 27 practices for teachers of students with ASD. To assess the effectiveness of AFIRM, users complete surveys on the usefulness, relevance, and quality of the online modules.
Objectives:

1. Describe the usage data (page views, session length) from the AFIRM site.
2. Examine the usability, relevance, and quality of AFIRM modules through collected survey data.
3. Examine how teachers and practitioners are using the AFIRM resources in practice

Methods:
Google analytics will be used to describe usage data of the AFIRM site. Following completion of a module, users have the option to complete a survey addressing the usability, relevance, and quality of the modules with Likert-type questions on a four point scale with 4 being the highest possible rating. In fall 2016, a survey of 9000+ AFIRM users will be completed. The results will identify how these practitioners are actually using the resources and materials in their classrooms. Descriptive statistics will be used to address the second and third objective.
Results:
Collection of data is ongoing as the number of modules expands and more users complete modules. Currently, the AFIRM website has over 15,500 registered users. The AFIRM site has had more than 1,170,000 page views with average session duration approximately 13 minutes. Users rated the quality of the modules highly with a mean of 3.5 (n=12,329). Users found the modules relevant to their work (m = 3.54, n=12,329) and useful (m=3.5, n=12,329). Based on a pilot survey of AFIRM users, AFIRM users (n=50) found the step-by-step guides, implementation checklists, tip sheets for professionals, and data sheets to be the most useful resources available on the site. Eighty-eight percent of respondents (n=33) visit the AFIRM site at least once a month. Nine-seven percent of respondents (n=33) found the AFIRM modules moderately helpful or very helpful in improving use of evidence-based practices. Data collected through March 2016 will be used to describe findings.
Conclusions:
Initial findings indicate that teachers, practitioners, and professionals who complete the AFIRM modules find them relevant to their work, useful, and the quality of the modules high. AFIRM users find the AFIRM supplemental materials and resources useful. Most AFIRM users return to the site on a monthly basis and feel the modules and resources are helpful in improving use of evidence-based practices.

20 **136.020** Autism Navigator®: Using Implementation Science to Improve Global Access to Early Detection and Intervention for ASD

C. Nottke[1]*, E. Kaiser*[2]*, C. North*[1]*, M. Nottke*[1]*, D. Jones-Ellis*[1]*, S. Mazzatenta*[1]*, L. Newton*[1]*, J. L. Stapel-Wax*[3]*, N. J. Chambers*[4]*, J. Woods*[5]*, A. Klin*[6] *and A. M. Wetherby*[1]*, (1)Florida State University Autism Institute, Tallahassee, FL, (2)Marcus Autism Center, Atlanta, GA, (3)Emory University School of Medicine, Atl, GA, (4)Child and Adolescent Psychiatry, UCT, Cape Town, SOUTH AFRICA, (5)Florida State University, Tallahassee, FL, (6)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA*

Background: Global prevalence estimates of autism spectrum disorder (ASD), ranging from 0.6%-1.5%, have raised awareness of ASD worldwide (Elsabbagh et al., 2012; Schendel et al., 2012). Research has documented the effectiveness of early intervention, which underscores the need for efficient, effective tools to support healthcare providers in detecting red flags by 18-24 months. There is a research-to-practice gap in high-resource countries that widens in low-resource countries. Implementation science offers a framework and systematic strategies to facilitate the process of adopting evidence-based practice and sustaining with fidelity in everyday settings that can be utilized to reduce the time between scientific advances and widespread implementation. Mobile technology offers one potential solution to bridging the research-to-practice gap. Autism Navigator®(AN) is a collection of web-based courses and tools with video illustrations that offers the potential for access globally. AN has used an implementation science framework to promote coordinated change for community uptake and sustained utilization in medical, social service, and early intervention systems.
Objectives: This technology demonstration will showcase AN's web-based collection of courses and tools and report on the process of development, deployment, and utilization of the courses.Â
Methods: AN was developed by the FSU Autism Institute. AN for Primary Care is an online course using interactive slides and illustrative video clips of toddlers with ASD. After completing the course, providers can use the online automated Smart ESAC (*Early Screening for Autism and Communication*) screening tool within an E-Co-System with provider and family portals linking to 5 resources on the FIRST WORDS Project website. The 16-by-16 Lookbooks and Social Communication Growth Charts are for all families. Families of children with a positive autism screen are invited to About Autism in Toddlers, ASD Video Glossary and the How-To Guide for Families. Input from advisory boards and focus groups involving stakeholders informed the development of the E-Co-System. The E-Co-System was built through an iterative process of feedback, review of material for cultural appropriateness, and revolving enhancements to the portal.
Results: We will describe the launch of AN over the past two years beginning with Florida and Georgia and then expanding to other states in the US and other countries including Canada, South Africa, and Brazil. We launched our first free course, About Autism in Toddlers in April 2015 and had 3,643 unique users enrolled from 21 countries in the first 12 months, which increased incrementally to 6,557 unique users from 103 countries after the next 6 months. Autism Navigator for Primary Care has 612 unique users enrolled from 7 countries. The How-to Guide for Families is being piloted with 85 users in 3 countries. Tablet computers will available to experience the screening tool and web-based resources.
Conclusions: Innovative models to increase the number of culturally and ethnically diverse professionals who can deliver evidence-based services are vital to improving global competence in early detection and intervention for ASD (Khan et al., 2012). AN provides a cost-efficient platform, using mobile technology to combine an automated screening tool, parent and provider portals, and links to web-based resources.

21 **136.021** Introducing a Novel Community-Based Assessment Tool: The Computerized Social Affective Language Task (C-SALT)

*N. Minyanou[1], L. Bateman[2], M. Liberman[3], C. Cieri[4], N. Ryant[4], J. Brown[5], E. S. Kim[6], Z. M. Dravis[5], E. Ferguson[2], K. Bartley[7], A. T. Pomykacz[8], J. Pandey[6], A. B. de Marchena[9], R. T. Schultz[6] and **J. Parish-Morris**[5], (1)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)The Center for Autism Research/CHOP, Philadelphia, PA, (3)University of Pennsylvania, Philadelphia, PA, (4)University of Pennsylvania Linguistic Data Consortium, Philadelphia, PA, (5)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (6)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (7)Center for Autism Research, Malvern, PA, (8)Children's Hospital of Philadelphia- Center for Autism Research, Philadelphia, PA, (9)Center for Autism Research, Philadelphia, PA*

Background: Social communication is a significant area of weakness for individuals with developmental differences like autism spectrum disorder (ASD), but is notoriously expensive and time-consuming to measure. A recent movement toward fine-grained behavioral imaging using cutting-edge technologies could drastically improve our ability to automatically capture subtle and complex social communication impairments, thus laying the groundwork to generate personalized interventions. To this end, we developed a self-contained, scalable 5-minute computer program to elicit vocalizations from individuals aged 6+ (C-SALT; Computerized Social Affective Language Task). Programmed in Unity3D, this cross-platform tool incorporates established research paradigms (e.g., a social narrative task, phonetic measures) into an engaging screen-based interface. Our ultimate goal is to generate clinically meaningful language profiles that can be compared to national norms, for the purposes of: (1) improving screening and diagnosis of social impairment in remote areas, (2) informing treatment planning (clarifying areas of strength and weakness), and (3) revolutionizing how we measure intervention efficacy. To accomplish these goals, we have begun to partner with colleagues and community organizations to deploy C-SALT in summer camps, schools, and via internet. Here, we describe our pilot efforts to collect data from child and adolescent participants with ASD, other psychiatric or psychological conditions, and typical controls.
Objectives: Assess the feasibility of using C-SALT, a low-cost computer program that children can operate independently, to gather vocalization data as part of a community-based social communication and motor battery.
Methods: C-SALT was administered to 67 children (mean age=10.6 years, 77% male) enrolled in summer camps for children with disabilities, or general YMCA programs. Thirty-seven participants had ASD according to parent report, 18 were typically developing controls, and 12 had non-ASD clinical diagnoses or first-degree relatives with ASD. C-SALT was the last task in a 20-minute mobile battery.
Results: Despite being the final task in the battery, C-SALT data was successfully collected from 80% of participants. Of the participants that did not complete C-SALT, 65% had autism and 50% had parent-reported speech-language impairments (mean age: 11.29 years). In response to this finding, we developed C-SALT-PL, containing paradigms modified to suit the needs of pre-literate or minimally verbal participants. Using largely automated methods (e.g., time stamps built into C-SALT output for each child), we have begun segmenting and analyzing facial expressions, gestures, and audio data collected via C-SALT. Although these analyses are preliminary, we expect that participant vocalizations will diverge in two primary areas that affect social communication: acoustic properties of voice (pitch variation, volume control, shimmer and jitter), and word choice (word frequency, lexical diversity, social/nonsocial focus). Our measure of sustained phonation, in particular, holds promise as a language-agnostic measure of vocal-motor control.
Conclusions: This project capitalizes on a natural synergy between computational linguistics and developmental psychopathology to precisely quantify real-world social communication difficulties in children with ASD. We will have C-SALT and C-SALT-PL available and prepared to demonstrate at IMFAR 2017, along with pilot data demonstrating the ability of these measures to distinguish diagnostic groups and quantify social communicative ability with high precision.

22 **136.022** "Tots Guide - Track and Act", an Online Early Developmental Screening Tool for Parents

***A. David**[1], P. Sunil[1], D. Murnal[1], S. Kumar[1], A. Jayaraman[1] and N. N. Mundkur[2], (1)Center for Child Development and Disabilities, Bangalore, India, (2)Centre for Child Development and Disabilities, bengaluru, INDIA*

Background: Â Early identification of developmental disorders is critical for the well-being of children and their families. It is the responsibilityÂ of primary care professionals to improve developmental outcomes through early surveillance and appropriate referral of children with developmental delays. However, factors such as limited consultation time in busy office practice, inappropriate methods of screening, high threshold for referral and negligence of parent's concern diminish the effectiveness of early surveillance. Therefore, it is important to develop a tool that is systematic, easy, and convenient for primary care practitioners to improve the effectiveness of developmental surveillance and referral patterns.
Objectives: Â To develop and test the accuracy of a web-based developmental screening toolÂ "Tots guide – Track and Act" for long-term monitoring of milestones in young children.
Methods: Â In a pilot study, 80 children (4–30 months of age) visiting our centre and fulfilling the inclusion criteria were enrolled. The inclusion criteria were children between the ages of 4 months to 30 months presenting with concerns in their development, and born at term gestation with no antenatal or post-natal complications. The exclusion criteria were children born at pre-term gestation, and those with physical deformities/syndromes. Parents were informed about the online screening tool "Track and Act" in www.totsguide.com at the initial meeting. The scores were automatically sent to the center's mail account when parents completed the online screening. The online screening tool assessed 4 domains of development – language and communication, movement and physical, cognitive, and socio-emotional, through a series of "Yes/No" questions corresponding to the age of the child [Score: 61–100 (normal development), 41–60 (developmental concern/borderline delay), <40 (developmental delay)]. The children also underwent a formal developmental assessment using the Developmental Assessment Scales for Indian Infants (DASII) that consisted of 230 items to test the motor and mental development in children less than 30 months [Score: >85 (normal development), 70–85 (developmental concern/borderline delay), <70 (developmental delay)]. The results obtained from this screening were compared with those of DASII in these 80 children.
Results: Â According to our analysis, the online screening tool scoring showed similar results to DASII scoring in 74% of children (59/80) in the mental domains, and in 85% children (68/80) in the motor domain, which indicates significant comparability.
Conclusions: Â Based on our pilot results, we can conclude that the online screening tool may be a reliable initial screening tool that parents can use for preliminary assessment of developmental milestones in their children. In cases of lower and borderline scores, parents can consult their pediatrician for further required and recommended assessments and interventions. This is an ongoing study and we are continuously recruiting more eligible subjects to this study to increase the sample size to conduct domain-specific statistical analyses. The online screening tool is also available in three regional Indian languages to facilitate usage by non-English speakers, and is being developed as an App. We hope that this tool will help in increasing the early detection and diagnosis of developmental disorders such as autism spectrum disorder, leading to timely intervention.

23 **136.023** Integration of Knowledge Extracted from Clinical Notes with Patient Reported Outcomes and Genetic Reports for Advancing Research into Phelan Mcdermid Syndrome

C. K. Saravanamuthu[1], M. Wack[1], C. Hassen-Khodja[1], S. Finan[2], G. Savova[2], M. O'Boyle[3], G. Bliss[4], A. Cornell[3], L. Horn[3], R. Davis[3], J. E. Jacobs[5], I. S. Kohane[6] and ***P. Avillach****[1], (1)DBMI - Harvard Medical School, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)Phelan-McDermid Syndrome Foundation, Arlington, VA, (4)Phelan-McDermid Syndrome Foundation, Houston, TX, (5)Phelan-McDermid Syndrome Foundation, Baltimore, MD, (6)Harvard Medical School, Boston, MA*

Background: Phelan McDermid Syndrome (PMS) is a rare genetic disease (~1100 diagnoses worldwide) primarily diagnosed in children caused by loss of function of the SHANK3 gene, which is also implicated in Autism. Diagnosis is only Seapossible with genetic testing and often delayed. Knowledge extracted from clinical notes and Patient Reported Outcomes (PRO), two underused sources of detailed information about patient conditions, could significantly augment our understanding of PMS.
Objectives: The objective of this work is to demonstrate the integration of: a) knowledge extracted from patient clinical notes with b) PRO data sourced from the PMS International Registry (PMSIR) and c) the content of curated genetic reports, on the PCORI PMS Data Network (PMS_DN).
Methods: Manual curation of clinical notes deleted pages with unusable content such as illegible text, images, ECG readouts, and cursive handwriting. Forms and surveys with checkboxes and formatted questions that could lead to false positive errors in the knowledge extraction process were also removed. The Tesseract optical character recognition tool extracted raw text content from the curated notes. Then, the MITRE MIST scrubber and the Scrubber toolkit (in the Apache cTAKES natural language processing engine) erased Protected Health Information. Apache cTAKES extracted knowledge by identifying occurrences of concepts defined in the Unified Medical Language System and mapping these concepts to concept definitions in 20 clinical terminologies including ICD-9/10, MeSH, SNOMED, and the Human Phenotype Ontology. Knowledge extracted from clinical notes can be verified by experts with a novel validation tool that allows them to crosscheck the identified concepts against the raw text. PRO data from the PMSIR, comprising answers to developmental, clinical, and adult behavior questions were preprocessed for statistical analysis. Extract-Transform-Load pipelines loaded the knowledge extracted from clinical notes and the PRO data along with curated genetic reports of the PMS patients into the i2b2-tranSMART clinical data repository.
Results: PMS Foundation (PMSF), a nonprofit organization advocating for PMS research, obtained informed consent to participate in PMSIR from 981 families (461 in USA). Of these, 557 families (300 in USA) consented to share their data, including PRO, genetic reports, and clinical notes, with Harvard Medical School. Manual curation of clinical notes of 114 patients (with 47938 pages), sourced from healthcare providers by a 3rd party vendor, removed 7618 unusable pages. Apache cTAKES extracted the knowledge content of the remaining 40320 pages. This knowledge was loaded into PMS_DN alongwith preprocessed PRO data from 344 patients and curated genetic information from 121 patients. Authorized autism investigators can browse and interrogate the aggregates of this integrated patient data on the PMS_DN Web portal (https://pmsdn.hms.harvard.edu). Investigators with the appropriate IRB clearances can obtain advanced, raw data download privileges on PMS_DN from PMSF.
Conclusions: PMS_DN facilitates research into PMS by providing authorized investigators access to high-quality knowledge extracted from clinical notes, PRO data, and genetic reports, enabling novel insights into the origin, progression, and treatment of this disorder. This exemplifies the potential of collaborations between academic researchers and family organizations such as PMSF to drive clinical research.

24 **136.024** Automated Measurement of Head Movement Coordination in Infant-Parent Dyads and Later ASD Outcomes

K. B. Martin*[1], D. S. Messinger[2], Z. Hammal[3] and J. F. Cohn[4], (1)Psychology, University of Miami, Coral Gables, FL, (2)Psychology, University of Miami, Miami, FL, (3)Carnegie Mellon University, Robotics Institute, Pittsburgh, PA, (4)Psychology, University of Pittsburgh, Pittsburgh, PA*

Background:
The Face-to-Face/Still-face (FFSF) is an early index of social-emotional functioning, which assesses infant and parent abilities to coordinate emotion and arousal states. Early atypicalities during social interactions, such as unusual head movements, may contribute to the social impairments that characterize children with autism spectrum disorder (ASD). Symptoms of ASD may alter the coordination of head movements between infant and parent during interactions, disrupting successful communication and social interactions. The quantity and speed of head movement—pitch (nods), yaw (turns), and roll (lateral inclinations)—between infants and parents may be more or less coordinated over early interactions in ASD.Â Compared to human coding, automated measurement can objectively quantify movement behaviors in infants with and without ASD risk.Â Our group recently found that older children with and without ASD systematically differ in their head movements in response to social stimuli.
Objectives:
Examine whether coordination of the quantity of infant and parent head movement in the FFSF differs by ASD risk and outcome.
Methods:
Infant-parent dyads (N=64) completed the FFSF at 6 months. Dyads included infants with (high-risk) and without (low-risk) an older sibling with ASD. Three degrees of rigid head movement—pitch, yaw, roll— were tracked from the video-recordings using an automated, computer-vision approach (Zface; Jeni, Cohn, & Kanade, 2015). Head angles were quantified as angular displacement and angular velocity. Root mean square values were calculated to measure the magnitude of angular displacement (*quantity*) and angular velocity (*speed*) of head movement. At 36 months, infants were assessed for ASD by a clinician, informed by the Autism Diagnostic Observation Schedule. We assessed differences in head movement coordination between infants and parents in low-risk children (Low-Risk/No-ASD, *n*=22), high-risk children without ASD (High-Risk/No-ASD, *n*=31), and high-risk children with ASD (High-Risk/ASD, *n*=10). Analyses were within-group, zero-order correlations of the total quantity of infant and parent displacement and velocity of head movement in the FFSF. R-to-Z transformations were used to compare correlations between groups.
Results:
Infant-parent correlations of angular displacement tended to be greater for the High-Risk/ASD group than the High-Risk/No-ASD (*p*s<.09) and the Low-Risk/ASD groups (*p*s<.09) for pitch, yaw, and roll. Infant-parent correlations of angular velocity were greater for the High-Risk/ASD group than the High-Risk/No-ASD group for pitch and roll (*p*s<.01) and tended to be greater for yaw (*p*=.09). Infant-parent correlations of angular velocity were greater for the High-Risk/ASD group than the Low-Risk/ASD group (*p*s<.05; **Table 1, Figure 1**).
Conclusions:
Here, automated measures of early interaction revealed that infants later diagnosed with ASD had the highest levels of coordination with their parents in the quantity and speed of head movement. For angular displacement and angular velocity, High-Risk/ASD infants and parents exhibited the highest associationsÂ of head movements. Low-Risk/No-ASD infants and parents exhibited the lowestÂ associationsÂ of head movements.Â High-Risk/No-ASD infants and parentsÂ typically exhibitedÂ associationsÂ of head movements between the other two groups. While it is unlikely that infantsÂ matchÂ their parents' head movements, parents of High-Risk/ASD infants may match thoseÂ ofÂ their infants more vigilantly than parents of infants in other groups (Beebe, 2011).

25 **136.025** Application of Semi-Automated Video Scene Coding for Reducing Manual ROI Marking in Eye-Tracking-Based ASD Studies

A. Ataybi[1]*, A. Naples*[2] *and F. Shic*[3]*, (1)University of Washington, Seattle, WA, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Seattle Children's Research Institute, Seattle, WA*

Background: Defining dynamic regions of interest (ROIs) is an essential component in eye-tracking-based studies of autism that use dynamic videos. In dynamic videos, the content and ROIs change moment-by-moment. In order to track high level constructs such as moving faces, or people, it is necessary to adjust ROIs in a time-dependent manner. This labor intensive and time consuming task is usually done manually.
Objectives: To generate a semi-automated approach capable of identifying and marking any type of ROI in any video sequence automatically and with minimal human operator involvement.
Methods: The proposed mechanism for ROI tracking utilizes Speed Up Robust Features, a scale and rotation invariant object detector/descriptor method. 1)the algorithm detects ROIs new locations/orientations in the frame and defines new ROIs (objects not captured by ROIs) 2)the operator review the results and re-evaluates weakly detected ROIs using new manually markups. Nine video files, used for an activity monitoring eye tracking paradigm in toddlers with ASD (Shic et al., 2013), that contained 9 to 16 ROIs are considered. These videos included two people (P1 & P2) surrounded with multiple objects conducting a controlled activity. The ROIs included 1) dynamic: head(H),body(B), upper/lower-face(UF&LF) regions and 2) static: images on the wall(I) and toys on the ground(T) in the scene.
Results:
The ROIs that are identified with potentially faulty detections and the percentage of frames that their faulty detections occurred in are presented in following table. It should be noted that the results represent the first pass of the algorithm only while additional runs with corrected base ROI can help to re-detect/re-track the ROIs in question for frames with potentially faulty detections. Moreover, although the below ROIs are automatically marked as less successfully detected, a closer investigation indicated that a fair percentage of the potentially faulty detections are likely to be acceptable without any need for re-tracking.
It is noteworthy that majority of inaccurately tracked/detected ROIs are located within facial regions. This is likely due to 1) smaller size of these regions which makes the task of finding robust representative features more difficult and 2) the differences between the viewing angle and orientation of the head in the first frame (the basis of the ROI detection) and the later frames in the video. Data from Thirty-six 4-8 year-olds, ASD n = 14 (11 males,MDQ=88.36,SD=19.84) and non-ASD n=22 (13 males, MDQ=108.91,SD=12.38) shows that there are similarities between eye tracking result variables computed through ROIs developed through this semi-automated process and standard ROI specification techniques.
Conclusions: We have designed a computational method for ROI tracking which dramatically lowers the time burden of defining ROIs for complex, dynamic videos. This approach, which does not lead to identical ROIs as manual coding, nonetheless shows similar performance on certain measures of outcome. Further work will aim to expand the scope and flexibility of our region tracker and to explore the use of this technique on fully unconstrained video inputs, such as that acquired from head mounted eye trackers in natural interactions.

26 **136.026** Topological Data Analysis Reveals Meaningful Subgroups in ASD Research Data Based on Neural Responsivity and Behavioral Measures

T. McAllister[1]*, A. Naples*[2]*, S. A. A. Chang*[3]*, S. Hasselmo*[4]*, M. J. Rolison*[1]*, J. A. Trapani*[1]*, S. M. Malak*[1]*, K. A. McNaughton*[1]*, T. C. Day*[1]*, T. A. Halligan*[4]*, B. Lewis*[5]*, E. Jarzabek*[1]*, K. Ellison*[1]*, K. Stinson*[6]*, J. Wolf*[7] *and J. McPartland*[1]*, (1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Yale University, New Haven, CT, (4)Child Study Center, Yale University, New Haven, CT, (5)Yale School of Medicine, Darien, CT, (6)Yale University- Child Study Center, Milford, CT, (7)Yale Child Study Center, New Haven, CT*

Background:
Modern neuroscience research increasingly collects vast quantities of rich, multivariable data, but analytical methods remain largely unchanged. Without more sophisticated tools, much of the data will not be fully utilized. While clinical and electroencephalography (EEG) datasets from Autism Spectrum Disorder (ASD) research routinely contain hundreds of variables, standard statistical practices incorporate relatively few. Topological Data Analysis (TDA) is an approach designed to explore high-dimensional datasets. The Mapper algorithm (Singh, Mémoli and Carlsson, 2007) reduces dimensionality while maintaining structural features by generating clusters in the full high-dimensional space. Resulting cluster visualizations offer insights that can direct statistical investigation, support current methods, and foster understanding of complex interrelations between variables.
Objectives:
By implementing the Mapper algorithm, we: (1) visualize both EEG and clinical characterization data from a sample of individuals with ASD and typically developing controls (TD); (2) identify and describe subgroup clusters; (3) assess the utility of TDA for high-dimensional clinical neuroscience datasets.
Methods:
The Mapper algorithm was implemented using Javascript and Python, and used to analyze data from individuals with ASD and TD controls (ASD:n=61,mean age=14.08;TD:n=40,mean age=13.96). Results were visualized as 2D force-directed graphs in which cluster shading indicated the percentage of individuals in a group with a diagnosis of ASD. Clinical variables included measures from the Child Behavior Checklist, Social Responsivenss Scale, and Vineland Adaptive Behavior Scales II. Event Related Potential (ERP) variables included amplitude and latency at the P100 and N170 in response to dynamic faces. Naive clustering grouped subjects based on similarity in a high-dimensional space, then edges connected clusters with shared subjects.
Results:
We created visualizations for behavioral data, ERP data, and combinations of both. Resulting structures identified areas of diagnostic similarity suggesting that high-dimensional clustering can successfully differentiate groups in a data-driven manner. Groups containing both individuals with and without ASD suggest there are differentiable clusters that further parse heterogeneity within diagnostic categories. Figure 1 demonstrates a strong differentiation of diagnosis between cluster groups, based on 76 variables of only ERP data. Two regions outline groups of similar subjects with 100% and 27.27% of subjects diagnosed with ASD, respectively. 79% (n=73) of the eligible population (n=94) fit into these groups, with 2 subjects found in both.
Conclusions:
Our initial results indicated subgroups of participants that are diagnostically well-differentiated by high-dimensional neural data, and other subgroups which appear more heterogeneous. Ongoing work seeks to analyze which ERP measures discriminate most between subgroups, and thus improve predictive models of differences in clinical phenotype. Further work will examine using subgroups for stratifying samples in clinical trials, and whether smaller subgroups within diagnoses differ meaningfully. These visualizations of latent structure within our data are a novel and valuable tool for exploring clinical datasets and building unique insights that inspire further research. Our findings have already identified meaningful subgroups based solely on ERP data. TDA warrants further development and refinement, particularly in clustering methodology. This method will allow us to scale up to richer multi-modal datasets e.g. including clinical characterization and eye-tracking measures.

27 **136.027** Design of an Interactive Pretending System for Young Children with ASC

M. Dragomir[1], *H. Pain*[1], *S. Fletcher-Watson*[2] *and A. Manches*[3], *(1)School of Informatics, University of Edinburgh, Edinburgh, United Kingdom, (2)University of Edinburgh, Edinburgh, UNITED KINGDOM, (3)Moray House School of Education, Edinburgh University, Edinburgh, United Kingdom*

Background: A subcategory of play, pretend play is generally considered a fundamental stage for child development and education. However, pretend play is one of the most affected areas of development in Autism Spectrum Conditions (ASC). Yet, traditional interventions for supporting its development are extremely rare, and the effectiveness of interventions that do exist is reported to be moderate, at best. Recent work, however, has provided promising evidence for the potential of news forms of digital technology to facilitate pretend play in children with ASC. Yet, research is relatively limited in being able to inform the design of technology to promote pretend play in children with autism in real-world contexts (e.g. classroom).
Objectives: Building on previous work and inspired by current practice, the long-term aim of this research is to investigate how a technology-based application can support the process of pretend play in young children with ASC.
As a first step towards reaching that aim, the studies reported here: a) investigate current practice and procedures used by teachers and practitioners to help children with pretending; and b) explore a set of possible concepts and technologies that might be relevant to promoting pretend play in children with autism.
Methods: A focus group study with 13 education professionals (10 Speech and Language Therapists and 3 teachers) has been conducted. The study followed a semi-structured group discussion driven by a predefined set of topics: a) interventions/activities used; b) choice and use of objects; c) choice of prompts and prompt-fading strategies; and d) the use of structure.
This was followed by a design workshop with 4 education professionals using an adaptation of the Inspiration Cards Workshop technique.
The empirical data has been analysed using both deductive and inductive thematic analysis.
Results: Preliminary results have revealed that education professionals regard pretend play as an important element for learning in children with autism. However, due to the limited amount of resources (e.g. trained staff, time) and the higher priorities for building other abilities (e.g. language, joint attention) pretend play is either not targeted or used as a context for developing other skills. Also, most participants do not follow a particular model/intervention for promoting pretend play, but adopt various general guidelines, not specific to a particular model/intervention.
Scenarios of technology use have been identified along with a set of technology characteristics considered useful in practicing and supporting pretending with children with autism, such as: dynamicity, simplicity, personalisation, and flexibility
Conclusions: Early data suggests there is a lack of support for promoting pretending in ASC in real-world contexts. Such outcomes reinforce the motivation behind this research.
Based on these results and relevant literature, next steps will involve a series of low- and high-level prototyping sessions with education professionals that will shape the implementation of an interactive system for practicing and developing pretend play in children with autism.

28 **136.028** Engagement of Children with ASD Using a Tactile Robot

R. Spence[1], *T. S. Chou*[2], *L. Chukoskie*[1], *J. Krichmar*[2] *and* ***J. Townsend***[1], *(1)University of California, San Diego, La Jolla, CA, (2)Cognitive Science, University of California, Irvine, Irvine, CA*

Background: Individuals with autism spectrum disorder (ASD) have widely recognized challenges in social communication. Social robots have been designed and used to provide an alternative and perhaps easier way to promote engagement and communicative exchange in children with ASD.Â Here, we characterize the behavioral effects of children and adolescents with ASD using a tactile robot, not explicitly designed to promote engagement or communication. CARBO (short for CARetaker RObot) was built by incorporating a spiking judgment neural network robot "brain" (Chou, et al., 2015) that has the potential to learn from interactions. The robot's shell is covered with trackballs creating a smooth surface for tactile interaction.Â Two games (ColorMe and FollowMe) request hand movements in a particular pattern on the shell to illuminate LEDs beneath each trackball.Â Eight directions of the trackball are mapped to different colors of the underlying LEDs.Â The games are designed engage participants in producing a wide range of movements, as well as turn-taking activities that paint CARBO's shell.
Objectives: Through a series of structured play sessions with CARBO and another interactive toy serving as a comparison, we aimed to objectively characterize behaviors during interactions.Â The results of these interactions will be used to improve the games and to create a version of CARBO that can serve as a bridge in behavioral therapy for children with ASD.
Methods: We recorded multiple sessions of children and adolescents interacting with a tactile robot to test if interactions with CARBO modified sensory and motor behaviors and/or engagement and communicative behaviors in individuals with ASD. Using the data from CARBO, we assessed changes in movement behavior during game play. Using video data, we employed a dictionary of behaviors (including gestures and utterances) that we created for video-based coding and compared behaviors observed while each participant interacted with CARBO and another interactive toy.Â We also examined how behaviors changed over multiple visits. All coding was conducted using the multimodal annotation tool ELAN.
Results: We characterized interactions in 6 children and adolescents with ASD.Â These individuals spanned the continuum from non-verbal to very facile with verbal communication, and ages 9-17. Participants exhibited longer duration engaged interactions with CARBO than with other toys. We also noticed fewer instances of repetitive behaviors while participants were engaging with CARBO. Responses to CARBO's requests to change movement direction or speed were responded to promptly in most cases.
Conclusions: Â Our pilot study observations suggest that children are considerably more engaged with the tactile robot, CARBO than with an interactive game. The extended duration of the engagement and ability to use the robot in requesting and turn-taking behaviors make it a useful tool in behavioral therapy.

29 **136.029** Robots Teaching Autistic Children to Mind Read: A Feasibility Study of Child-Robot Interaction during Emotion-Recognition Training

*A. M. Alcorn[1], T. Tavassoli[1], S. Babović Dimitrijevic[2], S. Petrović[2], S. Skendzic[2], V. Petrović[2] and **E. Pellicano**[3], (1)UCL Institute of Education, University College London, Centre for Research in Autism and Education (CRAE), London, United Kingdom, (2)Serbian Society of Autism, Belgrade, Serbia, (3)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom*

Background: Autistic children often have difficulty recognising emotions and facial expressions relative to typically developing children. Several existing projects have shown promise in using robot-assisted interventions for social and academic skills teaching with autistic children, including emotion recognition. Robots can be more predictable and less complex than interaction with humans, and may be more "comfortable" for autistic children. Little is known, however, about the levels of language, cognitive skill, or sensory tolerance that are necessary or desirable for robot-assisted interventions to be implemented effectively for autistic children.
Objectives: This project tested the feasibility of an emotion-recognition training programme in developing the potential of robot-assisted interventions for autistic children in Serbia and in the UK.
Methods: Forty-two autistic children, aged between 5 and 12 years, have been assessed thus far (testing is ongoing): 23 children (3 girls) in the robot-assisted training condition and 19 children (3 girls) in the researcher-only comparison condition. The majority of children have additional intellectual disabilities and limited spoken communication. In both conditions and over a number of sessions, we implemented steps 1-4 of the emotion training programme, "Teaching Children with Autism to Mind Read" (Howlin, Baron-Cohen, & Hadwin, 1999), which is designed to teach recognition of photographic and schematic faces, and identifying emotions in stories. Critically, in the robot-assisted condition, a Robokind R25 humanoid robot ("Zeno") with realistic facial expressions helped to deliver the programme (controlled covertly by the adult). All sessions were recorded by audio, video, and depth sensors (Kinect).
Results: In each condition, children took between 3 and 8 sessions to complete the training steps, or reach a ceiling: 28 children completed all steps, 6 were unable to complete any steps, and 8 reached an intermediate step. Two of the 23 children were unable to engage in the robot-assisted condition due to sensory sensitivity. Overall, task scores and researchers' qualitative reports suggest that participating children gained knowledge of emotions, and interacted successfully and positively with the robot. Some more able participants found the current tasks and robot overly simple, and were better engaged when asked to take on a 'teaching' role toward him (e.g., ask robot to give an answer after child responded). Analysis is ongoing.
Conclusions: A humanoid robot can be a feasible, meaningful, and engaging tool in an emotion-recognition teaching programme for autistic children with limited spoken communication. Indeed, more children successfully engaged with the robot and the tasks than was initially predicted by researchers and parents. Robot-assisted intervention may be particularly valuable for those children who may not easily access other interventions due to their language or ability. This study was the first phase of data collection for this large-scale project, with further feasibility studies running in Serbia and the UK. The resulting data will form part of a large "benchmark" annotated dataset of behaviour, gestures, and speech of autistic children, which will be made available to the wider research community. Future analyses will also compare the effectiveness of robot- and researcher-assisted training on teaching emotional and social skills.

30 **136.030** Triadic Human-Robot Conversation for Easier Disclosing: A Case Study Involving Individuals with Autism Spectrum Disorder

***J. Shimaya**[1], Y. Yoshikawa[1], H. Kumazaki[2], Y. Matsumoto[3], M. Kikuchi[2], H. Ishiguro[4] and M. Miyao[5], (1)Osaka University / JST ERATO Ishiguro Symbiotic Human-Robot Interaction Project, Toyonaka, JAPAN, (2)Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan, (3)AIST, Tsukuba, Japan, (4)Osaka University / JST ERATO Ishiguro Symbiotic Human-Robot Interaction Project, Toyonaka, Japan, (5)National Center for Chid Health Development,, Tokyo, JAPAN*

Background: Individuals with autism spectrum disorder (ASD) often find it difficult to disclose their concerns to their caregivers (e.g., clinical psychotherapists, special education teachers, etc.). Previous research indicates that robots might be an easy conversation partner for individuals with ASD (Shimaya et al, 2016). An important next step is investigating how disclosing to robots can be bridged to disclosing to their caregivers. Triadic conversation including a robot, an individual with ASD, and his/her caregiver is expected to provide the bridge. However, the presence of the caregiver might decrease the advantage of easy conversation provided by robots.
Objectives: We examine whether individuals with ASD disclose their thoughts or concerns in the triadic conversation involving the robot and their teacher. We also examine whether the teacher can discuss the disclosed contents with them face to face after the triadic conversation.
Methods: Three individuals (two are male) with ASD participated in triadic conversations with a female teacher and a small desktop humanoid robot "CommU". Their ages ranged from 23 to 25. One of them had a relatively low IQ (< 40) and the other two had a relatively high IQ (> 70). The participants were chosen because their teachers had difficulty in understanding their thoughts or concerns. The robot was tele-operated by the first author. Its utterance was produced by using a keyboard interface, and its gaze, which indicated who it was talking to, was controlled by a GUI. The teacher was forbidden from speaking except when replying to the robot. A participant-specific undisclosed and interesting topic list (UDI-list), consisting of topics that the teacher was interested in but unaware of, was prepared. The conversation was conducted mainly between the robot and the participant, and the robot asked the participant questions about the topics in the UDI-list, whereas the robot-teacher conversation on the same topic was sometimes inserted.
Results: The average conversation time for the participants was 20.7 min (SD = 4.7). Approximately 86% and 14% of the conversation time was spent on the robot-participant conversation and robot-teacher conversation, respectively. No participant stopped the conversation until the robot suggested that he/she finish it. All of them disclosed at least one of their thoughts or concerns to the robot in the presence of the teacher, to whom they had never disclosed on the topics. Examples of disclosed contents were his/her anxiety about job-hunting, and their hobbies, etc. The teacher conducted additional conversation with one participant and could discuss the disclosed contents with her face to face.
Conclusions: It is important that the individuals with ASD disclosed their thoughts or concerns even though the teacher was included in the conversation. The result implies triadic human-robot conversation might be effective in getting individuals with ASD to disclose easily before their caregiver, which involves their chances of disclosing indirectly to their caregiver. Increasing the number and the period of the sample, as well as developing an easier interface for the robot tele-operation to manage triadic conversation are important issues worth considering in the future.

Panel Session
137 - Understanding Barriers That Families from Racial/Ethnic Minority Groups in the United States Face in Obtaining an Autism Spectrum Disorder Diagnosis and Services for Their Children
10:30 AM - 12:00 PM - Yerba Buena 3-6

Panel Chair: Amber Angell, *Occupational Therapy, University of Illinois at Chicago, Chicago, IL*

Discussant: Sandy Magana, *Disability and Human Development, University of Illinois at Chicago, Chicago, IL*

Children in the United States from racial/ethnic minority groups and low-income families experience persistent disparities in autism spectrum disorder (ASD) diagnosis and services. Compared to middle class White children, they are more likely to experience delays in diagnosis, less likely to be diagnosed at all, and are less likely to receive timely, high quality healthcare services. Research has made clear the existence of these disparities, but little is understood about their causes. Using diverse methodologies, this panel presents research on barriers that parents from racial/ethnic minority groups, and/or low income parents, face in obtaining an ASD diagnosis and services for their children in the United States. Barriers include both parent and provider factors, including parent knowledge about and experience with ASD; implicit provider biases in primary care screening/referrals; and parent access to information about safe and effective ASD treatments. These findings have implications for reducing disparities through targeted parent and provider education programs.

10:30 **137.001** Autism Spectrum Disorder Knowledge and Experience Among Low-Income Parents Attending WIC

K. Zuckerman[1], *A. E. Chavez*[2], *C. Regalado*[1], *O. J. Lindly*[3] *and J. A. Reeder*[4], *(1)Division of General Pediatrics, Oregon Health & Science University, Portland, OR, (2)Oregon Health & Science University, Portland, OR, (3)College of Public Health and Human Sciences, School of Social and Behavioral Health Sciences, Oregon State University, Corvallis, OR, (4)Oregon WIC Program, Oregon Health Authority, Portland, OR*

Background: Â Children in racial/ethnic minority and low-income families are more likely to experience delays in autism spectrum disorder (ASD) diagnosis, and are less likely to receive an ASD diagnosis overall. Little is known about low-income and minority parent knowledge about and experience with ASD.
Objectives: To assess ASD knowledge and information in a large, ethnically diverse sample of low-income parents.
Methods: We conducted a self-administered survey on 539 parents attending their child's appointment at the Supplemental Nutrition Program for Women, Infants, and Children (WIC) in six Oregon counties, from July through October, 2015. Eligible participants had a child aged 24-59 months enrolled in WIC. Surveys were conducted in English or Spanish; bilingual oral administration was available if necessary. Survey items assessed knowledge of early signs of ASD, self-reported knowledge about ASD, and having a friend or family member with ASD. Bivariable and multivariable analyses assessed differences in outcomes for following racial/ethnic/language groups: non-Latino white [NLW], Latino-English proficient [EP], Latino-limited English proficient [LEP], and non-Latino other race English proficient [NL-O].
Results: 79% of parents approached completed the survey. Overall, parents correctly identified 64.7% of early signs of ASD. NLW and Latino-EP parents correctly identified the most early signs of ASD, even after adjustment for sociodemographic differences among racial/ethnic/language groups.Â Overall 9.9% (95% CI=7.6%-12.8%) of families had "never heard of ASD" and 35.4% (31.4%-39.6%) reported they had "heard of ASD but didn't know much about it." On bivariable analysis, Latinos with LEP (15.3% [10.9%-21.2%]) and NL-O (15.7% [8.0%-28.5%])Â were more likely to have never heard of ASD compared to NLW (1.9% [0.6%-5.9%]).Â Overall, 71.4% (67.5%-75.1%) of participants had no friends and no family members ASD. Latinos with LEP (16.2% [11.6%-22.2%]) were significantly less likely to have a friend or family member with ASD as compared to parents in the other three racial/ethnic/language groups.
Conclusions: Low-income parents, particularly Latino-LEP and NL-O parents, have relatively little knowledge and personal experience with ASD. Study findings suggest that interventions to reduce disparities in ASD diagnosis should include increasing parent awareness in low income and ethnic minority communities.

10:50 **137.002** Evidence for Implicit Bias in the Implementation of Autism Screening Tools in Primary Care

C. Nadler[1], *G. Winningham*[1], *K. J. Reid*[1], *C. Low-Kapalu*[1], *L. Pham*[2], *K. Williams*[1], *G. Rahm*[1] *and S. Nyp*[1], *(1)Children's Mercy Kansas City, Kansas City, MO, (2)Baylor College of Medicine, Houston, TX*

Background: Health disparities associated with age of ASD diagnosis have been observed for racial/ethnic minorities (Mandell et al., 2002), females (Shattuck et al., 2009) and economically disadvantaged children (Mazurek et al. 2014). While ASD screening models and tools have been discussed as possible contributors to these disparities, biased primary care screening/referral patterns have not been directly investigated.
Objectives: The objective of this study was to investigate error patterns in primary care screening and referral that may contribute to later delays in ASD diagnosis and early intervention for minority children.
Methods: A retrospective review of 18- and 24/30-month well visits (n = 4886) at an urban academic medical center yielded data on primary care provider's interpretation of the Modified Checklist for Autism in Toddlers (M-CHAT); manual re-scoring of M-CHATs allowed for the provider's interpretation to be classified as a True Positive (TP), True Negative (TN), False Positive (FP) or False Negative (FN). Demographic data and referrals for diagnostic/intervention services were also extracted from the medical record.
Results: Children in the study sample were representative of the racial/ethnic diversity of the urban area (40.1% African American, 30.6% Hispanic; 17.3% Spanish-speaking), and 80.9% of the children were publically insured. Among children determined to have a positive M-CHAT upon manual re-scoring, unweighted logistic regression analyses revealed that females (OR = 1.98. p = .004) and children of Spanish-speaking parents (OR = 2.10, p = .047) were more likely be misclassified as a negative screen by their providers, but no other demographic variables were significant predictors. When the model was propensity weighted to control for associations between demographics and the availability of an original M-CHAT to re-score, the gender bias remained significant (OR = 1.82, p = .014) but the language bias did not (OR = 1.83, p = .23). Additional biases emerged when considering any kind of misclassification (FN and FP): weighted models indicated that African American children (OR = 1.47, p = .028), speakers of languages besides English or Spanish (OR = 1.62, p = .054), and children with public insurance (OR = 1.54, p = .046) were all more likely to be misclassified. Children with correctly identified (vs. overlooked) positive screens were more likely to be referred for diagnostic/intervention services, irrespective of demographics (p < .001).
Conclusions: Patterns of primary care provider errors in interpreting autism screening tools disproportionately impacted minority and disadvantaged children in this sample, impeding access to diagnostic and early intervention services. These results strongly implicate implicit provider biases as a factor in the downstream health disparities observed for minority children who receive ASD diagnoses later than Caucasian children, and are less likely to access quality intervention services. Beyond the development of enhanced tools and screening models, unconscious and unintentional biases must be monitored and mitigated by health care professionals and researchers to adequately serve all children and families.

11:10 **137.003** The Road to Diagnosis: Perceptions, Concerns, and Experiences of Racial and Ethnic Minority Parents of Children with Autism Spectrum Disorders

W. Zeleke[1] *and T. L. Hughes*[2]*, (1)Counseling, Psychology and Special Education, Duquesne University, Pittsburgh, PA, (2)Duquesne University, Pittsburgh, PA*

Background: Parents play a major role on the path to diagnosis of their children with Autism Spectrum Disorders (ASDs). Despite the current federal and state level efforts to reduce disparities in healthcare access and utilization, racial disparities still remain. Research has shown that White children are diagnosed earlier than minority children and minority children may express ASD symptomology differently than their White counterparts. Thus, it is imperative to better understand the pathways to diagnosis for racial and ethnic minority families to ensure that their children receive the aid they need and to reduce the aforementioned racial disparities in mental healthcare service utilization.
Objectives: The purpose of this study is to explore ethnic and racial minority families' journeys to diagnosis for their child with ASD. Specifically, we aim to find out if race predicts diagnostic seeking behaviors, perceptions of the condition, and perceptions of the quality of diagnostic services the child receives.
Methods: Using data from the 2011 Survey of Pathway to Diagnosis and Services ("Pathway") (N=1725; White= 1368, Minority=347), we conducted bivariate and multivariate logistic regression to examine the difference betweenÂ minority and White children with ASD in accessing and utilizing mental healthcare services. "Pathway" is a nationally representative survey of children ages 6-17 years who were identified by the 2009/10 National Survey of Children with Special Health Care Needs (NS-CSHCN). The data set takes a close look at current and past use of clinical treatment, intervention, and healthcare services.
Results: We found a statistically significant difference on parental concern and perception of the child's condition based on race. White parents presented with more medical concerns, verbal and nonverbal communication concerns, and learning ability concerns than minority parents. No statistical difference was found related to parental concern about the behavioral, social, and sensorial difficulties of the child, parental perceptions of the child's condition, and parental perception of diagnostic services that their child received, between White and minority parents. However, the analysis yielded a significant relationship between parents' and healthcare practitioners' behavior and delay on diagnosis among minority children.
Conclusions: The result of this study indicated that healthcare providers' and parents' behavior may contribute to diagnostic delay of minority children with ASD. There is a need to develop policy, multi-culturally competent practice, and family level strategies to reduce barriers to diagnostic services for minority children with ASD.

11:30 **137.004** "It's like You've Got to Do Everything on Your Own": Latino Parents' Experiences of Traditional and Alternative Medicine for Their Children with Autism Spectrum Disorder in Los Angeles

A. M. Angell[1]*, L. Yin*[2] *and O. Solomon*[3]*, (1)Occupational Therapy, University of Illinois at Chicago, Chicago, IL, (2)Children's Hospital Los Angeles/Keck School of Medicine of USC, los angeles, CA, (3)University of Southern California, Los Angeles, CA*

Background: Â Parents of children with autism spectrum disorders (ASD) have been found to rate their children's primary care physicians as "not good" at addressing autism-specific needs (Carbone et al., 2013). Latino parents report even greater challenges than White parents in accessing high-quality healthcare for their children with ASD (Magana et al, 2012). Parents may choose complementary and alternative medicine (CAM) treatments for their children with ASD when they are dissatisfied with conventional healthcare, e.g. for failing to address autism-related issues such as sleep problems or self-injurious behavior (Akins, Angkustsiri, & Hansen, 2010). While Latino parents choose CAM treatments for their children with ASD at least as often as White parents (Hall & Riccio, 2012; Levy et al, 2003), little is known about how they experience their children's healthcare services, either traditional or alternative.
Objectives: Â The purpose of this qualitative study was to understand the barriers and supports that Latino parents of children with ASD experience while seeking traditional and alternative healthcare services for their children.
Methods: Â This 12 month ethnographic study of 12 bilingual Latino families of children with ASD living in Los Angeles County was carried out in two phases. Phase 1: Two audio-recorded narrative interviews were conducted with 12 families (19 parents, 1 grandmother) about their experiences obtaining services for their children. After Phase 1, 6 families were from the original cohort were recruited using heterogeneity sampling to continue to Phase 2. Phase 2: Narrative interviews and participant observation were conducted with 6 families (11 parents) in home, clinic, school, and community contexts. Children's health records provided data triangulation. The data corpus consists of almost 80 hours of audio- and video-recorded data (40 interviews, 10 observations, 60 fieldnotes) and 333 records. NVivo 10 software was used for coding, using a narrative analytic approach (Reissman, 2005).
Results: Â All 12 families in the study utilized traditional healthcare to treat their child's illnesses, but parents did not view their pediatricians as resources for addressing their children's developmental and behavioral challenges. Parents reported feeling 'on their own' to learn about therapies and interventions. Six of the families (6 mothers, 4 fathers) utilized some form of CAM treatment for their children (e.g. diet modifications, vitamins, supplements, enzymes, Defeat Autism Now! doctors). These parents expressed frustration that their pediatricians were "hands off," contrasted with CAM practitioners who were viewed as helpful because they targeted children's development through "treatment plans," i.e. recommendations and suggestions.
Conclusions: Â The parents who chose CAM for their children with ASD viewed CAM providers as responsive, proactive, and optimistic in approaching children's developmental challenges. While pediatricians may be legitimately cautious about discussing CAM treatments with parents because many of these therapeutic modalities have been found ineffective and even harmful, the parents in the study experienced such silence as a failure to provide guidance about their children's development. These findings suggest that pediatricians can better meet families' needs by engaging with and educating parents about the safety and efficacy of a range of conventional and alternative treatments.Â

Panel Session
138 - Autism with Known Genetic Associations: Implications for 'Idiopathic' Autism
10:30 AM - 12:00 PM - Yerba Buena 7

Panel Chair: Caitlin Clements, *The Center for Autism Research/CHOP, Philadelphia, PA*

Discussant: Paul Wang, *Simons Foundation CRA, New York, NY*

Genetic syndromes associated with autism spectrum disorder (ASD) have been studied intensely in the hope of understanding the biology of these disorders and of ASD in general. These ASDs associated with mutations have become an important part of a genotype-first strategy for parsing the heterogeneity of ASD, illuminating the pathophysiology, and defining targets for pharmacological treatment. Prime examples include research on Fragile X and copy number variants such as 16p11.2 and 22q11.2. However, it remains unknown how well treatments based on these genetically defined forms of ASD will generalize to 'idiopathic' ASD. This uncertainty stems from the genomic heterogeneity of ASD and from the phenotypic heterogeneity within each syndrome. This panel examines four examples of this genotype-first strategy: Fragile X, 22q11.2 copy number variants, and disruptions in SCN2A and DYRK1A. Discussion will focus on phenotypic heterogeneity, implications for translational research, and the challenges to assessing clinical outcomes. Presentations will include an analysis of familial phenotypes (DYRK1A), identification of a critical region for ASD risk in 22q11.2, genotype-phenotype correlations observed in SCN2A mutations, and differences in language and social communication trajectories between idiopathic ASD and Fragile X syndrome.

10:30 **138.001** Opposing Effects on NaV1.2 Function Underlie Differences Between SCN2A Variants Observed in Individuals with Autism Spectrum Disorder or Infantile Seizures

R. Ben-Shalom[1], C. M. Keeshen[1], K. N. Berrios[1], J. Y. An[1], K. J. Bender[2] and ***S. J. Sanders****[2], (1)UCSF School of Medicine, San Francisco, CA, (2)UCSF, San Francisco, CA*

Background: Exome sequencing has revealed that *SCN2A* is one of the most frequently mutated genes in autism spectrum disorder (ASD). Variants in this gene are also important risk factors for developmental delay and infantile seizures. While the missense *SCN2A* variants observed in infantile seizures predominantly lead to gain of function in the neuronal sodium channel $Na_V1.2$ that it encodes, the effect of the missense variants observed in ASD on $Na_V1.2$ remains unknown.
Objectives: 1) To perform a literature search of *SCN2A* mutations and to assess genotype-phenotype correlations. 2) To characterize the missense mutations observed in ASD electro-physiologically.
Methods: To assess the allelic spectrum of *SCN2A* mutations, genotypes and phenotypes were collated from all papers with *SCN2A* in their title or abstract and all large exome studies (>50 cases) in neuropsychiatric disorders. Electrophysiological assessment was performed for all missense variants observed in the Simons Simplex Collection or Autism Sequencing Consortium using voltage-clamp recordings from HEK293 cells.
Results: The literature review revealed 117 unique *SCN2A* variants in 148 families. The 118 families with sufficient phenotypic data clustered in four phenotypic groups: 20 variants in families with benign infantile familial seizures (BIFS); 8 variants in individuals with infantile seizures and mild developmental delay; 51 variants in individuals with epileptic encephalopathy (EE) characterized by infantile seizures and moderate to severe developmental delay; and 39 variants in individuals with a developmental disorder characterized by ASD and/or intellectual disability. Of note, loss of function variants were only observed in this last category. Electrophysiology analysis shows that all loss of function variants completely prevent sodium conductance, as do five of the eight missense variants in ASD. The remaining three missense variants altered channel function in three different ways, all of which reduced neuronal excitability in pyramidal cell simulations to the same degree of loss of function variants. In contrast, variants associated with infantile seizures increased neuronal excitability.
Conclusions: While *SCN2A* variants in infantile seizures lead to gain of function in $Na_V1.2$, ASD variants lead to loss of function. Numerous genetic loci associated with neuropsychiatric disorders are observed across a range of diagnoses including developmental delay, ASD, and schizophrenia. Here, we show that functional analysis of apparently similar *SCN2A* missense mutations can distinguish two neuropsychiatric phenotypes: infantile seizures and ASD/developmental delay. This observation suggests that distinct neurobiological processes relating to specific neuropsychiatric disorders may be characterized through the investigation of single gene mutations, the first such example to our knowledge.
These data allow us to revise our estimate of the contribution of *SCN2A* mutations to ASD risk. We observe *SCN2A* mutations in 0.29% of ASD cases, a figure marginally higher than that for *CHD8* (0.24%), making *SCN2A* the gene with the strongest evidence for ASD-association based on exome analysis and second only to Fragile X Syndrome as a single gene cause of ASD.
Examination of the neurobiology consequent to *SCN2A* haploinsufficiency, alongside parallel analysis of genes related to chromatin regulation, synaptic structure, and Fragile X Syndrome, is likely to provide critical insights into the etiology of ASD.

10:50 **138.002** Increased Risk of Autism Among Individuals with Atypical 22q11.2 Deletions or Duplication Involving COMT and RANBP1

C. C. Clements[1], *T. L. Wenger*[2], *J. Miller*[3], *A. B. de Marchena*[4], *A. Zoltowski*[1], *L. M. DePolo*[5], *D. M. McDonald-McGinn*[6], *E. H. Zackai*[7], *B. Emanuel*[7] *and R. T. Schultz*[3],

(1)The Center for Autism Research/CHOP, Philadelphia, PA, (2)Pediatrics, Craniofacial Center, Seattle, WA, (3)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)Center for Autism Research, Philadelphia, PA, (5)Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, (6)The Children's Hospital of Philadelphia, Philadelphia, PA, (7)The Children's Hospital of Philadelphia, Philadelphia, PA

Background: Increased rates of Autism Spectrum Disorder (ASD) have been observed in individuals with copy number variations (CNVs) of the 22q11.2 region, including both deletions (Fine et al, 2005) and duplications (Wenger et al, 2016a).Â However, research has not yet identified which of the 30-40 genes in this region confer autism risk. One research strategy entails narrowing the search space to smaller regions by studying nested (termed "atypical") CNVs within the full 22q11.2 region. The 22q11.2 region includes four low-copy repeats (LCRs); CNVs usually span LCR-A to LCR-D while smaller, nested CNVs (e.g., LCR-A to B, LCR-A to C) affect fewer patients. We have hypothesized that the region between LCR-A and LCR-B might be particularly important for ASD (Wenger et al, 2016b). This region contains a gene, *RANBP1*, involved in the metabatropic mGluR network, with important roles in neuronal excitation. mGluR signaling has been implicated in autism via syndromic ASD (Fragile X and tuberous sclerosis) and non-syndromic ASD (Hadley et al, 2014).
Objectives: To compare autism risk associated with 22q11.2 in individuals with and without involvement of the LCR-A to LCR-B region.
Methods: Thirty-six individuals with atypical duplications (n=9) or deletions (n=27) of 22q11.2 were recruited from a genetic specialty clinical at the Children's Hospital of Philadelphia. Participants included 13 individuals with affected LCR-A to B regions (LCR-A to B n=10, and LCR-A to C n=3) and 23 without (LCR-B to D n=17, and LCR-C to D n=6). Autism diagnoses were ascertained via review of the participants' electronic health record and additional medical or psychoeducational records provided by participants. Proportions were analyzed with a chi-square test. Parents of a subset of participants completed measures of social communication and psychiatric symptoms (SRS n=16, SRS-2 n=5, SCQ n=17, and CASI-4R n=22). Comparisons will be made to existing data from typically developing controls (t=73), individuals with idiopathic ASD (n=70), and individuals with typical deletions (n=62) and duplications (n=28) of 22q11.2.
Results: A significantly higher rate of ASD diagnoses (38.4%, 5/13) was observed for those individuals with a CNV involving the LCR-A to B region compared to those without involvement of LCR-A to B (8.7% rate, 2/23) $\chi^2(1,N=36)=4.70$, p=0.03. LCR-A to B involvement occurred only in individuals with deletions. In analysis restricted to deletions, rates remained similar (38.4% and 7.1%) and the result remained marginally significant $\chi^2(1, N=27)=3.83$, p=0.050. Record review results were supported by preliminary parent symptom report results. We observed higher mean scores in individuals with involvement of LCR-A to B on the SCQ (mean=16.0(9.4), range=5,30) and SRS (mean t-score=80.8(12.7), range=64,96) compared to individuals without involvement of the region (SCQ: mean=11.3(8.3), range=1,24; SRS: mean t-score=72.9(19.2), range=39,100). However, *nota bene*, group differences on continuous measures were not statistically significant, perhaps because of insufficient sample size; data collection is ongoing.
Conclusions: Among individuals with atypical CNVs in the 22q11.2 region, we identified a smaller region implicated in many but not all cases of ASD. LCR-A to B involves COMT and RANBP1, which may warrant further investigation for association with ASD.

11:10 **138.003** Phenotypic Presentation and the Role of Parental Phenotype in Accounting for Variability in Individuals with Disruptive DYRK1A Mutations

R. K. Earl[1], *C. M. Hudac*[2], *J. Gerdts*[3] *and R. Bernier*[3], *(1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA, (3)University of Washington Autism Center, Seattle, WA*

Background: Dual-specificity tyrosine phosphorylation-regulated kinase 1A, or *DYRK1A*, is a gene recurrently disrupted in 0.1-0.5% of the ASD population (Iossifov et al., 2014; O'Roak, Vives, Fu, et al., 2012). Individuals with disruptions to *DYRK1A* present with similar features, including microcephalic head size, intellectual disability, speech delay, ASD, and facial dysmorphisms (Bronicki et al., 2015; Ji et al., 2015; van Bon, Coe, & deVries, 2015). In previously published cases assessed for ASD, incidence of ASD remains variable, suggesting variable expressivity for the gene (Bronicki et al., 2015; Van Bon et al., 2015). Additional dimensional characterization of ASD symptoms and co-occurring impairments in individuals with mutations to *DYRK1A* is needed to understand the observed clinical variability. Phenotyping efforts have yet to situate individuals with *DYRK1A*in the context of larger familial genetic background, which may provide important information regarding genetic impact across domains of functioning and variability between carriers.
Objectives: Objectives are 1) to summarize categorical and dimensional phenotypic features of known cases of *DYRK1A* mutations; 2) to compare incidence of features to those in a large sample of individuals ascertained for ASD and a cohort of individuals with other disruptive genetic events associated with ASD, such as *CHD8;* 3) to situate phenotypic variability in cases of *DYRK1A*in the context of their non-carrier parents' phenotype, thus accounting for familial background and "expected" outcome in the absence of the mutation.
Methods: Participants of this study include 61 individuals with *de novo DYRK1A* mutation (i.e. probands), including previously published cases and participants of The Investigation of Genetic Exome Research (TIGER) study at the University of Washington. A subset of 10 probands and their non-carrier parents who received standardized assessments of IQ, social behavior (Social Responsiveness Scale), motor skills (Purdue Pegboard Test), and physical measurements (e.g. head circumference, height, weight) will be used to calculate effect sizes between probands and their parents. Comparison samples include two large cohorts of participants with ASD: the Simons Simplex Collection and the Genetic Linkage Study of Autism. Additional comparisons will be made with subjects from the TIGER study with ASD-associated *CHD8*mutations. Nonparametric analyses will be used to compare categorically-measured phenotypic features and univariate ANOVA will be used for continuous phenotypic variables.
Results: Preliminary findings from analysis of 29 *DYRK1A* probands reveal high rates of Intellectual Disability (100%), language delays (100%), microcephaly (90%), feeding difficulties (89%), and ASD (60%) (see Table 1). Data collection is ongoing with further analyses identifying parent-proband effect sizes for a cohort of individuals with *DYRK1A* mutations and their parents (n = 10) and comparing effect sizes to cohorts with ASD and those with *CHD8*mutations.
Conclusions: Recurring features emerge across individuals with mutations to *DYRK1A*. Specifically, a majority of individuals with *DYRK1A* exhibit intellectual disability, speech delays, motor impairments, microcephaly, seizures, ASD, and feeding difficulties as has been reported in smaller cohorts in previous literature. Analyses of parent-proband effect sizes will provide an estimation of *DYRK1A*'s impact on cognitive, behavioral, and physiological domains, and will inform the variability in phenotype observed across individuals.

11:30 **138.004** Understanding the Comorbidity of Autism Spectrum Disorder and Fragile X Syndrome: Moving Beyond a Categorical Approach

L. Abbeduto[1]*, A. J. Thurman*[2] *and A. McDuffie*[3]*, (1)M.I.N.D. Institute, UC Davis, Sacramento, CA, (2)Psychiatry, M.I.N.D. Institute, UC Davis, Sacramento, CA, (3)UC Davis, Sacramento, CA*

Background: Fragile X syndrome (FXS), the leading inherited form of intellectual disability, results from a mutation in the *FMR1* gene on the X chromosome, which leads to a reduction in the associated protein (FMRP). Autism spectrum disorder (ASD) is a common comorbid condition in FXS. The prevalence of ASD in FXS has been estimated at >50%, with FXS accounting for 3-6% of ASD cases. It has been assumed that ASD symptoms reflect the same underlying psychological and neurobiological impairments in FXS and idiopathic ASD and, therefore, drugs showing benefit for FXS will also be beneficial for idiopathic ASD.
Objectives: In contrast, we have previously presented data documenting important differences between individuals with comorbid FXS and ASD and those with idiopathic ASD in terms of ASD symptoms, behavioral and psychiatric correlates, and developmental trajectories. In this presentation, we will discuss three new studies, each involving a different cohort, designed to further clarify the comorbidity of FXS and ASD. The studies entail comparisons of FXS and idiopathic ASD in terms of profiles of language impairments and predictors of impairment (Study 1), analysis of predictors of variation in the developmental trajectories of social-communication impairments within FXS (Study 2), and analysis of predictors of variation in ASD symptoms within FXS (Study 3).
Methods: In Study 1, we examined scores on measures of structural language (i.e., receptive and expressive vocabulary and grammar) in 4- to 10-year-old males with FXS (*n* = 51) or idiopathic ASD (*n*= 36), as well as the predictors of those scores, which included age, IQ, and ASD symptom severity. In Study 2, we examined predictors of within-syndrome variation in the developmental trajectory of social-communication using an experimental measure of the skills involved in correcting communicative misunderstandings. Participants in Study 2 were males with FXS (*n* = 36), ages 10-16 years and followed longitudinally. In Study 3, we examined the prediction of social-affective and restricted and repetitive behavior symptom severity (measured by the ADOS) from a variety of factors, including language ability, nonverbal cognitive ability, and FMRP. Males with FXS (*n* = 58), ages 15-23 years, participated in Study 3.
Results: In Study 1, we found a different profile of language impairments and different predictors of language impairment in FXS and idiopathic ASD, even when the FXS sample was limited to those with an ASD diagnosis. In Study 2, we found that individual differences in this measure of social-communication were related to differences in nonverbal cognitive ability and FMRP, but not to ASD symptoms (contrary to expectations for idiopathic ASD). In Study 3, we found that language ability and nonverbal cognitive ability predicted social-affective and restricted and repetitive behavior symptom severity, respectively, which is unlike the pattern reported for idiopathic ASD.
Conclusions: These studies reinforce the notion that there are clinically and mechanistically important differences between FXS and idiopathic ASD that are masked by the categorical diagnosis of ASD. Thus, we argue for a symptom-based approach rather than a categorical diagnosis-based approach future research, including in studies of treatment efficacy.

Panel Session
139 - Interventions to Improve Transition Outcomes By Strengthening Environmental Supports
10:30 AM - 12:00 PM - Yerba Buena 8

Panel Chair: Julie Taylor, *Vanderbilt University Medical Center, Nashville, TN*

Discussant: Kara Hume, *University of North Carolina, Chapel HIll, Carrboro, NC*

Poor outcomes among adults with autism spectrum disorder (ASD) are well-documented and result in significant economic costs. Nearly all existing interventions focus on the adults themselves, building skills or alleviating problem behaviors. Yet, according to the International Classification of Functioning, Disability, and Health (ICF), functioning is also a product of the environments and contexts in which one finds oneself. Currently, few interventions seek to leverage supportive environments to improve outcomes for youth/adults with ASD. In this panel, we present initial findings from four interventions to improve transition outcomes by strengthening environmental supports. Presentations focus on how to improve outcomes by: (1) strengthening transition planning in schools; (2) training parents to effectively advocate for adult disability services for their son/daughter; (3) training peers to support students with ASD in post-secondary educational settings; and (4) increasing informal supports available to young adults with ASD and their families. Dr. Kara

Hume will serve as the discussant. She is Co-PI for the Center on Secondary Education for Students with ASD, the largest intervention study to date focused on supporting adolescents with ASD in the high school setting, and will focus on the unique challenges of conducting intervention research in this age group across contexts.

10:30 **139.001** A Randomized Controlled Trial of Compass for Transition Youth

L. A. Ruble[1], *M. W. Jackson*[2], *A. D. Rodgers*[1], *W. H. Wong*[1], *Y. Yu*[3] *and J. H. McGrew*[4], *(1)University of Kentucky, Lexington, KY, (2)University of Kentucky, Winchester, KY, (3)Indiana University - Purdue University Indianapolis, Indianapolis, IN, (4)Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN*

Background: Research on transition planning and implementation indicates we are falling short for students with autism spectrum disorder (ASD). Only a quarter of parents report the transition planning process as very useful; while a third desire more involvement, and most troubling, a third report having no transition plan. Poor transition planning leads to poorer post-school outcomes, including low employment rates, limited community participation, and lack of friendships. Using an implementation science framework, we examined the effectiveness of a teacher consultation intervention as a strategy for infusing evidence based practices within transition planning and intervention for youth with ASD.
Objectives: The purpose of this presentation is to describe initial outcomes of randomized controlled trial (RCT) of the Collaborative Model for Promoting Competence and Success (COMPASS), an evidence based consultation intervention that improves educational outcomes of young children with ASD by enhancing environmental supports.
Methods: We adapted COMPASS for transition age youth using the Consolidated Framework for Implementation Science as a guide (CFIR; Damschroder, et al., 2009). To guide our adaptation we gathered information on issues of transition planning and implementation by conducting 10 focus groups with key stakeholders and asking them to describe desired outcomes, best ways to assess effectiveness, and features of good transition planning and implementation. The findings (a) described a need for information on the transition process and services that were clear and understandable, (b) informed areas of assessment for post-school goals based on understanding of student interests and strengths, (c) indicated necessity of goals for parents and teachers, in addition to students, (d) identified key players (e.g., vocational rehabilitation), and (e) suggested process changes, such as flexibility for how people are involved in meetings and individualization of assessment process based on student abilities. These themes were used to adapt COMPASS. Following adaptation, we piloted COMPASS within an RCT over two waves. Each wave occurred over a school year. Youth in their final year of school (*N*=24), their parents (*N*=24), and their teachers (*N*=24) were recruited. If teachers had more than one student with ASD, a student was randomly selected for participation. Teachers were randomized to COMPASS or a placebo control condition. Goal attainment outcomes from IEP objectives were evaluated at the end of the school year by an independent observer unaware of group assignment.
Results: Results from our first wave of participants (*N* = 7; Age_m = 18.5 years) revealed higher goal attainment change scores for students whose teachers received COMPASS (*M* = 3.2) compared to the control (*M* = 0.75). The second wave of data are currently being collected. In addition to final results, we will elaborate on the themes identified by the focus groups, how we adapted COMPASS based on the themes, and final results.
Conclusions: The limited post-school outcomes of young adults with ASD calls for directed attention to the transition planning process. The findings help provide direction for future implementation research on transition for students with ASD.

10:50 **139.002** Effects of a Parent-Training Intervention on Service Access and Employment for Youth with ASD

J. L. Taylor[1,2], *R. M. Hodapp*[2], *M. M. Burke*[3], *S. N. Waitz-Kudla*[2] *and C. Rabideau*[2], *(1)Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)University of Illinois at Champaign-Urbana, Champaign, IL*

Background: When youth with autism spectrum disorder (ASD) leave high school, they encounter an adult service system that is underfunded and difficult to navigate; this serves as a significant barrier to accessing appropriate services and support. In response, our group developed the Volunteer Advocacy Program-Transition (VAP-T), which equips parents to more effectively navigate the adult service system on behalf of their son/daughter with ASD. In initial findings from a small randomized controlled trial (RCT), we found that relative to control group parents, those who participated in the VAP-T knew more about adult services, and felt more empowered and skilled in advocating. It is unclear, however, whether increased parental knowledge/empowerment leads to improved transition outcomes for youth.
Objectives: To test whether parent participation in the VAP-T led to increased service access and higher rates of community employment/post-secondary education (PSE) for transition-aged youth with ASD.
Methods: We examined the efficacy of the VAP-T using an RCT, waiting-list control design with families of youth with ASD who were within 2 years of high school exit. After completing pre-test measures, families were randomly assigned to the intervention group or a wait-list control. Parents in the intervention group met weekly for 12 weeks; each session lasted 2.5 hours. Sessions covered aspects of the adult service system (e.g., Vocational Rehabilitation, post-secondary education programs, SSI, SSDI) and advocacy skills. All youth had ASD diagnoses confirmed using the Autism Diagnostic Observation Schedule-2 administered by research-reliable clinicians. 38 families (19 treatment, 19 control) have completed the 6-month follow-up thus far. At this time, 55% of youth were in high school and 45% had exited. The sample of youth was 18% female, and 32% had an intellectual disability. Outcomes, measured six months after the intervention group completed the VAP-T, included the number of services youth were receiving and whether youth were currently working in the community or in a PSE program.
Results: Youth with ASD whose parents were in the treatment group were more than twice as likely as the control group to be working in the community or in PSE (47% vs. 21%), Fisher's Exact Test p-value = .09. Group effects were more pronounced for those out of school; 86% of treatment group youth who had exited high school were working in the community or in PSE, compared to 30% of control group youth, Fisher's Exact Test p-value = .04. Relative to the control group, treatment group participants may be receiving more services (3.60 vs. 3.00), although the difference was not statistically significant. Further analyses will examine whether intervention effects on service access depend on high school exit (in/out of high school) or whether the youth has an intellectual disability.
Conclusions: Â Training parents how to navigate the adult service system may lead to higher rates of employment/PSE participation for youth with ASD, and perhaps to better service access. Discussion will highlight the importance of intervening at the level of the family, when working to strengthen environmental supports for youth with ASD during the transition to adulthood.

11:10 **139.003** Realist Evaluation of Specialist Peer Mentoring for University Students with ASD

C. Thompson[1,2], *T. Falkmer*[1,2], *S. Taylor*[1], *S. Bolte*[3,4,5] *and S. J. Girdler*[1,2], *(1)School of Occupational Therapy and Social Work, Curtin University, Perth, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Institutionen för kvinnors och barns hälsa (KBH), Karolinska Institutet, Stockholm, Sweden, (4)Curtin University, Bentley, Australia, (5)Stockholm County Council, Center for Psychiatry Research, Stockholm, Sweden*

Background: While many adults with Autism Spectrum Disorder (ASD) have average to high intellectual capabilities they still experience numerous challenges impacting their ability to negotiate everyday life. Post-secondary education has been identified as a means of improving outcomes in adulthood. Despite recognition of the benefits of education and intellectual abilities of many adults with ASD, the rate of those completing post-secondary education remains below those of others with and without disabilities. Specialist peer mentoring for adults with ASD has been proposed as an intervention that may enable success at university.
Objectives: This study aimed to identify the contexts, mechanisms and outcomes; and the relationship between these components of a specialist peer mentor program for university students with ASD.
Methods: Semi-structured interviews were explored a specialist peer mentor intervention for university students with ASD. The Realist Evaluation (RE) method provided a structured approach allowing for exploration of the contexts, mechanisms and outcomes of the program. RE facilitated the exploration of how the program worked, under what conditions, and what outcomes occurred as a result.
A total of 28 (23 female and 5 male; mean age=28.6; SD=6.9) peer mentors supporting university students with ASD completed semi-structured interviews ranging in duration from 30 to 90 minutes. Interviews were transcribed verbatim and systematically coded using the *context, mechanism* and *outcome* framework. The *context* of the program was considered circumstances present prior to the peer mentoring program, including aspects of the person, available services and the environment. The *mechanisms* were the components of the peer mentoring program; and the *outcomes* were the expected or unexpected consequences of *mechanisms* in a particular *context*. Following broad coding into categories of *context*, *mechanism* and *outcome*thematic coding was undertaken within each category.
Results: A total of 312 contexts, 961 mechanisms and 283 outcomes were identified. Within the context category thematic analysis revealed the themes of *university services*, *university course demands*, *environmental conditions* and *individual differences*. Themes within the mechanisms were *problem solving, the mentor*, *the structured program,* and *social interactions*. While the themes of *identifying positive mentor outcomes, identifying personal strengths*, *achieving goals*, *increased* independence and *mentor-mentee relationship*were identified within the outcomes.
Conclusions: The mechanisms of particular interest within the intervention were *problem solving* and *the mentor*. It is particularly interesting that even though ASD is a condition characterised by social communication difficulties several of the most pertinent mechanisms of the present intervention were forms of communication and social interaction. These findings indicate that to work effectively with university students with ASD mentors need to utilise therapeutic use-of-self and modelling to foster social communication and participation at university. It is also suggests that adults with ASD are able to effectively model social behaviours from their peer mentors. Modelling of appropriate and effective communication strategies by peer mentors is a powerful intervention to increase self-efficacy in social-communication for university students with ASD. Further research is required to describe the dynamics of the peer mentoring relationship and the impact of this intervention on ASD symptomatology.

11:30 **139.004** Working Together: Family Education and Support Intervention for Young Adults with ASD

***L. E. Smith**, J. S. Greenberg and M. R. Mailick, Waisman Center-University of Wisconsin, Madison, WI*

Background: Â Currently there is increasing interest in developing interventions to support positive outcomes across the lifespan for individuals with ASD. Given the current dearth of *formal* services for young adults with ASD, especially those without co-occurring intellectual disability, interventions are needed that increase a family's capacity to find and create *informal* supports and activities in the community. Addressing this gap, we developed a multi-family group psychoeducation intervention, *Working Together*, designed for disengaged young adults with ASD and their families.
Objectives: The present study aimed to evaluate the impact of *Working Together*, a multi-family group psychoeducation intervention for young adults with ASD, on (1) frequency of employment, (2) frequency of social interactions, and (3) supportive parental attitudes.
Methods: Data were drawn from the ongoing *Working Together* study. Young adults were eligible to participate if they coresided with their parents, had no intellectual disability, and had a medical/educational diagnosis of ASD confirmed by administration of the Social Communication Questionnaire. The present analysis focused on 17 adults and their parents who had completed data through 6-month follow up (40 families will be completed by IMFAR). After baseline assessment, families were randomized into an intervention (n=9) or waitlist control condition (n=8). The intervention included 2 individual family sessions, 8 weekly group sessions, 3 monthly group booster sessions, and ongoing resources and referrals. Although group sessions occurred separately for young adults and their parents, session topics were the same and included goal setting, problem-solving, coping strategies, planning for independence, and employment. Adults with ASD and their parents were assessed at baseline and at 6 month follow up on measures of employment, social interactions, and parental attitudes. Families also reported on satisfaction with the program.
Results: To test for differences between experimental and control groups at 6 month follow-up, we conducted a series of 2 (group) by 2 (time) repeated measures ANOVAs. Young adults in the intervention group showed improvements in frequency of working for pay based on both young adult and parent report compared to young adults in the control group (*partial eta squared* = .218 and .154 for parent- and young adult-report, respectively, representing medium effect sizes). Parents in the intervention group also showed more supportive attitudes about their young adult following the intervention compared to parents in the control group, *partial eta squared* = .263, reflecting a large effect size. There were no significant differences between groups over time for time spent with friends. Additionally, 100% of parents and adults with ASD were satisfied or very satisfied with the intervention program. Exit interview data suggested problem solving and independence were important areas of learning for the young adults.
Conclusions: The *Working Together* intervention was associated with increased paid employment for young adults with ASD as well as improved parental attitudes, suggesting benefits of family support for adult outcomes. Future research will examine the effectiveness of the *Working Together* model on quality of life and long-term employment and engagement in adults with ASD.

Panel Session
140 - Variability at the Minimally Verbal End of the Spectrum: Evidence from Biology and Behavior
10:30 AM - 12:00 PM - Yerba Buena 9

Panel Chair: Charlotte DiStefano, *University of California Los Angeles, Los Angeles, CA*

Discussant: Shafali Jeste, *UCLA, Los Angeles, CA*

Approximately 25-30% of individuals with ASD remain minimally verbal (MV) despite access to intervention (Anderson et al., 2007; Tager-Flusberg & Kasari, 2014). Although unified by the lack of spoken language, the MV ASD population exhibits considerable heterogeneity with regard to cognitive, social and receptive language abilities (DiStefano et al., 2016; Bal et al., 2016). This variability likely results from the fact that many different pathways can lead to expressive language impairment. Improving outcomes for this subgroup of the autism spectrum requires better characterization and understanding of this variability. This panel will present research from multiple levels of investigation within the MV spectrum, from brain to behavior. Panel presentations will include electrophysiological investigation of auditory, visual and lexical processing in both MV and verbal children with ASD, prosodic and acoustic characteristics of speech in MV children, and emotional/behavioral profiles of children with ASD across language levels. Throughout the presentations, we will discuss differences between MV and verbal children with ASD, variability within the MV group, and we will consider the ways in which these findings can inform our understanding of pathways to and outcomes of language impairment in the ASD population.

10:30 **140.001** Sensory Perception and Lexical-Semantic Processing in Minimally Verbal/Non-Verbal Children with ASD and Typical Controls Assessed Via Dense-Array EEG

C. Cantiani[1], *V. Shafer*[2], *Y. H. Yu*[3], *N. Choudhury*[4] *and A. A. Benasich*[5], *(1)Child Psychopathology Unit, Scientific Institute IRCCS Eugenio Medea, Bosisio Parini, Italy, (2)The Graduate Center, City University of New York, New York, NY, (3)Department of Communication Sciences and Disorders, St. John's University, New York, NY, (4)Psychology, Ramapo College of New Jersey, Mahwah, NJ, (5)Center for Molecular & Behavioral Neuroscience, Rutgers Univ., Newark, NJ*

Background:
We examined electrocortical activity associated with sensory perception (visual and auditory) and lexical-semantic processing in nonverbal (NV) or minimally verbal (MV) children with Autism Spectrum Disorder (ASD). Studies that have examined the neural correlates of higher-level linguistic processing in this population are rare. Specifically, there is no agreement on whether NV/MV ASD children as a group perceive and comprehend incoming linguistic input and whether speech, if perceived, is processed in a manner comparable to that of typically developing children. However, this is far from a homogenous group and our research, as well as that from other labs, suggests much individual variation across cognitive, social and receptive language domains. A key challenge in assessing this population is developing approaches to evaluating linguistic and cognitive abilities that do not confound linguistic performance with difficulties meeting task demands.
Objectives:
The purpose of this study was to use dense-array electroencepahalography (EEG) to examine the topography and time course of sensory/perceptual and higher-order linguistic skills in NV/MV children with ASD, and to compare their cortical responses and processing profiles to related visual and auditory input with that of typically developing children.
Methods:
Event related potentials (ERPs) of 10 NV/MV children with ASD and 10 neurotypical children (age range 4-7 years) were recorded during a passive picture-word matching paradigm. Still pictures of animals or inanimate objects were visually presented on a computer monitor while a word that either matched or mismatched the picture was auditorily presented. The specific paradigm used allowed us to investigate the entire pattern of information processing, from very early sensory perception (for both visual and auditory processing) through to lexical-semantic processing.
Results:
Atypical ERP responses were evident at all levels of processing in children with NV/MV ASD. Basic perceptual processing of visual and auditory stimuli was found to be significantly delayed but similar in amplitude and topography to control children. More significant differences were seen between children with ASD and typically developing children at the lexical-semantic level, suggesting more compromised higher order processes. Individual level analyses revealed that a reliable N400 component in response to the mismatch condition was detected in five of the ASD children and eight of the neurotypical children.
Conclusions:
These results suggest that although basic perception is relatively preserved in NV/MV children with ASD, higher levels of processing are impaired. However, we were also able to examine individual processing profiles, an important step in using such information to guide intervention. Thus, these studies represent a significant step towards developing a functional neurolinguistic assessment for this difficult-to-test population. The findings also challenge the notion that being nonverbal (i.e. “no spoken language”) implies an absence of language comprehension. In some individuals that may indeed be true, however, we have demonstrated that at least a subset of nonverbal ASD children may possess higher-level language processing skills than is evident from standardized testing procedures.

10:50 **140.002** ERP Evidence of Semantic Processing in Children with ASD

C. DiStefano[1], *A. T. Marin*[2], *E. Baker*[3] *and S. S. Jeste*[4], *(1)University of California Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)UCLA Center for Autism Research and Treatment, Anaheim, CA, (4)UCLA, Los Angeles, CA*

Background:
Language outcomes vary in children with ASD, with up to 30% remaining minimally verbal (MV). Electroencephalography (EEG) yields information about an individual’s neural response to a stimulus in real time, and in the context of language impairment may elucidate neural mechanisms underlying language processing in ASD. Lexical-semantic processing can be quantified through a paradigm in which information is presented in a semantically congruent or incongruent way (Bentin 1985; Hagoort et al., 2008). This paradigm has been recommended for assessing receptive language in individuals with limited speech (Connolly et al., 1999). The EEG response after the incongruent presentation (N400) has been found to be reduced in both high-functioning (Dunn & Bates, 2005) and MV children with ASD (Cantiani et al., 2016). No study has examined variability in semantic processing within children with ASD and, in particular, whether EEG correlates of semantic processing relate to direct assessment of language.
Objectives:
We examine EEG correlates of lexical-semantic processing in a large, heterogeneous sample of children with ASD, compared with an age-matched typically developing (TD) group, and we investigated the relationship between lexical-semantic processing and receptive language. We hypothesized that children with ASD would show a reduced N400 response compared with TD children and that larger, faster N400 response would be associated with better receptive language.
Methods:
Verbal and MV children with ASD (ages 5-11; n=16 in each group), and an age-matched TD group (N=18) participated in a semantic congruence EEG paradigm, during which pictures were displayed followed by the expected (match) or unexpected (mismatch) spoken word. EEG data were collected using a 128-electrode Hydrocel Geodesic Sensor Net System (EGI), filtered at 0.3-30 Hz, and processed in NetStation. Participants with a minimum of 10 artifact-free segments per condition were included in analysis. Assessments included Differential Ability Scales (IQ), Peabody Picture Vocabulary Test (receptive vocabulary) and Autism Diagnostic Observation Schedule (diagnostic confirmation).
Results:
The mismatch condition elicited an N400 component in all groups (F=5.43, p=.024), with a shorter latency in the TD group (t=-3.15, p=.003). N400 latency was negatively correlated with receptive vocabulary (r=-.33, p=.03). A late negative component (LNC; 550-900ms) also was evident in the mismatch condition, with a group by condition by region interaction (F=2.5, p=.026). *Post hoc* analyses revealed that the LNC was present across frontal and central regions in the TD group (p-values .05-.002), in the mid-central region in the MV ASD group (t=2.5, p=.03), and approaching significance in the mid-frontal region in the V ASD group (t=1.99, p=.06).
Conclusions:
Findings indicate that both MV and verbal children with ASD demonstrate some EEG evidence of semantic processing, but their processing may be delayed and have reduced integration with mental representations. This supports the notion that at least some MV children show higher-level lexical processing, and performance on this task may be a meaningful stratification biomarker for understanding differential language trajectories. These findings differ from previous studies that did not find significant N400 response in children with ASD, likely due to our larger sample size and differences in the experimental paradigm.

11:10 **140.003** Vocalizations of Minimally Verbal Children and Adolescents with Autism: A Prosodic and Acoustic Analysis

J. C. Thorson[1] *and H. Tager-Flusberg*[2], *(1)Boston University, Croydon, NH, (2)Psychological and Brain Sciences, Boston University, Boston, MA*

Background:
Variations in prosody convey lexical, grammatical, and pragmatic meaning, all essential for successful communication. Individuals with autism spectrum disorder (ASD) show deficits in communication and pragmatic use of language (Tager-Flusberg Paul & Lord, 2005), with mixed results for how stress, intonation, and phrasing distinctions are employed (Paul et al., 2005; McCann et al., 2007; Shriberg et al., 2001). Critically, research to date has largely focused on verbal individuals with ASD, and only a few studies include acoustic analyses to more closely examine the nature of expressive impairments (Baltaxe, 1984; Diehl et al., 2009).
Objectives:
The current investigation was designed to elucidate the prosodic abilities of minimally verbal school-aged children with ASD, a previously understudied population, in an effort to better understand communication abilities across the spectrum. Due to challenges in collecting data from a population with a range of behavioral and intellectual issues, research has been limited within this group. Our goal was to acoustically analyze different types of vocalizations to better identify and understand natural prosodic features.
Methods:
Speech from 24 minimally verbal children and adolescents was analyzed (see Table 1). All speech was extracted from a standardized interview (ADOS) and labeled as spontaneous, echolalia, or elicited imitation. Average F_0 was extracted from successive 250-ms time windows, resulting in four data points per second. *Average pitch* is the average of these data points, and p*itch range* is the standard deviation in average F_0. Due to the heterogeneity of this population, we predicted that participants would demonstrate differences in prosody through the varied use of F_0, with pitch fluctuating as a result of verbal ability. This is in contrast to typically developing populations where variability stabilizes over time. Verbal ability was measured by analyzing how many unique words were uttered during the assessment (Lexical Score), allowing for a more fine-grained verbal analysis.
Results:
Substantial prosodic variation was observed across participants. Strong correlations were found between Lexical Score and the child's score on a parental questionnaire of receptive and expressive vocabulary ($r(21) = .758$, $p < .001$; $r(21) = .786$, $p < .001$, respectively). Lexical Score negatively correlated with *average pitch*, with more verbal children demonstrating lower overall pitch ($r(20) = -.563$, $p = .006$). *Pitch range* varied more within spontaneous productions than the echolalia and elicited imitations, the latter two showing overall greater variation in range (Figure 1). In comparison to previous research with verbal children with ASD and typically developing children, our data show more pitch range variation for minimally verbal children (Diehl et al., 2009).
Conclusions:
Results indicate that participants vary considerably in how they modulate pitch during different types of speech productions. This first exploration into the prosodic patterns of pitch in minimally verbal school-aged children with ASD provides further insight into how prosody varies along the autism spectrum. We also investigated how pitch varies for this group as a function of speech type, shedding light on unique processing and production strategies. Identifying prosodic characteristics aids early intervention strategies and provides a baseline for melodic-based therapies.

11:30 **140.004** Assessing Emotional/Behavior Problems in Children with ASD: Differences in ABC and CBCL Profiles By Language Level

M. Fok[1]*, E. Rosenberg*[1] *and V. Hus Bal*[2]*, (1)University of California, San Francisco, San Francisco, CA, (2)STAR Center for ASD & NDD; Dept of Psychiatry, University of California, San Francisco, San Francisco, CA*

Background:
There has been an increasing focus on assessment of social-communication, cognitive and language skills in minimally verbal (MV) children (Kasari et al., 2013), but little attention to psychiatric comorbidities in this clinical population. The Child Behavior Checklist is commonly used to assess emotional/behavior problems (EBP; Achenbach & Rescorla, 1991), but includes items reflecting internal experiences that may be difficult to evaluate in MV children. The Aberrant Behavior Checklist (Aman et al., 1985) was developed to assess EBP in individuals with intellectual disability (ID); it may be well-suited for assessing MV children but miss more internalized experiences of verbal children. Previous studies suggest the ABC is appropriate for use with children with ASD (Kaat et al., 2014); no study has examined whether item response patterns vary by child language level.
Objectives:
Examine the utility of the ABC and CBCL for assessing EBP in children with ASD across different language levels and use items from the ABC to gain insight into how EBP may manifest differently in MV vs. verbal children.
Methods:
Participants were 1,964 6-18 year olds with ASD from the Simons Simplex Collection. ABC (Irritability, Lethargy, Hyperactivity) and CBCL (Internalizing, Externalizing) were used to examine EBP. ADOS module was used as a proxy for language level (Module 1=MV, 2=phrases (P), 3=verbally fluent (VF)). One-way Analysis of Variance with post-hoc Bonferroni tests were used to compare EBP across language levels. Chi square analyses were used to assess language group differences in a)children meeting clinical cut-offs for CBCL subscales and b)ABC item response patterns. Correlations between EBP, ASD symptoms and IQ were assessed within language groups.
Results:
Each ABC subscale showed language group differences (all $p<.001$). MV children had higher Lethargy scores than P and VF groups ($p<.001$), but differed from only the VF group on Hyperactivity and Irritability (MV>VF, $p<.001$). On the CBCL, language groups showed different Internalizing ($p<.001$), but not Externalizing scores ($p=.48$). In contrast to the ABC, the VF group had higher Internalizing scores than MV or PS groups ($p<.001$). Within the Internalizing domain, only 1% of the MV group fell in the range of clinical concern (t-score ≥ 70) on the Anxious/Depressed subscale, compared to 4% of the PS and 20% of the VF group ($p<.001$). Scores on other Internalizing subscales did not differ by language level.
Across the three ABC scales, seven items showed similar response patterns across language groups. Scales also showed differential relationships with IQ and ASD symptoms across language levels, including within the MV group. Language group differences in item distributions and associations with other child characteristics will be discussed with respect to differences in manifestation of ASD symptoms and overlap with EBP in MV vs. verbal children.
Conclusions:
The ABC and CBCL showed different patterns of EBP across language levels, underscoring a need for careful consideration of the assessment of EBP in MV children. Findings have implications for the use of ABC and CBCL in large samples of varying language abilities, as EBP may manifest differently in MV and verbal children.

Poster Session
141 - Brain Structure (MRI, neuropathology)
12:00 PM - 1:40 PM - Golden Gate Ballroom

31 **141.031** Age-Related Changes in Cortical Morphometry; A Longitudinal MRI Study of Males with Autism and Controls.

E. Daly[1], *A. Marshall*[2], *D. Andrews*[3], *A. Shahidiani*[3], *C. Ecker*[4] *and D. G. Murphy*[1], *(1)Sackler Institute for Translational Neurodevelopment and Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (2)King's College London, London, United Kingdom, (3)Sackler Institute for Translational Neurodevelopmental Sciences, IoPPN, King's College London, London, United Kingdom, London, United Kingdom, (4)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychiatry, Goethe-University Frankfurt am Main, Frankfurt, Germany*

Background:
Cortical volume (CV) is the product of 2 underlying components: cortical thickness (CT) and surface area (SA). This is of importance because both CT and SA have distinct genetic and developmental origins. Hence measurement of CT and SA allows us to 'fractionate' the underpinning mechanisms behind differences in brain volume in people with autism spectrum disorders (ASD), and to investigate how these differ over time.
Objectives:
We acquired structural MRI over multiple time periods to investigate brain morphometry and growth trajectory differences between individuals with ASD and typically developing controls.
Methods:
We included 64 males – 32 with ASD and 32 controls. ASD was diagnosed using ADI and ADOS. We obtained 62 scans from individuals with ASD (mean age = 15 years; range 6-19 years; mean inter-scan interval 1.1 years) and 54 scans from 32 typically developing controls (TDC) males (mean age = 14 years; range 8-19 years; mean inter-scan interval 1.0 years). FreeSurfer, image analysis software, was used to measure CV, CT and SA. Automatic longitudinal processing was used to obtain reliable measurements at each time point. Cross-sectional between group (i.e. TDC, ASD) comparisons at baseline were carried out using a general linear model and the SurfStat toolbox. Differences in developmental trajectories over multiple time points were investigated using linear mixed effects models.
Results: At baseline, there are main effects of group for CV and SA. The ASD group had significantly greater CV and SA in insula/postcentral gyrus. There was no difference in CT. Longitudinal analysis revealed significant age related changes in CV, CT and SA globally in both groups. However, the ASD group showed more CV, CT and SA reductions with age than the TD group globally in frontal, temporal, parietal, and occipital lobes.
Conclusions:
Individuals with ASD have significantly greater age-related loss of brain tissue than controls. Larger studies, and including older (and aged) populations, are required to determine if these age-related differences are associated with change in symptomatic and/or cognitive profile.

32 **141.032** Altered Functional and Structural Brain Connectivity in ASD Individuals with SHANK3 Defect

C. Liu[1], *D. Li*[2] *and X. Xu*[2], *(1)15111240007@Fudan.Edu.Cn, Children's Hospital of Fudan University, Shanghai, China, (2)Children's Hospital of Fudan University, Shanghai, China*

Background: SHANK3 is a postsynaptic scaffolding protein, whose molecular variations is thought to be responsible for 22q13 deletion syndrome (Phelan-McDermid Syndrome) and autism spectrum disorders (ASD). However, it remains unclear how SHANK3 defect are related to abnormal brain development in ASD.
Objectives: To assess the GM and WM development of SHANK3 defect children ascertained for ASD and explore the relationship with clinical phenotypes.
Methods: MLPA and Sanger sequencing were carried out to confirm the *SHANK3* deficiency of 8 Chinese children with ASD (SHANK3 group), followed by systematic and comprehensive evaluations. Then we recruited 24 ASD children without *SHANK3*deficiency (ASD group) and 25 typically developing controls (TD group). ADOS scale was applied to examine the severity of autism and Griffith scale was used to assess the development level of SHANK3 group and ASD group. In addition, MRI scans of the three groups were analyzed using voxel-based morphometry (VBM) and Diffusion tensor imaging (DTI). Normalized modulated GM maps were statistically analyzed using the general linear model. The integrity of WM fiber was evaluated using fractional anisotropy (FA).
Results: Six participants lacked the whole gene of *SHANK3*, one lacked part of it, and one with de novo *SHANK3* mutation was included. The sample was characterized by high rates (100%) of ASD, developmental delay, hypotonia, several dysmorphologies and perception abreaction. As to the clinic phenotypes, there was no significant statistical difference between SHANK3 and ASD group. Whereas SHANK3 defect children displayed severer developmental delay in language, performance and other items comparing with ASD group ($p<0.0005$). As to the MRI performance, VBM showed that SHANK3 group showed significant gray matter volume decrease in the left middle frontal gyrus, right postcentral and left dorso-lateral superior frontal gyrus, compared with TD and ASD group ($p<0.001$). What's more, SHANK3 group had significantly less gray matter in the left cerebellar crus, left triangle inferior frontal gyrus, left inferior parietal and left fusiform gyrus than ASD group ($p<0.001$). Additionally, as to the DTI result, corpus callosum (body, splenium and genu) tracts in SHANK3 group displayed significantly lower FA than ASD and TD group ($p<0.001$). Other tracts, such as middle cerebellar peduncle, bilateral superior and anterior corona radiate and bilateral superior longitudinal fasciculus, also had significant abnormalities ($p<0.001$).
Conclusions: These results imply that *SHANK3* defect associated with ASD may be rooted in neural anatomy, and autism symptoms in individuals with *SHANK3* defect and ASD might have, at least partially, different underlying etiologies. Moreover, an obvious phenomenon of imbalance between left and right side in *SHANK3* defect children was existed, which may be associated with the different functions of each brain region and the diversity of clinical phenotypes.

33 **141.033** Amygdala Growth Trajectories, Fear Potentiated Startle Response, and Anxiety in Children with Autism Spectrum Disorder

L. Libero[1], *A. Schneider*[2], *D. Hessl*[3], *B. Winder-Patel*[4], *M. Solomon*[5], *C. C. Coleman*[5], *N. Sharma*[3], *C. W. Nordahl*[5] *and D. G. Amaral*[5], *(1)Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (2)Pediatrics / MIND Institute, University of California at Davis, Sacramento, CA, (3)UC Davis MIND Institute, Sacramento, CA, (4)MIND Institute, University of California, Davis, Sacramento, CA, (5)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA*

Background: Symptoms of anxiety are reported commonly in ASD, with approximately 40-50% of individuals with ASD meeting criteria for an anxiety disorder (Kerns & Kendall, 2012). Alterations in amygdala morphology and activity are also commonly reported in ASD, yet the relationship between alterations in the amygdala and the development of co-morbid anxiety disorders is unclear. Given that the amygdala is functionally related to fear and anxiety (Amaral et al., 2003), investigating amygdala growth trajectories and probing amygdala function using a fear potentiated startle paradigm may provide insight into autism-related anxiety disorders that emerge during middle childhood.
Objectives: To examine amygdala growth trajectories, fear potentiated startle response and clinically significant anxiety in children with ASD and age-matched typically developing (TD) children.
Methods: Participants to date include 22 children with ASD (15 male/7 female; IQ range 32-138; ADOS-2 composite score range 3-10) and 14 typically developing children (10 male/4 female; IQ range 98-140). The children are currently between 9 and 13 years of age and enrolled in the ongoing Autism Phenome Project. T1-weighted structural MRIs were collected for each child at around 2-3 years-of-age and again at present. Amygdala volumes were measured bilaterally at each age based on these scans. The rate of amygdala growth was calculated as the change in volume over time, normalized to total brain volume growth. Fear potentiated startle response was measured as a probe of amygdala function. The fear potentiated startle response was evaluated using a paradigm previously tested in adolescents with ASD (Sterling et al., 2013) that was adapted for testing with children with low IQ and limited verbal abilities. Clinically significant anxiety was measured using the Anxiety Disorders Interview Schedule (ADIS-IV) with the Autism Spectrum Addendum.
Results: In the fear potentiated startle task, children with ASD had significantly reduced mean percent potentiation compared to TD children. Interestingly, the ASD group also demonstrated significantly increased baseline startle magnitudes. Within the ASD group, the rate of amygdala growth was negatively correlated with percent fear potentiation such that children with the fastest amygdala growth rates demonstrated the most reduction in percent fear potentiation. In addition, percent fear potentiation was also significantly correlated with the clinical severity rating scores for each child's principal anxiety diagnosis. Children with ASD and the highest ratings of anxiety demonstrated the greatest level of fear potentiation.
Conclusions: A significant association between amygdala growth and fear potentiated startle response suggest that alterations in the developmental trajectory of the amygdala may be driving the reduced fear response in the ASD group. At the same time, greater fear potentiated startle response was related to higher clinical ratings of anxiety, indicating that this probe of amygdala function may be a useful tool for evaluating anxiety level particularly in non-verbal lower functioning individuals.

34 **141.034** Anatomical Connectivity Abnormalities and Social Perception Deficits in Children with ASD: A MRI-DTI and Eye-Tracking Study

A. Vincon-Leite[1], *A. Saitovitch*[1], *H. Lemaître*[2], *J. M. Tacchella*[1], *E. Rechtman*[1], *E. Douard*[1], *N. Chabane*[3], *A. Philippe*[4], *D. Grevent*[1], *R. Calmon*[1], *F. Brunelle*[1], *N. Boddaert*[1] *and M. Zilbovicius*[1], *(1)INSERM U1000, Institut Imagine, Paris, France, (2)INSERM U1000, Institut Imagine, Université Paris Sud, Paris, France, (3)INSERM U1000, Paris, France, (4)UMR 1163, Institut Imagine, Paris, France*

Background: Autism spectrum disorder (ASD) is highly heterogeneous. Nevertheless, a core deficit in social interaction, notably a difficulty to establish a direct eye-contact, constitutes a frequent characteristic across the autism spectrum. Eye-gaze behaviour, crucial for human interaction, can be measured objectively with eye-tracking methodology. Moreover, it is now admitted that these social human abilities, disrupted in ASD, have a neural substrate. In a network point of view, recent advances in brain imaging as diffusion tensor imaging (DTI) permit to explore white matter (WM) microstructure mediating anatomical connectivity.
Objectives: In this context, after demonstrating that in our cohort, children with ASD met atypical eye-tracking pattern compared to typical developed (TD) children, the current study sought to investigate (i) whether children with ASD exhibit differences in WM microstructure approached by fractional anisotropy (FA) compared to TD children (ii) whether WM microstructure correlates with individual tendency to drive more or less interest to the eye region, which can be viewed as a social perception indicator.
Methods: Twenty-eight children with ASD (age = 8.4 ± 4) and twenty-five TD children (age = 10.4 ± 3) participated in this study. ASD diagnosis was based on DSM IV-R and ADI-R criteria. Tobii-T120 eye-tracker was used to measure eye-gaze processing during passive visualization of social movies, displaying two characters engaged in peer to peer social interactions. WM integrity was voxel-wise assessed over the whole brain diffusion tensor imaging (DTI). Diffusion data were acquired on a GE-Signa 1.5T using an echoplanar sequence (40 directions, TE=70 ms; TR=8800 ms; 2*1.8*1.8 mm3; b=1500 s/mm2). We used a whole-brain Tract-Based Spatial Statistics method. Firstly, whole brain FA values were compared between ASD and TD children controlling for age. Subsequently, whole brain correlation analysis was performed between normalized DTI images and the number of fixations to the eyes. For both analyses general linear model framework within FSL was used.
Results: Compared with the TD group, the ASD group had significantly reduced FA values ($p < 0,05$, corrected) in the fronto-temporo-parietal circuit, in particular in the right arcuate fasciculus, which connects frontal to temporal regions, known to be important for social perception and cognition. Moreover, the results for ASD children showed a significant positive correlation between FA values and number of fixations in the eyes in widespread clusters including the entire bilateral arcuate fasciculus. Interestingly, we found a significant interaction between groups and number of fixations in the eyes ($p <0,05$, uncorrected), localised in the right anterior temporal pole. In this anterior temporal region, ASD FA values strongly correlate with the number of fixations in the eyes whereas TD children FA values seem to be constant independently of the eye fixation.
Conclusions: The present study showed differences in WM connectivity between ASD and TD children, particularly in temporal regions. In addition, for the first time to our knowledge, we describe a significant correlation between the anatomical brain connectivity within temporal regions and an objective measure of visual social perception. Interestingly, taken together these results point to common temporal abnormalities across the autism spectrum.

35 **141.035** Associations Between White Matter Diffusion Properties and ASD Impairments: A Tract-Based Spatial Statistics Study

C. Buckless[1], *D. Crocetti*[2], *N. Wymbs*[2,3] *and S. H. Mostofsky*[2], *(1)716 North Broadway, Kennedy Krieger Institute, Baltimore, MD, (2)Kennedy Krieger Institute, Baltimore, MD, (3)Neurology, Johns Hopkins University, Baltimore, MD*

Background:
Autism spectrum disorder (ASD) has often been characterized as a disorder of connectivity. Studies have revealed white matter anomalies across a wide range of networks including those commonly associated with ASD such as motor and social networks. Diffusion tensor imaging (DTI) has been used to investigate structural connectivity across major white matter pathways. In an effort to shed light on the inconsistent and widespread findings from prior studies, we opted to utilize an unbiased approach for localizing anomalous regions of white matter connectivity in children with ASD. This study employed tract-based spatial statistics (TBSS), a non-hypothesis driven approach of the whole brain rather than localized regions and/or networks.
Objectives:
To isolate differences within FA and MD and symptom severity between children with ASD and typically developing (TD) children within major white matter connections of the whole brain.
Methods:
Diffusion weighted imaging was acquired on 50 children with ASD and 50 TD children aged 8-12 years. Groups were balanced for sex, age and cognitive ability. All children were right handed. TBSS was used to create a skeleton of major white matter tracts. A whole brain voxel wise analysis was performed to identify areas of significant difference within the white matter skeleton between groups for fractional anisotropy (FA) and mean diffusivity (MD). Threshold-free cluster enhancement was used to control for multiple comparisons. Atypical white matter regions in ASD were localized using a standardized whole brain atlas. Pearson's correlations were used to examine associations between MD and symptom severity.
Results:
Preliminary analysis from TBSS revealed widespread increased MD in children with ASD as seen in Figure 1. When these significant networks are overlaid with the standardized whole brain atlas, findings were localized to 39 of the 90 regions; all but 10 of these 39 regions lie in the left hemisphere. Pearson's correlation further revealed a positive correlation in children with ASD between the MD and ADOS communication score in 10 regions with only two within the right hemisphere. These regions included the left body of the corpus callosum (p=0.045, r=0.285), left cuneus (p=0.018, r=0.334), left lingual gyrus (p=0.017, r=0.335), left precentral gyrus (p=0.049, r=0.279), left inferior occipital gyrus (p=0.041, r=0.290, left middle occipital gyrus (p=0.004, r=0.404), left posterior thalamic and optic radiation (p=0.020, r=0.327), left superior corona radiate (p=0.038, r=0.294), right angular gyrus (p=0.020, r=0.327), and right middle occipital gyrus (p=0.010, r=0.361). No differences in FA were observed.
Conclusions:
Consistent with prior findings, we found that children with ASD show increased MD in major white matter regions including but not limited to motor and social networks predominately within the left hemisphere. This left lateralization is supported by several studies have found networks including motor and social networks to have decreased FA and increased MD in children with ASD. Increased MD in children with ASD is associated with increased impairment in communication including functional, social and gestural communication as measured by the ADOS communication score.

36 **141.036** Biological Sex Modulations on Cortical Thickness in Autism Spectrum Disorder: An Analysis of Autism Brain Imaging Data Exchange II

***A. K. Azeez**, X. Di and B. Biswal, Biomedical Engineering, New Jersey Institute of Technology, Newark, NJ*

Background: There is a higher prevalence of males diagnosed with autism spectrum disorder (ASD) than females. This disproportionality in pathology is a question of great interest, but it is still largely unknown on the underlying neural basis of the sex differences. Large scale data sharing, such as ABIDE (Autism Brain Imaging Data Exchange) has enabled the study of sex differences in brain structures and functions (Di Martino et al., 2014). Analyses of ABIDE I data have shown similar expanded gray matter volumes in bilateral temporal lobe in females and males (Di and Biswal, 2016), and sex-dependent gyrifications in the ventromedial prefrontal cortex (Schaer et al., 2015). With the latest release of ABIDE II, we aimed to examine sex modulations on cortical thickness alterations in children with ASD.
Objectives: To determine if there exist sex-dependent or sex-independent brain structural alterations in children with ASD compared with typically developing (TD) children.
Methods: A total of 552 subjects were used from ABIDE II, with sites that have at least 2 females with ASD. Subjects younger than 20 years old and with those with a full scale IQ greater than 70 were included. Exclusions taken into account, leave us with ASD pool of 237 children (42 females) and 315 TD children (115 females). With a 2 (diagnosis) by 2 (sex) design, we examined whether there are brain alterations in ASD compared with TD that are modulated by sex (a diagnosis by sex interaction) or similar in both sexes (a diagnosis main effect).
T1 weighted MRI (magnetic resonance imaging) images were analyzed using FreeSufer. It performs skull stripping, gray-white matter segmentation, and cortical thickness, a measure of the distance between the white matter and pial surfaces. A 15 mm^2 Gaussian smoothing was applied. Using FreeSufer's Query, Design, Estimation, Contrast (QDEC) application a 2 x 2 factorial design was created, with diagnosis and gender as factors, and age, IQ, and site of scan serving as cofactors. Statistical analysis was done for each hemisphere. Clusters are initially threshold at $p < 0.01$ to find clusters of interest, followed by Monte Carlo cluster-level multiple comparison with $p < 0.05$.
Results: One region in the right lateral occipital cortex revealed a diagnosis by sex interaction (Figure 1A) (cluster size = 2171.66 mm^2, Talairach coordinates: 45.1, -72.2, 6.5). In addition, the anterior cingulate cortex in the left hemisphere showed reduced cortical thickness in the ASD group compared with the TD group (Figure 1B) (cluster size = 1631.33 mm^2, Talairach coordinates: 11.5, 31.0, 17.4).
Conclusions: We identified sex-dependent cortical thickness alterations in ASD in the right occipital cortex, which may relate to sex differences in sensory processing in ASD. Sex-dependent cortical thinning was also observed in the anterior cingulate cortex. Both clusters were not reported in studies using ABIDE I data (Di and Biswal, 2016; Haar et al., 2014; Schaer et al., 2015). It may due to sampling variability, and suggests that there may be large heterogeneity in ASD samples. Further studies are needed to examine consistency and heterogeneity of results from ABIDE I and II.

37 **141.037** Brain Enlargement Persists through Adolescence in ASD, but Is Not Predicted By Clinical Severity

***L. D. Yankowitz**[1,2], J. D. Herrington[3], J. Pereira[4], B. E. Yerys[5], J. Pandey[4] and R. T. Schultz[4], (1)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadlephia, PA, (2)Department of Psychology, University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Center for Autism Research/CHOP, Philadelphia, PA*

Background: Converging evidence indicates that toddlers and early school age youth with Autism Spectrum Disorders (ASD) have larger brains than Typically Developing Controls (TDC). It remains unclear, however, if this enlargement persists beyond early development or whether there is later a period of arrested brain growth in ASD such that group differences disappear by adolescence or adulthood. Unfortunately, a majority of studies on this topic may be underpowered to detect the expected effects. Even well-powered studies are also often confounded by failure to match groups on characteristics correlated with brain volume (age, sex-ratio, and IQ). While toddlers with ASD have larger brains, there is limited evidence of a correlation between brain volume and ASD symptom severity. This is puzzling given reported group differences.
Objectives: We seek to determine, using a large, well-characterized single-site sample: 1) whether there is a persistent brain enlargement in ASD from childhood through early adulthood, and 2) whether volume difference is related to ASD severity.
Methods: Â A total of 477 individuals with (N=254) and without ASD (N=223) aged 6-25 (mean=13±3.79) completed a structural MRI study. The sample included a large number of females (N=102) and spanned a wide IQ range (47-158).Â This is perhaps the largest structural MRI study of ASD to date conducted with a single MRI scanner and sequence. High-resolution T1-weighted anatomical MRI images were examined for group differences in total brain, ventricular, gray, and white matter volumes. ASD severity was assessed with the Social Responsiveness Scale – 2 (SRS-2), the ADOS-2 calibrated severity score, and the Social Communication Questionnaire (SCQ).
Results: Â Total brain, gray, white, and ventricular volumes were larger in the ASD group (effects of diagnosis partial η2=0.06, 0.07, 0.03, and 0.04, respectively, all ps<0.001, between-group percent differences=2.7, 2.9, 2.4, and 19.5%), with no interactions between diagnosis and age or sex. However, there were significant interactions between diagnosis and IQ, such that normative positive correlations of IQ and brain volume are absent in ASD. When controlling for age, sex, and IQ, neither ADOS severity score, the SRS, nor the SCQ significantly predicted brain volume within the ASD group.
Conclusions: These results clarify our understanding of ASD brain size at different ages, showing that brain enlargement persists into adulthood. However, the magnitude of the ASD volumetric enlargements is greatest for those with lower IQs. The absence of volume by IQ correlations in ASD suggests that the cognitive advantages typically conferred by increased brain volume are absent in ASD. Importantly, the failure to find within-ASD correlations with disorder severity concurrent with the categorical between-group brain volume difference suggests that brain size enlargement might not be related to the core features of ASD per se, but rather is incidental to having ASD. This suggests that increased brain volume is not an underlying source of ASD phenotypic differences, which might instead be related to cortical microstructure or connectivity differences. Alternatively, the absence of a correlation between brain size and ASD severity might indicate that our putative severity metrics fail to capture important aspects of ASD heterogeneity.

38 **141.038** Brain Network Organization Correlates with Autistic Features in Preschoolers with Autism Spectrum Disorders and Their Fathers

L. Billeci[1], *S. Calderoni*[2], *A. Lagomarsini*[3], *E. Conti*[4], *A. Narzisi*[2], *C. Gesi*[3], *C. Carmassi*[3], *L. Dell'Osso*[3], *G. Cioni*[1,3], *F. Muratori*[1,3] *and A. Guzzetta*[1,3], *(1)IRCCS Stella Maris Foundation, Pisa, Italy, (2)University of Pisa – Stella Maris Scientific Institute, Pisa, Italy, (3)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, (4)Department of Sciences for Health Promotion and Mother and Child Care "G. D'Alessandro", University of Palermo, Palermo, ITALY*

Background:
Autism Spectrum Disorders (ASD) are neurodevelopmental conditions characterized by an abnormal brain connectivity. Given its highly heritable origin, first-degree relatives could show a set of ''sub-threshold'' features resembling milder manifestations of ASD (broader autism phenotype –BAP). There is great interest in evaluating whether BAP characteristics extend also to neuroanatomical connectivity of first-degree relatives of ASD probands. A powerful tool for the investigation of this topic is Diffusion Tensor Imaging (DTI) technique that, for the first time, was used in parents of individuals of ASD.
Objectives:
We aimed to investigate the correlation of the structural brain network: (a) with the autistic traits in fathers and (b) with the severity of ASD in their probands. We recruited only fathers since, according to the literature, they generally have a higher probability of expressing BAP traits.
Methods:
16 ASD child-father dyads were recruited. Autism severity in children (all males, age: 1.5-5.2 y) was evaluated by ADOS calibrated severity score (ADOS-CSS). Autistic traits in fathers were assessed with the Autism-Spectrum Quotient (AQ). Structural parcellation was obtained. After pre-processing of DTI data, fiber orientation distribution was estimated using constrained spherical deconvolution. Anatomically-constrained tractography was obtained and number of streamlines weighted connectomes were generated. Global measures (global efficiency, transitivity, characteristic path length and small-world propensity) and local measures (local efficiency - EL - and clustering coefficient - CC) were computed. A general linear model was performed to evaluate correlations between network and clinical measures.
Results:
No significant correlations with global measures were found. In children, ADOS-CSS positively correlated with EL of left Paracentral Lobule (p=.019) and left Superior Temporal Gyrus (p=.037) and CC of left Cingulate Cortex (p=.02). In fathers, total AQ negatively correlated with CC of left Transverse temporal cortex (p=.04). "*Attention switching*" negatively correlated with EL and/or CC of bilateral Superior Frontal Gyrus (left: p=.15, p=.015; right: p=.007, p=.005), left Inferior Frontal Gyrus (p=.01; p=.01), bilateral Middle Frontal Gyrus (left: p=.038, p=.013; right: p=.009, p=.004), left Frontal Pole (CC: p=.04), left Orbitofrontal Cortex (p=.006, p=.01), left Lateral Occipital Cortex (p=.025, p=.008;), left Postcentral Gyrus (p=.032, p=.049), bilateral Cingulate Cortex (left: p=0.1, p=.015; right: p=.016, p=.016), right Supramarginal Gyrus (p=.038, p=.03), right Precuneus (p=.022, p.014), right Cuneus (p=.016, p=.026), right Superior Temporal Gyrus (CC: p=.027), right Inferior Temporal Gyrus (p=.039), and right Insula (p=.024, p=.034). "*Imagination*" negatively correlated with CC of Nucleus Accumbens (p=.02). "*Attention to details*" positively correlated with EL of left Inferior Frontal Gyrus and (p=.026) and "*communication"* with EL and CC of right Superior Frontal Gyrus (p=.024, p=.024).
Conclusions:
Significant correlations were found between local network measures and autism severity in ASD children and autistic traits in fathers. In fathers correlations were mostly negative indicating an association of that autistic phenotype with the decrease in local efficiency. Conversely, in ASD children all correlations were positive in line with the "early over-connectivity" theory of ASD. Interestingly, some regions of impairment overlap between the two groups suggesting an intergenarational transmission of neural substrates. Overall, these results may help elucidating the neurostrctural endophenotype of ASD.

39 **141.039** Cerebellar Volume in Autism: Meta-Analysis and Analysis of the Abide Cohort

R. Toro[1], ***N. Traut***[2], *T. Bourgeron*[3], *A. Beggiato*[4], *A. L. Paradis*[5], *L. Rondi-Reig*[5] *and R. Delorme*[2], *(1)Institut Pasteur, Paris, FRANCE, (2)Institut Pasteur, Paris, France, (3)Neuroscience, Institut Pasteur, Paris, France, (4)Institut Pasteur, Paris, Paris, FRANCE, (5)Université Pierre et Marie Curie, Paris, France*

Background: Many reports suggest that cerebellar dysfunctions may be implicated in autism spectrum disorders (ASD). The cerebellum is a heavily folded region of the rombencephalon, with a number of neurons comparable to that of the neocortex. The cerebellum has been traditionally involved in the performance of precise motor behavior, but there is now evidence for its involvement in cognitive and affective functions as well.
Objectives: Our aim was to objectify a possible alteration of the cerebellar volume in ASD.
Methods: We looked for a difference of mean or variance between the cerebellar volume distributions of ASD and controls. We first performed a meta-analysis of the literature by looking for studies reporting cerebellar MRI volume measurement on ASD patients and typical controls. We used the PRISMA guidelines for the selection of articles. We combined the effect sizes using the random effects model. We also looked for possible factors of variability across studies by making a meta-regression on age and intelligence quotient (IQ). We then tried to replicate the results of the meta-analysis by analyzing the cerebellar volume segmented with FreeSurfer from the ABIDE cohort. We analyzed the effect of the variables group, site, age, IQ and sex on cerebellar volume by both a linear model approach and a meta-analysis approach.
Results:
Meta-analysis: 16 studies met the criteria for inclusion (635 patients and 424 controls). Although the studies were highly heterogeneous (I^2=72%, $p<0.0001$), we found a larger cerebellar volume in individuals with ASD compared with typical controls (Cohen's d=0.32, 95% confidence interval: [0.08; 0.56]; p=0.0089). Individually, the mean statistical power that the studies had to detect such an effect size was only 22.7%. We also found a significative negative impact of age on Cohen's d (-0.041 year-1, 95% confidence interval: [-0.065; -0.016]), suggesting a faster cerebellar volume decrease in individuals with ASD during adulthood. Age and IQ were not the only factors of heterogeneity between studies, as the residual heterogeneity was still statistically significant (I^2=49%, p=0.016) after covarying with these factors. We did not find a statistically significant difference in the variance between individuals with ASD and typical controls (combined log-variance ratio=0.19, 95% confidence interval: [-0.12; 0.50]). ABIDE: After quality control, 341 patients and 360 controls were retained. The mean cerebellar volume did not differ significantly between individuals with ASD and controls. There was a strong impact of the site on the measured volume. We were able to see evidences for effects of age IQ and sex on cerebellar volume, but none of the effects were statistically significantly different between groups.
Conclusions: The MRI analyses did not confirm the results of the meta-analysis. These discrepancies could be explained by a higher heterogeneity between the studies of the meta-analysis than in the sites of ABIDE, but could also result from methodological biases. Our results call into question the validity of results obtained from small, underpowered cohorts, and underline the utility of data sharing and collaborative work to obtain larger samples.

40 **141.040** Chandellier Cells Modify the Balance of Excitation / Inhibition in Autism

V. Martinez Cerdeno[1], *J. Ariza Torres*[2] *and E. Hashemi*[3], *(1)UC Davis, Sacramento, CA, (2)Pathology and Lab Medicine, UC Davis, Sacramento, CA, (3)Uc Davis, Sacramento, CA*

Background: Â An interneuron alteration has been proposed as a source for the modified balance of excitation / inhibition in the cerebral cortex in autism. We previously demonstrated a decreased number of parvalbumin (PV)-expressing interneurons in prefrontal cortex in autism. Our most recent data indicates that a specific type of PV-expressing neuron is altered in autism, the Chandellier (Ch) cell. Chandellier cells are interneurons that generate fast-spiking action potentials and synchronize the activity of numerous pyramidal cells through rhythmic inhibition. Chandellier cells innervate the axon initial segment of pyramidal cells – in contrast to the rest of interneuron input that takes place on dendrites. As a consequence, the loss of small numbers of Ch cells could critically alter pyramidal neuron output and impair cerebral cortex function.
Objectives: Â As discussed in our previous publication investigating PV+ interneurons in the autistic neocortex (Hashemi et al., 2016), the decreased number of PV+ Ch cells we detected in in autism may represent an actual decrease in cell number, on the other hand it may represent an apparent decrease in cell number resulting from reduced PV protein levels in Ch cells. To determine if the number of Ch cells, rather that the expression of PV by Ch cells, is altered in autism, we quantified Ch cartridges in autism and control tissue. If the number of Ch cells is decreased we also expect to find a decrease in the number of Ch cartridges.
Methods: We collected prefrontal BA9, BA46, and BA47 in samples obtained from 10 autism, 10 autism with seizure, and 10 control age-matched cases. The tissue was obtained from the Autism Tissue Program (ATP), currently known as Autism BrainNet, and the UC Davis Medical Center. We cut the tissue and performed immunostaining for GAT1 that clearly labels cartridges. We quantified the number of cartridges in 3 mm wide sections of cortex, and statistically compared data between groups.
Results: Our preliminary data indicate that in area BA 46 there is a decrease in the number of GAT1-cartriges in the autism and the autism with seizure groups when compare to the control group.
Conclusions: Here we demonstrated that both Ch cells and also their terminal axons, the Ch cartridges, are numerically decreased in autism. A decrease in the number of Ch cells could result from different factors including 1) decreased production of Ch cells by precursor cells during prenatal development, 2) increased cell death among Ch cells during development, or 3) altered migration of Ch cells to their final destination in the cerebral cortex. This finding expand our understanding of GABAergic system functioning in the human cerebral cortex in autism, which will impact translational research directed towards providing better treatment paradigms for individuals with autism.

41 **141.041** Changes in Local Gyrification Index Across Childhood and Adolescence in Autism Spectrum Disorder (ASD)

J. S. Kohli[1], *R. A. Carper*[1], *C. H. Fong*[1] *and R. A. Müller*[2], *(1)Psychology, San Diego State University, San Diego, CA, (2)Brain Development Imaging Laboratory, Department of Psychology, San Diego State University, San Diego, CA*

Background:
A large body of evidence from volumetric MRI supports an atypical trajectory of early cerebral overgrowth in Autism Spectrum Disorder (ASD) followed by abnormally slow growth. Comparatively few studies have examined local patterns of gyrification, and the relationship between gyrification and measures of cortical thickness (CT) and surface area (SA) remains poorly understood. Developmentally, gyrification is thought to be influenced by mechanical forces resulting from differential rates of early cortical expansion (radial and tangential expansion, differences in laminar expansion). Atypical gyrification patterns may therefore reflect the timing of brain growth abnormalities in ASD and elucidate the history of early developmental disturbances.
Objectives:
In an earlier study, we found that the local gyrification index (lGI) decreased with age more rapidly in an ASD than a TD comparison group. The current study sought (1) to replicate these findings in an independent sample, and (2) to investigate the relationships between CT, SA, and lGI.
Methods:
T1 weighted MRI sequences (1mm^3) were downloaded from the Autism Brain Imaging Data Exchange for 137 right-handed males aged 7–18 years (60 ASD, 77 TD; all from New York University). FreeSurfer (v5.3.0) was used to obtain measures of CT, SA, and lGI. Following quality assurance and group matching on age and non-verbal IQ, 31 ASD and 31 typically developing (TD) participants were included in analyses. A general linear model was used with group and age (continuous) as predictors and Social Responsiveness Scale (SRS) scores as a correlate. Correction for multiple comparisons used Monte Carlo null-z simulations.
Results:
For lGI, significant diagnosis-by-age interactions were found bilaterally in rostral middle frontal gyrus, in left inferior frontal gyrus (pars triangularis), and in right precuneus. Whereas lGI was relatively stable across age in the TD group, the ASD group exhibited a significantly greater negative slope (decreasing lGI with age). A main effect of group (ASD<TD) was also found in left medial orbitofrontal and right inferior parietal clusters. For CT, a significant group effect (ASD>TD) was found in a left lateral occipital cluster. No significant effects were observed for SA. Correlation analyses in the ASD group revealed that greater social impairment (higher total SRS) was associated with lower lGI bilaterally in fusiform clusters, after controlling for age.
Conclusions:
Declining lGI with age is often reported in typical adolescence, and here, regions of steeper age-related decrease were observed in ASD compared to TD participants in frontal and parietal lobes. A similar interaction was found in our earlier study on an independent sample, in partially overlapping cortical regions, largely within the frontal lobe. Together, these findings indicate an atypical developmental trajectory for frontal lGI in ASD. Correlations between fusiform lGI and SRS add additional support to the functional relevance of this morphometric measure. Further comparisons will be presented to directly assess associations between lGI, CT, and SA in larger samples.

42 **141.042** Cortical Thickness and ASD in 22q11.2 Deletion Syndrome; An International Collaboration

M. Gudbrandsen[1,2]*, E. Daly*[2]*, C. M. Murphy*[2]*, L. Kushan*[3]*, D. Sun*[3]*, D. G. Murphy*[2]*, C. Ecker*[4]*, C. Bearden*[3] *and M. C. Craig*[5]*, (1)The Sackler Institute for Translational Neurodevelopmental Sciences, IoPPN, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Psychiatry and Biobehavioral Sciences, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, CA, (4)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychiatry, Goethe-University Frankfurt am Main, Frankfurt, Germany, (5)IoPPN, London, UNITED KINGDOM*

Background: Individuals with syndromic forms of autism spectrum disorder (ASD) provide a unique opportunity to understand specific genetic risk mechanisms.Â For example, individuals with 22q11.2 Deletion Syndrome (22q11DS) are at significant risk (30–50%) of developing ASD (Schneider et al., 2014). The neurobiological mechanisms contributing to this increased risk are unknown – but likely include genetically determined differences in particular developmental pathways. We and others previously reported that individuals with ASD have significant differences in cortical thickness (CT) (e.g. (Ecker et al., 2013). CT is important because it results from distinct neurodevelopmental pathways and is a proxy measure of dendritic arborization and pruning.
Objectives: We wished to establish whether variation in CT is associated with comorbid ASD in 22q11DS individuals.
Methods: We included 73 individuals with 22q11DS (23 males and 34 females), aged between 6 and 33 years (mean age=14, SD=6). Of these, 36 individuals met diagnostic criteria for ASD based on the ADI-R & ADOS. The resulting two groups (i.e. 22q11DS+ASD & 22q11DS-ASD) did not differ significantly on age or IQ. Participants underwent structural T1-weighted magnetic resonance imaging (MRI) at the Institute of Psychiatry, Psychology and Neuroscience, London & The Semel Institute for Neuroscience, UCLA. CT was measured using FreeSurfer (http://surfer.nmr.mgh.harvard.edu). Vertex-wise statistical analysis of CT measures were estimated by regression of a GLM including group as categorical fixed effect factor. A random-field-based cluster-threshold (p<0.05) was applied to correct for multiple comparisons (Worsley 1999).
Results: Individuals with 22q11DS+ASD, when compared to 22q11DS-ASD, had significantly increased cortical grey matter thickness in 2 right hemisphere brain areas; the inferior frontal gyrus (BA47) & postcentral gyrus (BA43)(Fig. 1).
Conclusions: This is the first known study to indicate that absence or presence of comorbid ASD is associated with genetically determined variation in cortical morphometry. Future research is required to determine how genetic variation within the deleted region determines outcome.

43 **141.043** Cross-Disorder Comparison of Idiopathic Autism, Fragile X, Angelman Syndrome, and Typical Development: An MRI and DTI Study of Brain Structure

M. D. Shen[1]*, M. Styner*[1]*, M. R. Swanson*[1]*, S. H. Kim*[1]*, B. Philpot*[1,2]*, J. Piven*[1] *and H. C. Hazlett*[1]*, (1)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)UNC Neuroscience Center; Department of Cell Biology & Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: Brain abnormalities are common in autism and related neurodevelopmental disorders, but no study has directly compared the brain structure of children with idiopathic autism, Angelman syndrome, Fragile X, and typical development.
Objectives: We conducted an MRI and diffusion tensor imaging (DTI) study of school-age children with related neurodevelopmental disorders to determine the extent and specificity of neural alterations and their associations with clinical symptoms.
Methods: Participants were n=11 children with Angelman syndrome (AS; 5 female), n=19 with Fragile X syndrome (FXS; all male), n=31 with autism spectrum disorder (ASD; 1 female), and n=31 age-matched typically developing controls (TD; 3 female). MRIs were conducted at 4-12 years of age, including T1- and T2-weighted ($1mm^3$ voxels) and diffusion-weighted scans ($2mm^3$ voxels; 45 directions). Tissue segmentation yielded cerebral white matter (WM), grey matter (GM), and total cerebral volume (TCV=WM+GM). Diffusion tensor tractography of specific fiber tracts yielded fractional anisotropy (FA), axial diffusivity (AD), and radial diffusivity (RD). Analysis of covariance tested for group differences in dependent variables (WM, GM, TCV, DTI measures) while accounting for differences in age and sex; hierarchical multiple regression tested associations between fiber tracts of interest and behavioral data, while testing for effects of age and sex.
Results: There was a significant main effect of group on WM volume ($F_{3,87}$=21.74, p<.0001), with the AS group having significantly smaller WM volume compared to all other groups (p<.0001), and the FXS group having significantly larger WM volume compared to all other groups (p<.05) (**Fig. 1**). There was a significant main effect of group on GM volume ($F_{3,87}$=17.75, p<.0001), with the AS group having significantly smaller GM (p<.0001), but there were no significant differences between the other groups. The AS group had significantly smaller TCV ($F_{3,87}$=22.36, p<.0001). **Figure 1** illustrates the least-squares means, adjusted for age and sex. The AS group showed a disproportionate reduction in WM volume (32% smaller vs. TD group) compared to GM volume (18% smaller vs. TD group).
Following this finding of WM reduction in children with Angelman syndrome, tractography was performed in several WM tracts including the corpus callosum, corticospinal tract, and corticothalamic tracts. In each of these tracts, the AS group showed significantly lower FA (p<.0001) and higher RD (p<.0001) compared to TD controls. In the AS group, higher RD in these motor tracts was significantly associated with poorer motor ability (r=-.58, p<.05) (**Fig. 2**).
Conclusions: Differences in white matter are evident in monogenic syndromes such as Angelman syndrome and Fragile X, even using coarse measures such as overall WM volume. However, more detailed attempts must be made to tease apart the heterogeneity of idiopathic autism. DTI, for example, has been previously shown to identify connectivity alterations associated with specific clinical symptoms in ASD and FXS, and here we show associations between corticospinal connectivity and motor ability in Angelman syndrome, a disorder marked by pervasive and disabling motor deficits. DTI analyses of the ASD and FXS group are underway and will be presented along with associations with repetitive behaviors, anxiety measures, and social and communicative ability.

44 **141.044** Developing White Matter Microstructure Networks in Autism Spectrum Disorders

D. C. Dean[1], *B. G. Travers*[1], *J. Villaruz*[1], *A. A. Freeman*[1], *N. Adluru*[1], *B. A. Zielinski*[2], *M. D. Prigge*[2], *P. T. Fletcher*[2], *J. S. Anderson*[2], *E. D. Bigler*[3], *N. Lange*[4], *J. E. Lainhart*[1] *and A. L. Alexander*[1], *(1)University of Wisconsin - Madison, Madison, WI, (2)University of Utah, Salt Lake City, UT, (3)Brigham Young University, Provo, UT, (4)McLean Hospital, Cambridge, MA*

Background: Brain imaging findings in children with autism spectrum disorder (ASD) suggest the disorder is associated with altered brain development and disrupted structural and functional brain "connectivity." Thus, while white matter microstructure is fundamental to such brain connectivity, developmental disruptions to networks of white matter may provide a core neurobiological feature of ASD. Diffusion tensor imaging (DTI) is an integral neuroimaging technique to assess the white matter microstructure and has been influential to the study of white matter alterations in ASD. However, while vast white matter differences have been reported to exist in ASD, these differences are often reported at the regional level. Thus, information can only be gleaned in regards to the evaluated region of interest. As distinct white matter regions work harmoniously with others, a more informative approach may be to study the patterns and characteristics of white matter networks in ASD.
Objectives: We utilized a data-driven technique to identify underlying white matter networks in a large sample of ASD individuals and subsequently characterized the developmental trajectories of these white matter networks.
Methods: Participants for this study consisted of 100 males with ASD between 3 and 39 years of age. DTI data were acquired from each participant, images were corrected for distortion and head motion and maps of fractional anisotropy (FA), were calculated. Diffusion tensors were spatially aligned to a study-specific template and the resulting transformations were used to bring each individual's FA map into spatial alignment. Spatially aligned FA maps were subsequently smoothed with a 5mm full-width-at-half-maximum kernel and concatenated into a single 4D image file. Spatial independent component analysis (sICA) was then performed using the MELODIC tool (http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/MELODIC), providing spatially independent networks. Trajectories of these networks were examined using mixed-effects models using R.
Results: A total of 57 spatially independent networks were found to exist, though 11 of these were observed to be associated with artifacts (errors resulting from image misregistration or motion). The remaining 46 components were visually assessed to correspond to biologically plausible bilateral and unilateral white matter regions spanning both individual and multiple white matter tracts. Mixed effects modeling of FA from these networks show that FA significantly (p<0.05, Bonferroni corrected) changes across the examined age range, while the timing of age-related changes are distinct among the different networks.
Conclusions: Our results suggest that measures derived from diffusion imaging combined with data-driven analysis techniques, such as sICA, may be used to parcellate the brain into biologically meaningful networks. Future analyses will examine whether the developmental trajectories of these white matter networks relate to the autism severity measures. We will additionally compare the developmental patterns from these distinct networks to those estimated from individuals with typical development.

45 **141.045** Diffusion Tensor Imaging in Unaffected Siblings of Individuals with Autism: A Pilot Study Using Tract-Based Spatial Statistics

E. Lecarie[1], *J. Lei*[1], *H. Turner*[1], *D. Yang*[2,3], *P. E. Ventola*[1], *D. G. Sukhodolsky*[1], *K. A. Pelphrey*[4] *and R. J. Jou*[4], *(1)Yale Child Study Center, New Haven, CT, (2)Children's National Health System, Washington, DC, (3)Autism and Neurodevelopmental Disorders Institute, The George Washington University, Washington, DC, (4)Yale University, New Haven, CT*

Background: Numerous studies have been published using diffusion tensor imaging (DTI) to demonstrate white matter abnormalities in autism spectrum disorder (ASD). However, very few studies assess whether white matter abnormalities exist in unaffected siblings (UAS) of those with ASD. Among those published, including a recent report from the authors of this abstract, samples of modest size included both boys and girls in the same analysis. Consequently, findings may be influenced by the structural variability associated with gender. To address this limitation, the authors compare newly-recruited male UAS with stringently-matched control participants.
Objectives: To evaluate whether previously reported intermediate neuroendophenotypes in mixed-gender samples of UAS can be replicated in a new male-only group of participants, who were individually matched to typically developing males on age and IQ.
Methods: Participants included 12 pediatric male UAS (age in months: M = 129.99, SD = 41.68, Range = 64.9-203.8; Full-scale IQ: M = 112.92, SD = 11.21, Range = 96-135) and 12 pediatric male control participants (age in months: M = 132.47, SD = 45.7, Range = 62.9-197.57; Full-scale IQ: M = 109.83, SD = 14.62, Range = 89-141).Â T1-weighted and diffusion-weighted MRI (directions = 30 and b0 = 5) were acquired using a 3-Tesla scanner.Â FMRIB Software Library (FSL) was used to process/analyze diffusion-weighted data and compute the following WM microstructure metrics: fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD) and radial diffusivity (RD).Â Voxel-wise analysis of multi-subject diffusion data was conducted using FSL's Tract Based Spatial Statistics (TBSS). Areas of significant difference were computed using Threshold-Free Cluster Enhancement (TFCE) and displayed as p-value images, where $p < 0.05$ corrected for multiple comparisons across space.
Results: Â There were no statistically significant differences in age [$t(22) = 0.14$, $p = 0.89$] or IQ [$t(22) = -0.58$, $p = 0.57$]. There were no statistically significant group differences in FA, MD, AD, or RD when UAS were compared to control participants. Trends toward statistical significance were also not observed in comparison of the aforementioned WM microstructure metrics.
Conclusions: Unlike previous mixed-gender comparisons between UAS and control participants, this preliminary male-only comparison does not support the presence of an intermediate neuroendophenotype in male UAS. Lack of statistically significant differences in the UAS and control comparison does not preclude that aberrant WM microstructure exists in UAS males, especially if the effects are small. Future studies should investigate whether current findings replicate in larger studies with closely-matched comparison groups.

46 **141.046** Examination of Anterior-Posterior Connectivity in Children with Autism Spectrum Disorder

A. Crippa[1,2,3], *D. Crocetti*[2], *K. Hirabayashi*[4] *and S. H. Mostofsky*[2], *(1)University of Milano-Bicocca, Milano, Italy, (2)Kennedy Krieger Institute, Baltimore, MD, (3)Scientific Institute, IRCCS Eugenio Medea, Bosisio Parini, Italy, (4)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD*

Background: It has been hypothesized that the heterogeneous phenotype of Autism Spectrum Disorders (ASD) could implicate a greater likelihood of abnormalities in the connectivity between different neural networks rather than localized alterations. In particular, previous studies have provided evidence of underconnectivity in ASD, with particular respect to reduced long-range connectivity between frontal lobes and posterior brain regions (Just et al., 2004, Villalobos et al., 2005, Mostofsky et al., 2009). Structural connectivity can be effectively assessed in vivo using magnetic resonance techniques like diffusion tensor imaging (DTI). Exploring the hypothesis of an anterior-posterior underconnectivity in ASD might provide useful insight into the mechanisms of social communication, given the key role of these pathways for language, praxis, and imitation.
Objectives: To investigate whether a well-characterized group of high-functioning children with ASD would demonstrate reduced white matter integrity, denoted by reduced FA and increased MD, in inferior fronto-occipital fasciculus (IFOF), inferior and superior longitudinal fasciculus (ILF and SLF, respectively). On the basis of established findings for impairments in language and praxis in ASD, we further hypothesized that the findings would be more prominent in the left hemisphere.
Methods: Fifty-two children with ASD, ages 8 through 12 years, and fifty-four typically developing (TD) controls matched by sex, age, and intellectual reasoning ability participated to the study. DTI images were acquired with a single-shot, echo-planar diffusion-weighted sequence. Two runs were collected in each subject, with 32 gradient directions (b = 700 s/mm3) and one b0 in each run. Sixty 2.2-mm axial slices were acquired for each volume, with 0.8 mm in-plane reconstructed resolution. DTI data were analyzed using Automated Fiber Quantification toolbox, which employs deterministic fiber tracking for quantifying diffusion profiles along ten nodes for each reconstructed white matter tract. Diagnostic effects on fractional anisotropy (FA) and mean diffusivity (MD) were assessed using independent t-tests for each white matter tract.
Results: Â Analyses revealed that TD children exhibited higher FA in nodes along the posterior portion of the left ILF, and the anterior segment of the right ILF (all $p<0.05$). In children with ASD, higher mean diffusivity was observed in distinct nodes along the reconstructed fiber tracts (all $p<0.05$), with the left SLF showing a significant group difference in 5 out of 10 nodes (see Fig. 1). Overall, most of the group differences were lateralized in the left hemisphere.
Conclusions: Â The present study provides evidence for alterations in diffusion along a set of major anterior-posterior fiber tracts in children with ASD. In particular, our main finding is a consistently increased diffusivity in the left SLF in children with ASD. The SLF has been known to play a role in motor functions and other "higher" functions, including language and working memory. Accordingly, consistent with our hypothesis, our findings indicate a pattern of left-lateralized white matter abnormalities. Possible extension of the present work should investigate the relationship between localized differences in diffusion properties and core features of ASD, as well as measures of language, imitation, and motor function.

47 **141.047** Head Circumference and Brain Volume Trends in Autism Spectrum Disorder

J. Crucitti[1], *P. G. Enticott*[2] *and M. A. Stokes*[3], *(1)Deakin University, Geelong, Australia, (2)Deakin University, Geelong, AUSTRALIA, (3)School of Psychology, Deakin University, Melbourne, Australia*

Background: Head circumference (HC) and total brain volume (TBV) studies have consistently concluded Autism Spectrum Disorder (ASD) diagnosis to influence head size and TBV, respectively. Yet because HC and TBV findings are usually based upon small to moderate samples, the clarity of the overall picture is lost.
Objectives: To address this issue, an atlas of HC and TBV studies has been developed, based upon and comparing studies within ASD against each other, and against studies of typically developing (TD) individuals. It was hypothesised that HC and TBV would both be enhanced by ASD diagnosis.
Methods: Criteria for inclusion in to the atlas necessitated that the authors had provided raw data, or that it could be obtained from a publication using data capture techniques (Data Thief v.III; http://www.datathief.org; Tummers, 2006). Alternatively, where only means, SDs, and sample sizes were reported, we statistically modelled the data in two ways. First, we model the data with the mean value weighted by the sample size. In a second analysis, we statistically inferred a random sample within 1 SD of the reported mean for either or both age and HC or TBV of the participant. Additionally, ANCOVA's were performed on the raw HC and TBV data, controlling for age.
Results: Nineteen HC studies (N=3,051) and 22 TBV studies (N=1,210) of participants with ASD were obtained. Twelve HC studies and 19 TBV studies of TD individuals (N=1,434) were also included. Ages ranged from 0 to 51 years. Results found loglinear fits to account for the most variance in the HC data, and second order polynomial fits to be most appropriate for TBV data. As hypothesised, ANCOVA's highlighted HC, between ages 0 and 4 years, to be greater in individuals with ASD compared to TD participants. Furthermore, TBV was larger in those with ASD compared to TD individuals between ages 1 to 4 years, 5 to 12 years, and 19 years and above. However, no significant difference in TBV was found in individuals between 13 and 18 years of age.
Conclusions: The present study supports the position that ASD diagnosis influences HC and TBV. This is the first instance where this amount of data has been collected and while examining the variance in the data, establishing the trend of HC and TBV across a substantial range of age. Nonetheless, it is apparent that the publication of raw data in the literature would be of great assistance in future evaluations of this issue.

48 **141.048** Increased Global Covariance of Cortical Volume in Children with ASD

A. Michael[1]*, C. Dougherty*[1] *and C. Zhang*[1,2]*, (1)Autism and Developmental Medicine Institute, Geisinger Health System, Lewisburg, PA, (2)Rochester Institute of Technology, Rochester, NY*

Background: Structural covariance (SC) is the correlation between structural brain features and this metric may reflect long-term developmental influences, the effect of plasticity and mutual trophic influences [1, 2]. Regions with high SC often belong to brain systems such as salience or default mode networks [3] which serve specific functions [4]. By examining SC in ASD it may be possible to determine which regions are developmentally linked and further our understanding of brain development in this disorder
Objectives: Â We aim to examine global patterns of cortical volume SC in ASD and typically developing controls (TDC) in both children (age 7–13 years) and adolescents (age 13–18 years). We aim to: 1) characterize global patterns of cortical SC in ASD and TDC 2) determine if differences in SC exist between ASD and TDC and 3) whether changes in SC occur with age.
Methods: Structural MRIs and demographic information were obtained from ABIDE [5]. We investigate SC in a cohort of right handed male subjects which consists of 64 ASD (average age ± std: 10.88 ± 1.45 years) and 75 TDC (10.67 ± 1.35 years) children and 63 ASD (15.34 ± 1.58 years) and 61 TDC (15.49 ± 1.43 years) adolescents. MRIs were preprocessed and cortical volumes were computed using FreeSurfer [6]. SC was calculated using Pearson's correlation between the 34 cortical volumes listed in Table 1 and this resulted in 2,278 pairs of inter and intra hemispheric SCs. Significant SC differences were determined between ASD and TDC for children and adolescents separately. Permutation testing was performed ($N = 10^6$) to verify results.
Results: Â Results indicate inter and intra hemispheric SC differences in ASD children and that children with ASD have higher SC than TDC for most pairs (87%) of brain regions. In adolescents this difference was not present. The median SC were as follows: ASD children: 0.59, TDC children: 0.42, ASD adolescents: 0.39 and TDC adolescents: 0.39. Highly significant ASD vs. TDC SC differences were found in children (Figure 1A) but differences were not significant in adolescents (Figure 1B) after correction for multiple comparisons. Permutation testing further validated the above result. SC pairs containing left entorhinal cortex with left rostral anterior cingulate, left fusiform, right medial orbitofrontal, and right fusiform survived Bonferroni correction ($P<2.2x10^{-5}$) in children.
Conclusions: Many of the SC pairs that survived multiple comparisons correction in children have been implicated previously in ASD. Regions such as the right fusiform and medial orbitofrontal gyri are part of the face processing network[7] and the anterior cingulate has been implicated in social impairment[8]. This study raises the possibility that SC between the left entorhinal cortex, which plays a role in memory[9], and the above regions may underlie social impairment in ASD. We report altered cortical topography (both inter and intra) in children with ASD that normalizes during development in adolescence. To our knowledge this study is the first to characterize global cortical SC differences in ASD.

49 **141.049** Mapping Developmental Trajectories of Brain White Matter from Birth to Six Months Using Diffusion Tensor Imaging: A Preliminary Study

L. Li[1]*, S. Shultz*[1]*, M. Zeydabadinezhad*[1]*, A. Klin*[2] *and W. Jones*[2]*, (1)Marcus Autism Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA*

Background: Research on brain development may provide groundbreaking insights into the identification of brain systems that underlie the development of social cognitive functions(Johnson,2005) and developmental disabilities, such Autism Spectrum Disorder (ASD)(Wolff, 2013). Diffusion tensor imaging (DTI) quantifies brain white matter microstructures and has become a prominent tool for indexing white matter development(Basser,1995).
Objectives: To reveal critical transitions in regional brain development in typically developing infants from birth to 6 months as a benchmark against which to compare atypical transitions of brain development that may be a sign or symptom of ASD.
Methods: 24 typical developing infants (mean age: 115 days (27-218 days); 6 females) were enrolled. DTI data were collected from each infant at three pseudorandom time points between birth and 6 months, yielding a total of 53 scans. Data were collected on a 3T Siemens Trio scanner with 32-channel head coil and multiband sequence(Moeller, 2010). DTI parameters are: TR/TE of 6200/74ms, a multiband factor of 2 combined with a GRAPPA of 2, FOV of 184×184, spatial resolution of 2mm isotropic, b=0/700 s/mm2, 61 diffusion directions, extra 6 of b0s in both phase encoding directions. Distortion corrected(Andersson, 2003)Â brain tensor maps from each participant were aligned to a sample-specific common space using tensor-based registration(Zhang, 2006). The John Hopkin's Neonate Atlas(Oishi, 2011) was aligned to our common space, grouped into nine brain areas and multiplied with a white matter mask (mean fractional anisotropy, FA>0.25) (**Fig.1A**). Principal Component Analysis through Conditional Expectation (PACE)(Yao, 2005)—a method designed to overcome missing values, a common problem in longitudinal infant research—was used to fit changes in FA and its derivatives over time in each brain area.
Results: Â FA increases in all brain areas from birth to 6 months (**Fig.1B**), with subcortical, cerebellum and occipital lobes having the highest FA increase during infants' first 6 months. FA change rates decrease over time (**Fig.1C**), with orbitofrontal areas showing the highest FA change rate (although its FA value is lower relative to other brain regions at birth). By month 6, rate of change in FA decreases by approximately 8.6 fold. All brain regions show negative FA accelerations at birth, especially in cortical areas, followed by a rapid decrease in acceleration toward zero. Interestingly, FA accelerations reach a plateau around 5 months of age in most cortical regions.
Conclusions: Â We identified a potential critical time period around 5 months of age, in which FA accelerations reach a plateau for the majority of brain regions. Although the exact causes of this plateau are still under investigation, possible explanations include pruning processes(LaMantia, 1990), divergent trends of FA changes in white and gray matter, and/or the development of association pathways(Dubois, 2014). This work highlights the importance of using non-parametric curve fitting techniques, such as PACE, for modeling data and their derivatives, as approaches that specify the shape of brain developmental profiles a priori may miss critical dynamic information in brain development, especially in early infancy.

50 **141.050** Motor System Integrity in Older Adults with Autism Spectrum Disorder

B. R. Deatherage[1]*, B. B. Braden*[2]*, C. J. Smith*[3]*, T. K. Glaspy*[4]*, M. K. McBeath*[5]*, A. M. Thompson*[5]*, E. Wood*[6]*, D. Vatsa*[7] *and* ***L. Baxter***[1]*, (1)Barrow Neurological Institute, Phoenix, AZ, (2)Speech and Hearing Science, Arizona State University, Tempe, AZ, (3)Southwest Autism Research & Resource Center, Phoenix, AZ, (4)Tufts University, Boston, MA, (5)Psychology, Arizona State University, Tempe, AZ, (6)Xavier Preparatory Academy, Phoenix, AZ, (7)BASIS Charter School, Scottsdale, AZ*

Background: Gait disturbance, clumsiness, and other mild movement problems are often observed in persons with autism spectrum disorder (ASD; Maurer, 1982). This study focused on brain differences that may indicate the neural basis for these motor symptoms which are common, although not ubiquitous, among individuals with ASD.
Objectives: Using magnetic resonance imaging (MRI), we examined cortical and white matter integrity in brain regions associated with motor function (motor cortex, cerebellum, basal ganglia) in a cross-sectional study comparing middle-aged (40-65 years) adults with ASD and age-matched typically developing (TD) controls. We hypothesized gray matter and white matter tracts associated with motor functioning would be smaller in middle-aged adults with ASD, as compared to TD controls. We also expected to observe reduced motor performance (slower finger tapping speed) in the ASD group as compared to their TD counterparts.
Methods: Thirteen right-handed men with ASD (Age: 49.2 (7.3); Education: 14.9 (2.7); IQ: 109.5 (14.5)) and 17 matched-TD men (Age: 49.4 (6.9); Education: 15.8 (2.6); IQ: 110.1 (11.1)) were recruited. Motor performance was measured using a finger tapping task. 3D T1 structural and diffusion tensor images were obtained using a Philips 3T scanner. FreeSurfer was used to determine gray and white matter volumes. White matter integrity was assessed via fractional anisotropy (FA), masked with each person's white matter map via voxel based morphometry in SPM8.
Results: Â The mean number of right finger taps in the allotted time was less in the ASD (47.2 (13.0)) group compared to TDs (51.6 (7.0)), but was not statistically significant. However, this is likely due to the much greater degree of variability in the ASD group compared to controls. This finding was also observed for the left finger tapping. The ASD group had smaller white matter volume for bilateral cerebellum (left; p=0.05, right; p=0.04), and brainstem white matter volume (p=0.04) compared to the TD group. There were no significant differences between ASD and TD participants for cortical or subcortical (gray matter) volume.
Conclusions: Smaller cerebellar white matter volume may account for the slower motor differences observed in older adults with ASD. Previous studies have found anatomical differences in the cerebella of younger ASD subjects (Courchesne et al., 2001), consistent with our findings of cerebellar differences. This cross-sectional study aims to extend those findings to aging adults. Interestingly, finger tapping speed was extremely variable among the ASDs, and it is possible that other factors beyond the structures examined here play a role in sustained fine motor movements.

51 **141.051** Multimodal Non-Sedated MRI during an RCT of Simvastatin in Neurofibromatosis Type 1 (NF1)-Syndromic Autism.

*M. Tziraki[1], S. Garg[2], J. Mellor[3], H. Haroon[1], L. Parkes[4], S. Williams[1], J. Keane[5], J. Green[6] and **S. M. Stivaros**[1,3,7], (1)Imaging Sciences, University of Manchester, Manchester, United Kingdom, (2)University of Manchester, Manchester, UNITED KINGDOM, (3)Computer Science, University of Manchester, Manchester, United Kingdom, (4)Division of Neuroscience and Experimental Psychology, University of Manchester, Manchester, United Kingdom, (5)Computer Science, Unversity of Manchester, Manchester, United Kingdom, (6)University of Manchester, Manchester, United Kingdom, (7)Academic Dept of Radiology, Royal Manchester Children's Hospital, Manchester, United Kingdom*

Background: Understanding neurochemical and physiological dysregulation is thought to have potential as a basis to model developmental abnormalities in autism. The most common non-invasive technique used to acquire measures of both anatomical, neurochemical and physiological parameters in the developing brain is multi-modal Magnetic Resonance Imaging (MRI). Simvastatin is an HMG-CoA reductase inhibitor.
Objectives: To assess the feasibility and results of multi-modal MRI assessment of a range of neurochemical and neuro-physiological measures in non-sedated, awake children with Neurofibromatosis Type 1 (NF1) syndromic autism undergoing an early phase trial of Simvastatin intervention.
Methods: The patient cohort was acclimatised to awake MRI scanning using a social story and two weeks of exposure to mp3 recordings of specific MRI scan sequence noises at specified time points during the day when awake and during sleep preparation. Scanning was performed at baseline, then following twelve weeks of simvastatin or placebo exposure.
We measured the concentration of GABA and other neuro-metabolites in the left frontal white matter and deep grey nuclei using a single-voxel MEGA-PRESS sequence. We also acquired anatomical data using a whole brain gradient echo T1 volume acquisition with voxel size of 0.9mm^3. Brain perfusion measures were assessed using arterial spin labelling (ASL), whilst six-directional diffusion tensor imaging (DTI) was used to determine regional apparent diffusion coefficient (ADC) and regional fractional anisotropy. MEGA-PRESS data were analysed with the jMRUI v.5 software; the AMARES routine, was used to calculate metabolite concentration with tissue percentages extracted from a participant's T1 images for partial volume correction.
Results: In total 31 children presented for imaging, with 26 completing both baseline and week twelve imaging assessments (mean age 7.9, range 4.6-10.4). Absolute measures of GABA in the frontal white matter were seen to significantly increase in the treatment group (p=0.02) compared to the placebo group. Analysis for measure of change also identified significance at the 5% level in ASL perfusion in the ventral diencephalon and ADC in the cingulate gyrus in the treatment group, again not seen in controls. Finally there was significance in the interval change in glutamine + glutamate in the deep grey nuclei (p<0.05) again in the treatment group and not in the control cohort.
Conclusions: We have demonstrated that in this age group, made more challenging by the diagnosis of autism, careful patient preparation can result in successful multi-modal MRI assessment of both neuro-chemistry as well as physiological imaging in the awake patient. This is important as the effects of anaesthesia or sedation on the brain will impact on multi-modal imaging findings in such studies.
We have shown significant GABA changes after simvastatin exposure in this age group of NF1 autism. We also present the specific neurochemistry, perfusion and diffusion changes seen in these children indicative of measurable brain physiology changes after twelve weeks of treatment. These changes may be used to illuminate the pathogenesis of autism in this cohort, as well as being used as biomarkers for future phamaco-intervention studies.

52 **141.052** Sex Differences in Subcortical Morphometry of Children with ASD

***K. Hirabayashi**[1], D. Crocetti[2], B. C. Lee[3], X. Tang[4,5], D. J. Tward[3] and S. H. Mostofsky[2], (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Kennedy Krieger Institute, Baltimore, MD, (3)Center for Imaging Science, Johns Hopkins University, Baltimore, MD, (4)Carnegie Mellon University, Pittsburgh, PA, (5)Sun Yat-Sen University, Guangzhou, China*

Background: ASD is associated with impairments in social, goal-directed, and motor function. Subcortical structures contribute to the control of motor and social functions, including networks of communication, emotion, and reward. Due to the underrepresentation of girls in anatomical studies of autism, there is a paucity of literature exploring neuroanatomical correlates of sex-based differences in children with ASD.
Objectives: We compared the volumes and morphology of subcortical structures in ASD boys and girls to those of their typically-developing peers. We were particularly interested in examining how sex differentially affects the volumes and morphology of subcortical structures of ASD compared to TD populations. We examined differences in the left and right caudate, putamen, globus pallidus, and thalamus.
Methods: T1-weighted MPRAGE images were acquired from 107 children with ASD (20 girls) and 107 typically-developing children (19 girls). Subcortical parcellations were performed using MRICloud, a high-throughput neuroinformatics platform for automated brain MRI segmentation. Univariate ANCOVA tests were performed on the volumes of each structure, with the between-subject factor of diagnostic group and covariates of age, total cerebral volume (TCV), and head coil type. P-values were FDR-corrected. LDDMM was used to examine morphological features of the subcortical structures.Â Diagnostic effects were tested using a linear regression model including age, TCV and head coil as covariates. Non-parametric permutation testing was used to obtain corrected p-values for each vertex on a shape's surface. Partial correlations were conducted to assess associations between subcortical volumes and behavioral measures of motor and social function and autism symptom severity. Age, TCV, and head coil were used as covariates
Results: Â ANCOVA revealed that girls with ASD showed larger right caudate and right thalamus volumes compared to TD girls (p=0.012, d = 0.872; p=0.012, d = 0.873). No volume differences were observed in boys. No sex-by-diagnosis interactions on subcortical volumes were found. Correlations between subcortical volumes and ADOS scores were found predominantly in ASD girls. In ASD girls, higher ADOS total scores correlated with larger left caudate volumes (p =0.017, r=0.586). Higher ADOS Communication+Social Interaction scores correlated with larger left caudate, left putamen, and right putamen volumes in ASD girls (p=0.0008, r=0.638; p=0.014; r=0.601; p=0.017, r=0.585). No volume correlations with ADOS were found in ASD boys.
Linear regression revealed the effect of diagnosis on subcortical shape, including localized expansion on the right putamen and right thalamus for children with ASD compared to TD children in the whole group (19/553 vertices; 7/605 vertices). Within ASD girls, we observed expansions in the right putamen and right globus pallidus compared to TD girls (2/512 vertices; 5/234 vertices). Within ASD boys, we observed expansions in the right putamen and left globus pallidus compared to TD boys (3/525 vertices; 3/250 vertices).
Conclusions: Our volumetric findings indicate that girls with ASD display more robust differences within same-sex peers than boys with ASD. An increased sample size of girls may facilitate our understanding of the relationship between sex and diagnosis in subcortical structures. Additional analysis will include examining shape correlations with measures of ASD symptomology, and motor and social function.

53 **141.053** Stereological Study of the Superior Temporal Gyrus in ASD

R. Weir[1] *and C. M. Schumann*[2]*, (1)UC Davis, Sacramento, CA, (2)Psychiatry & Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA*

Background:
The superior temporal gyrus (STG) is a polysensory region that processes and integrates complex information from the auditory, somatosensory and visual cortices and is thus implicated in complex and social and linguistic functions. Since social communication deficiencies lie at the core of autism spectrum disorder (ASD), the STG is a prominent region of interest to investigate the etiology of this disorder. Magnetic resonance imaging (MRI) studies have demonstrated that cortical growth of the temporal lobe deviates substantially in children with ASD compared to TD controls (Schumann et al. 2010) and at the genetic level, microRNAs are differentially expressed in ASD and TD cases (Ander et al., 2015).
Objectives:
This study builds upon prior MRI findings, and moves towards elucidating the cellular underpinnings responsible for aberrant brain development in this region. Here we estimate neuron number and size in the supra- and infra-granular cell layers of the STG in TD and ASD cases using comprehensive stereological parameters.
Methods:
Sixteen postmortem histological samples were assembled from the Autism Celloidin Library (ACL), comprising of 8 typically developing and 8 ASD cases (age, sex and hemisphere matched, ASD cases diagnosed using the Autism Diagnostic Interview–revised ADI-R). Celloidin-embedded hemispheres were cut at 200µm, 300 µm or 600 µm and stained with gallocyanin (Wegiel et al., 2014). STG boundaries were traced in accordance with Barger et al, (2015) using StereoInvestigator software (MBF Biosciences), and delineated into supra- (layers II-III) and infra-granular (layer V-VI) regions. The optical fractionator and nucleator modules of StereoInvestigator were used to estimate neuron number and cell volumes, respectively. Neurons were marked as pyramidal or non-pyramidal and the somal volume of every fifth neuron was recorded.
Results:
In an preliminary analysis of a small subset (6 TD and 6 ASD cases, aged 7-48 years old) of the full case list, we have found a comparable number of pyramidal and non-pyramidal neurons in the supra and infra-granular regions of the STG in TD and ASD cases, however pyramidal neurons across both regions were found to be 20% larger in ASD than in TD cases.
Conclusions:
Greater somal volume of neurons in the ASD cases could explain the enlargement of the STG observed with MRI studies. However, prior postmortem studies of a similar nature, some with an overlapping sample population used here, have reported smaller somal volumes in subcortical brain regions in ASD cases versus TD controls. Together these data highlight that ASD pathology varies by region, age and cell type and warrants further detailed cellular studies to truly understand the etiology of ASD.

54 **141.054** The Impacts of Dysregulation on Cortical Thickness, Surface Area and Gyrfication for Males with and without Autism Spectrum Disorders

H. C. Ni[1]*, H. Y. Lin*[2]*, Y. J. Chen*[3]*, W. Y. I. Tseng*[3] *and S. S. F. Gau*[2]*, (1)Chang Gung Memorial Hospital- Linkou Medical Center, Taipei, Taiwan, (2)National Taiwan University Hospital & College of Medicine, Taipei, TAIWAN, (3)National Taiwan University Hospital, Taipei, Taiwan*

Background: Although dysregulation, involving impairments in affective, behavioral and cognitive control, is common in autism spectrum disorder (ASD), the neural mechanism of dysregulation in ASD remains elusive. For typically developing (TD) individuals, several brain regions, such as anterior cingulate cortex, dorsolateral prefrontal cortex, ventromedial prefrontal cortex and amygdala, is involved in dysregulation. Interestingly, most of these regions overlap with those implicated in pathophysiology of ASD, warranting further investigations.
Objectives: To test effects of dysregulation on neuroanatomy in ASD, and to investigate neurostructural correlates of dysregulation in ASD.
Methods: Surface-based morphometry using FreeSurfer was applied on structural MRI images from 85 males with ASD (ranging 7-17 years, mean=12.9, standard deviation, SD=2.3) and 65 TD (mean=12.3, SD=2.4). We defined dysregulation by the T scores of 3 subscales (Attention, Aggression and Anxiety/Depression) in the Child Behavior Checklist. Dysregulation was defined as total T scores of 3 subscales in the CBCL more than 180. There were 54 and 31 males with ASD in the ASD+dysregulation and ASD-dysregulation groups, respectively. First, we compared cortical thickness, surface area and gyrification for ASD and TDC and test if the main findings would be different when dysregulation was controlled. Second, we investigated difference of cortical thickness, surface area and gyrification among ASD+dysregulation, ASD-dysregulation and TDC groups. Third, we explored if there is similar or different association of cortical thickness, surface area and gyrification and dysregulation in ASD and TDC groups. Age, age square term and FIQ were taken as covariates in all the analysis above. Cluster-level correction for multiple comparisons based on Monte Carlo simulation was implemented.
Results: Males with ASD had increased cortical thickness in the right rostral middle frontal cortex, increased gyrification in the left inferior temporal cortex, right superior frontal cortex and right fusiform gyrus than TD. However, these findings all disappeared when dysregulation was controlled. For group difference among ASD+dysregulation, ASD-dysregulation and TD, ASD+dysregulation had thinner cortical thickness in the left superior parietal cortex and increased gyrification in the right lingual gyrus than ASD-dysregulation. ASD+dysregulation had thicker cortical thickness in the rostral middle frontal cortex and increased gyrification in the left inferior temporal, right insular and right superiorfrontal cortex than TD. ASD-dysregulation had thicker cortical thickness in right precentral gyrus than TD. Finally, ASD and TD groups had a shared association between dysregulation and several brain regions including surface area of the right lingual cortex and gyrfication of the left superior temporal and the right superior frontal cortex. Distinct association of dysregulation and surface area of the left postcentral cortex was found in ASD and TDC groups.
Conclusions: Our findings suggest that neurobiological abnormalities found in ASD might be partially accounted for by the level of dysregulation. To explore the neural mechanism of dysregulation in ASD, several different approach such as categorical, dimensional or subgroup analysis should be considered in the future studies.

55 **141.055** White Matter Abnormalities in Girls with Autism: A Tract-Based Spatial Statistics Study

H. Turner[1], *J. Lei*[1], *E. Lecarie*[1], *D. Yang*[2,3], *P. E. Ventola*[1], *D. G. Sukhodolsky*[1], *K. A. Pelphrey*[4] *and R. J. Jou*[4], *(1)Yale Child Study Center, New Haven, CT, (2)Children's National Health System, Washington, DC, (3)Autism and Neurodevelopmental Disorders Institute, The George Washington University, Washington, DC, (4)Yale University, New Haven, CT*

Background:
Many diffusion tensor imaging (DTI) studies implementing tract-based spatial statistics (TBSS) in samples consisting mainly of boys have shown widespread abnormalities in white matter (WM) microstructure in autism spectrum disorder (ASD). Even though girls make up a significant minority of individuals living with ASD, they are grossly understudied relative to boys, and few studies (if any) to date have implemented DTI with TBSS in the exclusive examination of ASD girls. While there is mounting evidence supporting differences in behavioral phenotype between girls and boys with ASD, much less is known about the neural phenotype in girls living with autism.
Objectives:
Characterize WM abnormalities in ASD girls in comparison to neurotypical (NT) girls using DTI.
Methods:
This study consisted of 46 girls: 26 ASD (Age: M = 9.22 y, SD = 4.18; Full-scale IQ: M = 96.79, SD = 21.15) and 20 NT (Age: M = 10.05 y, SD = 4.14; Full-scale IQ: M = 106.13, SD = 16.01). Participants underwent diffusion-weighted MRI (2.5mm3; 30 directions at b=1000s/mm2; 5 b=0; runs=3) on a 3T Siemens scanner. The best of three runs for each participant was selected for this preliminary analysis. All scans were pre-processed using FSL, including eddy current correction and estimation of the diffusion tensor, which enables calculation of the following WM microstructure metrics: fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD). Voxel-wise group comparisons in WM microstructure were performed using TBSS which co-registers all diffusion data and generates an average WM skeleton on which statistical comparisons are made. Areas of significant difference were identified ($p < 0.05$ corrected for multiple comparisons across space) using Threshold-free Cluster Enhancement (TFCE).
Results:
There were no significant differences in age and IQ between groups. There were widespread regions of both right and left hemispheres in which MD was significantly elevated in ASD compared to NT. There were also widespread regions of both right and left hemispheres in which AD was significantly elevated in ASD compared to NT. All fiber types were represented, including association, commissure, and projection fibers. No other group comparisons reached significance; however, there was a trend towards significantly increased RD in the ASD group compared to NT.
Conclusions:
This study uses DTI and TBSS to show that ASD girls have WM abnormalities in comparison to NT girls, thus indicating that probands exhibit structural abnormalities in the brain. The pattern of abnormalities is similar to boys with respect to widespread involvement. In contrast, there appear to be some differences in which WM microstructure metrics are abnormal in girls with ASD, suggesting potential gender differences in neural phenotype.

56 **141.056** White Matter Microstructure As Candidate Brain Phenotypes of Autism

J. Villaruz[1], *D. C. Dean*[1], *B. G. Travers*[1], *A. A. Freeman*[1], *B. A. Zielinski*[2], *M. D. Prigge*[2], *J. S. Anderson*[2], *E. D. Bigler*[3], *N. Lange*[4], *S. J. Schrodi*[5], *M. Leppert*[6], *N. Matsunami*[7], *A. L. Alexander*[1] *and J. E. Lainhart*[1], *(1)University of Wisconsin - Madison, Madison, WI, (2)University of Utah, Salt Lake City, UT, (3)Brigham Young University, Provo, UT, (4)McLean Hospital, Cambridge, MA, (5)Marshfield Clinic Research Foundation, Marshfield, WI, (6)University of Utah, Department of Human Genetics, Salt Lake City, UT, (7)University of Utah School of Medicine, Salt Lake City, UT*

Background: Autism spectrum disorder (ASD) is a highly heterogeneous condition that vastly influences brain structure and development. However, despite the effort to identify brain-based causes of ASD, the mechanisms that underlie the associated neurobiological alterations remain unknown. Though the heterogeneity of neuroimaging findings has made it challenging to pinpoint specific brain-related phenotypes of ASD, identifying such features may be informative to the clinical approach of ASD. We can compare the distributions of neuroimaging-based measures from ASD individuals to those of typically developing individuals and single out brain regions that differ between these two groups. Diffusion tensor imaging (DTI) is an integral tool for studying neurobiological change and has been used to associate ASD with microstructural variations in specific white matter tracts. Thus, DTI measures may be worthwhile to distinguish brain phenotypes of ASD.
Objectives: We examined distributions of white matter microstructure of individuals with ASD and typically developing controls (TDC) as initial steps to identify brain based phenotypes of ASD.
Methods: Participants were recruited across two sites, University of Utah and University of Wisconsin-Madison, and involved 140 ASD and 85 TDC males between the ages of 3 and 42-years-old. In total, 497 (320 ASD, 177 TDC) longitudinal DTI datasets were collected. Images were corrected for distortion and head motion, while maps of FA, MD, AD, and RD were estimated. Images were then aligned to a population-specific template and mean diffusion parameters were extracted from 46 major white matter tracts, as defined by the JHU ICBM-DTI-81 template. The bilateral stria terminalis was not included in these analyses due to lack of reliable fit across participants. T-tests were performed to compare the distributions from ASD and TDC individuals using combined data and data separated by collection site.
Results: In the combined data, the ASD group had significantly different (p<0.05) white matter microstructure in 21 major tracts compared to TDC. FA in the splenium, genu, and body of the corpus callosum were the most significantly different (p = 7.51*10^{-8}, p = 1.79*10^{-6}, and p = 3.80*10^{-5}, respectively). Utah data revealed 25 tracts that had significantly different (p<0.05) microstructure in the ASD group while Wisconsin data only showed significantly different (p<0.05) microstructure in 5 tracts. In Utah data, FA was most significantly different (p=1.36*10^{-8}) in the splenium of the corpus callosum, while in Wisconsin data it was most significantly different (p=0.011) in the middle cerebellar peduncle.
Conclusions: Our results suggest that measures derived from diffusion imaging may be informative to the development of brain-based phenotypes of ASD. In particular, the splenium of the corpus callosum may be an ideal candidate for such a brain phenotype. Although the findings from the two sites are similar, the discrepancies are likely due to the larger sample size and increased number of time points in the Utah data, making it more sensitive to overall group effects. Future analyses will investigate differences in MD, RD, and AD between groups, the effect of covariates such as age, and whether candidate imaging phenotypes begin to establish possible subgroups of ASD.

Poster Session
142 - Diagnostic, Behavioral & Intellectual Assessment
12:00 PM - 1:40 PM - Golden Gate Ballroom

57 **142.057** A Comparison of Aberrant Behavior Checklist (ABC) Factor Scores in Children with Autism Spectrum Disorder (ASD) and Prader Willi Syndrome (PWS)

***B. P. Taylor**, E. A. Doernberg, A. Kabasakalian, C. J. Ferretti and E. Hollander, Albert Einstein College of Medicine-Montefiore Medical Center, Bronx, NY*

Background: Autism Spectrum Disorder (ASD) is frequently diagnosed in association with Prader Willi Syndrome (PWS), a genetic disorder that results from lack of paternally derived imprinted material on chromosome 15q11-q13 (a region also implicated in the etiology of ASD). Previous studies have noted, however, that there are differences in the way that restricted and repetitive behaviors are displayed in children with ASD and PWS. To date, no research has investigated the potential differences/similarities in social impairments or associated symptoms (e.g., irritability or hyperactivity) between children with ASD and PWS.
Objectives: To compare the Aberrant Behavior Checklist (ABC) Factor Scores of (1) Lethargy/Social Withdrawal; (2) Stereotypic Behavior; (3) Inappropriate Speech; (4) Irritability; and (5) Hyperactivity/Non-compliance between children with ASD and PWS.
Methods: Children with ASD and PWS, ages 5-17, were enrolled in two separate studies. Children with ASD (n=23) participated in a randomized double-blind crossover study to evaluate the safety and efficacy of Trichuris Suis Ova (TSO), and children with PWS (n=20) participated in an 8 week double-blind treatment study of intranasal OXT (IN-OXT) vs. placebo. The ABC, a 58-item informant-based rating scale, was completed by parents during the baseline visit of both studies.
Results: There were no significant differences between children with ASD and PWS in terms of gender, race, or age. There were, however, significant baseline performance differences on the Stanford Binet-5 Abbreviated IQ (SB-5 ABIQ); children with ASD scored higher than children with PWS (t=2.204, df=41, p=0.033). The SB-5 ABIQ was therefore used as a co-variate in the analyses of the ABC Factor scores. After controlling for baseline ABIQ, children with ASD had significantly higher scores (i.e., more symptomatology) on the ABC Stereotypic Behavior Factor and the ABC Hyperactivity/Non-compliance Factor compared to children with PWS (F=33.235, p<0.001 and F=23.694, p<0.001, respectively). Differences on the ABC Irritability and Social Withdrawal/Lethargy Factors approached significance (F=3.83, p=0.057 and F=3.75, p=0.06, respectively), with ASD children again having elevated scores. No difference between the groups was found on the Inappropriate Speech Factor.
Conclusions: Compared to children with PWS, children with ASD were rated by their caregiver as having greater symptomatology across all but one of the ABC Factors. More specifically, children with ASD had significantly higher scores on the ABC Stereotypic Behavior and Hyperactivity/Non-compliance Factors. Elevated scores for children with ASD on the ABC Irritability and Lethargy/Social Withdrawal Factors approached significance compared to children with PWS. These findings were not due differences in baseline intelligence. Future studies should look at item differences *within* each ABC Factor, in terms of frequency and severity, to more explicitly differentiate their behavioral manifestations in children with ASD and PWS.

58 **142.058** A Comparison of Variability in Change Across Commonly Used Measures of Treatment Outcomes for Youth with ASD

***K. S. Dickson**[1,2], S. R. Rieth[1,3], J. Suhrheinrich[1,2] and A. C. Stahmer[1,4], (1)Child and Adolescent Services Research Center, San Diego, CA, (2)University of California, San Diego, La Jolla, CA, (3)San Diego State University, San Diego, CA, (4)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA*

Background:
In contrast to the several well-validated diagnostic and assessment measures of child symptomatology and functioning, there is little consensus regarding suitable measures to assess treatment outcomes (Matson, 2007). Within the treatment literature, measures of intelligence and adaptive skills measures are commonly used as indicators of change. However, their use present several issues, including questions regarding the sensitivity to changes (McConachie et al., 2015), especially given that many of these measures were designed to measure relatively stable constructs over time (e.g., intelligence). Given the significant empirical emphasis on evaluating intervention programs for youth with ASD, the identification of sensitive, suitable measures of treatment outcomes is critical.
Objectives:
The aim of the present study is to examine variability in rate of change observed across various outcome measures in a randomized trial of classroom-based ASD intervention, including standardized measures of cognitive and adaptive abilities.
Methods:
Participants include 263 students enrolled in a large effectiveness trial of a naturalistic behavioral intervention in school settings. Students were 3-11 year old (M = 5.9 SD = 2.24) and being served under the autism educational category in public school programs. Treatment outcome measures included: 1) standardized cognitive measures (either the Differential Abilities Scale-II or the Mullen Scales of Early Learning, as appropriate for developmental level) and the Vineland Adaptive Behavior Scales-II (VABS), as completed by the student's teacher. Each measure was administered in the fall and spring of the school year. Progress across the school year on individual student goals selected by the teacher and assessed via Goal Attainment Scaling (GAS goals) were also included as a measure of change.
Results:
Results indicate the largest change in scores for the cognitive measures as compared to the VABS-II.Â Examination of associations between corresponding subscales from the cognitive measures and the VABS-II indicate a significant relationship between rates of change in receptive language but not expressive language. Further, whereas a positive association was observed between receptive language change and VABS-II expressive language, there was a negative association between expressive language and VABS-II receptive language. In terms of changes in academic functioning, there was a strong positive association between receptive language and improved academic skills; this is in contrast to the negative association observed with the VABS-II language scales. Further associations as well as potential moderating variables will be discussed.
Conclusions:
The current results suggest variability in rates of change across various common measures of treatment outcomes as data demonstrated by an inconsistent pattern of association between specific cognitive and adaptive abilities. Overall, these results lend support to the sensitivity to change in these commonly used treatment outcome measures. However, the inconsistencies seen in rate of change or progress across measures warrants further exploration.

59 **142.059** A Proposed Model of Intelligence and Its Implications for Children with Autism Spectrum Disorder

L. A. Oakes *and T. Smith, University of Rochester Medical Center, Rochester, NY*

Background: Although research indicates that IQ tests are reliable and valid measures of cognition when administered to individuals with autism spectrum disorder (ASD), it also reveals that such tests have unusual psychometric properties in this population, notably low inter-correlation among subtests, distinctive patterns of strengths and weaknesses, and over-prediction of everyday functioning. A satisfactory factor structure that explains the cognitive strengths and deficits of this population has not been identified. Nor has there been an explanation of why their adaptive behavior is not commensurate with their cognitive abilities.
Objectives: This study evaluates a new model of the structure of intelligence in the ASD population that, if confirmed, would help account for the differences. A three-domain model is proposed, consisting of language ability, perceptual ability, and social ability, with each ability further broken down into a fluid reasoning component and crystalized knowledge component. The proposed model is then compared to a conventional IQ test in regards to its ability to predict adaptive behavior.
Methods: Children with ASD, ages 6-12, with full scale IQ scores above 50, were assessed on a standardized IQ test (Stanford-Binet Intelligence Test, 5th Edition), a test of social skills (NEPSY-II), and parent-rated adaptive behavior (Vineland Adaptive Behavior Scales-II) and executive functioning (BRIEF). Factor scores were estimated from 6 variables (Verbal Knowledge, Verbal Fluid Reasoning, Nonverbal Knowledge, and Nonverbal Fluid Reasoning from the SB-5; Affect Recognition and Theory of Mind from the NEPSY-II), and a path analysis was conducted to test the fit of a model relating these factors to (1) constructs representing cognitive abilities and adaptive abilities, and (2) constructs representing the components of the new model proposed in this study (language abilities, perceptual abilities, and social abilities).
Results: Fifty-three children (44 males, 9 females) with ASD, a mean age of 9.6 (SD = 1.9), and a mean Full Scale IQ of 92.49 (SD = 19.46; range: 51-126) participated in the study. Overall, results supported the use of the SB-5 with school-age children with ASD with high inter-correlations between subtests and Full Scale IQ, $r(51)$ = 0.73 - 0.89 and between domains and Full Scale IQ, $r(51)$ = 0.88 - 0.92. The proposed model was partially supported with the inclusion of social skills and only 4 subtests of the SB-5 ($\chi 2$ (6) = 1.166, p = 0.979) and predicted adaptive behavior at least as well as the full IQ test (β = 0.42, p = 0.002). BRIEF scores did not contribute significantly to the model.
Conclusions: Â In this study, adding measures of social skills to cognitive assessments reduced the number of variables needed to predict children's use of skills in their everyday environment and resulted in predictions that were at least as accurate as a more detailed cognitive assessment. Alternatively, assessment batteries that include Full IQ tests and social skills assessment may provide significantly more information compared to conventional batteries, supporting the use of different assessment batteries than are typically used in practice.

60 **142.060** A Stratified Analysis of Subtypes in Autism Spectrum Disorders with Unsupervised Machine Learning

E. Stevens[1]*, D. Dixon*[2] *and E. Linstead*[3]*, (1)Computer Science, Chapman University, Orange, CA, (2)Center for Autism and Related Disorders, Woodland Hills, CA, (3)Chapman University, Lakewood, CA*

Background: Increasing rates of diagnosis of Autism Spectrum Disorder (ASD) combined with high variance in abilities and disabilities of those diagnosed necessitate the need for empirically-based customization of treatment programs. Concurrently, the maturation of ubiquitous computing now allows for the large-scale and rapid collection of longitudinal clinical data which can be leveraged to train machine learning algorithms capable of detecting subtle patterns in large data repositories. Previously (https://imfar.confex.com/imfar/2016/webprogram/Paper22515.html) we demonstrated the application of unsupervised clustering models to extract behavioral subtypes of ASD based on 8 domains: cognition, executive functioning, language, motor, social, play, adaptive, and academic. These results showed that distinct skill profiles existed on the spectrum, and could serve as a basis for tuning therapy curriculum. Here we expand this work to track the stability of cluster profiles across age groups and genders, as well as model the response of patient learning in each cluster as a function of treatment intensity.
Objectives: The purpose of the present study was to identify if behavioral subtypes of ASD identified through machine learning remained stable as a function of age and gender. An additional goal of the study was to capture the relationship between learning outcomes and treatment intensity for each cluster in the age-stratified model.
Methods: Data from the SKILLS database was used to generate a 3500-dimensional vector model of patients with confirmed ASD diagnoses, with each vector element corresponding to the presence or absence of an individual behavior. These data were aggregated across the 8 domains enumerated above, resulting in an 8 dimensional feature space for approximately 2000 patients. This feature space was then stratified based on age and gender, and then clustered using Expectation Maximization with mixtures of Gaussians. Bayesian Information Criteria was used to determine the optimal number of clusters. The centroids of each cluster were then used to visualize cluster profiles for each age and gender group, as well as to measure for significance similarities and differences in clustering behavior across groups, including responsiveness to treatment intensity.
Results: Results of this study further confirmed the existence of subtypes on the autism spectrum, and the ability of these subtypes to be identified using unsupervised machine learning techniques. In particular, this study identified cluster profiles that retain the same general characteristics across age groups and genders, while others appear to change as a function of age. Similar observations were made to responses in treatment intensity. In practice this provides a heuristic for customizing treatment regimens for individuals, as well as evolving those treatment regimens in an informed fashion as the individual gets older.
Conclusions: Findings indicate the existence of distinct behavioral subtypes within a large sample of children with ASD, as well as how those subtypes vary as a function of age and gender. As noted in the past, the significance of these subtypes may span beyond behavioral treatment. Further exploration of other distinctions between these groups (e.g., genetic, medical, environmental, etc.) are warranted and currently underway.

61 **142.061** A Validation Study of the Observation for Autism Screening (OERA), a New and Brief Low-Cost Instrument to Screening for ASD

*C. S. Paula[1], D. Bordini[2], G. Rodrigues da Cunha[3], **S. H. Ribeiro**[4], D. Brunoni[5], A. C. Moya[6], J. J. Mari[7] and H. Cogo-Moreira[7], (1)Developmental Disorder Program, Mackenzie Presbyterian Univesrsity, Sao Paulo, BRAZIL, (2)Unifesp, Sao Paulo, BRAZIL, (3)Consultório Particular, Sao Paulo, Brazil, (4)UNIFESP, Sao Paulo, BRAZIL, (5)Developmental Disorders Postgraduate Course, Mackenzie Presbiterian University, São Paulo, Brazil, (6)Psyquiatry, Federal Unversity of São Paulo, São Paulo, Brazil, (7)psychiatry, Federal Unversity of São Paulo, São Paulo, Brazil*

Background:
The ADOS is the gold standard observational schedule for diagnosis of ASD. However, it is lengthy, time-consuming, costly and requires a high level of training, which makes it rarely feasible in non-research settings and large-scale proposals. This is particularly problematic in most Low-Middle-Income-Countries/LMIC. For that reason, our team developed a new tool called Structured Observation for Autism Screening/OERA.
Objectives:
(1) to describe the OERA instrument, (2) to assess its construct validity and invariance regarding gender and IQ, and (3) to calculate its sensitivity and specificity.
Methods: Local: São Paulo, Brazil. Participants: 99 children: N=79 with ASD, and n=23 children without ASD (11 with intellectual disability and 22 with typical development). Instruments: *ASD diagnosis* based on the ADI-R; *IQ* based on SON-R 2½-7 or WISC-III. Statistical analysis: (1) Evaluation of the agreement between two independent examiners via kappa coefficient, percentage of agreement and expected agreement. (2) Construct validity and invariance via confirmatory factor analysis/CFA.Â (3) Elaboration of ROC curve and its cutoff for sensitivity and specificity confronting OERA total score with clinical judgment by psychiatrist allowing to estimate the area under the curve.
Results:
OERA is an 8-item semi-structured assessment tool to screening ASD in children 3–10 years old of age. After a short training, non-specialists can administer the OERA in approximately 10 minutes, based on a standardized low-cost set of objects and toys. After that, an expert in ASD watches the record to code the 8 semi-structured items, and a list of 5 additional behaviors, summing 13 items. The unidimensional model for OERA showed:
(1) High agreement between the observers (all items above 80%);
(2) Good fitness of indices, high factor loadings (on average, factor loading=0.878), no item showed differential functioning item regarding gender and IQ, and;
(3) Area under the ROC curve=0.9443. Scores equal of greater than five correspond to a sensitivity=92.75% and specificity=90.91%.
Conclusions: The OERA was useful to identify ASD children with good psychometric features (construct validity and invariance regarding gender and IQ), discriminating children with ASD and typical development with good sensibility and specificity. This new instrument is promising to identify ASD, particularly in LMIC.

62 **142.062** A Window of Opportunity for Preventing Challenging Behavior: Increase in Heartrate Prior to Episodes of Challenging Behavior in Preschoolers with Autism

***H. J. Nuske**[1], E. Finkel[1], M. Pellecchia[1], J. D. Herrington[2], V. Parma[3], D. Hedley[4] and C. Dissanayake[5], (1)University of Pennsylvania, Philadelphia, PA, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)SISSA, Trieste, ITALY, (4)Olga Tennison Autism Research Centre, Melbourne, AUSTRALIA, (5)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia*

Background: Almost two thirds of children with Autism Spectrum Disorder (ASD) present with challenging behaviors which are often associated with difficulties in communication; three quarters have difficulty with emotional regulation. The most effective approach to reduce challenging behavior and its consequences require appropriate intervention before onset of the behavior. However, understanding the triggers to challenging behavior is difficult in some children, due to their limited communication abilities generally, and communicating emotions in particular. As physiological indicators such as increase in heart rate are well-established fine-grained measures of emotional regulation and stress, these indicators may provide important insights on the triggers to challenging behavior.
Objectives: To identify physiological precursors to challenging behavior episodes in pre-schoolers with autism who have frequent challenging behaviours.
Methods: Whilst wearing a lightweight wireless electrocardiogram (Biopac BioNomadix®) embedded in a speciality-made vest, 41 children with ASD aged 2-4 years were administered a testing battery including 10 tasks from the Preschool Version of the Laboratory Temperament Assessment Battery (Lab-TAB; Goldsmith, Reilly, Lemery, Longley, & Prescott, 1999). These Lab-TAB tasks were designed to mimic everyday life experiences in which children would need to regulate low-level stress (e.g. waiting for a snack, interacting with a stranger) and experience positive emotion (bubbles, peek-a-boo task), spanning approximately 1 - 1.5 hours. Coders blind to diagnostic group coded challenging behaviors including aggression, self-injury, property destruction, loud noises and non-compliance.
Results: We were interested in the physiological state of children from the present sample who exhibited frequent challenging behavior. Sixteen children met this criteria and were thus included in the analysis. Analysis of heart rate data (beats per minute) from the first 3 children (physiological data processing is ongoing) indicate a mean of 39.69% (range of 32.89 – 48.31%) increase in heart rate from baseline at a mean of 52.70 secs (range of 33.11 – 71.70 secs) prior to the onset of the challenging behavior episode. These data will be supplemented with physiological (HR variability, skin conductance) and behavioral data from the full sample for presentation at IMFAR in an effort to understand how physiological stress relates to different behavior functions.
Conclusions: Â The preliminary data indicate that children with ASD show clear physiological reactivity prior to the onset of challenging behaviors, thus identifying an important window of opportunity during which caregivers may intervene. Wearable biosensors may provide a useful means by which information about the onset of challenging behavior can be communicated, leading to efforts to teach emotional regulation in situations that matter most, such as the classroom.

63 **142.063** ADOS Autism Severity As a Predictor of Language Ability in Boys and Girls with Autism Spectrum Disorder

J. W. Keller[1]*, C. A. Nelson*[1]*, K. A. Pelphrey*[2]*, L. Gabard-Durnam*[1] *and S. J. Webb*[3]*, (1)Boston Children's Hospital, Boston, MA, (2)Yale University, New Haven, CT, (3)University of Washington, Seattle, WA*

Background:
Autism is a neurodevelopmental disorder that affects 1 in 42 boys and 1 in 189 girls (Christensen et al. 2016). Due to this large discrepancy, there has been relatively little research that explores how autism presents in girls. Of the research that has been done, recent findings suggest that girls with autism have worse communication skills than boys of similar autism severity as measured by the autism diagnostic observation schedule (ADOS) (Hartley and Sikora 2009).
Objectives:
In the current study, we aim to examine how receptive and expressive language performance relates to ADOS autism severity scores differently in girls and boys with autism. Given the subject sample spans puberty, we assess whether these associations are different based on pubertal status in both sexes.
Methods:
Data were collected from 29 prepubescent boys, 20 post pubescent boys, 16 prepubescent girls, and 35 post pubescent girls with autism or autism spectrum diagnoses. Pubertal cutoffs were determined using the Pubertal Development Scale, autism severity was determined using the autism diagnostic observation schedule, second edition (ADOS-2), IQ was determined using the differential abilities scale (DAS), and receptive and expressive language ability were determined using the clinical evaluation of language fundamentals, fourth edition (CELF-4). IQ, age, and receptive and expressive language scores were not significantly different between boys and girls in prepubescent and post pubescent groups respectively. Eight linear regressions were run (separate tests for each sex and pubertal group for two outcome variables) with ADOS score sum predicting either expressive or receptive language scores to assess the associations between autism severity and language ability.
Results:
Preliminary analysis revealed that autism severity significantly predicted receptive language in post pubescent girls ($p = .016$, $t = -2.526$, Beta = -.403). There were marginal effects found in which autism severity predicted expressive language ($p = .075$, $t = -1.926$, Beta = -.458) and receptive language ($p = .071$, $t = -1.952$, Beta = -.462) in prepubescent girls as well as expressive language in post-pubescent girls ($p = .077$, $t = -1.824$, Beta = -.303). Autism severity did not significantly predict receptive or expressive language performance for any other group.
Conclusions:
Based on these findings, ADOS severity relates to the measure of receptive language in post pubescent girls more robustly than in boys at any pubertal stage. Additionally, the relationship suggests that receptive language ability decreases with increasing autism severity in post pubescent girls. Data collection is ongoing and more subjects will be added to increase statistical power and to see if any more significant effects are created.

64 **142.064** ASD Concordance of Twins Across DSM-IV-TR and DSM-5 Diagnostic Criteria

E. P. McKernan[1]*, N. Russo*[1]*, C. Burnette*[2]*, E. A. Kaplan*[3]*, J. Kopec*[1]*, N. Shea*[1] *and W. R. Kates*[4]*, (1)Syracuse University, Syracuse, NY, (2)University of New Mexico, Albuquerque, NM, (3)Psychology, Syracuse University, Syracuse, NY, (4)Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY*

Background: Â Diagnostic criteria for autism have changed under *DSM-5*, with the removal of diagnostic subcategories in favor of a single category of autism spectrum disorder (ASD). Previous research has supported a high degree of concordance for ASD among monozygotic twins, but no studies have specifically examined pairwise concordance rates using *DSM-5Â* diagnostic criteria for ASD.
Objectives: Â This study aims to examine monozygotic pairwise concordance rates for ASD from the perspective ofÂ *DSM-IV-TRÂ* andÂ *DSM-5*Â diagnostic criteria.
Methods: Â Items of a parent report measure of ASD symptoms (Autism Diagnostic Interview–Revised) and a clinical observation instrument (Autism Diagnostic Observation Schedule) were matched to diagnostic criteria, as conceptualized by Huerta et al. (2012). Diagnoses of pervasive developmental disorder and ASD were assigned to 14 pairs of monozygotic twins, in whom at least one twin had an autism diagnosis, using *DSM-IV-TR* and *DSM-5* criteria. McNemar tests were performed to determine whether there was a significant difference in sample pairwise concordance rates between *DSM-IV-TR* and *DSM-5* diagnostic criteria.
Results: With the use of both parent report and clinical observation measures (Autism Diagnostic Interview-Revised *and* Autism Diagnostic Observation Schedule), eight of the fourteen twin pairs were classified as concordant using *DSM-IV-TR* criteria, and five out of the fourteen twin pairs were classified as concordant using *DSM-5* criteria, yielding pairwise concordance rates of 57.14% and 35.71%, respectively. The use of either parent report or clinical observation (Autism Diagnostic Interview-Revised *or* Autism Diagnostic Observation Schedule) resulted in pairwise concordance rates of 85.71% for *DSM-IV-TR* criteria and 78.57% for *DSM-5* criteria. Pairwise concordance rates were not significantly different across *DSM-IV-TR* and *DSM-5* diagnostic criteria using these two methods. *DSM-5* pairwise concordance rates were significantly different when evidence of symptoms was required from either measure (78.57%) versus both measures (35.71%).
Conclusions: Pairwise concordance rates using *DSM-5* diagnostic criteria were higher if diagnoses were assigned on the basis of information from either the Autism Diagnostic Interview-Revised or the Autism Diagnostic Observation Schedule than they were if information from both sources was used. The finding of a significant difference in concordance rates using either measure as opposed to both measures has important implications for diagnostic practice. Overall, despite concerns regarding changes to the diagnostic construct of ASD with the use of *DSM-5* criteria, the present findings suggest that sample pairwise concordance rates for ASD have not substantially changed from *DSM-IV-TR* to *DSM-5* criteria. The composition of the autism spectrum has remained consistent in this sample of monozygotic twins.

65 **142.065** ASD and Neurodevelopmental Characterization of Youth with XYY Syndrome

L. Joseph[1]*, A. Thurm*[2]*, L. Henry*[2] *and A. Raznahan*[3]*, (1)MSC 1255, National Institute of Mental Health, Bethesda, MD, (2)National Institute of Mental Health, Bethesda, MD, (3)NIH IRP, NIMH, Child Psychiatry Branch, Bethesda, MD*

Background: Sex chromosomal aneuploidies are numeric aberrations of X or Y chromosomes; in the case of XYY, an extra Y chromosome is present in males. Epidemiology estimates indicate a rate of XYY in 1/1000 births, although the diagnosis is reported less frequently (Stochholm, Juul, & Gravholt, 2010). Previous studies have found significant autism spectrum disorder (ASD) symptomatology in this population, although rates vary considerably (Margari, Lamanna, Craig, Simone, & Gentile, 2014). Other prominent characteristics previously described include a slightly lower average IQ than the general population, language impairments, learning disabilities, and a variety of psychiatric diagnoses, including attention deficit hyperactivity disorder (ADHD) (Bardsley et al.,2013; Bishop et al., 2011; Leggett, Jacobs, Nation, Scerif, & Bishop, 2010). Studies of this condition have thus far not included gold-standard diagnostic instruments for ASD.
Objectives:
The purpose of this study was to report on previous community diagnoses and findings from administration of gold-standard ASD diagnostic instruments in youth with XYY. We also sought to contextualize these data based on cognitive profiles, as well as specific learning disorder (SLD), intellectual disability (ID), and ADHD diagnoses.
Methods: A sample of 50 males with XYY were enrolled in a phenotypic characterization study. The sample included an age range of 5 to 25 years (mean age=13.25±5.94). Phenotypic characterization included an IQ estimate from a Wechsler intelligence test (WISC-V, WASI or WAIS-IV). Additionally, the Autism Diagnostic Interview-Revised (ADI-R), the Autism Diagnostic Observation Schedule, second edition (ADOS-2), the Woodcock Johnson Tests of Achievement, fourth edition (WJ-IV), and the Vineland Adaptive Behavior Scales, second edition were administered.
Results: Previous diagnoses of ASD in community had been made in 36% (n=18). Additionally, based on parent report, 60% (n=30) had a previous diagnosis of ADHD. Preliminary results from 25 participants indicate that while 32% (n=8), and 24% (n=6) met diagnostic criteria on the ADI-R and ADOS-2 respectively, only 16% (n=4) were given a DSM-5 diagnosis of ASD according to results from these instruments combined with clinical judgment and clinician review of DSM-5 criteria. ADOS-2 profiles (module 2, n=1; module 3, n=18; module 4, n=6) are shown in Figure 1. NVIQ was slightly higher than VIQ, with FSIQ falling approximately 1 SD below the population average, and adaptive behavior generally lower than estimated from IQ scores (Table 1). One participant met criteria for ID (FSIQ and Vineland ABC <70). Twenty one participants completed academic testing, and 61.9% (n=13) met for SLD (FSIQ>70 and achievement standard score in at least one area <78).
Conclusions: This study found a negatively skewed IQ range, and greater deficits in VIQ compared to NVIQ in youth with XYY, consistent with previous findings (Leggett et al., 2010). While community diagnoses of ASD were higher than reports in previous studies, cohort effects may explain some differences, since rates of ASD have increased ubiquitously. While research based categorical diagnoses of ASD were reduced compared to community diagnoses in the current study, symptomatology is present and needs further exploration, especially in light of the cognitive, language and learning profiles in this group.

66 **142.066** Age of First Concerns and Age of ASD Diagnosis in a Sample of Latin American Children

C. Montiel-Nava[1]*, D. Valdez*[2]*, A. Rosoli*[3]*, C. S. Paula*[4]*, R. A. Garcia*[5]*, S. H. Cukier*[6]*, G. Garrido*[7] *and A. Rattazzi*[6]*, (1)Graduate Studies, Universidad Latina de Panama, Panama, Panama, (2)FLACSO, Buenos Aires, Argentina, (3)OEI, Santo Domingo, Dominican Republic, (4)Developmental Disorder Program, Mackenzie Presbyterian Univesrsity, Sao Paulo, BRAZIL, (5)Universidad de Chile, Santiago, CHILE, (6)PANAACEA, Programa Argentino para Niños, Adolescentes y Adultos con Condiciones del Espectro Autista, Buenos Aires, Argentina, (7)Universidad de la República, Montevideo, URUGUAY*

Background:
Although parents report preoccupation with their child's development, it could take years to obtain a diagnosis of ASD. Among the reasons suggested for diagnosis delay are lower levels of parent education, lower socioeconomic status (SES), limited knowledge of parents about ASD, scarcity of trained specialists, and diminished health-care knowledge. Data are also lacking on the demographic and clinical variables that might explain disparities in parental first concerns and diagnosis of ASD for different ethnic groups.
Objectives: The goal of the study was to describe the age of parental concerns, types of first parental concerns, the age at first ASD diagnosis, and factors associated with age at the first diagnosis in a sample of Latin American children.
Methods: A needs survey for caregivers of people with ASD was performed in the Latin-American Region between 2015-2016 by the Red Espectro Autista Latinoamerica (REAL). 2965 families were surveyed in six Latin-American countries (Argentina, Brazil, Chile, Dominican Republic, Uruguay and Venezuela)Â using the Autism Speaks Caregiver Needs Survey. Age of parental recognition and description of first signs were ascertained through the direct questions of the survey
Results: Age of parental first concerns varied from 20.36 in Brazil to 28.05 months in Chile with a median age of recognition of 22.22 months (SD 18.94, for the total sample. The average age of diagnosis for the total sample was 51.88 (SD 48.21), with the earliest age of diagnosis in Venezuela at 41.66 and the latest in Brazil with 57.55 months. Linear regression analysis found that country of residence is a predictor of age of diagnosis but not for the age of first concerns. Also, gender (male) and professionals consulted (neurologists) were predictors of earlier age of diagnosis ($F=73.39$, $p=.003$, $R^2=.110$). For an earlierÂ age of firstÂ concerns, professionals consulted (pediatricians) and lower child's verbal ability were significant predictors ($F=34.57$, $p=.008$, $R^2=.055$).
Conclusions:
Latin American parents were aware of developmental difficulties before the second year of life, which is consistent with parental reporting in other countries. However, their children were diagnosed months later. These results highlight the role of culture in the ASD diagnostic process. Also points into the disparity of professionals training in the diagnosis and early intervention and scarcity of services in Latin American countries. These findings warrant further study of the cultural impact on autism diagnosis and developing of public policies to speed up the diagnostic process in Latin-Americans countries.

67 **142.067** Crowdsourced Validation of a Machine Learning Classification System for Autism and ADHD

M. Duda[1], *N. Haber*[2] *and D. Wall*[3], *(1)University of Michigan, Ann Arbor, MI, (2)Stanford University, Stanford, CA, (3)Stanford University, Palo Alto, CA*

Background: Autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) together affect >10% of the children in the United States, but considerable behavioral overlaps between the two disorders can often complicate differential diagnosis. Currently, there is no screening test designed to differentiate between the two disorders, and with waiting times from initial suspicion to diagnosis upwards of a year, methods to quickly and accurately assess risk for these and other developmental disorders are desperately needed.
Objectives: Our goal was to improve our previously published classification system to distinguish ASD from ADHD using a small set of caregiver-directed behavioral questions. We aimed to train a model that generalized well to unseen crowd-collected data comprised of subjects of varying severity to create a robust classifier capable of making accurate risk predictions as a real-world mobile screening tool.
Methods: As part of a large crowdsourcing effort, we electronically collected responses to 15 behavioral features from parents of children with ASD (n = 248) or ADHD (n = 174) to use in conjunction with our archival data set (n = 2925). We trained/tested five machine learning models on different subsets of our data (archive/survey, survey/archive, archive/archive, survey/survey, mixed/mixed) to find the model that best generalized to both data sets. We used a nested grid search cross validation for parameter optimization, and to overcome class imbalance in our training and testing trials we performed 100 random subsamplings of the majority class.
Results: Due to the high variability in our crowdsourced survey data set, our classification accuracy was lower for the survey data set than for the archive data set. However, we found that two of our models (Elastic Net and Linear Discriminant Analysis) were especially robust in classifying the crowdsourced data, specifically when trained on a mixed set of archive and survey data, indicating that including clear ASD/ADHD examples in the training set improved the classification of more difficult cases. Our final models performed with AUC = 0.89 ± 0.01 using only 15 questions.
Conclusions: These results support the potential of creating a quick, accurate, and widely accessible method for differentiating risks between ASD and ADHD for use inside or outside of clinical settings. Our success in crowdsourcing indicates that mobile administration of this screening tool is possible, and would be well received by parents of children at risk. Furthermore, the simplicity of the approach would allow for real-time calculation of risk scores and rapid feedback to clinicians and/or parents. By combining this machine learning classifier with others, we hope to create a mobile screening system that has the specificity to pinpoint ASD, ADHD, and other developmental delays. Such a mobile screening platform would provide actionable information to parents in need, regardless of geographic location or socio-economic status. Moreover, the data captured by this mobile approach would supplement the standard clinical encounter, providing both clinicians with an in-depth assessment of the patient before the clinical visit, speeding intake and accelerating the delivery of therapy.

68 **142.068** Agreement and Accuracy of ASD Diagnostic Instruments in a Sample of Adults with Average or Above-Average Intelligence

L. Fusar-Poli, *N. Brondino, M. Rocchetti, C. Panisi, U. Provenzani, S. Damiani, M. Vercesi and P. Politi, Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy*

Background: The main tools currently used for the diagnosis of Autism Spectrum Disorders (ASD), the Autism Diagnostic Observation Schedule (ADOS) and the Autism Diagnostic Interview-Revised (ADI-R), have been tested in children samples in the vast majority of published literature. However, the number of diagnoses of ASD in adulthood is constantly increasing, often representing a challenge in clinical practice. To the best of our knowledge, very few studies have addressed the reliability of the diagnostic instruments in adult high-functioning individuals.
Objectives: The present study aims to evaluate the agreement among the DSM-5 criteria, the ADOS-2 and the ADI-R scores in a sample of adults with average or above-average intelligence. Additionally, sensitivity and specificity of the diagnostic instruments will be analyzed by means of ROC curves.
Methods: From June 2013, the Autism Lab of the University of Pavia recruited 84 patients meeting the following inclusion criteria: (1) age>18 years; (2) IQ>70; (3) good comprehension of written and spoken Italian. The ADOS-2 Module 4 was administered to all patients and the ADI-R was administered to their parents or caregivers, when available. A clinical diagnosis was performed by a senior psychiatrist according to DSM-5 criteria. Statistical analysis was conducted using SPSS 21.0.
Results: 67% of our sample met diagnostic criteria for ASD. The agreement between DSM-5 criteria and ADOS-2 scores was substantial (k=0.76). On the contrary, the ADI-R fairly agreed to DSM-5 criteria (k=0.36). The accuracy resulted to be good in ADOS-2 (AUC=0.87) and fair in ADI-R (AUC=0.75).
Conclusions: Our results confirm that ADOS-2 Module 4 is a reliable instrument for the diagnosis of ASD also in adult patients with average or above-average intelligence and good verbal fluency. On the contrary, the ADI-R appears less sensible and specific for ASD diagnosis in adults.

69 **142.069** An Examination of School Psychologists' Confidence in Conducting Evaluations for Autism Spectrum Disorder

L. S. Woods[1,2], *M. R. Silva*[3,4], *S. Simons*[4,5], *S. Gillespie*[6] *and L. Dilly*[7], *(1)University of North Carolina at Chapel Hill, Mebane, NC, (2)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University, Atlanta, GA, (3)Unviersity of Massachusetts Boston, Boston, MA, (4)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA, (5)Oklahoma State Unviersity, Stillwater, OK, (6)Emory University School of Medicine, Atlanta, GA, (7)Marcus Autism Center, Atlanta, GA*

Background: Recent estimates from the CDC suggest approximately 1 in 68 individuals are diagnosed with autism spectrum disorder (ASD) in the United States (Christensen et al., 2016). Within this group, boys are approximately 4.5 times more likely to be diagnosed than girls, which may reflect a difference in symptom presentations between boys and girls (“Facts About ASDs,” 2016; Rynkiewicz et al., 2016). The median age of initial ASD diagnosis ranges between 3 years, 10 months and 6 years, 2 months. Further, as many as 24% of children are first evaluated for ASD while enrolled in public schools. These figures suggest school psychologists must possess both competence and confidence when conducting ASD evaluations that lead to appropriate educational placement and services (Shriver, Allen, & Mathews, 1999). While little research has been conducted in this area, initial findings suggest a relationship between confidence and accuracy with school-based providers when identifying individuals with ASD (Hedley and colleagues, 2016).
Objectives: The current study examined confidence levels reported by school psychologists working for public school districts in Georgia.Â Specifically, we explored confidence levels related to the assessment of ASD with consideration for both students’ gender and age. We also examined predictive factors associated with higher levels of confidence including a) the average number of initial ASD evaluations conducted each year, b) years of experience as a school psychologist, and c) level of education.
Â Methods: AÂ 28-question, electronic survey was completed by 300 school psychologists who currently work in Georgia public schools. Based on IDEA section 618 data (U.S. Department of Education, 2016), the respondents represented approximately 42% of school psychologists in the state. Sample representativeness was deemed sufficient through a comparison of the respondents’ reported geographic region and the student populations for the 12 regions in the state.Â Chi-square tests of independence and binary logistic regression were employed to gauge statistical relationships.
Results: Results revealed no difference in school psychologists’ confidence when assessing ASD in male versus female students (p = 0.114). High versus Low Confidence levels were evaluated across age levels served, including preschool (2:10 – 4 years), elementary school (5 – 10 years), and middle/high school (11 – 18 years) aged children. High Confidence ratings for preschool-aged children were significantly lower than High Confidence ratings for elementary and middle/high school-aged children (33.3% versus 80.4% and 83.3%; p < 0.001). Univariate logistic models, considering school psychologists’ High Confidence in assessing ASD, found the highest confidence levels in practitioners with a doctoral degree (p = 0.090) and those who conducted more than ten initial ASD evaluations (p = 0.020) each year.
Conclusions: School psychologists reported similar levels of confidence in evaluating children across gender. Our findings support that greater educational training and clinical practice is predictive of higher confidence, which is consistent with results from the literature (Rasmussen, 2009). Further, school psychologists reported less confidence when assessing preschool children, a critical point given the current focus on early identification.

70 **142.070** An International Clinical Cross-Sectional Study on Ability and Disability in Autism Spectrum Disorder (ASD) Using the WHO ICF-CY Framework

S. Mahdi[1], *K. Albertowski*[2], *O. Almodayfer*[3], *V. Arsenopoulou*[4], *S. Carucci*[5], *J. Dias*[6], *M. Khalil*[3], *A. Knuppel*[7], *A. Langmann*[8], *M. B. Lauritsen*[7], *G. Rodrigues da Cunha*[9], *T. Uchiyama*[10], *N. Wolff*[2] *and S. Bolte*[11], *(1)Women's and Children's Health, Karolinska Institutet, Stockholm, Stockholm, Sweden, (2)Uniklinikum Dresden, Dresden, Germany, (3)Ministry of National Guard -Health Affairs, Riyadh, Saudi Arabia, (4)Theotokos Foundation, Ilion, Greece, (5)Microcitemico--NPIA, Cagliari, Italy, (6)Centro Hospitalar do Porto - Departamento de Pedopsiquiatria, Porto, Portugal, (7)Research Unit for Child and Adolescent Psychiatry, Aalborg University Hospital, Aalborg, DENMARK, (8)Philipps-Universität Marburg, Fachbereich Psychologie, AG Kinder- und Jugendpsychologie, Marburg, Germany, (9)Consultório Particular, Sao Paulo, Brazil, (10)Department of Clinical Psychology, Taisho University, Tokyo, JAPAN, (11)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Institutionen för kvinnors och barns hälsa (KBH), Karolinska Institutet, Stockholm, Sweden*

Background:
The International Classification of Functioning, Disability and Health was developed by the World Health Organization (WHO) to provide a comprehensive and universally accepted framework for describing aspects of health-related functioning. The ICF is based on an integrative bio-psycho-social model of functioning, comprising of 1685 categories related to various components of health, specifically; body functions, body structures, activities (execution of tasks), participation (involvement in life situation) and environmental factors (physical, social and attitudinal environment of people). Although the ICF provides a comprehensive and in-depth description of health-related functioning aspects, using it in clinical practice would be rather impractical, as all categories are not applicable to a certain health condition. To address this issue, the development of ICF Core Sets was initiated; lists of generally agreed-upon ICF categories pertinent to a specific health condition. In this project, Karolinska Institutet Center of Neurodevelopmental Disorders (KIND), in cooperation with the WHO, has initiated the process of developing ICF Core Sets for Autism Spectrum Disorder (ASD). The development process includes four preparatory studies, each aiming to capture specific perspective on functioning and disability in ASD.
Objectives:
This study is the fourth empirical investigation to develop ICF Core Sets for ASD. The objective was to identify common problems in functioning experienced by individuals with ASD in clinical setting as documented by the ICF.
Methods:
An empirical cross-sectional multicenter study was conducted, involving 10 countries from 4 WHO-regions (Eastern Mediterranean, Europe, The Americas and Western Pacific). Experienced clinicians and clinical researchers rated the functioning level of individuals with ASD across the lifespan using an ICF checklist. The checklist consisted of 148 categories, of which 65 were related to activities and participation, 48 to body functions and 35 to environmental factors. The rating of functioning level was based on different information sources, namely medical records, medical history, interviews with participant or caregivers, and clinical observation. Absolute and relative frequency analysis was conducted to identify functioning categories that were considered to be significantly affected by ASD.
Results:
The study yielded in total 122 clinical cases of ASD. To include the most relevant ICF categories pertaining to ASD, only those that were identified to be significantly affected by ASD in at least 10 % of the cases were selected as candidate categories. This left us with 64 activities and participation categories (most identified category; d220 undertaking multiple tasks, n = 106; 87 %), 41 body functions (most identified category; b122 global psychosocial functions, n = 108, 89 %) and 35 environmental factors (most identified category; e310 immediate family, n = 103, 84 %).
Conclusions:
The present study identified broad arrays of functioning aspects and contextual factors to be relevant in ASD, supporting the notion that the impact of ASD extends beyond the core behavioral features of the condition. This study, along with three other preparatory studies, will provide the scientific basis to define ICF Core Sets for ASD, of which assessment or diagnostic tools can be used in multiple settings involving clinical care, education and research.

71 **142.071** Analysis of Autism Diagnostic Observation Schedule (ADOS) Applied to Chilean Children with Suspicion of Autism Spectrum Disorder (ASD)

A. C. Yanez*, C. López, M. Troncoso, P. Maira, P. Rebolledo, K. Guajardo and A. Villalba, Child Neuropsychiatry Service, San Borja Arriaran Hospital, Santiago, Chile*

Background: The increasing prevalence of ASD in developed countries has been well documented. However, lack of knowledge is reported with regards to the prevalence of this condition in developing countries, with the consequent unawareness of the global variation of these disorders (Germain et al. 2015). In our clinical practice in a Chilean child Neuropsychiatry service, increasing prevalence has been noticed in the last decade. Great importance has been given to the adjustment of our diagnostic tools for timely treatment, considering that the diagnosis and early intervention improves prognosis in these patients (Zwaigenbaum et al., 2015). The Autism Diagnostic Observation Schedule (ADOS) is considered one of the "gold standards" in the diagnosis and research of ASD, determining severity and helping to plan the intervention. Studying a sample of patients under control with this tool will allow us to contrast Chile´s reality with the rest of the world.
Objectives: To evaluate the characteristics of a representative sample of Chilean patients with suspicion of ASD by using the ADOS, and compare the results with those reported in international publications.
Methods: Observational retrospective study of patients with suspicion of ASD, tested with ADOS in a Neuropsychiatry service of a Chilean Public Hospital. 108 children were included, between 1 and 15 years (average age=5.79, median=4). Patients were separated by age and range of severity and the results were analyzed statistically.
Results: Of the 108 children who were tested with ADOS, 88% met criteria for ASD, while 13 did not qualify as ASD (12.0%). Severity: In all, 6.6% had minimal evidence, 9.4% had mild ASD, 4.7% had moderate ASD, 5.6% had mild autism, 34.5% had moderate autism and 23,6% had severe autism. Age: In the sample composed by infant, toddler, preschoolers and schoolchildren, 58% were diagnosed with ASD. In the adolescent group, 54% were autistic. Among the patients that met ADOS criteria for ASD, children between 0 and 5 years graded 2.87 points higher in social affectation than children with ages between 6 to 15 years (p=0.00886). Non-significant differences were found in restricted and repetitive behaviors between different age groups (p=0.519)
Conclusions: Although the diagnosis of ASD is clinical, the ADOS relates to a useful diagnostic tool in the clinical practice, which allows determining severity and make valid comparisons between different populations. Our study confirmed the diagnosis in 88% of patients with suspicions of ASD, a reality in accordance with the data reported in international literature (Molloy et al. 2011).

72 **142.072** Anandamide As a Blood-Based Biomarker in Children with Autism Spectrum Disorder

D. S. Karhson[1], *K. M. Krasinska*[2], *R. A. Libove*[1], *J. Ahloy Dallaire*[3], *A. S. Chien*[2], *J. P. Garner*[3], *A. Y. Hardan*[1] *and K. J. Parker*[1], *(1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Stanford University Mass Spectrometry, Stanford, CA, (3)Comparative Medicine, Stanford University, Stanford, CA*

Background: Autism spectrum disorder (ASD) is a brain disorder that emerges in early childhood and is characterized by social functioning impairments and repetitive, and stereotyped behaviors. Optimal outcomes rely on early identification and intervention, but progress has been hindered by a poor understanding of ASD pathophysiology. Identification of a diagnostic or phenotypic ASD biomarker would enhance therapeutic development by identifying novel intervention targets. Recent data have shown that endogenous cannabinoids (endocannabinoids, or eCBs), a class of lipid neuromodulators that regulate neurotransmitter release, also contribute to social functioning. Moreover, preclinical ASD research implicates the major eCBs, anandamide (AEA) and 2-arachidonoylglycerol (2-AG), in ASD pathophysiology.
Objectives: We sought to develop a reproducible liquid chromatography with tandem mass spectrometry (LC-MS/MS) method to detect and quantify endocannabinoid (eCB) levels in small volumes of peripherally sampled human blood. LC-MS/MS is the most comprehensive method to quantitatively characterize lipids in children with ASD. The methodology was used to compare plasma eCB levels between children with and without ASD and to test whether eCB levels predicted behavioral measures. We hypothesized that children with ASD would have altered eCB tone compared to neurotypical controls, and that plasma eCB concentrations would be related to variation in ASD behavioral functioning.
Methods: A conventional toluene liquid-liquid extraction was compared to a modified salting-out assisted liquid-liquid extraction (SALLE) with acetonitrile on reproducibility, efficiency, and matrix effects. Following lipid extraction, an optimized LC-MS/MS method was used to quantify AEA (350Da) levels in banked plasma samples collected from phenotypically well-characterized children with ASD (N=57) and matched neurotypical controls (N=54). A TSQ Vantage triple quadrupole mass spectrometer coupled with an Accela 1250 HPLC system was operated in positive mode using heated electrospray ionization. Data acquisition was performed in selected reaction monitoring mode and processed with Xcalibur software. We used JMP 12.1 to analyze data with general linear models that corrected for age, gender, ethnicity, and LC-MS/MS sample run.
Results: SALLE reduced extraction time, increased recovery, and enhanced inter-sample consistency. LC-MS/MS methodology was highly sensitive with lower limits of quantitation for AEA at 50fg. Blood AEA levels were similar in children with ASD and neurotypical controls (mean ± SE: 334±14 vs. 343±14 pg/mL; $F_{1,102}$=0.73; p=0.395). Among children with ASD, IQ was both lower than in controls (83.6±3.7 vs. 115.5±1.3; $F_{1,102}$=59.46; p<0.0001) and negatively correlated with AEA concentrations ($F_{1,57}$=8.05, p=.007). Thus, when controlling for IQ, blood AEA concentrations were significantly lower in children with ASD than in neurotypical controls ($F_{1,101}$=6.63; p=0.012). In children with ASD, blood AEA levels, controlling for IQ, negatively predicted total scores on the Vineland Adaptive Behavior Scale (VABS; $F_{1,46}$=5.22; p=0.027), and more specifically, scores on the Socialization ($F_{1,47}$=4.28, p=0.044) and Motor Skills ($F_{1,46}$=7.17, p=0.010) subscales.
Conclusions: These preliminary findings demonstrate that children with ASD show abnormalities in blood eCB levels compared to neurotypical control children, and that blood eCB levels may predict behavioral measures in children with ASD. Results implicate a meaningful role of AEA tone in ASD pathophysiology and suggest that AEA may hold promise as a peripheral marker of ASD pathophysiology.

73 **142.073** Anxiety Problems Relate to Teacher-Reported Classroom Performance in Children with ASD but Not ADHD

M. F. Skapek[1], *L. G. Anthony*[2], *A. D. Verbalis*[2], *C. E. Pugliese*[3], *A. B. Ratto*[3], *J. Safer-Lichtenstein*[4], *S. Seese*[2], *K. Tiplady*[5], *D. Limon*[6], *K. Hardy*[2], *B. J. Anthony*[4] *and L. Kenworthy*[2], *(1)Children's National Health System, Rockville, MD, (2)Children's National Health System, Washington, DC, (3)Children's National Medical Center, Washington, DC, (4)Center for Child and Human Development, Georgetown University, Washington, DC, (5)University of Florida, Ashburn, VA, (6)Children's National Medical Center, Rockville, MD*

Background:
Comorbid psychiatric disorders occur at elevated rates in individuals with Autism Spectrum Disorders (ASD). In particular, assessments reveal that anxiety and ADHD symptoms frequently exist in the ASD population. A meta-analysis found an anxiety rate of 39.6% in children with ASD (van Steensel et al. 2011). Emotions and behaviors associated with psychiatric problems exacerbate impairments that individuals with ASD face, and increased anxiety relates to suboptimal outcomes in adults. The classroom presents a real-world scenario to assess outcomes in children. A recent school study indicated that social anxiety predicts poor outcome related to cognitive ability (Pellecchia et al. 2016). Further analysis of the relationship between anxiety and classroom performance will provide insight into the factors that contribute to outcome in youth with ASD. Exploring the specificity of the effect to ASD relative to other developmental disorders is also relevant. This study thus included an ADHD group as a comparative sample.
Objectives:
To determine whether anxiety symptoms in children with ASD relate to teacher-reported classroom performance after accounting for sex, IQ, ASD, and ADHD symptoms, and to explore the specificity of the effect to ASD.
Methods:
Children with ASD (N=36) or ADHD (N=88) participated in a randomized comparative study of two school-based intervention programs. Parents completed the Child Behavior Checklist (CBCL, Achenbach & Rescorla, 2001) as a baseline measure of emotional and behavioral characteristics. Teachers reported classroom performance using the Swanson, Kotkin, Agler, M-Flynn, and Pelham Scale, which includes 11 standard items that are rated on a 7 point scale (SKAMP, Swanson, 1992). The relationship between parent-reported anxiety and classroom behavior was analyzed using a linear regression model. CBCL Anxiety Problems and Attention Deficit/Hyperactivity Problems *t*-scores were used as measures of anxiety and ADHD symptoms. After first controlling for the effects of sex, IQ, and ASD symptoms alone and subsequently accounting for ADHD comorbidity, the model measured the effect of anxiety on the total SKAMP scores in the ASD group. A similar analysis accounting for sex, IQ, and ADHD symptoms was repeated for the ADHD group.
Results:
After controlling for the effects of sex, IQ, and ASD symptoms, anxiety was significantly related to SKAMP scores in individuals with ASD (β=.473, p=.009) and accounted for 21.2% of the variance. The effect remained when ADHD symptoms were incorporated into the model (β=.398, p=.041). After accounting for sex, IQ, and ADHD symptoms, this pattern was not observed in the ADHD group (β=-.201, p=.139). Given these findings, Pearson correlations between individual SKAMP items were explored. Significant associations were found in the ASD group related to starting assignments, sticking with tasks or activities, attending to activities or discussions, and completing assignments (Table 2; all r>.414, p<0.012).
Conclusions:
The analysis suggests that parent-related anxiety relates to teacher-reported classroom performance in children with ASD after accounting for sex, IQ, and ASD symptoms. This association was not observed in the ADHD group. The knowledge that anxiety contributes to aspects of classroom outcome, such as completing assignments, underscores the importance of recognizing and treating anxiety in children with autism.

74 **142.074** Application of the Brief Observation of Social Communication Change (BOSCC) to a Short Term Parent Mediated Intervention Trial

K. Sterrett[1], *T. Carr*[2], *M. L. Mattos*[3], *W. I. Shih*[4], *A. Gulsrud*[5] *and C. Kasari*[4], *(1)University of California Los Angeles, Los Angeles, CA, (2)Autism Discovery Institute, Rady Children's Hospital San Diego, San Diego, CA, (3)University of California, Los Angeles, Woodland Hills, CA, (4)University of California, Los Angeles, Los Angeles, CA, (5)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA*

Background: The measurement of small yet meaningful social communication change in children with autism spectrum disorder (ASD) is critically important to the development of effective short-term interventions (McConachie et al., 2015). To that end, the Brief Observation of Social Communication Change was developed (BOSCC; Grzadzinski, Lord et al., 2016). The BOSCC is a measure of social communication change for use in children with little to no language coded from parent-child play interactions. It has been found to have high inter-rater, test-retest and convergence with other measures (Gradzinski et al., 2016; Kitzerow et al., 2015).
Objectives: To assess the sensitivity to change of the BOSCC over the course of a short term (10-week; 20 sessions) randomized intervention trial and three months later at follow-up. Additionally, to determine the effect of a number of moderating variables on BOSCC scores at entry.
Methods: Eighty-six parent child dyads were randomized to receive a ten-week parent mediated social communication intervention. A prior analysis found that the group receiving the parent-mediated JASPER intervention spent significantly more time spent jointly engaged and showed higher parental responsivity compared with the psychoeducation control group (Kasari et al., 2015; Shire, Gulsrud & Kasari, 2016). The primary outcome measure for this analysis was the BOSCC, scored by two reliable coders from a ten-minute unstructured parent-child play interaction. Additionally, data from the Autism Diagnostic Observation Schedule (ADOS), Early Social Communication Scales (ESCS), the Mullen Scales of Early Learning (MSEL), the Reynell Developmental Language Scales-Revised (Reynell) and Maternal Behavior Responsiveness Scales (MBRS) as well as demographic information were collected at each time point.
Results: Group differences on BOSCC TOTAL composite or domain scores were not found and so data was collapsed across groups. Change across time was assessed at the item, domain, and composite level using a linear mixed effects model. Overall, there was a significant decrease (signifying improvement) on BOSCC scores for the total composite score (d=.56) as well as both the social communication (SC; d=.56) and restricted and repetitive behaviors domains (RRB; d=.27). These decreases maintained at follow-up. Seven of ten SC domain items evidenced significant decreases from entry to exit (table 1). A median split was conducted for significantly correlated predictors and independent samples T-tests were run comparing the TOTAL composite scores of the median split groups. Significant differences on BOSCC scores at entry were found between the median-split groups for mental age (MA), IJA, composite language score, and parental responsivity (Table 2) with lower BOSCC scores associated with higher abilities.
Conclusions: Overall, the sensitivity of the BOSCC as a measure of social communication change was confirmed. Significant differences were found over the ten-week intervention period which were maintained at follow-up three months later. Additionally, it was found that a number of predictors such as MA, IJA, language, and caregiver responsiveness moderate BOSCC scores at entry. As caregiver responsiveness was found to be related to BOSCC scores, future directions include further exploration of the parental factors that influence the validity of the BOSCC as a measure of children's social communication change.

75 **142.075** Are Diagnostic Instruments Equally Accurate at Classifying Autism Spectrum Disorder in Males and Females?

E. F. Perry[1], *D. H. Skuse*[2], *M. Murin*[3] *and W. Mandy*[4], *(1)Clinical Psychology, Royal Holloway, Egham, United Kingdom, (2)UCL GOS Institute of Child Health, London, UNITED KINGDOM, (3)Great Ormond Street Hospital for Children, London, UNITED KINGDOM, (4)University College London, London, United Kingdom*

Background: In cognitively-able samples, the male to female ratio in Autism Spectrum Disorder (ASD) is up to 10:1 (Fombonne, 2009). One hypothesis for the sex discrepancy isÂ thatÂ diagnostic criteria is orientated towards a presentation typically seen in males (Kreiser & White, 2014). It is argued as a result, females are systematically under-diagnosed, a phenomena termed the 'male bias' (Kirkovski et al., 2013). With increasing evidence that females presenting with clinically significant traits are less likely to receive a diagnosis, many are highlighting the need for gender-specific thresholds in ASD assessments (Constantino and Chairman, 2012;Â Dworzynski et al., 2012). However, examination of diagnostic instruments is required to ascertain whether tools are indeed less accurate at diagnosing ASD in females, and to identify the areas of inaccuracy, before such gendered tools may be developed.
Objectives: Three aims were identified; 1) to examine whether diagnostic tools' classifications of males and females differed in diagnostic accuracy. 2) To compare the accuracy of diagnostic tools by sex i.e. to investigate whether a tool may be more accurate at diagnosing females. 3) To investigate whether behavioural domain classifications (i.e. areas of deficits that relate to diagnostic algorithms) of males and females differed in diagnostic accuracy, in order to identify specific areas of inaccuracy for the development of gender-specific thresholds.
Methods: Autism Diagnostic Observational Schedule (ADOS) (Lord et al., 2000) and Developmental, Dimensional and Diagnostic Interview (3Di) (Skuse et al., 2004) classifications of 256 males and 60 females were compared against the 'gold standard' multidisciplinary team assessment diagnosis.Â Receiver Operating Characteristics curves of ADOS and 3Di classifications of males and females were performed to describe diagnostic accuracy, measured by sensitivity and specificity. Participants data was selected from a database of consecutive referrals for the assessment of high-functioning ASD. ADOS and 3Di assessments took place concurrently as part of routine clinical practice.
Results: Chi-square and Fisher's exact test found no significant differences in the sensitivity or specificity of overall or behavioural domain classifications of males and females. McNemar's test found no significant differences in the sensitivity of ADOS and 3Di classifications of males or females but found the 3Di showed significantly lower specificity than the ADOS of males and females.
Conclusions: The 3Di and ADOS are found to be equally accurate at classifying ASD in males and females. The 3Di and ADOS show comparable accuracy classifying both males and females but the 3Di showed comparably lower accuracy classifying non-spectrum individuals. Thus, when ruling out ASD is of greater importance, the ADOS may be a more accurate diagnostic instrutment for both males and females. No behavioural domain was found to be less accurate classifying females, thus the results do not identify areas of inaccuracy to recommend the development of gender-specific thresholds in these tools. In conclusion, the 3Di and ADOS show equal accuracy classifying high-functioning males and females referred for clinical assessment.

76 **142.076** Assessing PTSD in Persons with Autism Spectrum Disorders

T. L. Shepler[1] *and A. J. Lincoln*[2]*, (1)PsyD Clinical Psychology, Alliant International University, San Diego, CA, (2)Alliant International University, San Diego, CA*

Background: Previous research has indicated that roughly 63% to 77% of adolescents diagnosed with ASD will experience bullying (IAN, 2012; Cappadocia, Weiss, & Pepler, 2012). Idsoe, Dyregrov, & Idsoe (2012) explored the psychological impact of bullying in neurotypical students by assessing students for symptoms of PTSD. They reported that approximately one third of bullied students met criteria for PTSD.
Objectives: The primary objective of the current study was to examine the association between bullying victimization and PTSD symptoms in adolescents with ASD. Research questions sought to assess if adolescents diagnosed with ASD would report being bullied more frequently than their neurotypical peers, and if PTSD symptoms would be reported at similar rates for both ASD and neurotypical youth.
Methods: A total of 33 adolescents (*n*=10 in the ASD group; *n*=23 in the non-ASD group) and 52 parents (*n*=19 in the ASD group; *n*=33 in the non-ASD group) participated in an online survey. The survey assessed the frequency that the adolescent has experienced bullying, has participated in bullying others, and PTSD symptoms that were a consequence of bullying experiences. All participants were administered the Olweus Revised Bullying and Victimization Questionnaire (OBQ) as well as the Children Revised Impact of Events Scale (CRIES; 8) and CRIES (13).
Results: Sixty-seven percent of parent respondents in the ASD group reported their child was bullied at least two to three times per month, and 55% of parents reported their child was bullied at least once a week. Forty percent of victims in the ASD group met or exceeded cutoff criteria on both the CRIES (8) and CRIES (13) PTSD measure. Within the non-ASD group, 15% of parents reported their children experienced victimization two to three times per month, and 12% of victims met criteria for the CRIES (13), while 27% met criteria for the CRIES (8). There was strong agreement between adolescent and parent report.
Conclusions: Results of the current study suggest that there was indeed an association between bullying victimization and meeting PTSD cutoff criteria in both groups. Moreover, results of the current study are consistent with research that has assessed the frequency that ASD youth experience bullying (IAN, 2012; Cappadocia et al., 2012) as well as research that has assessed the frequency neurotypical youth experience PTSD symptoms as a result of bullying experiences (Idsoe et al., 2012). The findings of the current study indicate a clear need for future research relating to assessing PTSD in the ASD population as well as research that seeks to accurately capture the frequency that youth diagnosed with ASD experience bullying. Future research could also focus on the efficacy of bullying prevention programs and how those programs may reduce the frequency and impact that bullying can have in the ASD community.

77 **142.077** Assessing Social, Behavioral and Emotional Functioning in Autism: A Feasibility Pilot Study

K. M. R. Hall[1]*,* ***E. Grossi***[1]*, L. Reale*[2] *and M. Bonati*[3]*, (1)Villa Santa Maria scs, Tavernerio, Italy, (2)Laboratory for Mother and Child Health, Department of Public Health,, Mario Negri, Institute, Milano, Italy, (3)Laboratory for Mother and Child Health, Department of Public Health,, IRCCS-Istituto di Ricerche Farmacologiche Mario Negri, Milano, Italy*

Background:
The clinical assessment of global functioning in children with autism is essential in order to identify needs and to arrange therapeutic and educational interventions. Appropriateness of using rapid and cost-effective instruments, as the Strengths and Difficulties Questionnaire (SDQ) and the Health of the Nation Outcome Scales for Children and Adolescents (HoNOSCA), needs further evaluation and definition, in particular in children with low-functioning autism.
Objectives:
Through a pilot observational study to describe the trend in different areas (behavior, socialization, emotions) using SDQ and HoNOSCA, and to explore correlation pathways between the two instruments, thus to plan an adequate and wide collaborative study.
Methods:
Ten consecutive new patients with low-functioning autism (age 5-14 years) were enrolled between November 2015 and October 2016. The SDQ is a 25-item questionnaire useful to screen emotional, behavioral and social problems in children aged 4-16 years. Scores for the 5 subscales (emotional symptoms, conduct problems, hyperactivity/inattention, peer problems and prosocial behavior) are classified in “normal”, “borderline” and “abnormal” ranges, according to the original cut-offs. The HoNOSCA is a 15-item clinical assessment scale used as part of the routine outcome monitoring in mental health services, especially in Netherlands, UK, Australia and New Zealand, which measures global functioning in patients aged 3-18 years through 4 different areas: behavioral, impairment, symptoms, social functioning. The SDQ completed by the educators was compared to the results of the global functioning evaluation of the clinician, who has used the HoNOSCA scale. A single psychologist completed the HoNOSCA questionnaire. Associations have been assessed with Pearson linear correlation index and minimum spanning tree algorithm.
Results:
The SDQ subscales with abnormal mean scores were “peer relations” (mean: 5.8, SD: 1.03) and “pro-sociality” (mean: 1.4, SD: 1.4), while in the HoNOSCA the social functioning domain resulted as the most problematic area. Linear correlation matrix between the items of the two instruments showed interesting values of r- index between behavioral score of HoNOSCA and both emotional difficulties (r = 0.71, *p* 0.02) and peer relationships of SDQ (r = 0.55,Â *p* = 0.09), and between social functioning score of HoNOSCA and behavioral problems of SDQ (r = 0.52, *p* = 0.12). These association were also confirmed by a map projection using the minimum spanning tree method (fig.1).
Conclusions:
The correlation between SDQ and HoNOSCA can be a simple and efficient way to screen for emotional disorders and behavioral problems in child and adolescents with low-functioning autism. It could help to recognize co-occurring disorders and reduce with appropriate interventions their impact on social functioning and peer relationship domains. However, further more systematic attempts at validation are warranted.

78 **142.078** Assessing Visuomotor Deficits in Children with SPD

***A. Brandes-aitken**, J. A. Anguera, J. Owen, P. Mukherjee and E. Marco, University of California, San Francisco, SAN FRANCISCO, CA*

Background: Visuomotor control is the process by which individuals integrate visual perception and motor coordination systems. Visuomotor control is thought to have important implications for academic and social development. Mounting evidence suggests that abnormal visuomotor processes are common to various neurodevelopmental disorders. Specifically, children with sensory processing dysfunction (SPD) are anecdotally reported to have challenges with dysgraphia which is predicated on visuomotor integration. Previously, scant attention has been devoted to directly assessing visuomotor deficits in this population.
Objectives: In this study, we aim to determine whether children with SPD show deficits in visuomotor integration using two direct assessment measures, one a standard clinical test and the other an experimental assessment. Further we are interested in investigating correlations between visuomotor outcomes and measures of white matter integrity in the SPD group to better understand the biologic underpinnings of this disorder.
Methods: In this project, we collected visuomotor assessments and DTI imaging in 42 children with SPD (mean age 10 +/- 1.5) and 34 typically developing controls (TDC; mean age 10.2 +/- 1.3). The visuomotor battery included the Beery-Buktenica Developmental Test of Visual-Motor Integration, (Beery™Â VMI; copying, matching and tracing subtests) and the Project: EVO™ (EVO™) navigation assessment. The EVO™ tool is a scientifically derived iPad videogame-like assessment with embedded adaptive algorithms. The EVO™navigation assessment requires the player to steer their character through a dynamically moving environment with the goal of avoiding the walls and obstacles. Further, we assessed for correlations between our visuomotor measures and mean fractional anisotropy (FA) in selected regions of interest (ROI).
Results: Outcomes from our independent t-test group analysis revealed no significant group differences in any of the Beery VMI subtests, however the SPD group did preform significantly worse compared to the TDC group in the EVO™ navigation assessment. Results from our neuroimaging brain-behavior correlational analysis showed that the copy, matching and tracing subtests of the Beery VMI and the EVO™navigation assessment showed some overlapping and some unique tracts which appear to mediate these visuomotor abilities. The tracing subtest of the Beery VMI showed the most significant correlations.
Conclusions: These finds suggest that EVO™ navigation assessment may be more sensitive than the Beery VMI for assessing visuomotor integration deficits in children with neurodevelopmental disabilities, including SPD. This could be due to the adaptive and game-like features of the EVO™ navigation assessment, which minimize boredom and increase engagement. The ROIs that correlated with visuomotor deficits are areas thought to be involved in connecting lower-cortical regions to the motor cortex and frontal lobes. This might suggest faulty connectivity between these regions in children with SPD. These findings provide new insight into the biological implications for visuomotor deficits observed in children with SPD.

79 **142.079** Autism Quotient Scores Modulate the Perception and Production of Text Specificity in Typical Adult Females

***J. J. Li**[1], J. Parish-Morris[2], L. Bateman[3] and A. Nenkova[1], (1)Computer and Information Science, University of Pennsylvania, Philadelphia, PA, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)The Center for Autism Research/CHOP, Philadelphia, PA*

Background: Successful communication is a careful balancing act: speakers must gauge the appropriateness of producing statements that are highly detailed vs. statements that are more general. Whereas too much detail may overwhelm the listener, vague statements with too little detail can sound vacuous. In this study, we begin to test the hypothesis that some communication difficulties experienced by individuals with autism spectrum disorder (ASD) may be due to challenges in understanding or producing appropriate levels of communicative specificity during conversation. To enhance the scalability of our efforts, we use a novel, automated tool to accurately quantify sentence specificity (Li & Nenkova, AAAI 2015). Our long-term goal is to determine the extent to which existing automated tools and computational theories of language vagueness and specificity can elucidate differences between individuals with ASD and typical controls, for the purposes of enhancing screening, diagnosis, treatment planning, and intervention response measurement.
Objectives: Test whether people with high- vs. low-Autism Quotient scores (AQ; Baron-Cohen et al., 2001) differ in their (1) perception of sentence specificity and (2) propensity to generalize content during a summarization task, as indicated by automatic measures of sentence specificity.Â
Methods: Participants included 62 typically developing undergraduate students (38 females, all native speakers of English). Participants took the AQ test (higher scores indicate more ASD-like symptoms), rated for specificity 40 sentences drawn from news (0-6, lower rating=more specific), and summarized two texts, one with rich specific detail and one more general. An automated specificity measurement tool was applied to the original articles and to article summaries produced by participants. We computed Spearman correlations between participants' AQ scores and: (1) the deviation of their sentence specificity ratings from average sentence ratings collected from ~30 independent raters per sentence, and (2) specificity scores of the article summaries.
Results: Preliminary analyses revealed significant gender differences in both AQ and specificity judgments; male and female data were thus analyzed separately. We found no correlation (rho=-0.01) between male judgments of specificity and AQ. For females, however, the correlation between perceived specificity and AQ score was -0.29, trending toward significance (p=0.08). Women with higher AQ scores perceived sentences to be more specific than women with lower AQ scores. In the summarization task, we found that females with higher AQ scores tended to write summaries that were more general (rho=-0.22, p=0.18).
Conclusions: Our study is the first to examine the perception and production of linguistic specificity in people with varying degrees of autism-like symptoms. Although preliminary, our results reveal previously unexplored gender differences, which we plan to confirm with a larger sample and participants with official ASD diagnoses (anticipated by May 2017). This is the first step in a research program aimed at developing technology-augmented interventions to visualize the mismatch in expectations regarding specificity to both typical people and individuals with ASD, to improve the quality of communication across the two groups. Furthermore, we aim to develop a battery of tests to quantify an individual's perception of specificity, and explore the use of these metrics for assessing intervention effectiveness.

80 **142.080** Autism Screening in High-Risk Children in a Community Early Intervention Setting

*D. Thao[1], **K. L. Reeb**[2], E. Hammer[3], I. Toll[3], M. Green[3], S. Anderson[3], M. Yudell[4] and D. L. Robins[5], (1)AJ Drexel Autism Institute, Philadelphia, PA, (2)AJ Drexel Autism Institute - Drexel University, Philadelphia, PA, (3)Elwyn SEEDS, Philadelphia, PA, (4)Drexel University School of Public Health, Philadelphia, PA, (5)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Early detection of autism spectrum disorder (ASD) is imperative for access to ASD-specific intervention which leads to better outcomes for children with ASD. Children may be at increased risk for ASD due to a number of factors, including having an older sibling with ASD and/or being flagged for possible developmental delays. High-risk children are in need of timely referrals for ASD evaluation and ASD-specific intervention. While research suggests that the Modified Checklist for Autism in Toddlers (M-CHAT) is effective at screening in older and/or high risk children, there is limited research on the feasibility of screening within these populations.
Objectives:

1. To assess three components of feasibility: demand, implementation, and integration of M-CHAT-R/F screening among intake staff at Elwyn SEEDS, which is the local education agency for preschool early intervention services (ages 3-5) in Philadelphia.
2. To measure preliminary validity of the M-CHAT-R/F in this population.

Methods:
Elwyn SEEDS agreed to administer the M-CHAT, Revised, with Follow-Up (M-CHAT-R/F) during all intake calls. Intake staff attended training prior to deployment of the screening protocol. Archival records (n=792) of children who completed intake between May and August 2015 were extracted and reviewed. Mean age at intake was 41.36 months (SD=10.59, range 27.40-70.13 months). Variables extracted from records included demographic variables, M-CHAT-R item responses and total score, diagnosis, eligibility, referral source, and interventions received.
Results: Feasibility of M-CHAT-R administration during intake was variable. Demand was low: less than half of the files included a completed M-CHAT-R. Implementation was poor: 75 M-CHAT-R forms contained one or more errors. Integration showed some change following deployment of the screening protocol, 23% of children who screened positive (n=15) were referred for ASD evaluation compared to 3% of children who screened negative M-CHAT-R (n=5) and 9% of those who did not have an M-CHAT-R screen (n=30). There were 90 (24.59%) positive M-CHAT-R screens in this sample, of whom 15 were diagnosed with ASD; an additional 48 were diagnosed with developmental delays, but it is unknown if they were referred for an ASD evaluation. Three additional cases diagnosed with ASD screened negative on the M-CHAT-R. Estimates of psychometric properties were 83% for sensitivity, 75% for specificity, and 24% for PPV, but must be interpreted with caution due to poor adherence to the screening protocol.
Conclusions: Screening is important for detecting ASD in children, which leads to better outcomes for a child. Demand, use of the tool, was low in a high-risk community setting. Implementation, correctly administering the tool, was poor, and integration, or incorporation of the tool into current processes, showed some improvement. The low completion rate suggests barriers to implementing screening during intake at Elwyn SEEDS. However, when used, the M-CHAT-R is successful at detecting many of the cases diagnosed with ASD. Therefore, it is essential to improve uptake of screening procedures in community settings. Strategies to increase feasibility of autism screening include qualitative studies to determine the barriers to screening, completing evaluations, ongoing training for the staff administering the MCHAT-R and understanding early intervention providers' beliefs.

81 **142.081** Broader Autism Phenotype in the Mother Is Associated with Discordance in the Social Communication Questionnaire Compared to Best Clinician Estimate

***E. Rubenstein**[1], L. D. Wiggins[2], G. C. Windham[3], L. A. Schieve[2], C. DiGuiseppi[4], L. Young[5] and J. L. Daniels[1], (1)University of North Carolina, Chapel Hill, NC, (2)Centers for Disease Control and Prevention, Atlanta, GA, (3)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (4)University of Colorado - Denver, Aurora, CO, (5)University of Pennsylvania, Philadelphia, PA*

Background:
Parent-based screening for autism spectrum disorder (ASD) is a common, efficient way to identify children needing further evaluation for ASD. To reduce misdiagnosis, it is important to identify factors that influence parent ratings of ASD characteristics. One bias that could increase misreporting isÂ presence of the broader autism phenotype (BAP) in the informant (usually the mother). BAP reflects sub-clinical ASD traits (including pragmatic and broad communication difficulties and poor social skills) reported more frequently in families of children with ASD.
Objectives:
To determine whether BAP in mothers is associated with their reports of at-risk ASD characteristics for their children on an ASD screening instrument when discordant with best estimate clinical judgment. We assess whether discordance is due to over- or under-reporting on the screening instrument compared to the clinician's best estimate.
Methods:
We used data on children aged 3-5 years with ASD or developmental disabilities potentially related to ASD, identified through health clinics, early intervention and special education programs, who participated in the Study to Explore Early Development. Upon enrollment, children were screened using the mother-completed Social Communication Questionnaire (SCQ). To increase sensitivity, SCQ scores ≥ 11 were considered positive for ASD risk. These children underwent full developmental assessments, which included the Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview–Revised (ADI-R). Children who had previous ASD diagnosis or clinician suspicion of ASD underwent full developmental assessment, even if SCQ scores were <11. Best clinical estimate of ASD was determined using the Ohio State University Autism Rating Scale (OARS). A study clinician condensed information from the ADOS, ADI-R, SCQ, and clinician impression to complete a five point rating scale of certainty that a child has ASD; scores ≥4 were considered "positive". Screening discordance was defined as "over-reporting" (a positive SCQ with negative OARS) or "under-reporting" (negative SCQ and positive OARS). The mother's spouse, close family member, or friend completed a standardized questionnaire, the Social Responsiveness Scale-Adult (SRS-A), to describe mother's social traits. BAP was defined as a SRS-A T-score ≥ 60. Regression analyses calculated associations between maternal BAP and risk of screening discordance.
Results:
Our sample included 819 mothers with data on relevant instruments. Seventy-nine mothers were BAP positive (9.6%) and 308 (37.6%) had discordance with clinical judgement. Mothers with BAP had 1.24 times the risk of discordance compared to mothers without BAP (95% confidence interval (CI): 0.96, 1.61, P= 0.1). Risk of over-reporting in mothers with BAP was 1.43 times that of mothers without BAP (95% CI: 1.08, 1.90, P=0.01). Under-reporting was less likely in the BAP group compared to the non-BAP group (RR=0.53; 95% CI: 0.17, 1.60, P=0.3), but not statistically significantly. Effect estimates were similar when a positive SCQ was defined as ≥15.
Conclusions:
Mothers with BAP were more likely to over-report child ASD symptoms on the SCQ and presence of BAP in the mother was not associated with under-reporting of ASD symptoms in the offspring. Further work will examine differences by child ASD severity and whether specific SRS-A domains are associated with screening discordance.

82 **142.082** Case Series of Subclinical ASD: Evidence Towards the Female Protective Effect

***M. L. Braconnier**, D. G. Sukhodolsky, S. M. Abdullahi, J. Lei, C. Kautz and P. E. Ventola, Yale Child Study Center, New Haven, CT*

Background: The sex ratio of males to females with ASD is 4:1. Females with ASD often have greater social communication weaknesses yet fewer restricted and repetitive behaviors than males (Rivet & Matson, 2011; Hartley & Sikora, 2009); however, recent evidence points to how current diagnostic criteria may miss females with ASD (Kirkovsk et al, 2013).
Objectives: We identified and characterized a subset of children who exhibited impairment in social functioning but did not reach the threshold necessary for an ASD. Their deficits were also not characterized by a different developmental or psychiatric disorder.
Methods: From a dataset of 1,626 children (793 females), ages 4-17, referred because of social communication deficits, 4 females and 1 male were identified who exhibited clear social and communication impairments, yet did not meet the threshold for a diagnosis of ASD based on criteria from gold standard diagnostic instruments and clinical judgment of highly expert clinicians. Social communication functioning was assessed using the Autism Diagnostic Observation Schedule (ADOS), Autism Diagnostic Interview, Revised (ADI-R), the Social Responsiveness Scale (SRS), the Social Communication Questionnaire (SCQ), and the Vineland Adaptive Behavior Scales-Second Edition (Vineland-II).
Results: Four females (.5%) and one male (.1%) from the overall dataset (N=1,626) presented with sub-threshold ASD symptoms. The females were between the ages of 6 and 12 years and of average to above average cognitive abilities (Full Scale IQ Range 92 to 118). The male was 9 years old and also exhibited average cognitive abilities (IQ = 97). The children had clear, yet either mild or inconsistent, social communication impairments. ADOS Total Scores (Module 3) ranged from 1-5, SRS T-Scores ranged from 53 to 90, and SCQ Total Scores ranged from 4-32, with a Total Score above 15 suggesting social impairments. Each individual had at least one measure within the range of clinical social communication impairment. Additionally, the children with completed Vineland Adaptive Behavior Scales (n =3) had highly significant impairments in adaptive functioning, with scores ranging from 61-68. Qualitatively, all of the parents reported noticeable difficulties with social verbalization, reciprocal conversation, and imaginative play due to limited flexibility.
Conclusions: A small but meaningful group of children exhibit sub-threshold ASD symptoms. This subclinical presentation is more common in girls than boys, despite the skewed sex ratio towards boys in ASD. These children with subclinical symptom presentation, particularly given the sex ratio, may provide information towards understanding the female protective effect.

83 **142.083** Categorical Meets Dimensional: A Fuzzy Categorical Conception of Autism Spectrum

***B. Tunc**[1], D. Parker[1], J. Pandey[2], R. Verma[1] and R. T. Schultz[2], (1)University of Pennsylvania, Philadelphia, PA, (2)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Autism spectrum disorder (ASD) is presumed to have a categorical distinction from other disorders and the general population. Much current research, however, concentrates on testing whether ASD is better described by dimensional traits defined over continua. This oversimplifying dichotomy of "categorical vs. dimensional" obscures more finely graded possible alternatives, corresponding to structures that are neither purely categorical nor purely dimensional. In order to give a rigorous account of the nature of ASD, dimensional and categorical aspects of the disorder should be considered in a unified formulation.
Objectives: To demonstrate that a *fuzzy category*concept can better represent the ASD phenotype. A fuzzy category lacks sharp boundaries and is neither a discrete category nor a perfect continuum, including intermediate cases between those who are clearly affected and those clearly unaffected. In addition, we aim to show that an underlying ASD severity dimension can account for the heterogeneity and the overlapping nature of subcategories.
Methods: Our dataset consisted of 768 participants (678 males, 90 females): 554 children (age: 15.2 ± 3.3 years) with ASD (confirmed by a clinical expert using the ADOS and other assessments), and 214 typically developing children (TDCs) (age: 16.3 ± 3.2 years). A comprehensive phenotypic battery covered domains of social communication, language abilities, executive functioning, general intelligence, anxiety, attention, and hyperactivity. Using taxometric analyses, complex network analysis, and probabilistic inference with the phenotypic data, we defined the sample's categorical and dimensional characteristics. Finally, we attempted to validate those phenotypic results using brain connectivity analyses with a subset of the sample that had diffusion tensor imaging (DTI) data. 283 participants (239 male and 44 female) had diffusion imaging data (150 ASD and 133 TDC).
Results: The taxometric analyses suggested a categorical structure. Using complex network analysis, we identified communities of participants at multiple neighborhood scales, based on phenotypic relationship between participants. This yielded multiple communities including an intermediate one with a mixture of individuals from both ASD and TDC samples. The identified communities were not stable across different neighborhood scales, indicating heterogeneity and variations inside putative categories. Dynamics of community formation at different scales, revealed clear dimensional effects, with ASD severity regulating participant behavior in forming their communities. Neurobiological analyses, supporting our fuzzy categorical model, resulted in both categorical connectivity differences, and dimensional severity-related alterations.
Conclusions: We provided a computational portrait of ASD phenomenology, as described by phenotypic measures of multiple behavioral domains. Our results confirmed the intricate nature of ASD with categorical and dimensional aspects complementing each other. Even when we tried to identify putative categories in our sample, we saw clear dimensional effects, with ASD severity modulating phenotypic relationship between participants. Our neurobiological results further supported our hypothesis that ASD phenomenology can best be explained by a hybrid model, combining both categorical and dimensional structures. It should be noted, however, that our results are specific to our sample, which include those who met criteria for ASD via gold standard assessments and those who qualify as TDCs. Future work should include unselected clinical samples.

84 **142.084** Child and Parent Factors That Influence Social Communication Questionnaire Scores: An Examination of an English- and Spanish-Speaking Sample

N. M. Reyes[1]*, E. Moody*[2]*, K. Kaparich*[3]*, S. Davidon*[4]*, S. Rosenberg*[5] *and L. Kubicek*[6]*, (1)Box C-234, University of Colorado - Denver, Aurora, CO, (2)University of Colorado, Denver, Aurora, CO, (3)University of Colorado Denver, Aurora, CO, (4)Department of Pediatrics, University of Colorado, AMC, Denver, CO, (5)University of Colorado, Aurroa, CO, (6)University of Colorado, Aurora, CO*

Background: The Social Communication Questionnaire (SCQ) is a frequently used screening tool for Autism Spectrum Disorder (ASD). Although the SCQ has been translated into several languages, including Spanish, the performance of the Spanish SCQ and factors that could influence SCQ scores have not been examined.
Objectives: The aim of this study was to examine whether child behavioral problems and parent characteristics (e.g., maternal education, language) influence the SCQ scores in a community sample of English and Spanish speaking caregivers.
Methods: This study included 104 English- and 96 Spanish- speaking caregivers, their child, and their child's teacher from a large suburban school district in Colorado. Caregivers completed the SCQ in English or Spanish and a brief demographics questionnaire; and the child's teacher completed the Behavior Assessment System for Children, Second Edition (BASC-2), Teacher Rating Scale (TRS) to assess child's behavioral problems.
Results: Simple and multiple linear regressions were used to determine how much variance in the SCQ is explained by maternal education or BASC-2 scores and whether language modified the relationship between maternal education or BASC-2 scores and SCQ scores. Whereas maternal education explained 9% ($F(1, 93) = 9.69$, $p = .002$) of the variance of the SCQ in the Spanish group, the BASC-2 explained 5% ($F(2, 101) = 5.62$, $p = .020$) of the variance of the SCQ in the English group. The English and Spanish groups were combined to explore the association between maternal education, language, and SCQ scores. Model 1 included maternal education and language, and model 2 included the interaction term (maternal education X language). In model 1, maternal education and language explained 3% of the variance in SCQ ($F(2, 195) = 3.45$, $p = .037$). In model 2, language modified the relationship between the maternal education and SCQ scores ($R^2 = .08$, $F(3, 194) = 3.98$, $p = .001$). That is, higher maternal education predicted lower SCQ scores.
Similarly, to examine the association between BASC scores, language, and SCQ scores, model 1 included BASC-2 scores and language, and model 2 included the interaction term (BASC-2 scores X language). In model 1, BASC-2 scores and language explained 6% of the variance in the SCQ ($F(2, 195) = 5.89$, $p = .003$). In model 2, although language explained 6% of the variance in the SCQ ($F(3, 194) = 4.05$, $p = .008$), language did not modify the relationship BASC-2 scores and SCQ scores.
Conclusions: Previous findings suggest that child and parental factors may affect ASD symptoms in school aged children. That is, maternal education and child behaviors were associated to SCQ scores in the English- and Spanish-sample, respectively. Learning about the performance of the SCQ in English and Spanish speaking families and factors that influence its scores can help clinicians and researchers decide when it is appropriate to use the SCQ and how to interpret SCQ scores in a diverse population.

85 **142.085** Cluster Analysis of Daily Living Skills in School-Aged Children with ASD

A. Duncan*, A. Lonnemann and R. Adams, Cincinnati Children's Hospital Medical Center, Cincinnati, OH*

Background: While daily living skills (DLS) are not a core symptom of individuals with autism spectrum disorder (ASD), they typically fall far below chronological age (e.g., Duncan & Bishop, 2015) and have been linked with factors such as language and cognitive abilities (e.g., Kanne et al., 2011). Studies have also found that internalizing and externalizing behaviors may predict DLS, which may in turn make it difficult to target the acquisition of these skills (De Bildt et al., 2005). It is critical to gain a better understanding of DLS profiles in children with ASD in order to determine how to develop interventions that effectively target these skills while also taking into account autism symptomatology, cognitive and language skills, behavior, and other factors.
Objectives: The primary aims of the current study were to (1) examine whether there are subgroups of children with ASD defined by both their Vineland-II DLS subdomain raw scores and language abilities and (2) explore the relationship between internalizing and externalizing symptoms on DLS subgroups.
Methods: The current sample included 959 children with ASD between the ages of 6 to 11 who participated in the initial baseline visit of the Autism Treatment Network, which is a registry collection of children with medical diagnoses of ASD across 14 sites in the United States and Canada. Inclusion criteria for the current study included the following: a completed Autism Diagnostic Observation Schedule (ADOS), a completed Vineland Adaptive Behavior Scales, 2nd Edition (Vineland-II) including DLS domain and 3 subdomains; a completed Child Behavior Checklist (CBCL); and demographic information on parental education, race, age, and gender. Due to limited data on cognitive abilities, the ADOS was utilized as a measure of functioning level. Specifically, children who received an ADOS Module 1 or 2 were classified as being in the *Low Language group* and children who received an ADOS Module 3 were classified as being in the *High Language group*.
Results: A five-cluster solution was found when utilizing age, ADOS module, and Vineland-II DLS domains. An examination of the means of the five clusters, found two groups with *Low Language*; *Low DLS* group (*n* = 143, 14.9%) and *High DLS* group (*n* = 170, 17.7%); and three groups with *High Language*; *Low DLS* group (*n* = 189, 19.7%), *Medium DLS* group (*n* = 254, 26.4%), and *High DLS* group (*n* = 203, 21.3%). The *High Language, Low DLS* group had significantly higher scores on the CBCL domains as compared to the other 4 groups.
Conclusions: Within the Low *Language* group, the *Low DLS* group has DLS that fall far below what would be expected based on their functioning level. Interestingly, the *Low Language, High DLS* group had better or equivalent daily living skills as compared to the *High Language, Low DLS* and *High Language, Medium DLS* groups. Age equivalent scores on the Vineland-II demonstrated the gap between age and functioning level, even for those with intact language skills (e.g., High Language, Low DLS group had age equivalents ranging from 3-5 years). Additional results and implications for intervention will be discussed.

86 **142.086** Comparing ASD Screening Measures for Toddlers and Preschoolers

S. M. Kanne[1], *L. A. Carpenter*[2], *C. Lajonchere*[3] *and Z. Warren*[4], *(1)Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO, (2)Medical University of South Carolina, Charleston, SC, (3)UCLA Institute for Precision Health, Los Angeles, CA, (4)Vanderbilt University, Nashville, TN*

Background: With burgeoning waitlists for comprehensive diagnostic assessment of ASD, finding accurate methods and tools for advancing diagnostic triage becomes increasingly important. The current study compares the efficacy of three oft used paper and pencil measures, the Modified Checklist for Autism in Toddlers Revised with Follow-up (MCHAT-R/F), the Social Responsiveness Scale, Second Edition (SRS-2), and Social Communication Questionnaire (SCQ), to a novel measure developed by Cognoa, Inc. (Cognoa) using machine learning technology. Cognoa incorporates parent-report questions along with ratings of short video segments collected via parent smartphones and was designed to cover an age range from toddlers to preschoolers.
Objectives: To compare the sensitivity and specificity of four separate ASD screening measures in the same group of toddlers and preschoolers referred for a question of autism.
Methods: Data were collected from 230 children (*M* age = 40.3 months, *SD* = 14.9, range = 18.2 to 71.9) who were referred to one of three autism centers in the United States for a diagnostic question of ASD. Each participant completed the Cognoa screener and the other screening instruments (appropriate to age) prior to their scheduled appointment. Clinicians were blind to the Cognoa results. As part of a comprehensive developmental assessment, all participants completed traditional measures of cognitive abilities, adaptive functioning, and ASD symptoms (ADOS-2). Clinical Best Estimate Diagnosis was assigned based on DSM-5 criteria.
Results: Receiver operating characteristic (ROC) curves were plotted for each measure in their respective age groups along with sensitivity and specificity calculations. The results were as follows (at the suggested cutoffs for each measure): MCHAT R/F sensitivity = .87, specificity = .40; SCQ sensitivity = .63, specificity = .40; SRS-2-Pre sensitivity = .66. specificity = .42; SRS-2-SA sensitivity = .87, specificity = .26; Cognoa sensitivity = .75, specificity = .62.
Conclusions: Â Overall, Cognoa appears to have the strongest balance between sensitivity and specificity. This pattern remains in each measure's respective age group. For example, in the 18–30 month age range, Cognoa's optimal point was a sensitivity of .71 and specificity of .60 compared to MCHAT R/F's .87 and .40. Results suggest that combining traditional parent-report questions with clinician-scored video samples may result in improved screening performance for ASD. The current sample is a clinical population of 1.5 through 5 year olds all referred for a question of ASD; thus, the psychometric properties of the screening measures may be impacted by a greater presentation of symptomatology compared to a more general population sample (e.g., reduced sensitivity and specificity). Given that Cognoa spans the entire age range in question, and in the context of its relatively stronger and better balanced sensitivity and specificity, it may be more pragmatic for clinical use.Â A post-hoc revision of the Cognoa algorithm resulted in further improvements in sensitivity and specificity, particularly among younger children aged 18 to 30 months. Overall, results suggest that combining parent report and behavioral coding may result in improved performance in screening measures for ASD. Future studies are planned to prospectively evaluate the revised algorithm.

87 **142.087** Comparison of Behavioral Outcomes and Crisis Service Utilization Across the Six Specialized Inpatient Units in Phase I of the Autism Inpatient Collection (AIC)

K. A. Smith[1,2], *S. L. Santangelo*[3], *R. Gabriels*[4], *G. Righi*[5] *and M. Siegel*[6], *(1)Maine Medical Center Research Institute, Portland, ME, (2)Tufts University School of Medicine, Boston, MA, (3)Maine Medical Center, Portland, ME, (4)Children's Hospital Colorado, Aurora, CO, (5)Alpert Medical School of Brown University, Rumford, RI, (6)Maine Medical Center - Tufts School of Medicine - Spring Harbor Hospital, Westbrook, ME*

Background:
Children and adolescents with Autism Spectrum Disorder (ASD) are psychiatrically hospitalized at a much higher rate than non-ASD children Â due to serious emotional and behavioral problems including aggression, self-injury and tantrum-like behaviors. There is no comparative information, however, examining phenotypic differences, changes in serious problem behaviors, and use of crisis services, across specialized child psychiatry units.
Objectives:
Test for differences in demographic and clinical factors, patient characteristics, and site characteristics between six specialized child psychiatric units. Examine changes in child problem behavior over time (admission, discharge, and two month follow-up) both across the full sample and between sites. Examine changes in patients' use of crisis services two months prior to admission versus two months post-discharge.
Methods:
350 youth aged 4-20 years, with an ADOS-2 confirmed ASD diagnosis, admitted to specialized inpatient psychiatry units, were prospectively enrolled in the Autism Inpatient Collection (AIC) study, a six-site consortium investigating phenotypes, genotypes and behavioral outcomes among children. Parents completed measures at admission, discharge and two months post-discharge, and reported their child's demographics, problem behaviors (Aberrant Behavior Checklist – Irritability subscale, ABC-I), expressive communication and adaptive behavior (Vineland – 2), and crisis service utilization for the two months before and after hospitalization. Analysis of variance and chi-square tests were used to quantify site differences between subjects' demographic and clinical variables as continuous and categorical variables respectively. Paired t-tests were calculated to examine change in crisis services utilization over time. Changes in problem behavior over time were examined using multilevel model repeated measures analysis of covariance.
Results:
Site differences were found for children's ethnicity, race, non-verbal IQ, expressive communication, and hospital length of stay (see Table 1). There was a significant decrease in child problem behavior between admission and discharge for all sites, and slight increases in problem behaviors post-discharge, which varied by site. Improvement in problem behaviors, however, was not uniform across sites, even after controlling for significant site differences in our sample. There were also notable differences in the two subdomains of the ABC-I, tantrum-like behaviors (TLB) and self-injurious behaviors (SIB). SIB and TLB decreased while children were hospitalized, but we found an increase in TLB after discharge. Length of stay was the only statistically significant covariate in all models. Lower expressive communication scores predicted SIB but not TLB. We found an overall reduction in post-hospitalization utilization of crisis services for all sites combined. The decrease in emergency department visits and police contacts reached statistical significance at only three sites.
Conclusions:
Hospitalization in specialized child psychiatry units appeared to be effective in reducing the severity of child behavior problems from admission to 2-months post discharge for children and adolescents with ASD. Understanding the factors that contribute to variations in behavioral outcomes and crisis service utilization may enhance treatment for this population. Examining the comparative effectiveness of hospitalization in specialized units and general child psychiatric units, while matching for ASD symptom and behavioral severity in future studies would further inform public policy decisions on investing for services for this growing, high-need population.

88 **142.088** Conceptual Coverage of Vineland Adaptive Behavior Scales, Second Edition (Vineland™-II): Concept Mapping to a Patient-Centered Conceptual Model of Autism Spectrum Disorder (ASD)

T. Willgoss[1], *F. A. McDougall*[2], *F. Bolognani*[3], *L. Murtagh*[3] *and E. Anagnostou*[4], *(1)Roche Products Ltd, Welwyn Garden City, United Kingdom, (2)Patient Centered Outcomes Research, Roche Products Ltd, Welwyn Garden City, United Kingdom, (3)F. Hoffmann - La Roche AG, Basel, SWITZERLAND, (4)University of Toronto, Toronto, ON, Canada*

Background:
As new treatments for autism spectrum disorder (ASD) are developed, it is necessary that clinical outcome assessment (COA) measures used to measure treatment efficacy are both valid and reliable. To this end, health authorities recommend that COAs are evaluated for selection based on their content, specifically that instrument content should be aligned with a conceptual model of a disease or disorder.
The Vineland™-II, a measure of adaptive behavior from birth to adulthood, was recommended by a recent Autism Speaks expert panel as an appropriate measure of social communication deficits in ASD. The instrument is considered to have strong psychometric properties and high clinical relevance. However, to date, no study has critically evaluated the conceptual coverage of the instrument to an ASD-specific conceptual model.
Objectives:
The objective of this research was to evaluate the conceptual coverage of the Vineland™-II by mapping its content to a recently developed conceptual model of high functioning ASD.
Methods:
Items of the Vineland™-II Socialization, Communication and Daily Living Skills domains were mapped to a newly developed conceptual model of high functioning autism. The conceptual model (in press) was developed through an iterative process incorporating a review of qualitative literature and DSM-V Diagnostic Criteria, in-depth interviews with high functioning autistic individuals and their caregivers, and expert review. The conceptual model presents a visual summary of relevant symptom concepts, as well as the wider humanistic impacts and burden of ASD.
Results:
Concept mapping demonstrated that the Receptive, Expressive and Written sub-domains of the Vineland™-II Communication domain align closely with the core communication deficits of ASD included in the conceptual model. Moreover, Interpersonal Relationships, Play and Leisure Time and Coping Skills sub-domains of the Vineland™-II Socialization domain address concepts related to core socialization deficits. As expected, the Vineland™-II did not cover repetitive and restrictive behaviors. Concept mapping also showed that the Daily Living Skills sub-domains (Personal, Community and Domestic) of the Vineland™-II captures impairments in activities of daily living, identified as one of the most detrimental impacts of ASD. In addition, the Vineland™-II addresses some distal symptom concepts, namely cognitive functioning (for example, short-term memory and ability to follow instructions).
Conclusions:
Mapping of items of the Vineland™-II to a newly developed patient-centered conceptual model of ASD demonstrates that the Vineland™-II provides a comprehensive assessment of social communication deficits associated with ASD. Moreover, the mapping exercise demonstrates that the Vineland™-II also assess important concepts related to the broader impacts of ASD. These findings provide additional support that the Vineland™-II is a valid measure of social communication deficits for clinical trials in ASD.

89 **142.089** The Minimal Clinically-Important Difference (MCID) on the Vineland-II: Analysis of Data from 3,400 Individuals with ASD

*F. Bolognani[1], T. Charman[2], **C. H. Chatham**[3], X. Liogier D'ardhuy[4], M. del Valle Rubido[1], E. Eule[5], A. Fedele[6], A. Y. Hardan[7], E. Loth[8], L. Murtagh[1], A. San Jose Caceres[9], L. Sikich[10], L. Snyder[11], K. Taylor[12], J. E. Tillmann[2], P. E. Ventola[13], K. L. Walton-Bowen[14], P. Wang[15] and T. Willgoss[16], (1)F. Hoffmann - La Roche AG, Basel, SWITZERLAND, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development Roche Innovation Center Basel, Hoffmann La Roche, Basel, SWITZERLAND, (4) Neuroscience, Ophthalmology and Rare Diseases, F. Hoffmann-La Roche Ltd, Basel, Switzerland, (13)Yale Child Study Center, New Haven, CT, (14)Seaside Therapeutics, Cambridge, MA, (15)Pediatrics, Yale University School of Medicine, New Haven, CT, (16)Hoffmann-La Roche, Basel, Switzerland*

Background: Autism Spectrum Disorder (ASD) is associated with impairments in adaptive abilities in multiple domains including personal, social, and communication. Relative to age-matched peers, these impairments become increasingly pronounced across development, and are present regardless of comorbid intellectual disability. The Vineland Adaptive Behavior Scales, Second Edition (Vineland™-II) is the most commonly used instrument for quantifying these impairments but Minimal Clinically-Important Differences (MCIDs) on the Vineland™-II have never been established. Determining MCIDs for the Vineland™-II would facilitate the evaluation of new interventions for ASD, given the increasing use of the Vineland™-II in clinical trials.
Objectives: To generate anchor-based and distribution-based estimates of the MCID on the Vineland™-II adaptive behavior composite and standard scores for the socialization, communication and daily living subdomains.
Methods: We pooled data from several consortia/registries (EU-AIMS LEAP study, ABIDE-I, ABIDE-II, INFOR, Simons Simplex Collection) and clinical trials (Stanford, Yale, Roche). Quality control procedures were applied to the combined dataset (n>3,400 individuals), including the re-derivation of domain-level scores and outlier exclusion. The combined sample was stratified by age (children, adolescents and adults) and presence of comorbid intellectual disability (full-scale IQ < 70). Within each stratum, we adjusted for the fixed effects of age, gender, full-scale IQ, and the method of Vineland administration; we also adjusted for the random effect of dataset where possible. Two approaches were used to estimate the MCID: distribution-based methods and anchor-based methods. Distribution-based MCIDs include the standard error of the measurement, as well as one-fifth and one-half the covariate-adjusted standard deviation (both cross-sectionally [3,467 observations] and longitudinally [348 observations]). Anchor-based MCIDs include the slope of linear regression of CGI-S on Vineland score (630 observations), the slope of linear regression of CGI-I category on Vineland change (848 observations), the Vineland change score maximally differentiating minimal from no improvement on the CGI-I, the linking equation (Fayers & Hays, 2014), and equipercentile equating. Each MCID is reported separately, in addition to sample size-weighted averages for each MCID approach (anchor- vs. distribution-based).
Results: A Working Group was formed with representatives from Autism Speaks, Duke, King's College London, Roche, Simons Foundation, Stanford, and Yale.Â The first outcome was a consensus Statistical Analysis Plan (SAP) describing the QC process and methods for MCID estimation. At the time of writing, estimates of the Vineland™-II MCID individuals fall within the range of 1.83 to 4.67 points for the Vineland composite score across strata (d-MCID range: 1.83-3.15; a-MCID range: 2.05-4.67), with a trend towards lower MCIDs in the younger and intellectually-disabled populations due to increased variance among adults. MCIDs will be further refined as our pooled sample size increases.
Conclusions: Â Collaboration across academia, advocacy groups, and industry is critical to establishing a consensus on interpretation of clinical endpoints. Use of the Vineland™-II as an outcome instrument must take into account both the statistical and clinical significance of any observed change. Our ongoing analyses will inform the evaluation of new interventions for ASD by providing estimates of the Vineland™-II MCID across a wide range of ages and intellectual abilities.

90 **142.090** Age-Binned Normalization of Vinelandtm-II Increases Variability in Standard Scores: Implication for Clinical Trials in ASD.

***J. Hipp**[1], K. Taylor[1], C. H. Chatham[2] and F. Bolognani[3], (1)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development Roche Innovation Center Basel, F. Hoffmann-La Roche Ltd, Basel, Switzerland, (2)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development Roche Innovation Center Basel, Hoffmann La Roche, Basel, SWITZERLAND, (3)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development Roche Innovation Center Basel, F. Hoffmann - La Roche AG, Basel, Switzerland*

Background: Â Adaptive behavior is the performance of daily activities required for personal and social sufficiency. Autism Spectrum Disorder (ASD) patients' adaptive behavior is impaired, even in patients with normal or above normal IQ levels. The most commonly used instrument to measure adaptive behavior is the Vineland Adaptive Behavior Scales, second edition (Vineland™-II) which has been extensively used in ASD research and in clinical practice. More recently Vineland™-II has been used in clinical trials which aim to measure changes in adaptive behaviors over time. A given patient's raw score on the Vineland™-II scale must be adjusted for the score expected by the corresponding healthy control group of the same age. Importantly, the Vineland™-II manual provides normalization tables for these conversions for different *age ranges* (i.e., age 'bins') for the Composite score as well as for the Socialization, Communication, and Daily Living Skills domains scores. Thus, continuous raw scores are mapped onto discretized expected scores defined by categories of age ranges. Since both age and behavioral development are continuous variables, it is expected that this form of normalization will induce a certain amount of error, especially when a given patient's age deviates from the midpoint of the age bin. Moreover, additional error may be induced in change scores from clinical trials and longitudinal studies when patients move to an older age bin during the course of the study.
Objectives: To estimate the impact of the age binning on simulated clinical trial Vineland™-II change data and to develop a continuous normalization function for the age normalization.
Methods: Â The means of the 9 Vineland™-II raw-scores were extracted from the manual and interpolated with smooth splines to derive continuous estimates of the developmental trajectory. Then 1000 "average" study subjects (i.e. lying on the mean of the distribution) were simulated with an enrolment age randomly selected between 5 and 7 years. The standard domain scores were estimated for enrolment and 12 or 24 week assessments and the variances in the differences were estimated. By definition the difference should be 0 (i.e. effect of treatment was modeled) but as a result of age quantization, variance was induced that was set into relation to the variance observed in several studies that employed Vineland™-II.
Results: Simulations of 12-week long Vineland™-II clinical trial data with subjects aged 5 to 7 years showed that age binning increased variability of domain standard change scores by up to 2 units. Since the naturally occurring variation in domain change scores is as low as 6 standard scores in some clinical trials, this increase in variability corresponds to up to 12.5% of the variance. As expected, the continuous normalization function generated zero increase in change score variability in the simulated clinical trial data.
Conclusions: The use of Vineland™-II in clinical trials should take into consideration the increased variability introduced by the age binned normalization. Larger sample sizes should be considered to compensate for this higher variability. Alternatively, validation of continuous age normalization will improve the Vineland™-II use in clinical trials and observational studies.

91 **142.091** Vineland Adaptive Behavior Scale in Multicenter International Clinical Trials: Challenges and Solutions for a Successful Implementation.

L. Kingery[1], *P. E. Ventola*[2], *M. del Valle Rubido*[3], *M. Nallewar*[4], *X. Liogier D'ardhuy*[5], *C. Goeldner*[6], *F. Bolognani*[3], *O. Khwaja*[3] *and V. Lo*[4], *(1)Cogstate, Geneva, NY, (2)Yale Child Study Center, New Haven, CT, (3)F. Hoffmann - La Roche AG, Basel, SWITZERLAND, (4)Cogstate, New Haven, CT, (5)Neuroscience, Ophthalmology and Rare Diseases, F. Hoffmann-La Roche Ltd, Basel, Switzerland, (6)F. Hoffmann-La Roche, Basel, Switzerland*

Background:
The assessment of adaptive functioning is critical in neurodevelopmental disorders (e.g., Autism Spectrum Disorder (ASD), Down syndrome (DS)). The Vineland Adaptive Behavior Scale, Second Edition (Vineland-II™) is the gold standard measure for assessing adaptive functioning. The Vineland-II™ is a complex clinical assessment that poses several challenges to the successful implementation in multicenter, international clinical trials. A rigorous rater selection and a standardized rater training program, linguistically validated translations including expert clinical review to assess cross-cultural appropriateness of item content, and specialized data management, are needed for the successful implementation of the Vineland-II™ in these studies. Because hand scoring is prone to error, use of the scoring software program is required. Procurement and merging of the Vineland-II™ output from multiple sites requires accurate processing of the files from the scoring software in a standardized manner to a central resource. The management of these data requires both sophisticated data management processes and expert clinical review to ensure data accuracy.
Objectives: Â Summarize challenges and solutions for the successful implementation of the Vineland-II™in multicenter, international clinical trials.
Methods: Â Data for this research are derived from Cogstate's implementation of rater training, data management, and monitoring of the Vineland-II™ in three pharmaceutical industry sponsored trials (one USA trial in ASD, one USA trial in Down syndrome, and one international trial in Down syndrome (USA, France, and Spain). Data from 596 Vineland- II™administrations from 140 raters across 47 sites were available for processing and review.
Results: To our knowledge, these data reflect one of the largest compilations of Vineland-II™data from industry sponsored clinical trials. A few sites implemented the software and data transfers without difficulty. Many sites had considerable difficulty using the software and transferring data accurately. Common problems included incorrect entry of date of birth, missing scores, incorrect application of basal and ceiling rules, and mislabeling of files for processing. Detailed metrics regarding the frequency of these issues and required site follow-up will be presented in the full poster.
Conclusions: By combining expert clinical review of Vineland-II data and specialized data management expertise, we implemented a process that resulted in the successful transfer and processing of nearly 600 Vineland- II™ administrations. Several important conclusions follow from this work. First, sites and CRAs require considerable training on the implementation of the Vineland-II™ scoring software to ensure accurate and timely data transfers. Second, clinical reviews need to be conducted on an ongoing basis during the study (e.g., identification of patterns of scoring for each patient population, review of outliers in data defined by 5th and 95th percentiles, and consistency of scores compared to other clinical assessments). Third, a clear process must be implemented to manage the scale-specific queries generated during the data reviews. Fourth, centralized data entry into the scoring program could be utilized instead of relying on site-level entry. Finally, our clinical quality assurance indicates that systematic efforts must be made to review data outliers, changes in raters across visits, unusual patterns of change scores, as well as identical scores across visits.

92 **142.092** Development and Testing of a Health-Related Independence Measure for Young Adults with Autism Spectrum Disorder

N. C. Cheak-Zamora[1], *M. Teti*[1] *and A. Maurer-Batjer*[2], *(1)Department of Health Sciences, University of Missouri, Columbia, MO, (2)University of Missouri, Columbia, MO*

Background: Health care transition (HCT) services assist youth in the transition from pediatric to adult care, promote health insurance retention, and encourage independence. The provision of HCT services is important to all youth but imperative for those with special health care needs such as Autism Spectrum Disorder. Unfortunately, less than a quarter of the 500,000 young adults with Autism Spectrum Disorder (YA-ASD) receive HCT services. Further, no measure of independence related to health care activities (health-related independence) exists for YA-ASD.
Objectives: This study created a Health-Related Independence (HRI) measure to evaluate YA-ASD's independence related to their health care needs and to promote successful transition to adult care.
Methods: A collaborative team of YA-ASD, caregivers, health care providers, and ASD-experts used a multi-stage, iterative process to develop the HRI measure. The first phase included focus groups with caregivers (7 groups with 39 total participants) and individual interviews with YA-ASD (27 participants 16-25 years old) to discuss transition needs and identify important HRI topics. Qualitative thematic analysis was used to identify 14 HRI themes (e.g. knowledge of condition, medication management, caregiver stress, safety, and sexuality).
Within phase two, the collaborative team ranked themes according to importance and frequency that young adults encounter these issues, outlined sub-themes, and created questions addressing each theme and subtheme. Exact language YA-ASD and caregivers used in the phase one interviews and focus groups and items from previously validated measures were used when possible. Two center wide meetings, at a local Autism diagnostic and treatment facility, were scheduled with clinicians, staff, and caregivers (n=30) to review, discuss, and develop specific questions and response options.
The third phase of this study involved cognitive interviewing and pretesting to evaluate specific questions, response options, and survey formatting. Fifteen caregivers participated in cognitive interviews examining 25 questions within the measure that the collaborative team considered to be especially complex. The final measure was pretested by twenty-one caregivers using a secure web-based survey tool, REDCap. Revisions to questions and measures were made iteratively based on participant data and team feedback.
Results: The final HRI measure includes 8 themes (60 items): Knowledge of medical/mental health conditions; Self-care; Medication management; Health care visits; Safety; Sexual health; Health care financing; and Goal planning. Initial qualitative data identified new HRI topics important to YA-ASD and caregivers. Cognitive interviews and pretesting identified problems with language, resulting in better item comprehension and improved response options.
Conclusions: The HRI measure is a self-administered measure of health care transition and level of independence of a unique and under-represented population- YA-ASD. This measure identifies their specific transition needs and will assist in developing tailored-interventions. The HRI measure will be full-scale tested at five ASD-specific clinics across the national in 2016-2017.

93 **142.093** Diagnostic YIELD of ASD Arena Assessment MODEL

P. Manning-Courtney[1], *H. L. Johnson*[2], *L. Kuan*[3], *E. Emanuelson*[4], *J. S. Anixt*[1] *and J. Meinzen-Derr*[5], *(1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Cincinnati Children's Hospital Medical Center, Monroe, OH, (3)Division of Developmental and Behavioral Pediatrics, Cininnati Children's Hospital Medical Center, Cincinnati, OH, (4)Ohio State University, Columbus, OH, (5)Biostatistics and Epidemiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH*

Background: An increasing number of young children are referred for assessment of possible Autism Spectrum Disorder (ASD). Access to initial diagnostic assessment for ASD or any developmental concern is poor in many regions, delaying time to diagnosis, and eventual treatment. In addition, not all children referred for possible ASD receive this as a final diagnosis. Our center redesigned our ASD/Developmental Concern diagnostic model for children under age 3 years, to improve access, and we also sought an improved understanding of the ultimate yield of ASD diagnosis for children under 3 referred for possible ASD or other developmental concern.
Objectives: (1) Determine diagnostic yield of arena assessments for children age 3 and under, referred for ASD or other developmental concerns; (2) Determine if ASD specific language in the referral modifies the likelihood of ASD diagnosis; (3) Assess average time to diagnosis.
Methods: Multidisciplinary arena assessment model for ASD or other developmental concern was tested and implemented (previously reported). Charts of 319 patients under 3 years of age (range 13-35 months), evaluated for ASD or other developmental concern between Jan. 2015 and May 2016 were reviewed for referral factors (referral reason, referring provider), and for final diagnostic determination. Time from referral to evaluation and final diagnosis were tracked as part of an ongoing Quality Improvement Initiative addressing access.
Results: 293 (91%) patients completed an evaluation for possible ASD or other developmental concern and were included in analysis. 116 patients (39.5%) received a final diagnosis of ASD, regardless of referral question. 189 patients (64.5%) had ASD specific language in their referral ("concern for autism", "MCHAT", "rule out autism"). Children with ASD specific referral language were more likely to have a final diagnosis of ASD compared to children without ASD referral language (46.6% vs. 26.9%; p=0.001).
Children not diagnosed with ASD received other developmental diagnoses, including global developmental delay (46.9%), language delay (23.2%), and behavior disorder (17.5%).
Average time from referral to evaluation was 20 days and time from referral to final diagnosis was 40 days.
Children referred who were age <24 months (n=226) were more likely to receive a diagnosis of ASD than those referred 24-36 months (42.5% vs. 29.9%)
Conclusions: Fewer than half of children referred for possible ASD received a final diagnosis of ASD, even when referral includes autism specific language. Children not receiving a diagnosis of ASD had other developmental concerns warranting intervention. Average time to final diagnosis was improved in our center through the development of a comprehensive arena assessment model, the addresses both possible ASD and other developmental concerns.

94 **142.094** Differences in the Behavioral Phenotype of Autism Spectrum Disorder in a Population Sample of Somali, White, Non-Somali Black, and Hispanic Children in Minneapolis

A. N. Esler[1], *J. A. Hall-Lande*[2], *K. Hamre*[3], *J. Poynter*[3], *A. A. Gulaid*[3], *L. Hallas-Muchow*[3] *and A. Hewitt*[4], *(1)Rm 340, University of Minnesota, Minneapolis, MN, (2)UCEDD, University of MN, Minneapolis, MN, (3)University of Minnesota, Minneapolis, MN, (4)U of MN, Minneapolis, MN*

Background: Previous research suggests that immigrant families from countries with a low human resource index are at increased risk for autism spectrum disorder (ASD) and have greater levels of impairment than other children with ASD (e.g., Barnevik-Olsson et al. 2008; Keen et al. 2010; Magnusson et al. 2012).
Objectives: Results are presented from a public health surveillance project in Minneapolis designed to determine if more Somali children had ASD than non-Somali children. A secondary goal was to identify differences in the behavioral phenotype of ASD across racial and ethnic groups; this is the focus of the present study.
Methods: A multi-step records review process was used to identify cases of ASD from educational and medical records of Minneapolis children who were 7-9 years old in 2010. Data documenting DSM-IV-TR autism symptoms, intellectual ability, and related behavioral and medical concerns were collected and used to characterize behavioral phenotype. Frequencies and percentages were used to describe DSM-IV-TR symptoms and associated features and were compared across Somali, white, non-Somali black, and Hispanic children with ASD. Categorical differences in ASD symptoms, cognitive level, and associated features across racial/ethnic groups were assessed with chi-square analyses for nominal data, and odds ratios with confidence intervals of 95% were used to estimate effect size. Differences in number of symptoms and features documented across racial/ethnic groups were compared using ANOVA as a metric of symptom severity.
Results:Â Somali children with ASD were far more likely to have intellectual disability (ID) than children with ASD in all other racial and ethnic groups. 100% of Somali children with cognitive data in their records had IQ ≤ 70 compared with 32.6% for the total sample. Regarding DSM-IV-based symptoms, Somali children were more likely than all other racial/ethnic groups to have lack of pretend play documented in their records and more likely than white and Hispanic children to have deficits in seeking to share enjoyment. Regarding restricted/repetitive behaviors, Somali children were more likely than Hispanic children to have preoccupations with parts of objects. Fixated interests were noted more frequently for white children than Hispanic children. White and Somali children were documented more often than Hispanic children with repetitive motor mannerisms. Somali and white children had a greater number of DSM-IV repetitive behavior symptoms documented in their records than Hispanic children, and Somali children were more likely to have co-occurring concerns of abnormalities in eating and drinking patterns than white and non-Somali Black children. In all cases, differences were no longer significant when the sample was limited to those with ASD+ID.
Conclusions: Results indicate a striking difference in the presence of ID in Somali children with ASD compared with other children. These results are consistent with previous research that found immigrants from low human resource index countries, and Somali children in particular, had higher rates of ASD+ID than other groups. Potential reasons for these findings and implications for practitioners will be discussed.

95 **142.095** Discordance Across Time in Caregiver Report during the Autism Diagnostic Interview-Revised (ADI-R): Findings from a Canadian Inception Cohort of Children with Autism Spectrum Disorder (ASD)

T. Savion-Lemieux[1], *R. Bruno*[2], *M. Elsabbagh*[3], *M. Steiman*[4], *P. Szatmari*[5], *T. Bennett*[6], *E. Duku*[7], *S. Georgiades*[7], *P. Mirenda*[8], *I. M. Smith*[9], *T. Vaillancourt*[10], *W. Ungar*[11], *J. Volden*[12], *C. Waddell*[13], *L. Zwaigenbaum*[14] *and A. Thompson*[7], *(1)4018 St Catherine St W, Research Institute - McGill University Health Centre, Montreal, QC, Canada, (2)Research Institute of the McGill University Health Centre, Montreal, QC, CANADA, (3)McGill University, Montreal, CANADA, (4)Montreal Children's Hospital, Montreal, QC, CANADA, (5)Centre for Addiction and Mental Health, Toronto, ON, CANADA, (6)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (7)McMaster University, Hamilton, ON, CANADA, (8)University of British Columbia, Vancouver, BC, CANADA, (9)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (10)University of Ottawa, Ottawa, ON, CANADA, (11)Sick Kids Research Institute, Toronto, ON, Canada, (12)University of Alberta, University of Alberta, AB, CANADA, (13)Simon Fraser University, Vancouver, BC, V6B 5K3, CANADA, (14)University of Alberta, Edmonton, AB, CANADA*

Background: The ADI-R algorithms rely on accurate timing of the first manifestations of ASD symptoms. Caregiver recall of developmental milestones and the emergence of symptoms are thus key to an accurate diagnosis, especially when the evaluation occurs later in life. Previous studies in ASD found “telescoping” in caregiver report of language milestones, such that older ages of attaining milestones were reported as time passed (Hus et al. 2011). Several proposed factors influencing recall (Barsky, 2002; Hus et al., 2011; Jones et al., 2015) include characteristics of the informant (e.g., state at the time of recall, beliefs about etiology), the child (e.g., delays in development), and the interview (e.g., order of questions, time since the recalled event).
Objectives: In the present study we examined telescoping in caregivers’ longitudinal reports of their children’s early development in a prospective cohort study of children diagnosed with ASD. Specifically, we focused on ADI-R reports of age of first concerns, age of first words, and age of first phrases**.** We also examined possible moderators of telescoping including caregiver education level and child’s age and cognitive level at the time of diagnosis.
Methods: Data were drawn from Pathways in ASD, a study of 400 preschoolers followed across five Canadian sites. We included in the analysis cases for whom three longitudinal ADI-R interviews were available (n = 136 participants; 117 Males) and excluded cases for which caregivers either reported that their child had no functional language at study entry and/or possible/definite language regression at any point. ADI-R interviews were completed when the children were 2-4 years old (around time of diagnosis; mean = 46.6 months, SD = 7.9), 6-7 years old *(*mean = 79.8 months, SD = 4.0), and 10-11 years old (mean = 128.4 months, SD = 2.3). We explored as covariates: maternal education, child’s age of diagnosis (mean = 44.7 months, SD = 7.7), and the child’s cognitive ability measured with the Merril-Palmer-Revised (mean = 77.9 months, SD = 24.5) around the time of diagnosis.
Results: Â We found no telescoping effects in report of symptom onset; caregivers reported similar ages of onset across the three interviews. In contrast, we observed significant telescoping effects in reported age of language milestones. Over time, caregivers tended to report older ages of acquiring first words (p=.006) and first phrases (p<.001). We also examined potential moderators of telescoping. Caregiver reports of symptom onset over time did not interact with maternal education or with child age and cognitive ability around diagnosis. However, more telescoping of language milestones was evident in caregivers of children with lower cognitive ability (first words p=.01; first phrases p<.001). There were no significant interactions between report of language milestones over time and child’s age of diagnosis or maternal education.
Conclusions: Overall, our findings in a Canadian inception cohort replicate previous results of telescoping in caregiver-reported ages of language acquisition but not of first concerns. We will discuss implications of reliance on retrospective recall of information for clinical diagnosis and research, especially later in life.

96 **142.096** Does Anxiety Inflate Autism Severity Measures?

A. Taheri[1], *B. L. Ncube*[2], *A. Perry*[3] *and J. Koudys*[4], *(1)York University, Toronto, ON, Canada, (2)York University, York, ON, CANADA, (3)Psychology, York University, Toronto, ON, CANADA, (4)Centre for Applied Disability Studies, Brock University, St. Catharines, ON, Canada*

Background:
Anxiety disorders are among the most common comorbid disorders in individuals with Autism Spectrum Disorders (ASD). Even amongst individuals who do not meet criteria for a comorbid anxiety disorder, symptoms of anxiety are common (e.g., Hartley & Sikora, 2009; Kim et al., 2000). A number of studies have found higher anxiety to be related to more severe symptoms of ASD, including social deficits (e.g., Dubin et al., 2015; Eussen et al, 2013) and repetitive behaviours (Rodgers et al., 2012). As a result of this relationship, some researchers have expressed concerns regarding the discriminant validity of measures of ASD and anxiety (Renno & Wood, 2013). Hartley and Sikora (2009) found that the DSM-IV social communication criteria were largely able to discriminate individuals with ASD from those with anxiety disorders. Conversely, Cholemery and colleagues (2014) found that the Social Responsiveness Scale showed poor discriminant validity in the identification of ASD versus anxiety symptoms. Overall, little research has examined the influence of comorbid anxiety symptomatology on severity of ratings assigned to individuals with ASD on other commonly used measures, such as the Autism Diagnostic Observation Schedule (ADOS) and the Childhood Autism Rating Scale (CARS).
Objectives:
The purpose of this pilot study is to report on an initial examination of the relationship between two autism measures and four indicators of anxiety.
Methods:
The data for this study came from a project evaluating the long-term outcomes of Intensive Behavioural Intervention (IBI). Twenty-one youth (13-20 years) diagnosed with ASD were reassessed after receiving IBI as children. Analysis for this study was conducted with a subsample who had complete data for four anxiety indicators (parent and youth ratings on Achenbach and SCARED) and two ASD measures (ADOS and CARS) (N = 15; M_{age} = 15.2).
Results:
The ADOS total score and the algorithm score for Social Communication and Repetitive Behaviours were weakly correlated with anxiety. The total CARS score was also weakly correlated with anxiety. Based on clinical cut-off scores on all anxiety measures, we dichotomized individuals in two groups (anxious vs. not anxious). We found no significant differences between the anxious and not anxious groups in terms of ADOS or CARS scores.
Conclusions:
Clinicians are often concerned regarding the overlap between symptoms of anxiety and ASD. For example, obsessive behaviours seen in anxiety disorders can sometimes look similar to repetitive or stereotyped behaviours. Thus far, there has been little research examining the influence of anxiety levels on the ADOS and CARS. The results from this pilot study indicate that the ADOS and CARS scores are not likely influenced by varying levels of anxiety. Given that these are well established and commonly used measures, it is promising to know that they are relatively independent of anxiety symptoms. However, this study was based on a small sample of high functioning and older individuals. Therefore, since ASD is greatly heterogeneous, more research is needed with a larger and more variable sample (i.e., varying levels of ASD severity and cognitive functioning).

97 **142.097** Does the Age of Diagnosis of Autism Contribute to Differential Cognitive and Behavioral Outcomes during Middle Childhood?

M. Clark[1]*, C. Dissanayake*[2] *and J. Barbaro*[3]*, (1)Kingsbury Drive Bundoora, La Trobe University, Melbourne, VIC, Australia, (2)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (3)Olga Tennison Autism Research Centre, School of Psychology & Public Health, La Trobe University, Melbourne, Australia*

Background: Early diagnosis of Autism Spectrum Disorders (ASDs) is now considered best practice so that children may access early intervention (EI) in a timely manner. However, the majority are diagnosed after 3-years.
Objectives: The aim in the current study was to establish whether the developmental outcomes at school age differ as a function of the age when children are diagnosed with ASD.
Methods: The cognitive, behavioural and adaptive outcomes of children diagnosed with ASD at 24-months (n=48) was compared to outcomes in a group of children diagnosed after 3-years and prior to school entry at 5-years (n=37). All children were aged between 7- to 9 years at follow-up.
Results: Children diagnosed early had received more intervention than those diagnosed later, and had significantly better verbal abilities and overall cognitive abilities at school age. A greater percentage of these children were in mainstream schools and significantly fewer received ongoing support compared to children in the late diagnosis group. However, no differences were found between groups in adaptive behaviour or autism severity scores at school age.
Conclusions: The findings support the importance of diagnosing ASD early, which maximizes children's opportunities to receive EI, leading to improved outcomes at school age

98 **142.098** EU-AIMS Clinical Network: Evaluating Sex- and Age-Related Differences in ADI-R and ADOS Scores in a Large ASD Sample

Background: Developing a greater understanding of the sex-and age-related differences in the severity of the core symptoms of Autism Spectrum Disorder (ASD) has been impeded by small sample sizes, variation between samples in age and IQ of participants and large heterogeneity in symptom expression both between and within individuals. Large-scale samples are therefore necessary to better understand these relationships. In response, we set up a platform as part of the EU-AIMS clinical network to collaboratively pool data from major ASD clinical and research institutions across Europe. 22 sites situated in 10 different European countries have already shared demographic (e.g. sex, age, diagnosis and ethnicity), phenotypic (e.g. ADI-R, ADOS), behavioural (Vineland) and cognitive data (IQ) for secondary analysis.
Objectives: (1) To describe the current sample in relation to between-site variability in demographic and clinical measures and (2) examine differences in core ASD symptomatology between males and females with ASD on diagnostic instruments.
Methods: This preliminary sample is composed of 1386 participants (males = 1151, females = 235; 80% male-female ratio) ranging in age from 12 months to 30 years. Autism symptom data were obtained from the Autism Diagnostic Interview–Revised (ADI-R) total and domain scores (social, communication, and restricted/repetitive behaviour) and Autism Diagnostic Observation Schedule (ADOS) Calibrated Severity Scores (CSS). Linear mixed-effects models were used to investigate variability between sites in relation to demographic information (age and sex) and Intraclass correlation coefficients (ICCs) reflecting the ratio of between-site variance to total variance were calculated. For sex and age-dependent analyses, a random effect for site was included in all models to take into consideration the multi-level nature of the data, as well as to account for site heterogeneity across outcome measures.
Results: Overall, there were significant site effects on all demographic and core characterisation measures reflecting the variable recruitment pattern across multiple sites and countries. While these site effects were very pronounced for age of participants (*ICC*=.67), they were less so for sex ratio (*ICC*=.02) and only moderate for core ASD symptom measures (e.g. ADI-R domain totals: all *ICC* <.20). On the core ASD measures, no significant effects of age or sex were found for ADI-R Social and Restricted, Repetitive and Stereotyped Behaviours and Interests (RRB) domain total scores (all p >.3). However, females scored significantly lower than males on the Communication domain, $x^2(1) = 5.78$, $p = .016$, $d = .24$. Effects of age and sex on ADOS CSS Total, Social Affect and RRB will also be reported.
Conclusions: Pooling datasets across European clinical and research sites as part of EU-AIMS will help to establish a valuable resource for ASD research in Europe. In the future, this resource will not only boost research capacity, but also improve transparency, openness and research efficiency of autism research in Europe.

99 **142.099** Effectiveness of Screening Tools in a Community-Based Sample: Which Children Are Missed and Why?

S. Richardson[1], *M. Reid*[1], *C. Beacham*[1] *and C. Klaiman*[2], *(1)Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA*

Background:
Early screening of Autism Spectrum Disorder (ASD) is essential for referring children for evaluations and early intervention, with benefits found in starting intervention as young as possible (Zwaigenbaum et al., 2015). With pediatricians on the front lines, providers are in need of measures that efficiently and effectively identify concerns. The Ages and Stages Questionnaire-3 (ASQ-3) is a common developmental screener for general developmental concerns and the Modified Checklist for Autism in Toddlers, Revised (M-CHAT-R) is a widely used autism specific screening tool. Our previous work has shown that parent concern on the ASQ accurately captures developmental delays in children with ASD, but that only the communication scale was associated with autism symptomatology on an ADOS, suggesting the need for an ASD specific screener as well (Hamner et al., 2015).
Objectives:
To build upon our previous work by evaluating two commonly used screening tools and their effectiveness in identifying children in need of further evaluation.
Methods:
78 children (64 boys) between the ages of 16-43 months (mean = 28.80 months, SD = 6.93) referred based on parent concerns and/or provider recommendations who received an ASD diagnosis. Approximately 85 additional participants are expected before May 2017. Parents completed the ASQ-3 and M-CHAT and children were administered the Mullen Scales of Early Learning and the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2).
Results:
On the ASQ, 63 out of 78 children failed the communication scale (81%), 58 (74%) failed the problem-solving scale, and 56 (72%) failed the personal-social scale. Of the 15 children who passed the communication scale, 6 more were identified by either the problem-solving or personal-social scales. On the M-CHAT, 66 (85%) screened with concerns (total score 3 or higher), of which 61 also failed at least one ASQ scale. When combining the ASQ communication scale and the M-CHAT, 72 (92%) of children were identified and combining an ASQ fail on any scale and the M-CHAT increases that number to 96%. Children who passed the ASQ communication scale performed significantly higher on Mullen visual reception ($t(77) = 4.56$, $p < .01$), receptive language ($t(77) = 5.44$, $p < .01$), and expressive language ($t(77) = 4.37$, $p < .01$) scales. A similar, significant pattern was seen for problem-solving and personal-social scales. Additionally, those who passed the communication scale were significantly older ($t(77) = 2.80$, $p < .01$); this pattern was not seen on other scales. Children missed on the M-CHAT had significantly higher visual reception scores ($t(76) = 2.04$, $p < .05$) and a trend for higher expressive language scores ($t(76) = 2.01$, $p = .06$).
Conclusions:
In our community sample, both the ASQ and M-CHAT flagged the majority of children with ASD, supporting the utility of these measures in pediatric practices. The most children were identified with the combination of ASQ scales and the M-CHAT, indicating a need for both measures. Higher functioning children are more likely to be missed when using only one of the measures. Pediatricians are encouraged to monitor parent concerns in children without developmental delays even if passing screening measures.

100 **142.100** Evaluation of a Training Workshop to Enhance General Pediatrician Diagnostic Skills for Autism Spectrum Disorder

M. Penner[1], *J. A. Brian*[1], *A. Townley*[2], *J. Chiba Branson*[1] *and A. Kawamura*[1], *(1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Evidence To Care, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

Background: The increase in autism spectrum disorder (ASD) diagnoses over the past decade has placed strain on access to ASD diagnostic assessments. One potential way to improve diagnostic capacity is through training general pediatricians to provide ASD diagnoses in their practices.
Objectives: The objective of this work was to evaluate a workshop designed to enhance ASD diagnostic abilities among general pediatricians, specifically evaluating whether participants changed their practice and their motivation for practice change.
Methods: Twenty-four general pediatricians attended a workshop that was designed to teach skills in: assessing for ASD (including history/observation and interaction); communicating the ASD diagnosis through in situ simulation with actors playing parents; connecting families to resources; and billing effectively. Further ongoing mentorship was also available in the six months after the workshop for participating pediatricians. A web-based survey was sent out to all participants before the workshop to provide information on attendees and six months after the workshop to determine the impact of the workshop on their practice. Eight participants were also interviewed by a researcher who was not part of the workshop. Interviews were transcribed, coded, and reviewed by study team to determine whether the workshop achieved its objectives.
Results: Prior to the workshop, 15 of the 23 respondents (65.2%) performed ASD diagnostic assessments in their practice. Fifteen participants completed the six-month post-workshop survey (62.5% response rate); of these, 80% (n = 12) performed ASD diagnostic assessments. Among the six-month post-workshop survey respondents, 43% of participants agreed or strongly agreed with feeling confident diagnosing ASD prior to the workshop; after the workshop, this increased to 67%. Analysis of the eight in-depth interviews grouped participants into three categories: 1) Participants who were already diagnosing ASD in their practices (5 of the 8 participants interviewed); 2) Participants who started diagnosing ASD as a result of attending the workshop (2 of the 8 participants interviewed); and 3) Participants who continued not diagnosing ASD after the workshop (1 of the 8 participants interviewed). Participants who already diagnosed ASD prior to the workshop still ascribed value to attendance. The workshop increased their feelings of confidence, let them know that their peers were also diagnosing ASD, gave them approval from experts for their practice, and gave them direct access to experts. The two participants who started performing ASD assessments after attending the workshop described a change of perspective about whether ASD diagnosis was a “reasonable” part of their practice. They felt empowered to be able to help families access resources faster. One participant did not perform ASD diagnoses before or after the workshop. This participant still did not feel comfortable communicating the ASD diagnosis to the family.
Conclusions : For general pediatricians to start doing ASD diagnoses in their practices, they need to feel that this change is reasonable and supposed by both peers and experts. Attitudes towards ASD play a big role, particularly as they relate to communicating the ASD diagnosis to families.

101 **142.101** Examining Agreement in Parent and Teacher Report for School-Aged Children at-Risk for Autism Spectrum Disorder

C. Butcher[1], *C. C. Bradley*[2], *A. D. Boan*[2] *and L. A. Carpenter*[2], *(1)Developmental-Behavioral Pediatrics, Medical University of South Carolina, Charleston, SC, (2)Medical University of South Carolina, Charleston, SC*

Background: Â Parents and teachers are frequently asked to provide information about a child's emotional, behavioral, and social functioning when there is a question of possible Autism Spectrum Disorder (ASD). Two commonly used measures include the Achenbach Child Behavior Checklist (CBCL) and the Social-Responsiveness Scale, Second Edition (SRS-2). Parent and teacher report are important factors when considering a possible ASD diagnosis for school-age children. Therefore, it is important to understand the relationship between reports from these informants.
Objectives: Â To examine the relationship and inter-rater consistency (ICC) between parent and teacher report for a sample of children at-risk for ASD.
Methods: Â Data for this study is from the South Carolina Children's Educational Surveillance Study (SUCCESS), which is designed to assess the prevalence of ASD through direct screening and evaluation.Â Children born in 2004 and aged 8-11 at the time of participation were identified as being at risk for ASD via population-based screening using the Social Communication Questionnaire (SCQ). Children at-risk for ASD received full developmental assessments to determine diagnostic status (n=292). For the majority of children (n=247), both parents and teachers completed questionnaires including the SRS-2 and the Achenbach Child Behavior Checklist (CBCL). Data analyses included parent versus teacher predicted means via mixed model approach and estimated ICC.
Results: In the total sample of children at-risk for ASD, both the Social Communication Index (SCI) and Total Score of the SRS-2 were rated higher by parents than by teachers (LSM difference 6.27 (SE=0.87); $p < .0001$; 6.09 (SE=0.87); $p < .0001$, respectively). ICC was fair for the SCI (0.39) and moderate for the Total Score (0.42). Significant differences in parent and teacher ratings on the SRS-2 were observed in children both with and without the diagnostic classification of ASD. In the total sample, parents also rated children higher in internalizing problems on the CBCL (LSM difference 4.42 (SE=0.88); $p < .0001$, and ICC was fair (0.23). However, no significant differences were found between parent and teacher report of externalizing problems on the CBCL. Among children who screened at-risk but were not diagnosed with ASD (n = 202), parents also rated children higher in internalizing (LSM difference 5.16 (SE=0.96); $p < .0001$) and externalizing problems (LSM difference 1.85 (SE=0.83); $p=0.027$) on the CBCL. However, among children diagnosed with ASD (n = 45), there were no significant differences between parent and teacher report on internalizing or externalizing behaviors on the CBCL. ICCs were fair for both internalizing (0.20) and externalizing problems (0.37).
Conclusions: Results suggest that, on average, parents are more likely to endorse social communication concerns than teachers. Parents also endorse more internalizing and externalizing behavior problems among children who are at-risk but do not go on to be diagnosed with ASD, while there is greater agreement between parents and teachers on these scales for children subsequently diagnosed with ASD.

102 **142.102** Examining Measures Used for the Diagnosis of Autism Spectrum Disorder

J. Esteves[1], *A. Taheri*[1], *A. Perry*[2] *and J. Koudys*[3], *(1)York University, Toronto, ON, Canada, (2)Psychology, York University, Toronto, ON, CANADA, (3)Centre for Applied Disability Studies, Brock University, St. Catharines, ON, Canada*

Background:
To date, there is no known biological marker for Autism Spectrum Disorder (ASD) (Huerta & Lord, 2012). Thus, in order to formulate a diagnosis, clinicians often use various standardized measures to gather information from parents and the child (Charman & Gotham, 2013). However, across the literature, there are inconsistent results with regards to agreement between measures and classification systems used for the diagnosis of ASD. For example, some have found that the Childhood Autism Rating Scales (CARS) is more conservative in comparison to the Autism Diagnostic Schedule (ADOS) (Reszka et al., 2014), while others have found that there is good agreement between these two measures (Ventola et al., 2006). Furthermore, there are mixed findings in the literature on the agreement of these measures in relation to the 4th and 5th editions of the DSM (Perry et al., 2005; Taheri et al., 2012). Additionally, in a systematic review, it was found that only 50 to 75% of individuals maintained ASD diagnoses with the shift from the DSM-IV to the DSM-5 (Smith et al., 2015), calling into question the agreement of these diagnostic methods.
Objectives: The purpose of this study was to examine the agreement among two commonly used observational measures (ADOS and CARS) and the DSM ASD criteria (4th and 5th edition). In addition, we explored ASD diagnosis for each measure in relation to child characteristics (i.e., cognitive and adaptive level).
Methods: The data for this study came from a research project evaluating the long-term outcomes of Early Intensive Behavioural Intervention (EIBI). Twenty-one youth (aged 13-20 years) diagnosed with ASD were reassessed after receiving EIBI as young children (ending approximately 10 years ago). The assessment battery consisted of four ASD diagnostic measures (CARS, ADOS, DSM-IV and DSM-5 criteria), and standardized measures of cognitive and adaptive functioning.
Results: In terms of percentage agreement between diagnostic measures, there was low agreement on most measures, with agreement for an ASD diagnosis being best between the DSM-IV and ADOS (86%), and agreement for a non-diagnosis being best between the DSM-5 and the CARS (67%). Chi square tests revealed that ratings on most of the measures (i.e. DSM-5 and ADOS; DSM-IV and CARS; DSM-IV and DSM-5; DSM-IV and ADOS; and ADOS and CARS) were independent of each other. In addition, those diagnosed with ASD on the CARS and DSM-IV had a significantly lower IQ and adaptive behaviour.
Conclusions: There are a number of research implications of this study. Changing definitions of Autism in research affects the whole knowledge base regarding Autism and ASD more broadly. Further, inconsistencies amongst measures can impact ASD prevalence reports in the literature, depending upon which assessment and classification system is used. It is concerning that there is not high agreement among various diagnostic measures, which may impact accessibility to suitable treatments or interventions. With inconsistencies amongst measures, clinical judgment is required more than ever when making the diagnosis of ASD.

103 **142.103** Examining Symptoms of Autism Spectrum Disorder in Children with Prenatal Drug Exposure

J. Hamel-Lambert[1,2], *J. F. Scherr*[1], *M. Stone*[1], *B. Dennis*[1] *and E. Butter*[3], *(1)Nationwide Children's Hospital, Columbus, OH, (2)Ohio State University, Columbus, OH, (3)Nationwide Children's Hospital, Westerville, OH*

Background: Newborn infants exposed to maternal drug use in utero often experience neonatal abstinence syndrome (NAS) characterized by symptoms of drug withdrawal shortly after birth. Infants with NAS are at an increased risk for language delays, inattentive behaviors, hyperactivity, and social-emotional problems in early childhood (Hunt et al., 2007;Logan et al., 2012; van Baar et al., 1994). The behavioral phenotype associated with NAS overlaps with symptoms observed in Autism Spectrum Disorder (ASD) including impairments of social-communication, withdrawal, and emotional dysregulation. Despite behavioral similarities in children with NAS and ASD, little is known about how symptoms of ASD present in children with NAS. It is important to identify populations that may be at-risk for ASD in order to inform differential diagnosis and treatment practices.
Objectives: The present study aims to examine symptoms of ASD in children with NAS. Developmental and behavioral profiles will be compared in children with NAS that meet and do not meet diagnostic criteria for ASD.
Methods: Participants consisted of 76 children that received a medical diagnosis of NAS in infancy and subsequently present to the Child Developmental Center at a tertiary care hospital between the years 2010-2016. Participants were categorized into two groups: children who received a diagnosis with ASD and NAS (N = 36) and children with NAS who did not receive an ASD diagnosis (N = 40). This retrospective chart review study enables the characterization of presenting problems, referral patterns, developmental trajectories, as well as psychological test results examining cognition, language, social communication, repetitive and restrictive behaviors, adaptive and broad behaviors for those who received interdisciplinary team evaluation for ASD. Specifically, the Autism Diagnostic Observation Schedule (ADOS), Autism Spectrum Rating Scale (ASRS), and Childhood Autism Rating Scale (CARS) were used as measures of autism symptomology. Developmental functioning was assessed using the Mullen Scales of Early Learning (MSEL) and behavioral symptoms were assessed using the Child Behavior Checklist (CBCL).
Results: Of the 76 children diagnosed with NAS that were evaluated for ASD, 47% met diagnostic criteria for ASD at a hospital-based child development clinic between the years 2010-2016. Trend analysis reveals an increase in NAS, which elevates the need to understand the relationship between NAS and ASD in future efforts to ensure screening and early identification in populations particularly at risk. Overall, preliminary results from this study indicate specific behavioral patterns of social-emotional and developmental outcomes in children with NAS and ASD.
Conclusions: NAS is associated with a unique behavioral phenotype in early childhood that often overlaps with symptoms observed in ASD. In the current study, we found that almost half of the children with NAS evaluated for Autism Spectrum Disorder met diagnostic criteria for ASD suggesting that infants with NAS are at-risk for pervasive developmental and behavioral problems. It is important to examine how behavioral symptoms emerge and present in children NAS in order to gain a better understanding of how different etiological pathways may result in similar behavioral profiles associated with ASD. Future efforts include the establishment of a rural outreach clinic to track the children at-risk for NAS given prenatal drug exposure.

104 **142.104** Executive Function in Preschoolers with ASD: Evaluation of a Test Battery with Minimal Verbal Demands

J. R. Bertollo[1]*, A. S. Nahmias*[2,3]*, L. Antezana*[4]*, S. R. Crabbe*[3]*, D. S. Mandell*[3] *and B. E. Yerys*[1]*, (1)The Center for Autism Research/CHOP, Philadelphia, PA, (2)University of California Los Angeles, Los Angeles, CA, (3)University of Pennsylvania, Philadelphia, PA, (4)Virginia Tech, Blacksburg, VA*

Background: Executive Function (EF) refers to a set of cognitive processes that regulate impulses and emotions and channel them into socially appropriate, goal-directed behavior. Core EF processes include working memory, inhibition, and shifting (Diamond, 2013). Impaired EF is linked to a number of poor outcomes in school-age youth and adults with autism spectrum disorder (ASD), including lower adaptive behaviors, more repetitive behaviors, and poorer social skills (Yerys et al, 2009; Pellicano, 2012). Less is known about EF in the preschool years, as few standardized measures have been validated in children of this age with developmental delays.
Objectives: This study evaluates the feasibility and reliability of an EF battery that places no expressive verbal demands and minimizes the need for receptive verbal skills in preschoolers with ASD.
Methods: A total of 56 preschoolers with ASD (mean age=51.6 months; 80% male) completed a 20-minute EF battery that included putative measures of inhibition (Balance Beam Task, Tongue Task, and NEPSY-II Statue Subtest), working memory (Leiter-3 Memory Subtests), and shifting (Spatial Reversal Task). To evaluate feasibility, completion rates were calculated for each measure, as the percentage of children who were willing and able to complete the task and demonstrated understanding of task instructions. The role of developmental functioning (according to the Mullen Visual Reception Age Equivalent (VRAE)) on task completion and performance was also evaluated. Task order was counterbalanced to account for possible order and fatigue effects in the battery. The battery was re-administered to 16 children within two weeks from the initial administration, and intraclass correlations (ICC) were calculated to measure test-retest reliability.
Results: Regarding feasibility, only the Spatial Reversal Task had a successful completion rate greater than 80% for the entire sample (i.e. <20% were unable to complete the task or scored a zero). However, completion rates were at least 80% for Tongue Task when VRAE from the Mullen was at least 19 months (n=20) and for Leiter-3 Forward Memory Subtest when VRAE was at least 14 months (n=38). The Balance Beam and Statue tasks demonstrated very poor feasibility in this sample. For the 16 children who were retested, completers versus non-completers were consistent across time for Spatial Reversal, Tongue Task, and Forward Memory (ICC>.75). Performance reliability was also acceptable for total correct responses on Spatial Reversal (ICC=.73) and excellent for the Tongue Task and Forward Memory (ICC>.90).
Conclusions: EF is an important aspect of cognition to accurately measure in ASD because of its strong relationship with several important outcomes in older children and adults with ASD. This study provides initial evidence for the feasibility and reliability of a preschool EF assessment that minimizes verbal demands, along with potential developmental age guidelines for administration. This study suggests that a valid preschool EF battery that is sensitive to delayed cognitive development is attainable.

105 **142.105** Feasibility of Wh-Question Test in NT and ASD

R. Shyam[1]*, L. Pesta*[2]*, E. Carlson*[3] *and* ***M. M. Kjelgaard***[2]*, (1)Boulder Brain Recovery, Boulder, CO, (2)CSD, MGH IHP, Boston, MA, (3)Kapost, Boulder, CO*

Background: Children are presented with a multitude of questions encompassing all wh- question forms *(e.g., what, who, when, where, why* and *how)* in daily life. Those who have difficulty comprehending the meaning of these questions likely encounter a significant number of communication breakdowns throughout their day. It has been observed that individuals with Autism Spectrum Disorder (ASD) have specific difficulty in comprehending and responding to wh- questions (Goodwin, Fein & Naigles, 2012; Doggett, Krasno, Koegel & Koegel, 2013; Secan, Egel & Tilley, 1989). This difficulty is potentially attributed to factors including overall language delays or difficulty regarding the pragmatics of asking and responding to questions, among many other factors. While this particular difficulty has been observed in individuals with ASD (Doggett et al., 2013, Goodwin, Fein & Naigles, 2015; Goodwin, et al., 2012; Secan, et al., 1989; Tager-Flusberg, 1999), there is a lack of engaging assessment tools to identify the wh- question forms with which a child has difficulty and the error patterns showing the strategies these children are using. The lack of a comprehensive assessment tool impinges upon Speech Language Pathologists and educators in their design of appropriate goals for intervention.
Objectives:
The study was conducted to assess 1) the feasibility of administrating a computer based Wh-Question assessment to identify language goals in NT and ASD elementary school children 2) whether error patterns were different in the two groups.
Methods:
The Wh- Question Test is a computer program that assesses the question forms of *who, what, where* and *when* with multiple-choice responses presented through verbal and visual stimuli. The test contains 10 unique contextual sentences, each with an accompanying illustration, and a corresponding *who, what, where,* and *when* question, resulting in 40 total questions. Each contextual sentence includes a subject, transitive verb, object, location and time; therefore, all information needed to answer each question form is provided in the contextual sentence.
Example item:
'The children played with blocks in the classroom before music.'
Question: 'What did they play with?'
a) blocks
b) before music
c) the children
d) drums
e) in the classroom
The program collects both accuracy as well as error type.

Group	Mean Age	N	SD	Minimum Age	Maximum Age
NT	6.54	41	0.977	5	8
ASD	8.81	16	1.515	6	10

Figure 2. Participants
Results:
A mixed model between group (2) within wh- question form (4) ANOVA a significant interaction was present between wh- question form accuracy and group (ASD or NT) ($F=6.657$, $p=0.001$). 'When' questions were most difficult for both groups, but especially for the ASD group.
Conclusions:
The Wh-Question test is a feasible and engaging way to assess Wh-Question comprehension in both NT and ASD elementary school age children. Both groups showed similar patterns of difficulty, but the ASD group showed more difficulty relative to the NT group especially for 'When' questions.

106 **142.106** Gender Differences in Children and Adolescents with High-Functioning Autism Spectrum Disorders

R. Loomes[1], *L. Hull*[1], *D. H. Skuse*[2] *and W. Mandy*[1], *(1)University College London, London, United Kingdom, (2)UCL GOS Institute of Child Health, London, UNITED KINGDOM*

Background: It has been proposed that there is a distinct female phenotype for Autism Spectrum Disorders (ASD) which leads to a number of females on the spectrum being diagnosed later than males or missed completely (Lai et al. 2015). This hypothesised phenotype states that: (1) females are more likely to adopt camouflage strategies to mask or compensate for their autism; (2) females are more socially motivated and consequently make more effort to establish friendships; (3) females are more likely to have internalising difficulties (anxiety, depression) which go unnoticed; (4) that females are more likely to have restricted and repetitive interests that are "relational" in nature, i.e., involve developing and maintaining relationships with others. These "others" could be animals; they could be real people including celebrities; they could be imaginary friends or fictional characters (Attwood, 2006).
Historically the development of gold-standard ASD assessment measures has relied upon predominantly male samples, causing them to have a male-centric understanding of how ASD presents. As such, current assessment measures for ASD, such as the Autism Diagnostic Schedule Observation (ADOS), are thought to fail to capture the hypothesised female ASD phenotype.
Objectives: To develop and pilot a coding frame, the Gendered Autism Behaviour Scale (GABS), which can measure the female ASD phenotype from videoed ADOS sessions.
Methods: 18 GABS items were developed based on current understanding of the female phenotype for ASD using a combination of research evidence and expert-clinician experience. ADOS Module 3 and 4 assessment recordings were then coded using the GABS to compare males (n=22) and females (n=22) with ASD aged between 9 and 15 years. Inter-rater reliability was evaluated using the Kappa statistic, and two-tailed Fisher's exact tests were carried out to compare GABS item scores for males and females.
Results: The GABS had acceptable inter-rater reliability with an average Cohen's kappa of .65. The reporting of camouflaging in ADOS interviews was very low across the genders with only 3/22 males and 5/22 females showing evidence of camouflaging and no significant differences were found. Whilst there was no difference between females and males in terms of the intensity of their focus interests, there was a gender difference in the nature of these interests: females were more likely to talk about relational interests, in particular, animals, whereas males described more non-social interests ($p<.001$). Females also reported higher degrees of internalising difficulties ($p<.05$) and being more affected by social acceptance and rejection than males ($p<.05$).
Conclusions: Preliminary findings indicate that the GABS is a reliable instrument for assessing gender differences in standard ADOS Module 3 and 4 assessments. It revealed significant differences in how males and females with ASD present, especially in terms of the nature of their restricted and repetitive interests and their social motivation. ASD measures should cover areas such as camouflaging and relational interests so as to improve early and accurate diagnosis and support for females with ASD.

107 **142.107** High Autistic Traits in Women with Eating Disorders

C. M. Brown[1], *M. Fuller-Tyszkiewicz*[1], *I. Krug*[2] *and* ***M. A. Stokes***[1], *(1)School of Psychology, Deakin University, Melbourne, Australia, (2)School of Psychological Sciences, University of Melbourne, Melbourne, Australia*

Background:
An increasing body of literature has demonstrated a degree of comorbidity between Autism Spectrum Disorders (ASD) and various eating disorders (EDs) in females, but little is known about the relationship EDs have with ASD, and what effect an ED has on the detection and diagnosis of ASD.
Objectives:
The current study aimed to evaluate whether females with high autistic traits were likely to receive a diagnosis of an ED, which may serve to obscure their potential diagnosis of an ASD. It was hypothesised that women with high autistic traits would be undiagnosed with ASD in many cases, and would instead present with a diagnosis of an ED.
Methods:
Using an online data collection method, 670 women over the age of 18 were recruited through social media and specialist ASD and ED support services. The women completed two screening measures: the Autism-Spectrum Quotient (AQ) and the Eating Attitudes Test (EAT-26).Â Participants were classified as either 'high' or 'low' on specific variables based on established cut off scores for these instruments, and designated the following labels: high autistic traits (HATs); low autistic traits (LATs); high eating disorder traits (HEDs); low eating disorder traits (LEDs).
Results:
Of all 670 participants, 21.5% were classified as HATs and 78.5% as LATs, while 24.0% were classified as having HEDs and 76.0% as having LEDs. Of the total, 16.7% reported having received a diagnosis of ASD, and 21.7% reported having received a diagnosis of an ED. Fewer women with HATs were diagnosed with ASD than with an ED (Z=3.33, p<0.001). When asked if they had symptoms typical of an eating disorder, 49.3% responded that they had. Women with HATs (diagnosed & undiagnosed) were significantly more likely to also display HEDs than LEDs ($\chi^2_{(1)}$=24.31, p<0.001). Women with a diagnosis of ASD, compared to those without, were significantly more likely to display HED traits ($\chi^2_{(2)}$=22.21, p<0.001). However, women with HATs but no diagnosis of ASD, were not more likely than those with LATs to receive a diagnosis of ED ($\chi^2_{(2)}$=0.43, OR=1.3 95%CI [0.623, 2.580], p=0.32). Participants, who were otherwise undiagnosed, but displayed high traits of ASD, were not more likely to have been diagnosed with an ED. Last, women with an ED were significantly more likely to be in the HATs group than women without an ED ($\chi^2_{(2)}$=16.16, p<0.001).
Conclusions:
The results support the conclusion that women with HATs are more likely to be diagnosed with an ED than ASD. While it may appear that this diagnosis may obscure a diagnosis of ASD, preventing early intervention, the finding that those lacking a diagnosis but having HATs were not more likely to receive a diagnosis of an ED, suggests that an ED diagnosis does not preclude or camouflage a diagnosis of ASD. Nonetheless, the high rate of ED traits in women with ASD reflects the obsessional nature and desire for environmental control that is frequently found in ASD.

108 **142.108** How Can We Assess the Broader Autism Phenotype More Systematically? Insights from a Multiple Measure Study

A. Riccio[1], *S. K. Kapp*[2], *N. Najjar Daou*[3], *Y. Nishio*[4] *and K. Gillespie-Lynch*[1], *(1)Department of Psychology, College of Staten Island and The Graduate Center, CUNY, New York, NY, (2)College of Social Sciences and International Studies, University of Exeter, Exeter, United Kingdom, (3)American University of Beirut, Beirut, Lebanon, (4)Graduate School of Human Development and Environment, Kobe University, Kobe, Japan*

Background: Â Research examining the Broader Autism Phenotype (BAP), or subclinical autistic traits, among emerging adults suggests that the BAP is characterized by difficulties understanding one's own and others' emotions and perspectives, reduced prosocial behavior and emotional intimacy, sensory atypicalities and enhanced creativity (Austin, 2015; Brewer et al., 2015; Best et al., 2015; Gokcen et al., 2014; Jameel et al., 2014; 2015; Jobe & White, 2007). Although most of the aforementioned studies relied upon self-report measures, none of them assessed susceptibility to the social desirability bias. This is problematic because the BAP is associated with reduced understanding of social pretense (Yang & Baillargeon, 2013). In addition, prior research has typically not used a range of measures to determine which characteristics remain associated with the BAP when other characteristics are controlled for or examined if associations are apparent with more than one BAP measure.
Objectives:

1. To examine if the BAP is associated with reduced social desirability bias.
2. To obtain a more comprehensive characterization of the BAP using multiple measures.

Methods: College students (N = 391; 18-25 years old) completed an online survey that included measures of autistic traits, the Autism Spectrum Quotient (AQ) and Social Responsiveness Scale (SRS-2), the sensory subscale of the Ritvo Autism and Asperger Diagnostic Scale, the Basic Empathy Scale, the Toronto Alexithymia Scale, the Marlowe-Crowne Social Desirability Scale, and a Divergent Thinking task. We also examined self-reported prosocial behaviors using scenarios Jameel and colleagues (2014; 2015) developed to demonstrate that heightened autistic traits were associated with reduced self-reported prosocial behaviors across 10 contexts. To avoid carry-over effects, we randomly assigned participants to two groups using a between-subjects research design. Scenarios presented as ambiguous (e.g. help a young man) for one group of participants were presented as clear-cut (help an old lady) for the other group and vice versa.
Results: The AQ and SRS-2 were positively correlated with each other, r(389)=0.499, p<0.001. Social desirability scores were inversely correlated with the AQ, r(389)=-0.15, p=0.003 and the SRS-2, r(389)=-0.37, p<0.001. In a linear regression predicting AQ scores, reduced cognitive empathy and heightened alexithymia (ps<=0.001) were associated with autistic traits; sensory atypicalities, affective empathy, social desirability, creativity, and prosocial behaviors were unrelated to the BAP. In a linear regression predicting SRS-2 scores, reduced cognitive empathy and social desirability and heightened alexithymia and sensory atypicalities were associated with the BAP (ps <0.001); creativity, prosocial behaviors, and affective empathy were unrelated to SRS-2 scores.
Conclusions: Â Findings indicate that reduced social desirability is associated with the BAP but prosocial behaviors are not consistently associated with the BAP. The concurrent measurement of multiple potential BAP constructs provides insights about what is central to the BAP. Difficulty understanding one's self and others is a consistent aspect of the BAP in emerging adulthood; difficulty understanding others is also part of the BAP among schoolchildren (Tsang et al., 2016). Findings highlight the importance of assessing social desirability and multiple potential aspects of the BAP when using self-report measures.

109 **142.109** How Certain Are Clinicians in Determining Outcome Diagnoses in 2 Year-Olds?

A. Kincheloe[1], *T. Aronson*[2] *and C. A. Saulnier*[3], *(1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (3)Children's Healthcare of Atlanta, Emory University, Marcus Autism Center, Atlanta, GA*

Background:
Clinicians have become increasingly more reliable with identifying autism spectrum disorder (ASD) as young as age two (Mandell, et al., 2005). Community providers are recognizing symptoms earlier, resulting in earlier referrals to specialists (Charman et al., 2002), and use of the *Autism Diagnostic Observation Schedule* (ADOS) enhances diagnostic validity (Gotham, et al., 2009). The impact of clinician's *certainty* in determining ASD diagnoses in toddlers, however, is less clear.
Objectives:
This study examines certainty ratings made by experienced, licensed and research-reliable psychologists when determining diagnoses of 24-month-old toddlers participating in autism research studies that involved diagnostic outcome evaluations.
Methods:
Toddlers participated in studies at the Marcus Autism Center. The clinically-referred sample was collected through a study on early detection consisting of 181 toddlers: Mean age=24.1m; 75% male; 134 with ASD; 47 with non-ASD developmental delays (DD). The infant sample was collected through a longitudinal prospective study on infants siblings of children at High Risk (HR) or Low Risk (LR) for ASD. This sample consisted of 107 toddlers at their 24-month diagnostic evaluation: Mean age=24.5m; 64% male; 11 with ASD; 13 with broader phenotype (BAP); 7 with DD; and 75 with typical outcome (TD). Measures included *Mullen Scales of Early Learning (Mullen); ADOS-2; Communication and Symbolic Language Scales (CSBS), and Vineland Adaptive Behavior Scales, 2nd Edition* (*Vineland-II*).
Results:
Clinically-Referred Sample: Independent *T*-Tests revealed a significant difference in clinician certainty ratings (CR) between toddlers diagnosed with ASD vs. DD (Mean CR = 86.8% vs. 77.2%, respectively; $t(1,179)=-3.13$, $p<.01$). A trend for negative correlations were found between CR and *ADOS-2* social affect (-2.7; $p=.07$) and RRBs (-.26; $p=.09$) scores for the DD toddlers. *However*, strong positive correlations were found between CR and *ADOS-2* SA and RRB scores (.49 and .33, respectively; $p<.001$).
Infant Longitudinal Sample: ANOVA results revealed significant differences in CR percentages for diagnoses in the infant sample ($F(3,105)=10.1$; $p<.001$). Clinicians were most confident in determining TD outcome (CR mean=88.13%) compared to ASD (79.1%), DD (77.1%), and BAP (71.5%). Clinicians were also more confident in diagnoses merely based on risk status (LR mean=86.4%; HR mean=80.8%; $t(1,106)=2.22$; $p<.05$). In contrast to the clinically-referred toddlers, no significant correlations were found between CR and *ADOS-2* scores for the DD-outcome infants; however, strong negative correlations were found in the TD infants ($r=-.46$ for ADOS-2 SA and -.53 for RRB, $p<.001$). In the ASD-outcome infants, a positive correlation was found between *ADOS-2* SA and CR ($r=.76$; $p<.01$).
Gender, race, and maternal education levels had no impact on CR for either sample.
Conclusions:
Findings highlight that, for both samples, clinicians are more confident in diagnosing ASD versus non-ASD developmental delays. For HR toddlers, clinicians are less confident in diagnosing BAP. When blind to risk status, clinicians are less confident when determining diagnosis in HR toddlers. Increased symptomatology enhances certainty for ASD toddlers, whereas the opposite is true for TD toddlers. These results underscore the importance of clinician training in accurate and reliable assessment of ASD, particularly for young children and those who are at high-risk for ASD.

110 **142.110** How Reliable Is the Autism-Spectrum Quotient at Identifying Low and High Autistic Traits in College Students?

J. L. Stevenson[1] *and K. R. Hart*[2]*, (1)Ursinus College, Collegeville, PA, (2)Mathematics, The Hotchkiss School, Lakeville, CT*

Background: The Autism-Spectrum Quotient, a measure of autistic traits, is commonly used to identify neurotypical adults (often college students) with low and high levels of autistic traits for comparison. However, researchers disagree on whether the Autism-Spectrum Quotient should be scored by converting items to a binary scale or maintaining the 4-point Likert scale. Furthermore, researchers use different methods to categorize adults as having low or high autistic traits which range from inclusive (e.g., median split) to restrictive (e.g., upper/lower deciles). Additionally, restrictive identification methods often require a time delay between administration of the Autism-Spectrum Quotient and the task(s) of interest. Research is needed to assess the reliability of the Likert scoring method and identification of low/high autistic traits in neurotypical adults.
Objectives: The present study systematically investigated the reliability of the Autism-Spectrum Quotient for identifying autistic traits in college students. In particular, this study aimed to elucidate whether reliability varies by scoring method (binary or Likert) or categorization method (median split, upper/lower tertiles, quartiles, or deciles).
Methods: Four hundred three college students completed a computerized version of the Autism-Spectrum Quotient while their eye movements were recorded. A subset of students (n = 178) completed a second version at least one week later (M = 15.17 days, SD= 5.53).
Results: Internal consistency of the total scores was acceptable ($\alpha \geq .70$) for both scoring methods. Internal consistency for subscales varied ranging from acceptable (social skills for Likert scoring) to poor ($\alpha \leq .50$; imagination for both methods). Internal consistency improved with Likert scoring for the total and all subscales scores except for attention switching (all others $\chi^2(1) \geq 6.74$, $p \leq .009$). Test-retest reliability was strong ($r \geq .80$) for total scores for both methods, and all subscales for Likert scoring with the exception of imagination. Furthermore, test-retest reliability improved when using Likert scoring for total, social skills, attention switching, and attention to detail scores ($zs \geq -2.02$, $ps \leq .04$). Similar patterns of internal consistency and test-retest reliability were seen for men and women; however, men's total scores decreased over time using binary scoring ($t(54) = 2.44$, $p = .02$), whereas women's total scores increased over time using Likert scoring ($t(120) = -3.45$, $p= .001$). Categorizing individuals as low and high autistic traits was consistent across scoring method when using more inclusive methods (e.g., median split: 90.57%); however, agreement was reduced with more restrictive methods (e.g., deciles: 75.26%). Across time, the Likert method was equivalent or more stable than the binary method at categorizing individuals (e.g., median split: 85.80% versus 76.14%).
Conclusions: Overall, the Autism-Spectrum Quotient reliably assesses students' autistic traits. The Likert method is superior in internal consistency and test-retest reliability. Furthermore, the Likert method may have better consistency at categorizing adults as low or high in autistic traits. Therefore, it is recommended that researchers move to using Likert scoring. However, researchers should be cautious about using restrictive identification methods because categorization at extremes may change over time.

111 **142.111** Implications of Using the Social Responsiveness Scale in First-Time Diagnostic Assessment

A. Merz, ***C. M. Taylor*** *and T. Nelson, Geisinger Health System, Lewisburg, PA*

Background: The Social Responsiveness Scale (SRS) is a 65-item, Likert scale assessment designed to measure ASD-specific symptoms. While this scale is commonly used in diagnostic assessment, several studies have shown that the SRS may be correlated with traits other than ASD. For example, some studies have indicated that the SRS may be associated with general behavioral problems, cognitive functioning level, sex, and age.
Objectives: The purpose of this study was to determine whether there was an association between SRS scores and ASD diagnosis in a clinical pediatric population, when controlling for potential cofounding variables, including non-ASD behavioral problems and cognitive impairment.
Methods: This study included patients (ages 2-17) who presented for first-time diagnostic assessment. As part of their diagnostic assessment, parents of children completed the SRS in addition to other non-ASD clinical measures (e.g., CBCL). All children in our sample were diagnosed with one or more developmental disorders at the conclusion of their visit by a neurodevelopmental pediatrician or pediatric psychologist. Analysis of SRS total T-scores was conducted on the full population of patients for which SRS results were available. Subsequently, a regression analysis was performed on a subset of this population, in order to assess the degree of association between SRS total T-scores and ASD diagnosis, when controlling for behavioral and demographic factors. The variables controlled for in this analysis included age, sex, cognitive level (IQ), and behavioral problems (measured by the Child Behavior Checklist Externalizing Behavior section, or CBCL-E).
Results: Within the full group with SRS results available (n = 289), mean SRS scores were higher for participants diagnosed with ASD (t = 3.242, p = .001). However, both the mean T-scores of the group diagnosed with ASD and the group diagnosed only with non-ASD developmental disorders fell within the range of “moderate impairment”. When a regression model was fit to the subset of participants with IQ and CBCL-E scores available (n = 61), only behavioral problems (CBCL-E T-score) had a statistically significant relationship with the SRS total T-score (coefficient = .776, p < .001). ASD diagnosis had a small positive association with SRS score (coefficient = 3.580), but was not statistically significant. Subsequent analysis of the correlation between the SRS and CBCL-E found that the CBCL-E explained about 43% of the variance in the SRS scores.
Conclusions: The results of this study indicate that SRS scores are highly correlated with non-ASD behavioral problems, as measured by the CBCL-E, in a clinical pediatric population. In addition, while SRS scores were higher for participants diagnosed with ASD, both the ASD and non-ASD groups had scores that were elevated to clinically significant levels. Overall, this study supports the interpretation of the SRS in the context of a broader behavioral phenotype at first-time diagnostic visits.

112 **142.112** Initial Observations of Girls’ Social Presentation in a Clinical Setting

C. Hall[1], *J. Cash*[2], *B. A. Brooks*[2] *and S. Hoffenberg*[2], *(1)Marcus Autism Center, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA*

Background:
Autism spectrum disorder (ASD) is estimated to be almost 5 times more common in boys than girls (Baio, 2014).What we know about profiles of ASD in girls lags behind what is known about boys, but research has shown inconsistencies in profiles of girls and boys. Greater cognitive impairment in girls (Frazier et al, 2014) and later age of diagnosis has been found, which can delay the start of intervention (Kavanagh et al., 2013; Rynkiewicz et al., 2012), while others have shown comparable developmental profiles between girls and boys (Zwaigenbaum et al., 2012). Clinicians in our diagnostic clinic often report different social presentations in girls that make diagnosis and case conceptualization difficult. In particular, clinicians note that many girls seem to initially present with strengths in eye contact, directed affect and play skills though weaknesses in these areas become more apparent over the course of the evaluation.
Objectives:
The purpose of this study is to analyze initial behavioral observations of girls who went on to receive ASD diagnoses in a clinical setting.
Methods:
A detailed record review was conducted of diagnostic evaluations for children ages 0-48 months between 1/1/2016 and 10/12/2016 in an autism center serving a diverse population. Children who were clinically referred received an initial diagnostic interview (DI) with a psychologist, neurologist or nurse practitioner. Those who were determined to have red flags for autism were referred on to receive diagnostic evaluations. Assessments each included a developmental/cognitive measure, adaptive measure and the ADOS-2.
Results:
84 girls (24% of total referrals) ages16-47 months were referred for a diagnostic assessment for ASD. Each patient received a diagnostic interview, after which autism was ruled out for 28% of the girls (compared to 15% for boys). The remaining 61 girls returned to assess for ASD, and of these 47 (78%) received an ASD diagnosis (compared to 88% for boys). Record review for those 47 girls, from initial behavioral observations during the diagnostic interview, revealed the following:Â 14 (30%) girls were noted to have “good” or “excellent” eye contact and an additional 14 (30%) were noted to have “inconsistent eye contact” or “moments of good eye contact.” In addition, thirteen (28%) girls were noted to have appropriate directed/shared affect and 7 (15%) girls were noted to engage in appropriate pretend play.
Conclusions:
These findings highlight the importance of comprehensive evaluations to assess for ASD in girls, especially given that initial clinical impressions noted strengths in key symptom areas (e.g., eye contact and directed facial expressions) in 30% of girls who went on to meet full behavioral criteria for ASD. Furthermore, these findings point to potential reasons for low referral rates of girls to autism specialty clinics; many providers may not recognize social vulnerabilities when initial impressions are that of good eye contact and directed affect. This underscores the importance of continued focus on symptom profiles of girls with ASD and translation of these findings to current clinical practices in screening and diagnosis of ASD in girls.

113 **142.113** Investigating the Causes of Informant Discrepancies in the Assessment of Autism Spectrum Conditions

J. J. Finnemann[1,2,3] *and K. Barnes*[1], *(1)Department of Psychology, University of Cambridge, Cambridge, United Kingdom, (2)Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (3)Department of Music and Performing Arts, Anglia Ruskin University, Cambridge, United Kingdom*

Background: Â
“Informant discrepancies are ubiquitous in research on the assessment, development and treatment of psychopathology” (De Los Reyes, 2011) and pose a major challenge to the diagnostic process of neurodevelopmental conditions such as autism. The current ‘gold standard’ for diagnosing autism includes an observational assessment (ADOS) and a caregiver interview (ADI), but little is known about the causes of discrepancies between these.
Past research has shown that parent report of child behaviour is influenced by factors including parental mental health (Treutler, 2003), parental gender (Hay, 1999), the age of the child (Bitsika, 2016) and parental income (Johnston, 2010).
Objectives: Â
We were interested in investigating whether there are systematic differences in evaluations of children with autism and whether specific contributions to these discrepancies can be identified.
Methods:
The sample consisted of 364 children (who took part in a randomised controlled trial of music therapy) between the ages of 4 and 8. The baseline assessment included the ADOS, the ADI, the Social Responsiveness Scale (SRS) and a life satisfaction questionnaire (QoL) for the child and the family. All children were followed up with ADOS assessments after 2, 5 and 12 months and parents filled in the questionnaires and attended counselling sessions. The latter were evaluated by conducting sentiment analyses on the transcripts of the sessions.
Growth curve modelling was used to examine the longitudinal data: The final model was a parallel linear growth model for informant discrepancies (z-scores of the ADOS and SRS scores were used to derive a signed difference score across time) and QoL. The predictors tested included the age of the child, the linguistic ability of the child, parental education and the gender of the parent.
Results:
As data collection finishes in November 2016 only preliminary results are currently available.
However the findings replicate previous research indicating stronger correlations between the parent report measures (ADI and SRS) than between parent and clinician measures (ADI & ADOS and SRS & ADOS).
In addition both the quality of life ratings as well as obtained sentiment scores correlated negatively with autism severity reported in the SRS, whereas none of the measures correlated with the total ADOS scores.
Only language ability emerged as a significant predictor in the growth curve analysis.
Conclusions:
Two factors were identified which are associated with informant discrepancies: the language ability of the child and parental wellbeing.
Language delay is often the first concern noted by parents (De Giacomo & Fombonne, 1998) and thus could play a role in the perceived severity of the condition by parents whereas behavioural observations should be sensitive enough to assess other diagnostic domains which are sometimes missed by parents of young children (Chawarska et al. 2006).
Furthermore the impact of the family's quality of life on the cognitive appraisal of the child's condition underlines the need to investigate the importance of post-diagnostic support on parental wellbeing.

114 **142.114** Longitudinal Prediction of Adaptive Behavior from Sensory Features and Intensity of Services in Children with ASD and Other DD

K. L. Williams[1], *L. R. Watson*[2], *A. V. Kirby*[3], *J. Sideris*[4], *J. C. Bulluck*[1] *and G. T. Baranek*[1], *(1)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)University of North Carolina- Chapel Hill, Chapel Hill, NC, (3)University of Utah, Salt Lake City, UT, (4)Frank Porter Graham Child Development Institute, Chapel Hill, NC*

Background:
Many behavioral therapies target sensory features in autism spectrum disorder (ASD) and other developmental disabilities (DD) throughout childhood. Little is known about the association of these sensory features with adaptive functioning over time in ASD, how these adaptive outcomes may vary in association with various treatments, and if these associations differ by diagnosis.
Objectives:
Our aims were to (1) examine the longitudinal association between early sensory features [hyporesponsiveness (HYPO), hyperresponsiveness (HYPER), and sensory interests, repetitions, and seeking behaviors (SIRS)] and adaptive functioning outcomes (daily living, socialization, communication, and an overall composite score); and (2) determine if these associations are moderated by services received or diagnostic category.
Methods:
50 children with ASD [Time 1: 5.5(2.3) years] and 31 children with DD [Time 1: 5.7(2.6) years] participated across two time points approximately 3.6(1.5) years apart. Sensory measures at Time 1 included two parent-report measures: the Sensory Experiences Questionnaire Version 3.0 and the Sensory Profile; and two observational assessments: the Sensory Processing Assessment and the Tactile Defensiveness and Discrimination Test-Revised. Adaptive outcomes at Time 2 were measured using the Vineland Adaptive Behavior Scales-Survey Edition. We also collected data on amounts of therapy (occupational, speech-language, and physical) and special education services received between timepoints. Data were analyzed using a series of step-down regression models, with diagnostic group and services included as potential moderators. Covariates included child gender, age at baseline, IQ, household income, mother’s education, and time between data collection points.
Results:
Greater parent-reported HYPO behaviors were associated with lower Daily Living scores after controlling for therapy ($F(1, 59) = 4.17$; $p = 0.05$) and special education services ($F(1, 59) = 4.52$; $p = 0.04$), with a steeper decline for DD than ASD. The same trend was significant for ABC scores ($F(1, 73) = 4.16$; $p = 0.05$) and Socialization ($F(1, 73) = 3.89$; $p = 0.05$) when controlling for special education services but not significant when controlling for therapy services.
Greater parent-reported HYPER scores predicted poorer ABC ($F(1, 76) = 5.65$; $p =0.02$) and Daily Living outcomes ($F(1, 62) = 14.02$; $p < 0.001$) across groups and services amount. Three-way interactions between HYPER, group, and educational treatment ($F(1, 70) = 6.20$; $p = 0.02$) and Communication ($F(1, 70) = 4.60$; $p =0.04$) were also significant for ABC.
Higher parent-reported SIRS behaviors were associated with better adaptive outcomes for the DD group, and poorer adaptive outcomes for the ASD group on all outcomes of the VABS after controlling for both service types. These trends were in the opposite direction in observer-measured SIRS. As scores increased, ABC outcomes increased for the ASD group and decreased for the DD group ($F(1, 73) = 4.74$; $p = 0.03$).
Conclusions:
Sensory features and therapy services were associated differentially with later adaptive outcomes, sometimes influenced by type of sensory measure (parent-report or observed) or diagnostic group. Interestingly, services were associated with poorer adaptive outcomes, possibly because children with more severe ASD receive more services regardless of effectiveness. Future treatment studies using RCTs are needed to address this question.

115 **142.115** M-CHAT-R/F - Translation & Validation in Hindi

N. Singhal[1], *R. Pradhan*[2], *T. Behl*[2], *D. Taneja*[3] *and M. Barua*[4], *(1)Action For Autism, New Delhi, Delhi, India, (2)Action For Autism, New Delhi, India, (3)Action for Autism, New Delhi, INDIA, (4)Action For Autism, New Delhi, INDIA*

Background: Internationally, many validated tools are available for screening, diagnosing, and characterizing individuals on the autism spectrum. However, use of these measures is limited in non-English speaking countries, such as South Asia. India is a country of many languages, and based on the Indian Census data, Hindi is the primary language of over 41% of the Indian population. Translation into regional languages and validation is the first step towards establishing clinical and research standards in India and other South Asian countries. The Modified Checklist for Autism in Toddlers – Revised with Follow up (M-CHAT-R/F) is a freely available tool that is used widely to screen for autism spectrum conditions and other developmental delays in toddlers within the age group of 16 – 30 months. In a low resource country like India, having a freely accessible autism screening tool in the local language is crucial to identify young children on the spectrum and ultimately impact the access to intervention and prognosis of children with autism.
Objectives: To translate the M-CHAT-R/F to Hindi and to validate the translated version of M-CHAT-R.
Methods: The translation process involved the 4 step procedure namely – translation of the English M-CHAT-R/F into Hindi by two independent teams fluent in both the languages, compilation in to one document by a third team, blind back-translations and finally getting the translation edited and reviewed. The blind back translations were done by independent language experts, and were then evaluated by bilingual members of the research team. This cycle was repeated until the blind back translations were close to the original tool. In order to validate the translated Hindi version of the tool, it was administered with parents of 53 toddlers from New Delhi. Of the 53 toddlers, 32 children showed typical development and 21 toddlers had a diagnosis of autism spectrum disorder.
Results: An independent samples t-test showed significantly different mean scores (t =24.1, df = 7.77, P = 0.00) for autism (M = 8.61, SD = 4.21) and the typically developing group (M = 1.12, SD = 1.57). 20 out of the 21 children with autism screened positive on M-CHAT-R. Of the typically developing sample, 91% screened at low risk, 6% were found to be at medium risk and the remaining sample of 3% screened at high risk. The follow up indicated a negative screening for all typically developing toddlers who screened at medium or high risk on M-CHAT-R.
Conclusions: This holds direct implications for improving diagnosis of autism, by clinicians within the Hindi speaking population in India and other South Asian countries.

116 **142.116** Measurement Properties of Tools Used to Assess Suicidality in Adults with and without Autism Spectrum Conditions: A Systematic Review

L. Bradley[1]*, J. Rodgers*[2]*, E. Bowen*[3] *and S. A. Cassidy*[1]*, (1)Coventry University, Coventry, United Kingdom, (2)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom, (3)University of Worcester, Worcester, United Kingdom*

Background: Recent research has shown significantly increased rates of suicidal thoughts, behaviours and death by suicide among adults with Autism Spectrum Conditions (ASC), and hence a need to effectively assess suicidality in research and clinical practise. However, it is unclear what tools if any are currently available to assess suicidality in people with ASC, or whether tools used in the general population need to be adapted for this group.
Objectives: 1) To identify tools used to assess suicidality in adults with and without ASC; and 2) To evaluate these tools for their appropriateness and measurement properties.
Methods: Electronic databases including Medline, Psychinfo, Web of Knowledge, Cochrane database and registers were searched for studies of suicidality in a) adults with ASC, and without co-morbid learning disability; and b) adults from the general population, and without any co-morbid conditions. Articles examining the measurement properties of these identified tools were then searched for using a methodological filter in PubMed, and the quality of the evidence for each tool evaluated using the COSMIN checklist.
Results: No studies were identified which utilised a validated tool to assess suicidality in adults with ASC. Twenty-two articles were identified which have utilised 12 tools to assess suicidality in general population adults, 4 of which had been used frequently with evidence of validity. These 4 tools were evaluated for the quality of the evidence of their measurement properties.
Conclusions: Overall 3 tools were found which were robust in their measurement properties; the Beck Scale for Sucide Ideation, the Columbia Suicide Severity Rating Scale, and the Suicide Behaviour Questionnaire Revised. However, none of these scales have yet been used to assess suicidality amongst those with ASC. Future research needs to adapt and validate these tools for adults with ASC. This is key to ensure that suicide risk is properly assessed in this high risk group in future research and clinical practise.

117 **142.117** Parent Reported Development and Withdrawal Informs Differential Diagnosis of Autism Spectrum Disorder Versus Developmental Language Disorder in Children Under 6

A. E. Richard[1]*, E. Homeister*[2]*, A. Buthman*[1] *and E. K. Hodges*[1]*, (1)Psychiatry, University of Michigan, Ann Arbor, MI, (2)University of Michigan - Dearborn, Dearborn, MI*

Background: Efforts to improve rates of identification of Autism Spectrum Disorder (ASD) at younger ages have largely focused on differentiating children with ASD from neurotypicals children. In clinical practice, among children under age 6 presenting with concern for ASD who are not ultimately diagnosed with ASD, one of the most common diagnoses is Developmental Language Disorder (DLD). Easily administered parent-report measures may be helpful in facilitating differential diagnosis of ASD versus DLD. However, no measures for this specific purpose are currently available, and it remains unknown whether existing measures may be helpful in this regard.
Objectives: The current study aimed to identify aspects of parent-rated development and emotional/behavioral symptoms that may facilitate differentiation of ASD (with or without comorbid DLD) from DLD (without ASD) among children under age 6 presenting with concern for ASD.
Methods: Medical record review was conducted for 90 children ages 19 months to 5 years, 5 months (M_{age} = 3 years, 4 months) who were evaluated within a multidisciplinary autism evaluation clinic within the University of Michigan Health System Department of Neurology. Of these, 54 children were diagnosed with ASD (with or without DLD) and 28 were diagnosed with DLD (without ASD). Record review included results of parent report questionnaires (Child Development Inventory [CDI], Child Behavior Checklist [CBCL], and Social Communication Questionnaire [SCQ]). Mann-Whitney *U* tests were conducted to examine group differences in CBCL and SCQ standardized scores. For CDI, difference scores were calculated by subtracting age equivalence scores from chronological age. Chi square tests were conducted to determine group differences in the probability of falling within the delayed range (Z score ≤ -1.5) on the CDI.
Results: Â As expected, SCQ scores were significantly higher for children with ASD than DLD (U = 389, p < .005). On the CDI, children with ASD had greater difference scores than DLD (U = 455, p < .05) and were more likely than DLD to be classified as delayed in general development (χ^2 = 7.8, p < .05). Specifically, children with ASD were more likely to be classified as impaired in the domains of social development (χ^2 = 7.05, p < .05) and language comprehension (χ^2 = 5.22, p < 0.05). Additionally, difference scores for children with ASD were significantly greater than DLD for both receptive (U = 438, p < .05) and expressive language (U = 455, p < .05). Children with ASD were also rated as significantly more withdrawn on the CBCL than DLD (U = 418, p < .05).
Conclusions: Â Parent ratings on the withdrawal subscale of the CBCL and social, receptive and expressive language subscales of the CDI may add useful information in the differential diagnosis of ASD versus DLD among children under age 6 presenting with concern for ASD. Development of a parent-report measure including items indexing social and language development as well as withdrawal may provide greater clinical utility in this regard.

118 **142.118** Parent and Teacher Report of Behavioral Symptoms in Autism Spectrum Disorders: Assessing the Impact of Demographic and Socioeconomic Factors

S. B. Vanegas*, K. Acharya and S. Magana, Disability and Human Development, University of Illinois at Chicago, Chicago, IL*

Background:
Clinical evaluations of children with suspected neurodevelopmental disorders often requires observations of the child across settings, as well as, report of behavioral symptoms by multiple raters. This can be particularly informative as symptoms may be expressed differently across settings (Kanne, Abbacchi, & Constantino, 2009). However, reporting of behavior may be influenced by the reporter's own perception of the behavior and may be subject to potential biases. Thus, understanding the validity and reliability of behavioral reports within clinical and research settings is critically important.
Objectives:
The goal of this study it so assess the impact of demographic and socioeconomic factors in the reporting of behavioral symptoms by parents and teachers in a diverse sample of children with ASD.
Methods:
The current study is part of a larger study evaluating developmental profiles of diverse children with ASD who visited a developmental disabilities clinic located in an urban city in the United States. Clinic records of children between 3 and 12 years of age with clinical diagnoses or educational classifications of an Autism Spectrum Disorder were reviewed. Information about demographics (e.g., race, ethnicity, nativity), socioeconomic factors (private vs. public insurance) were collected from the clinic records. As the measure of children's behavioral symptoms, the Child Behavior Checklist (CBCL; Achenbach, 2000, 2001) and Teacher Report Form (TRF; Achenbach, 1997, 2001) administered in English or Spanish were scored as the dependent variable.
Results:
Preliminary analyses were conducted on the subset of children who were between 3 and 5 years of age (n = 21). Descriptions of the sample are included in Table 1. Paired-sample t-tests compared parent and teacher report of behavioral symptoms, specifically the t-scores for the DSM Oriented Scales of the CBCL and TRF. Paired-sample t-tests initially compared parent and teacher reports separately across race groups (White, African-American), finding significant discrepancies between parents and teachers report on anxiety, ADHD, and oppositional defiant behaviors for African-American children with ASD (all p's < .05). However, for White children with ASD, discrepancies between parent and teacher report of behavioral symptoms were only observed for ADHD symptoms (p< .001). Additional analyses will be presented at IMFAR that will include additional subscales from the CBCL and TRF and the entire sample of children with ASD (age 3 to 12 years).
Conclusions:
Although there is extensive research on the utility of the CBCL and TRF in the identification of children with ASD, there is limited research investigating the impact of demographic and socioeconomic factors on the validity and reliability of these tools in diverse populations. These preliminary analyses found that teachers in general reported greater ADHD behaviors than parents did for young children with ASD. However, teachers also reported greater difficulties with anxiety and oppositional defiant behaviors for African-American children with ASD. It may be that these challenges emerge to a greater extent in the school setting. Additional analyses will investigate whether the discrepancies between parent and teacher report of behavioral symptoms varies as a function of other demographic and socioeconomic factors.

119 **142.119** Parent-Reported Executive Functioning and Adaptive Social Skills in School-Age Children with ASD

***L. E. Miller**, J. Donelan and D. A. Fein, Psychological Sciences, University of Connecticut, Storrs, CT*

Background: Individuals with autism spectrum disorder (ASD) present with deficits in socialization and communication. Research has also documented impaired executive functioning (EF) in this population, yet few studies have looked at the expression of specific EF deficits in the everyday social skills of children with ASD.
Objectives: This study assessed the relationship between components of EF and adaptive social skills in school-age children with ASD.
Methods: Participants were 29 children (25 males; mean age 9.4 ± 1.6 years) drawn from a larger study on the early detection of ASD, in which they were diagnosed with either Autistic Disorder or Pervasive Developmental Disorder, Not Otherwise Specified (PDD-NOS) at 2 and 4 years. Diagnosis was confirmed at school-age follow-up using the Autism Diagnostic Observation Schedule (ADOS), and IQ was assessed with the Differential Ability Scales, Second Edition (DAS-II) or Stanford-Binet Intelligence Scales, Fifth Edition (SB-5). EF and adaptive functioning were measured using parent reports: the Behavior Rating Inventory of Executive Function (BRIEF) and Vineland Adaptive Behavior Scales, Second Edition (VABS-II). Correlation and hierarchical regression, controlling for IQ, were used to examine the relationship between EF scales and adaptive social skills. Due to the small sample size and risk of Type I and Type II errors, a conservative cutoff of α = .01 was used for all analyses.
Results: VABS-II Socialization and Communication were negatively correlated with BRIEF Emotional Control, Inhibit (Socialization only), Monitor, Shift (Socialization only), and Working Memory (all Pearson's r's > .50, all p's < .01). Results of partial correlations controlling for IQ (i.e., DAS-II General Conceptual Ability or SB-5 Brief IQ) were consistent with Pearson's correlations, with one exception; the correlation between VABS-II Communication and BRIEF Monitor (r = -.405, p = .040) was no longer significant using our conservative cutoff. Hierarchical regressions were then run with IQ entered first, followed by each BRIEF scale entered individually in a second block. Results were consistent with partial correlation findings.
Conclusions: This study examined the relationship between parent-reported EF and adaptive social skills in school-age children with ASD. Results suggest that EF deficits are significantly related to the social and communication impairments seen in children with ASD. Specifically, BRIEF Emotional Control, Inhibit, and Shift, which assess ability to regulate behavior, exercise flexibility, and modulate emotional response, were significantly associated with VABS-II Socialization. BRIEF Monitor and Working Memory, which measure ability to assess one's own performance and hold information in mind to complete a task, were also significantly associated with level of social skills. Further, a strong relationship between VABS-II Communication and BRIEF Emotional Control and Working Memory was found, suggesting that children with greater emotion regulation and information processing capabilities demonstrate higher language skills. These findings held when overall cognitive level was controlled. It is possible that children with limited social interaction learn fewer EF skills through instruction or modeling, but it is equally or more probable that EF deficits lead to impaired social communication skills. Thus, children with ASD may benefit from targeted EF intervention to improve everyday social behaviors.

120 **142.120** Parent-Reported Features Associated with Clinical Ratings of Autism Severity in Preschool Children:

***L. D. Wiggins**[1], S. Rosenberg[2], K. Thomas[3], L. A. Schieve[1], J. Pandey[4] and S. E. Levy[5], (1)Centers for Disease Control and Prevention, Atlanta, GA, (2)University of Colorado, Aurroa, CO, (3)University of North Carolina - Chapel Hill, Chapel Hill, NC, (4)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Early detection of autism spectrum disorder (ASD) symptoms facilitates early intervention associated with improved developmental outcomes. Developmental improvements gained in early intervention programs are most often seen in relation to co-occurring conditions, such as adaptive and cognitive delays, instead of the ASD diagnostic symptoms of social communication and interaction, and restricted interests and repetitive behaviors. More research is needed to identify parent-reported features of ASD associated with diagnostic symptom severity so those features can be evaluated in intervention programs.
Objectives: In order to highlight potentially modifiable child characteristics, this study aimed to identify parent-reported features associated with clinical ratings of ASD severity in preschool children.
Methods: Three groups of children 2-5 years old were ascertained for the Study to Explore Early Development (SEED): (1) those with known ASD, (2) those with another developmental delay or disorder, and (3) those identified through birth certificate records. All children were screened for ASD with the Social Communication Questionnaire upon enrollment. Children who screened positive for ASD or had a previous ASD diagnosis were asked to complete an in-person assessment that consisted of the Autism Diagnostic Observation Schedule (ADOS) and Mullen Scales of Early Learning (MSEL). Caregivers completed the Autism Diagnostic Interview – Revised (ADI-R) and an interview that gathered sociodemographic information. Children classified as ASD met ADOS criteria *and* either standard ADI-R criteria or one of three alternate ADI-R criteria (alternate ADI-R criteria are described elsewhere; Wiggins et al., 2015).
The association between domain scores from the ADI-R and ASD severity from the ADOS was assessed using regression analysis. Independent and dependent variables were assessed for multicollinearity. The following covariates were entered into the model: child age, child ethnicity, child race, child sex, household income, maternal age, maternal education, and MSEL expressive language, receptive language, fine motor, and visual reception scores. ADI-R domain scores associated with ASD severity were further evaluated to detect individual diagnostic items within those domains associated with ASD severity.
Results: 707 children met the SEED ASD case definition. Higher household income was associated with higher ASD severity, and more advanced expressive language skills was associated with lower ASD severity. Higher ADI-R behavioral and social domain scores were associated with higher ASD severity, when controlling for household income and expressive language ability. Within the ADI-R behavioral domain, more hand and finger mannerisms, repetitive use of objects, and unusual sensory response were each associated with higher ASD severity scores; more compulsions/rituals were associated with lower ASD severity scores. Within the ADI-R social domain, deficits in eye gaze, response to the approach of other children, and sharing enjoyment were each associated with higher ASD severity scores; less interest in other children was associated with lower ASD severity scores.
Conclusions: Our results highlight specific parent-reported ASD symptoms that are associated with clinical perception of diagnostic presentation and can be evaluated in intervention programs and research protocols. These results also highlight the need for multi-domain treatments that address the many needs of children with ASD and their families. Implications for intervention will be discussed.

121 **142.121** Predictive Validity of the MCHAT-R in a Clinical Sample

N. A. Broderick[1], *R. Brewster*[2], *H. Dyer*[2], *M. Santulli*[2] *and A. Vehorn*[3], *(1)Vanderbilt University Medical Center/Vanderbilt Kennedy Center, Nashville, TN, (2)Department of Pediatrics, Vanderbilt University Medical Center/Vanderbilt Kennedy Center, Nashville, TN, (3)Vanderbilt University Medical Center, Nashville, TN*

Background:
Extant literature upholds the importance of early, intensive intervention in maximizing positive outcomes for children with autism spectrum disorder (ASD; Sullivan, Stone, and Dawson, 2014; Warren et al., 2011). Research suggests that the most efficacious interventions for children with ASD start as early as risk is identified and persist during early childhood (Wallace & Rogers, 2010). Individuals with risk markers for ASD must be identified as soon as possible to initiate services. The Modified Checklist for Autism in Toddlers, Revised with Follow-Up (MCHAT-R/F) has demonstrated reliability and validity, as well as improved utility over the original MCHAT, in detecting ASD in low-risk toddlers (Robins, et al., 2014). MCHAT-R/F was designed to facilitate reduced age of diagnosis and commencement of early intervention.
Objectives:
The current research examines diagnostic agreement between the MCHAT-R and clinical diagnosis in clinical sample to further investigate validity of this instrument.
Methods:
Data was collected from young children (n=201; 33 = female, 168 male; and mean age= 28.69 months) who visited a hospital-based early diagnostic screening clinic regarding autism spectrum disorder-related concerns (9/1/2015- 9/1/2016). These patients participated in a full battery of testing, including diagnostic interview, MCHAT-R/F, ADOS-2, Mullen, and Vineland-II. The battery did not incorporate the MCHAT-R/F follow-up questions as clinicians conducted thorough clinical interviews with caregiver(s). All clinicians (n=6) were licensed clinical psychologists who have demonstrated research reliability regarding the ADOS-2.
Diagnostic outcomes included 133 diagnoses of autism spectrum disorder (ASD) and 68 diagnoses of No ASD. In order to examine diagnostic agreement, we calculated the M-CHAT-R sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) compared to clinical diagnostic decision. A 2x2 table was constructed based on the presence and absence of ASD as well as low risk (≤2) and medium-to-high risk scores (≥3) on the MCHAT-R.
Results:
With the current sample, MCHAT-R sensitivity was 86.46%, specificity was 32.35%, PPV was 70.7%, and NPV was 50%. Therefore, the probability of the MCHAT-R correctly identifying individuals *with ASD* was 86.56% and correctly identifying individuals with *No ASD* is 32.35%. With this sample, the probability of *ASD* with a positive MCHAT-R screen is 70.70% and the probability of *no ASD*with a negative MCHAT-R screen is 50%.
Conclusions:
Based on the current clinical sample of young children with red flags for ASD, the MCHAT-R demonstrates greater sensitivity than specificity and greater PPV rather than NPV. This suggests that the MCHAT-R often captures individuals with developmental concerns, including ASD; however, it indicates that a low risk score on the MCHAT-R may not be sufficient to rule-out an ASD diagnosis. Results from our sample suggest that the M-CHAT-R continues to be helpful in identifying broader developmental concerns in addition to ASD-related vulnerabilities. These results also highlight the importance of post-screening evaluation for differential diagnosis, particularly with complex presentations of developmental concerns. The present data supports further investigation regarding what factors might influence MCHAT-R scores/reporting to inform clinical practice.

122 **142.122** Profiling Autism Symptomatology in Females: An Exploration of the Q-ASC in a Clinical Setting

S. Ormond[1,2], *C. Brownlow*[1], *M. S. Garnett*[3], *T. Attwood*[3] *and A. Rynkiewicz*[4,5], *(1)School of Psychology and Counselling, University Of Southern Queensland, Darling Heights, Australia, (2)Specialist Clinic for Autism Spectrum Conditions, Minds and Hearts, West End, Australia, (3)Clincal Psychology and Diagnostics, Minds and Hearts, West End, Australia, (4)Center for Diagnosis,Therapy and Education SPECTRUM ASC-MED, Gdansk, Poland, (5)Faculty of Medicine, University of Rzeszow (UR), Rzeszow, Poland*

Background: Highlighted differences in the clinical research literature among children and adolescents with Autism Spectrum Disorder (ASD) reflect a unique presentation of ASD among females, demonstrated by greater compensatory capacity and ability in social masking, camouflaging and imitation. It is argued that such presentation may have an inhibitory potential in confirming a diagnosis using current diagnostic assessments and screening tools. Recent clinical experience, parental reports and autobiographies indicate psychological tension, distress and exhaustion for females with ASD in their attempts to compensate for difficulties in understanding and interacting with others. The emerging evidence of a presentation in females, distinct from the current and widely accepted features of ASD, based primarily on males, means current diagnostic assessments lack the required sensitivity to identify females with ASD. To address this gap, the Questionnaire for Autism Spectrum Conditions (Q-ASC) was developed by Attwood, Garnett and Rynkiewicz (2011) to identify gender-sensitive profiles of ASD symptomatology; prioritise and adjust the direction of clinical interventions; and support positive psychosocial outcomes and prognosis into adulthood.
Objectives: This study aims to provide an exploratory and preliminary statistical investigation of the interpretable and reliable constructs of the Q-ASC, and examine differences in presentation across male and female children and adolescents with ASD.
Methods: Drawing on archival data, the current research piloted the Q-ASC within a clinical population of 232 children and adolescents. Parent-completed Q-ASC data comprised clinical diagnoses of Autism Spectrum Disorder (ASD) – level 1 (without intellectual or language impairment). In addition, sociodemographic information included participants' age, and gender identification, and clinical information of diagnostic status. The sample included 134 males and 100 females with ages ranging between 5 -19 years (*M* = 12.18, *SD* = 3.8).
Results: Data analysis revealed eight interpretable and reliable components of the Q-ASC using Principle Components Analysis (PCA); *gender identity*, *sensory sensitivity*, *compliant behaviour*, *friendships and play, social masking*, *imagination*, *imitation*, and, *talents and interests*. Analysis of Variance (ANOVA) was used to examine mean differences between gender and age groups. Results found a statistically significant difference of parent-reported features among males and females, with greater levels of reported difficulty for females in behavioural characteristics related to the domains of *Gender Identity*, *Sensory Sensitivity*, *Social Masking*, *Imagination*, *Imitation*, and *Talents*.
Conclusions: This study represents an exploratory and systematic review of potential female presentations in children and adolescents across a clinical setting, with meaningful differences noted. The results of this study support previous autobiographical, anecdotal and clinical observations to suggest important practical and clinical significance in understanding the difference in ASD characteristics between males and females. The eight interpretable and reliable constructs reported moderate to high internal consistency, with greater levels of parent-reported socio-behavioural characteristics for females, compared to males, with ASD. The findings from this study aim to identify improvements in the validity and robustness of Q-ASC to assess the sensitivity and diversity of ASD presentations among female children and adolescents.

123 **142.123** Race Influences Parent Report of Concerns about Symptoms of Autism Spectrum Disorder

M. R. Donohue[1], *A. W. Childs*[2] *and D. L. Robins*[3], *(1)Georgia State University, Atlanta, GA, (2)Yale University, New Haven, CT, (3)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Despite progress in the early identification of autism spectrum disorder (ASD), Black children are diagnosed later than their White peers (Mandell et al., 2007, 2009). Mandell and colleagues (2007) found that Black children were often misdiagnosed with conduct and oppositional defiant disorders prior to an ASD diagnosis. The researchers posited that Black parents may relate concerns about their children's development to healthcare providers in ways that de-emphasize ASD-specific symptoms and emphasize disruptive behaviors, which may impact clinicians' consideration of ASD.
Objectives: We tested the hypothesis that compared to White parents, Black parents of children with ASD would report fewer concerns about their children's behaviors specific to ASD, and would be more likely to report concerns about children's disruptive behaviors.
Methods: A sample of parents (N=207; 135 White, 72 Black parents) and their 18-40 month old toddlers (mean age=25.84 m, *SD*=4.74) with ASD participated. After screening positive for ASD risk, but prior to the diagnostic evaluation, parents completed free-response questions soliciting concerns about their children's development. Parent responses were coded for the presence or absence of 10 domains of concerns, which were grouped into ASD-specific concerns (i.e., speech/communication, restricted and repetitive behaviors (RRB), social deficits, and directly naming autism/ASD as a concern) or non ASD-specific concerns (e.g., general developmental concerns, disruptive behavior concerns), adapted from Ozonoff and colleagues (2009) by Richards and colleagues (2016). ASD symptom severity, measured by the domain and total severity scores from the Autism Diagnostic Observation Schedule (ADOS-2; Gotham et al., 2009; Hus et al., 2014), were used as covariates to control for the possibility that racial differences in ASD-specific concerns are due to group differences in symptom severity in our sample.
Results: White parents (*M*=2.47, *SD*=1.31) endorsed a greater number of categories of concerns (i.e., the sum of all 10 concern categories) than Black parents (*M*=1.85, *SD*=.94), $t(187.01)=3.91$, $p<.001$, partial $\eta^2=.08$. There was a significant effect of race on ASD-specific concerns $F(1,167)=10.04$, $p<.001$, partial $\eta^2=.06$. Black parents reported significantly fewer ASD-specific concerns than White parents ($M_{diff}=.42$, $SE=.13$, $p<.001$). In particular, Black parents were less likely than White parents to report concerns about social deficits, $\chi^2(3)=8.217$, $p=.04$ and RRB, $\chi^2(4)=18.97$, $p<.001$, even after controlling for ASD symptom severity. There was not a significant effect of race on non ASD-specific concerns ($p=.28$) or disruptive behavior concerns specifically ($p=.17$).
Conclusions: Reporting fewer ASD-specific concerns by Black parents may impact providers' abilities to identify children in need of evaluations. There was not a racial difference in parent report of concerns about children's disruptive behaviors, suggesting that underreporting of ASD-specific concerns is not likely explained by parent interpretation of ASD symptoms as disruptive behaviors. Future studies should examine factors that may explain report of fewer ASD-specific concerns by Black parents of children with ASD, such as less knowledge about ASD and cultural differences in expectations or interpretations of children's behaviors or willingness to report concerns specific to ASD. Future research should also examine other factors, such as clinician biases, that may contribute to delayed diagnosis for Black children with ASD.

124 **142.124** Relationship Between Cognitive Abilities and ASD Severity over Time in Early-Diagnosed Preschoolers

I. Giserman Kiss *and A. S. Carter, University of Massachusetts Boston, Boston, MA*

Background: According to the most recent prevalence study conducted by the Centers for Disease Control, 38% of children with ASD have a co-occurring Intellectual Disability (CDC, 2008). Previous studies have found that children with average cognition or mild-moderate cognitive delays at the time of initial ASD diagnosis demonstrate increased cognitive scores at follow-up, whereas children with severe cognitive delays at initial diagnosis show stable scores over time (Flanagan et al., 2015). Limited research has been conducted examining the relationship between cognitive functioning and expression of ASD symptoms. Matson et al. (2008) found that IQ predicted the presence of ASD-like behaviors in adults without ASD, but IQ was not related to the expression of ASD symptoms in adults with the disorder. In contrast, developmental level was associated significantly with symptom severity, similarly, in toddlers with Autistic Disorder, PDD-NOS, and no ASD (Matson et al., 2012). However, Goldin et al. (2014) found that higher ASD severity scores were associated with lower developmental abilities in toddlers.
Objectives: The goals of this study were to 1) examine the stability and mean level change of cognitive abilities in children with ASD, and 2) determine the relationship between ASD symptom severity at initial diagnosis and later cognitive ability, in a sample of early-diagnosed children.
Methods: 35 children (86% male) were evaluated at two time points (T1 mean age=27.9 months; T2 mean age=52.3 months) using the ADOS-2, expert clinical judgment, and measures of cognitive functioning (T1: Mullen Scales of Early Learning; T2: Differential Abilities Scales-II). All children met diagnostic criteria at Time 1, whereas 30 children (85.7%) met criteria at Time 2. The sample was racially and ethnically diverse (57.1% White, 17.1% Black/African American, 8.6% Asian, 2.9% Arab, 8.6% multiracial; 17% Hispanic/Latino). ASD symptom severity was determined by total ADOS-2 algorithm score (T1) and ADOS-2 comparison score (T2).
Results: Children demonstrated significantly improved IQ scores between Time 1 (M=65.9, SD=13.7) and Time 2 (M=82.7, SD=35.1) ($t(32)=-2.96$, $p<.01$). A multiple linear regression model was calculated to predict overall IQ score at Time 2, based on overall IQ score and ASD symptom severity at Time 1. A significant regression equation was found ($F(2,28)=11.65$, $p<.01$) with $R^2=.45$. Both overall IQ score and ASD symptom severity at Time 1 were significant predictors of overall IQ score at Time 2.
Conclusions: Children diagnosed with ASD at age 2 demonstrated significantly improved IQ scores at age 4, suggesting that early cognitive abilities may not be stable in children with ASD; once ASD symptoms are directly targeted in treatment, children may demonstrate increased capacity for learning. In addition, both overall IQ score and ASD symptom severity at age 2 uniquely predicted overall IQ score at age 4. This finding has implications for treatment planning for children diagnosed with ASD before 36 months, as all children in this sample received early intervention services prior to and between initial diagnosis and follow-up.

125 **142.125** Role of the AOSI in Predicting Autism Spectrum Disorder in Tuberous Sclerosis Complex

J. K. Capal[1], *B. Bernardino-Cuesta*[2], *P. S. Horn*[3], *D. S. Murray*[4], *A. W. Byars*[3], *N. Bing*[5], *B. Kent*[6], *S. E. O'Kelley*[7], *D. A. Pearson*[8], *R. Mansour*[8], *M. E. Williams*[9], *E. Hanson*[10], *A. Walsh*[11], *G. Cutter*[7], *H. Northrup*[12], *J. Y. Wu*[13], *M. Bebin*[7], *J. Peters*[11], *T. Mitchell*[3], *R. Filip-Dhima*[11], *S. Bruns*[3], *M. Goyal*[7], *M. Sahin*[14] *and D. A. Krueger*[1], *(1)Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)9Seccion de Neuropediatria, Hospital Infantil Universitario Nino Jesus, Madrid, Spain, (3)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Autism Speaks, Boston, MA, (5)Cincinnati Children's Hospital Medical Center, Cincinnat1, OH, (6)Developmental and Behavioral Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (7)University of Alabama at Birmingham, Birmingham, AL, (8)Psychiatry & Behavioral Sciences, University of Texas McGovern Medical School, Houston, TX, (9)Children's Hospital Los Angeles, Los Angeles, CA, (10)Children's Hospital Boston, Boston, MA, (11)Boston Children's Hospital, Boston, MA, (12)Pediatrics, University of Texas McGovern Medical School, Houston, TX, (13)Mattel Children's Hospital UCLA, Los Angeles, CA, (14)Neurology, Boston Children's Hospital, Boston, MA*

Background: Historically, autism spectrum disorder (ASD) has been reported in approximately 50% of individuals with Tuberous Sclerosis Complex (TSC). The severity and underlying causes of ASD are complex and highly variable, which presents a major barrier to identifying at-risk infants.
Objectives: Evaluate the ability of the Autism Observation Scale for Infants (AOSI) to identify at-risk infants with TSC who will later get diagnosed with ASD.
Methods: Analysis was performed on 130 patients ages 0-36 months with TSC participating in the TSC Autism Center of Excellence Network, a large multicenter, prospective observational study evaluating biomarkers predictive of ASD. Patients were evaluated longitudinally at ages 3, 6, 9, 12, 18, 24 and 36 months with standardized evaluations using cognitive, adaptive, and behavioral measures, as well as autism-specific testing at specific time points. At 12 months, the AOSI was administered to look for specific behavioral risk markers for ASD. The Autism Diagnostic Observation Schedule-Second Edition (ADOS-2) and Autism Diagnostic Interview-Revised (ADI-R) were administered at 24 and 36 months at which point a diagnosis of ASD or not ASD was assigned based on a combination of above stated measures, clinical impression, and consideration of comorbid diagnoses.
Results: At 24 months, 14 patients out of 65 were given a clinical diagnosis of ASD (21.5%). At 36 months, 4 patients out of 21 were given a clinical diagnosis of ASD (19%). The Mean AOSI total score in patients diagnosed with ASD at 24 months was 13.5 (SD 6.7) versus mean AOSI total score of 7 (SD 5.3) in patients not diagnosed with ASD ($p=0.003$). The odds ratio for the AOSI predicting ASD at 24 months was 1.19 ($p=0.003$ [CI 1.06-1.33]). In other words, for every 1 point increase in total score on the AOSI, the odds of going from non-ASD to ASD increases by 19%. The AOSI total score also significantly predicted meeting cut-off scores on the individual domains on the ADI-R in patients diagnosed with ASD at 24 months ($p<0.05$). There were also several individual items on the AOSI that were found to significantly predict ASD diagnosis at both 24 and 36 months. Additionally, diagnosis of ASD based on ADOS-2 classification alone was compared to clinical diagnosis. At 24 months the ADOS and clinical diagnosis agreed on all non-ASD diagnoses. In patients who were diagnosed with ASD, the ADOS-2 classification and clinical diagnosis agreed 46% of the time (17 out of 37 patients). However, 54% of patients (20 out of 37) met ASD classification on the ADOS-2 but did not receive a clinical diagnosis ($p<0.0001$). The study is ongoing and many patients have not completed 36-month assessments. This may help to explain the lack of significance for this age group.
Conclusions: The AOSI performed at 12 months predicts later diagnosis of ASD in patients with TSC at 24 months. Clinical diagnosis of ASD in individuals with TSC differs from classification based on the ADOS-2. This difference is likely due to other medical comorbidities seen in TSC. Further analysis will help to clarify these discrepancies.

126 **142.126** STAT Behavioral Domains As Predictors of ASD Severity and Cognitive Outcomes

S. R. Edmunds[1], *L. V. Ibanez*[2], *W. L. Stone*[3], *E. Schriver*[4], *D. Burkom*[5], *A. Golden*[6], *A. Kuo*[7], *K. Lakes*[8], *R. Landa*[9], *D. S. Messinger*[10], *S. Paterson*[11], *Z. Warren*[12] *and C. J. Newschaffer*[4], *(1)University of Washington, Seattle, WA, (2)UW READi Lab, Seattle, WA, (3)Psychology, University of Washington, Seattle, WA, (4)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (5)Battelle, Columbus, OH, (6)Department of Occupational Medicine, Epidemiology and Prevention, Northwell Health Hofstra Northwell School of Medicine, Great Neck, NY, (7)Health Care Transitions Research Network for Autism Spectrum Disorders, Los Angeles, CA, (8)Department of Pediatrics, School of Medicine, University of California, Irvine, Irvine, CA, (9)Kennedy Krieger Institute, Baltimore, MD, (10)Psychology, University of Miami, Miami, FL, (11)Children's Hospital of Philadelphia, Philadelphia, PA, (12)Vanderbilt University, Nashville, TN*

Background: The Screening Tool for Autism in Toddlers (STAT) is a brief, interactive, validated screening assessment for autism comprised of 12 activity-based items that provide 4 behavioral domain scores—play, imitation, requesting, and directing attention—as well as a total score indicating autism risk. The item-domain structure of the STAT has never been validated via confirmatory factor analysis (CFA). The STAT domains represent discrete, developmentally appropriate social-cognitive skills, and each domain may differentially predict both children's overall autism severity and cognitive ability at 2-3 years. Each domain of the STAT has been found to augment the STAT's overall high predictive validity with autism diagnosis. However, it is not known how differentially predictive the STAT domains are of autism symptomatology and cognitive ability in a large sample of children recruited from the general population with elevated autism concern.
Objectives: Â To (1) perform a CFA to confirm that items of the STAT theoretically proposed to form domains do indeed form the 4 STAT domains, and (2) perform a latent path model to assess the predictive validity of the STAT domains to gold-standard autism diagnostic instruments, the ADOS and Mullen.
Methods: Participants (*n*=380) were 24-39 months of age and recruited from eight sites funded as part of a National Children's Study formative research project. 79% of participants had prior autism concerns; 21% had concerns about developmental delay. Participants received diagnostic evaluations from a qualified clinician, including the ADOS and Mullen, in the community or as part of the study. The STAT was administered as part of a larger battery of autism screening tools. A CFA was conducted to assess how well the items comprising the 4 domains of the STAT—play, imitation, requesting, and directing attention—mapped on to each domain. A latent path model assessed how participants' latent STAT domain scores related to their ADOS severity score and verbal and nonverbal Mullen scores. State-of-the-art model-fitting procedures were employed for evaluation.
Results: The theorized 4 latent factors for the play, requesting, directing attention, and imitation STAT domains fit the data well (e.g., CFI=.98; RMSEA=.03), supporting the item allocation into each domain as originally designed. The 4 resulting latent STAT domains were highly correlated. The final latent path model fit the data well (e.g., CFI=.97; RMSEA=.03). Three of the 4 STAT domain scores (imitation, requesting, and directing attention) were found to significantly predict ADOS severity. STAT play and imitation domains were found to significantly predict Mullen nonverbal subscale score. The STAT directing attention domain was found to be the best predictor of Mullen verbal subscale score (Figure 1).
Conclusions: The STAT is both a theoretically and empirically coherent measure of 4 social-communicative behavioral domains. Three of these domains could be sufficient to serve as a predictor of autism severity. The STAT domains are also useful individually; they are brief measures of developmental ability and can provide specific clinical information on social-cognitive challenges for young children. Implications of the different STAT domains as indicators of general autism symptomatology and cognitive ability will be discussed.

127 **142.127** Sensory Hyper and Hyposensitivity to Sensory Stimuli As a Diagnostic Indicator of Autism Spectrum Disorder

R. L. Young[1] *and H. C. Ee*[2]*, (1)Flinders University of South Australia, Adelaide, SA, Australia, (2)Psychology, Flinders University, Adelaide, Australia*

Background:
Research has shown that people living with Autism Spectrum Disorders (ASD) are typically sensitive to sensory stimuli. Unusual sensory interests, either seeking or avoiding sensory stimuli, were thus introduced as a new criterion for ASD (B4) in the DSM-5 (APA, 2013). This criterion is broadly defined asÂ "Hyper- or hypo-reactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement)" (APA, 2013, p50). The inclusion of this criterion however, lacks empirical validation.
Objectives:
To identify the diagnostic relevance of the inclusion of hypersensitivity and hyposensitivity to sensory stimuli in the DSM-5 criteria for ASD
Methods:
Data from 245 clients (171 males, 74 females) who were referred to a local private practice for an autism assessment were extracted by the author from clinical report. Two hundred and six of the participants met the DSM-5 (APA, 2013) criteria for ASD, while 39 did not. Participants were between 12 months and 45 years of age, with a mean of age of 9.11 years old (*SD* = 7.18).
Results:
Results indicated that although the B4 criterion had high sensitivity, its specificity was low. Meeting B4 criterion was common among persons who went on to receive an ASD diagnosis (71%). Very few of those who did not meet this criterion went on to receive a DSM-5 diagnosis (2%). It is clear that the sensitivity of this criterion is high but the specificity is questionable with 41% of those who did not receive a DSM-5 diagnosis also meeting B4 criterion. Thus while the majority of persons with ASD experience sensory difficulties, it does not appear unique to this disorder with many people without the disorder also experiencing similar concerns.
Conclusions:
Clinicians need to be vigilant when using B4 as a diagnostic criterion as its presence is not unique to ASD – its absence however is more telling.
Keywords: DSM-5, sensory behaviours

128 **142.128** Sex Differences in ADOS-2 Scores and Classifications Among Verbally Fluent Children with Autism Spectrum Disorder

S. L. Bishop[1]*, M. P. Sweeney*[1]*, M. Huerta*[2]*, A. Havdahl*[3] *and C. Lord*[2]*, (1)Psychiatry, University of California San Francisco, San Francisco, CA, (2)Psychiatry, Weill Cornell Medical College, White Plains, NY, (3)University Hospitals Bristol, Bristol, United Kingdom*

Background:
Recent research suggests that females with ASD are at greater risk of not being identified, or for being identified later, than their male counterparts. Because currently available diagnostic and screening measures were developed and validated using primarily male samples, clinicians and researchers have proposed that these measures may lack sensitivity for detecting females with ASD. In particular, there is concern that females with higher cognitive and language abilities, who may be adept at "masking" social-communication difficulties in certain contexts, receive sub-threshold scores on instruments such as the Autism Diagnostic Observation Schedule (ADOS), because the extent of their difficulties is less apparent in clinical settings.
Objectives:
This study examined whether ADOS-2 classifications, domain calibrated scores, or individual item scores differed between verbally fluent males and females with ASD.
Methods:
Participants were drawn from an existing database of clinic and research referrals to the University of Chicago Developmental Disorders Clinic, University of Michigan Autism and Communication Disorders Center, or Center for Autism and the Developing Brain. Participants were selected for the current analyses if they had completed a Module 3, received a NVIQ score >=80, and received a best-estimate final diagnosis of ASD as part of a comprehensive diagnostic assessment. This resulted in a sample of 396 males [age= 8.9 years (2.9), NVIQ= 105(15), VIQ= 100(19)] and 85 females [age= 8.7 years (2.8), NVIQ= 104(15), VIQ= 105(17)].
Results:
Females with ASD were less likely to meet ASD cut-offs on the ADOS-2 Module 3 algorithm (85%) compared to males (94%), X^2 (1, N= 481)= 9.8, p= .002. Furthermore, results of logistic regression showed that even after controlling for age and VIQ, boys had increased odds of meeting ASD cut-offs (OR=2.90, p=.005). Linear regressions tested sex, age, and VIQ as predictors of ADOS overall calibrated scores and domain calibrated scores. Sex significantly predicted overall Calibrated Severity Scores (CSS) (B= -.57, CI 95% -1.08 to -0.06, p= .03) and RRB domain scores (B= -.89, CI 95% -1.4 to -.34, p= .002), but not Social Affect domain scores (B= -.39, CI 95% -.89 to 0.12, p= .13). VIQ had a significant effect on overall CSS (B= -.02, CI 95% -.04 to -.01, p= .000) and Social Affect domain scores (B= -.03, CI 95% -.04 to -.20, p= .000), but not RRB domain scores (B= -.003, CI 95% -.15 to 0.008, p= .55). We also explored item-level differences by sex; items with significant differences are shown in Figure 1.
Conclusions:
Consistent with previous studies, our results indicate that verbally fluent females with ASD exhibit fewer repetitive behaviors than males. While the majority of both males and females with clinical diagnoses of ASD met ASD cut-offs on the ADOS, a larger proportion of females received scores in the non-ASD range. These females still received clinical diagnoses of ASD, indicating that clinicians gathered sufficient evidence of impairments within and/or outside of the ADOS context to justify the diagnosis. However, future research should further investigate when and why some females with ASD are missed by these instruments.

129 **142.129** Sex Differences in Item Specific Analyses of ADI-R in Preschool-Aged Boys and Girls with ASD

A. L. Hechtman[1], *B. Winder-Patel*[2], *G. S. Young*[1], *D. G. Amaral*[3] *and C. W. Nordahl*[3], *(1)Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (2)MIND Institute, University of California, Davis, Sacramento, CA, (3)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA*

Background: Females are diagnosed with autism spectrum disorder (ASD) at a ratio of one for every four males and are often diagnosed at a later age. Evaluating sex differences in the behavioral profiles of children with ASD at the time of diagnosis may provide insight into why females are often diagnosed at a later age.
Objectives: Females in this cohort had a significantly higher ADI-R social communication algorithm score than males (p = 0.0177). We carried out item specific analyses in reciprocal social interactions (RSI), communication, and restrictive, repetitive, and stereotypical (RRS) behaviors measured on the ADI-R to further investigate this difference. As a secondary analysis, we conducted a median split of males and females by age of diagnosis to compare symptoms in younger versus older males and females.
Methods: Participants include 100 preschool-aged children with ASD (mean age 36.13 months). 50 females (age of diagnosis range 13-41 months; DQ range 29-112; ADOS composite score range 4-10) were matched to 50 males (age of diagnosis range 14-45 months; DQ range 29-113; ADOS composite score range 4-10). The ADI-R, an assessment that evaluates current and previous symptoms of ASD and aids in diagnosis, was administered to parents. To evaluate the effect of age at diagnosis on symptom severity, males and females were divided at the median to define those diagnosed at a younger age (< 30 months) versus a later age (> =30 months). Analysis of variance was used to investigate differences between males and females with ASD and males and females diagnosed at younger versus older ages for each item on the ADI-R algorithm.
Results: There were significant sex main effects in the RSI and communication sections. Within RSI, females were more affected in their failure to use nonverbal behavior to regulate social interaction (p = 0.0070), range of facial expressions used to communicate (p = 0.0071), seeking to share enjoyment with others (p = 0.0014) and quality of social overtures (p = 0.0430). In the communication section, females showed increased impairment in their lack of, or delay in, spoken language and failure to compensate through gesture (p = 0.0203) and in pointing to express interest (p = 0.0437). When evaluating groups split by age, we found these differences were most pronounced in the younger females with ASD relative to females diagnosed at an older age and males of all ages. No significant differences between males and females were observed in any items related to RRS patterns of behavior.
Conclusions: Females diagnosed at a younger age exhibited higher parent-perceived levels of impairment in specific aspects of reciprocal social behavior and communication, suggesting that younger females may need to exhibit greater perceived-impairment for parents to seek a clinical diagnosis. These differences in severity are seen only in the social and communication categories of the ADI-R. In contrast to recent reports showing less severe RRS patterns of behaviors in females with ASD, we did not observe any differences across males and females as measured by the ADI-R.

130 **142.130** Sex Differences in Presenting Concerns and ASD Diagnostic Outcome in a Clinical Sample

B. Ponjevic[1], *B. Lewis*[2] *and J. McPartland*[3], *(1)Yale University, New Haven, CT, (2)Yale School of Medicine, Darien, CT, (3)Child Study Center, Yale School of Medicine, New Haven, CT*

Background: According to the Center for Disease Control and Prevention, approximately 1 in 68 children have been identified with autism spectrum disorder (ASD). There is a higher rate of ASD diagnosis in males than females. ASD is characterized by qualitative deficits in areas of reciprocal social interaction, verbal and non-verbal communication, and the presence of repetitive, stereotyped behaviors and interests. However, males and females have been found to manifest these core symptoms differently. One of the key research priorities in autism research is the identification of early biological and behavioral indicators of ASD; at present, the influence of sex differences on clinical identification and diagnosis of children with ASD is poorly understood.
Objectives: To examine relationships among sex differences in identification of developmental concerns, ASD assessment results, and diagnosis in a sample of patients at a clinic specializing in developmental disorders.
Methods: The study sample included 34 children (26 males:6 females, aged 8+/-3 and 9+/-5, respectively; $t(30)=0.67$, $p=.51$]) referred to a specialty autism clinic within a two year period; data collection and retrospective analyses of additional historical cases are ongoing. All children were administered the Autism Diagnostic Observation Schedule (ADOS). Chi-square statistics were used to evaluate the likelihood of children meeting ADOS criteria for ASD as a function of sex. T-tests compared sexes in terms of age at which parents were concerned and initially sought help. Qualitative chart review examined differences in the nature of parents' concerns, clinical profiles, and diagnostic outcomes by sex.
Results: Girls and boys did not differ in age of first parental concerns (Male: 24.56+/-22.65 months; Female: 21.80+/-14.87 months; $t(28)=0.26$, $p=.80$) or age at which parents sought professional consultation (Male: 32.14+/-25.13 months; Female: 25.60+/-20.01 months; $t(25)=0.54$, $p=.59$). Despite these similarities, girls were significantly less likely to meet criteria for ASD on the ADOS ($\chi 2Â =11.13$, $p=.003$) during their clinic visit. Whereas 81.3% of boys met ADOS criteria for ASD, this was true of only 16.7% of girls. Qualitative chart review indicated parents' first concerns were similar for boys and girls (e.g., speech, social difficulties, atypical behaviors). Among the girls, 2 were given ASD diagnoses, 1 of whom received an ASD diagnosis despite not meeting ADOS criteria. Alternative diagnosis givenÂ to girls included Attention Deficit Hyperactivity Disorder, and description of anxiety, nonverbal learning profile, as well as no diagnosis.
Conclusions: Sex differences were not evident in when parents began to have concerns about their child and when they first brought their concerns to a professional. However, with respect to the identification and diagnosis of ASD, it was found that girls were significantly less likely to meet criteria on the ADOS. These data suggest a discrepancy in the identification between males and females and are consistent with the idea that females may be less likely to get an ASD diagnosis based on conventional diagnostic procedures.

131 **142.131** Special Education Assessment and Classification for Students with ASD: Perspectives of School Psychologists

M. R. Silva[1,2,3], *L. S. Woods*[2,4,5], *S. Simons*[1,2,6], *S. Gillespie*[7] *and L. Dilly*[2,7,8], *(1)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA, (2)Children's Healthcare of Atlanta, Atlanta, GA, (3)Unviersity of Massachusetts Boston, Boston, MA, (4)Marcus Autism Center, Children's Healthcare of Atlanta & Emory University, Atlanta, GA, (5)University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)Oklahoma State Unviersity, Stillwater, OK, (7)Emory University School of Medicine, Atlanta, GA, (8)Marcus Autism Center, Atlanta, GA*

Background: With autism spectrum disorders (ASD) in the United States reaching prevalence rates of 1 in 68 (Christensen et al., 2016), public schools are increasingly tasked with assessing students suspected of having ASD. However, special education data suggests many children with ASD are not classified for special education services in the area of ASD (Christensen et al., 2016; Pinborough-Zimmerman, 2012). Specifically in Georgia, 8-year-old children identified with ASD are only given an ASD classification 58% of the time. The next most prevalent eligibility category for students with ASD was significant developmental delay (SDD) at 29% (Christensen et al., 2016).
Objectives: This study examined the reasons special education classification may be established in SDD rather than ASD from the perspective of school psychologists, with a focus on geographical location (i.e., urban, suburban, rural). Further, this study examined the barriers school psychologists encounter when participating in preschool evaluations for children suspected of having ASD.
Methods: The survey for this study was developed by a team of clinicians and researchers to collect school psychologists' assessment procedures for students with ASD. Survey items were ranked by importance from 1-5 and then averaged and ordered by importance (i.e., lower mean ranks indicating higher importance). Differences in mean item ranks across the items and between geographic locations were considered using two-way ANOVA. The survey was emailed to 557 valid email addresses with 300 surveys completed yielding a response rate of 54%. The sample was found to represent approximately 42% of school psychologists in Georgia (U.S. Department of Education, 2016).
Results: The most salient reasons of establishing eligibility in SDD rather than ASD were "Children can qualify in the area of SDD, so an ASD specific evaluation is not needed" ($M = 2.51$) followed by "Parents of preschool children need time to process their child's differences before an ASD eligibility is established" ($M = 3.05$) and "It is difficult to identify ASD in preschool age children" ($M = 3.29$). Geographical location did not influence how participants ranked the reasoning behind eligibility decisions ($p = 0.199$).
The two greatest barriers for school psychologists to participate in preschool ASD evaluations were "Time constraints and scheduling problems to obtain school psychologists" ($M = 2.05$) and "There are not enough school psychologists available to hire to complete these evaluations" ($M = 2.46$). Regardless of geographic location, no significant differences were found in the ranking of barriers ($p = 0.480$).
Conclusions: Across both research questions, geographical location did not appear to influence participant responding, indicating future professional development should be distributed throughout Georgia. Results of this survey may also suggest school psychologists experience apprehension giving a classification of ASD. Although receiving a SDD classification rather than an ASD classification may not impact special education service delivery, it may create diagnostic confusion and decrease access to intervention outside of the school system. Further, although autism can be reliably diagnosed as early as 2- years-old (Lord, et al., 2006), these results suggest school psychologists may encounter barriers when completing these evaluations for young children.

132 **142.132** Stability of Risk Status in Toddlers with Autism Spectrum Disorder before Age 2: A Three-Year Follow-up

C. C. Wu[1], *Y. M. Hou*[2] *and C. H. Chiang*[3], *(1)Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan, (2)Psychiatry, Chia-Yi Christian Hospital, Chiayi City ,Taiwan, TAIWAN, (3)National Chengchi University, Taipei, TAIWAN*

Background:
Autism spectrum disorder (ASD) is thought as an innate and long-life neurodevelopmental disorder and characterized by impaired social communication and social interaction, as well as restricted and repetitive patterns of behavior and interest. Once thought to be a rare disorder, ASD has recently emerged dramatically. The increasing prevalence rate is due to improved awareness of ASD and service availability, and also highlights the importance of the early detecting. Knowing the importance of early detecting, the American Academy of Pediatrics (AAP) has recommended that all toddlers should receive screening for autism before age 2 (Johnson et al., 2007). However, few study examined the stability of risk status in toddlers with ASD before age 2.
Objectives:
Previous studies supported that a diagnosis of children with ASD appears to be stable as young as age 3. However, few studies examined stability and change of diagnosis for toddlers with ASD before age 2, especially for mid-term follow-up study. In this current study, longitudinal design was used to examine stability and change of diagnosis for toddlers with ASD before age 2.
Methods:
There were 63 toddlers participated the study, including 32 toddlers with ASD and 31 toddlers with developmental delay. All toddletrs had administrated both of the Screening Tools for Autism in Two-Year-Olds, Taiwan version (T-STAT) (Chiang et al., 2013) and Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 1999) between 18 and 24 months of age (Time 1, mean chronological age = 21 months) and received follow-up diagnostic and developmental reassessment between 54 and 67 months of age (Time 2, mean chronological age = 58 months). At Time 2, all toddlers were assessed and diagnosed according to DSM and with reference to developmental history and current concerns from parents, results of cognitive and adaptive function measures, observations of the child, and the results of ADOS by a multidisciplinary team that included senior child clinical psychologists with Ph.D. degree and senior child psychiatrists.
Results:
Based on classification of the T-STAT (cutoff = 2.25), the results showed that the sensitivity and specificity are .84 and .81, respectively. In addition, positive predictive value (PPV) is .82 and negative predictive value (NPV) is .83. However, based on classification of the T-STAT (cutoff = 2.50), the results showed that the sensitivity and specificity are .81 and .84, respectively. In addition, PPV is .84 and NPV is .81. Based on classification of the ADOS-module 1 (Time 1), the results showed that the sensitivity and specificity are .88 and .84, respectively. In addition, PPV is .85 and NPV is .87.
Conclusions:
The results of this current study showed that reliable diagnosis of toddlers with ASD could be made before age 2 and have good mid-term stability. In addition, the results of this current study showed that both the T-STAT and ADOS are promising tools to differentiate toddlers with ASD and toddlers with developmental delayed before age 2.

133 **142.133** Standardized Cross-Cultural Assessment of Ability and Disability in ASD: The New WHO ICF-CY Core Sets

S. Bolte[1]*, S. Mahdi*[2] *and M. Selb*[3]*, (1)Karolinska Institutet Center of Neurodevelopmental Disorders (KIND), Dept. Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (2)Karolinska Institutet Center of Neurodevelopmental Disorders (KIND), Women's and Children's Health, Karolinska Institutet, Stockholm, SWEDEN, (3)WHO ICF Research Branch, Schweizer Paraplegiker-Forschung, Nottwil, Switzerland*

Background:
The International Classification of Functioning, Disability and Health (ICF) by the World Health Organization (WHO) provides a universal framework to describe health-related functioning. The ICF is based on a bio-psycho-social model, comprising over 1600 categories of functional domains:Â body functions, body structures, activities and participation and environmental factors. In order to make the ICF more applicable in certain health conditions, so called “ICF core sets”, that are user friendy,Â empirically derived condensed versions of the ICF with a high fit for a certain diagnosis have been generated. Core set development is based on a rigorous scientific process including four preparatory studies in an international, cross-disciplinary setting: A systematic literature review (research perspective), an expert survey (expert perspective), qualitative study (client and caregiver perspective) and clinical cross-sectional study (clinical perspective). The findings from these studies are evaluated and compressed by a multi-stage voting procedure during an international consensus conference, resulting in the respective core sets.
Objectives:
To report the results of the ICF core set consensus conference for Autism Spectrum Disorder (ASD). Preparatory studies had yielded 168 ICF candidate categories for ASD. This evidence was used as a starting point to generate a Comprehensive, a Common Brief, and three age-specific WHO ICF ASD core sets.
Methods:
Twenty ASD experts, representing all six WHO-regions and various disciplines, were invited to participate in the 3-day consensus conference. The experts followed a three-stage decision-making and consensus process to decide on the ICF categories that should be included in the ICF Core Sets for ASD. In the first stage, the experts prioritized and selected ICF categories to be included in the Comprehensive ICF core set. The second stage consisted of defining the Common Brief core set for ASD. The third stage involved developing age-specific Brief core sets for ASD: ages 0 to 5 years, 6 to 16 and 16+ years.
Results:
Finally, 111 categories were included in the Comprehensive ICF Core Set with 59 categories from the activities and participation component, 31 environmental factors, 20 body functions and 1 body structure. The Common Brief ICF core set included 46 categories; 17 activities and participation categories, 15 environmental factors and 14 body functions. When defining the age-specific Brief ICF core sets, 14 categories were found to be common in all of the age groups. Thus, these 14 categories were added to the common Brief ICF core set, resulting in a set of 60 ICF categories. Together with the 60 Common Brief set categories, the Brief ICF core set for the 0 to 5 age group consisted of 73 categories, while the 6 to 16 age group had 81 categories and the adult group 79 categories.
Conclusions:
When defining the ICF core sets for ASD, a large number of categories were selected across all of the ICF components, supporting the notion that ASD impacts wide ranges of functions and contextual factors in life. From these core sets, assessment tools will be derived for future usage in clinical and research setting as well as health care administration.

134 **142.134** Symptoms of Autism Spectrum Disorder in Individuals with Down Syndrome or Williams Syndrome

R. Kirchner[1] *and K. M. Walton*[2]*, (1)The Ohio State University, Columbus, OH, (2)Psychology & Psychiatry, The Ohio State University, Columbus, OH*

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by persistent deficits in social communication, as well as restricted, repetitive patterns of behavior (American Psychiatric Association, 2013). Despite past research demonstrating that individuals with Down syndrome (DS) are not impaired on the social domain, and that Williams syndrome (WS) is a polar opposite of autism, individuals with these conditions display an increased prevalence of ASD. Previous research has shown that not only do more individuals with Down syndrome have a comorbid diagnosis of ASD in comparison to the reported CDC prevalence, but many children who do not receive an ASD diagnosis still exhibit elevated ASD symptoms. Research investigating the overlap of WS and ASD has shown that individuals with WS also display an increased prevalence of ASD, and display elevations both on assessments measuring symptoms of autism (Lough et al., 2015), and gold-standard autism diagnostic assessments (Klein-Tasman, Phillips, Lord, Mervis, & Gallo, 2009).
Objectives: The objective of this study is to investigate the overlap of symptoms associated with autism within the Down syndrome and Williams syndrome population, utilizing an autism screener (the Social Communication Questionnaire, SCQ), a dimensional measure of symptoms associated with autism (the Autism Spectrum Rating Scales, ASRS), and an adaptive behavior assessment (the Adaptive Behavior Assessment System, Third Edition, ABAS-3).
Methods: Parents and primary caregivers of children aged 6-18 with either an ASD, Down syndrome, or Williams syndrome diagnosis were asked to fill out an anonymous online survey, which contained demographic questions, as well as the aforementioned assessments. The goal is to recruit at least 28 individuals for each group, and to continue to recruit until we have received 75 per group. Currently, 77 parents of children with DS, 34 parents of children with WS, and 5 parents of children with an ASD diagnosis have completed the survey.
Results: Preliminary analyses show that more individuals with Down syndrome and Williams syndrome screened positive on the SCQ, in comparison to the population prevalence reported in previous research (Chandler et al., 2007). In this sample, 22% of individuals with a DS diagnosis screened positive on the SCQ (5 of the 77 individuals in the sample had a comorbid diagnosis of ASD, and all screened positive on the SCQ). Additionally, 53% of individuals with a WS diagnosis screened positive on the SCQ (4 of the 34 individuals in the sample had a comorbid diagnosis of ASD, and all screened positive on the SCQ).Â Additional analyses will compare the total score on the ASRS to the normative sample mean, examine the role of adaptive behavior in total scores on the ASRS, and compare each group's total scores on the three subscales: social/communication, unusual behaviors and self-regulation.
Conclusions: Â It is our hope that results of this study will shed light on the phenotypic overlap between autism and these genetic conditions, and will develop future directions for new research in how to best screen, diagnose, and create interventions for individuals with DS or WS who also display characteristics of ASD.

135 **142.135** Testing the Utility of Positive, Negative, and Cognitive Dimensions for Parsing ASD Heterogeneity

E. Isenstein[1], *J. Wolf*[2], *A. Kolevzon*[3], *J. D. Buxbaum*[3], *C. A. Mazefsky*[4] *and J. H. Foss-Feig*[5], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York City, NY, (2)Yale Child Study Center, New Haven, CT, (3)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (5)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY*

Background: Autism spectrum disorder (ASD) is very heterogeneous in its clinical presentation. While gold-standard assessment tools are effective for capturing the general presentation of the disorder and making diagnostic discriminations, there are currently no assessments that parse potentially diverse presentations within symptom domains; instead, existing assessments focus on the general notion of "abnormality." For example, many assessments probe for "atypical prosody," yet, due to broad wording, questions cannot differentiate whether prosody is over-animated and cartoonish versus robotic and monotone. This lack of specificity limits the capacity to characterize phenotypic heterogeneity, which may reflect dissociable underlying biology or relate to different treatment outcomes. In schizophrenia, conceptualizing symptoms along positive, negative, and cognitive dimensions has been fruitful in treatment development (Chen et al. 2013); it has recently been proposed that applying a similar conceptualization to the ASD phenotype could be a meaningful endeavor (Foss-Feig et al. 2015).
Objectives: To test the utility of capturing ASD symptoms along positive (presence of an atypical feature not seen in normative development), negative (decrease or absence of a behavior characteristic of normative development) and cognitive (abnormality in thought processes) dimensions as a way to assess variability within facets that intersect traditional symptom domains and differentially associate with low-level processes.
Methods: A battery of social, language, sensory, and diagnostic assessments was administered to 28 children (age 10-13 years) with ASD. Individual items were selected from the Social Responsiveness Scale (SRS) and Clinical Evaluation of Language Fundamentals Pragmatics Profile (CELF-PP) that best mapped onto the Positive, Negative, and Cognitive dimensions in the social domain (5, 6, 6 items, respectively), as outlined in Foss-Feig et al (2015). Bivariate correlations evaluated whether variability along these new dimensions was dissociable from traditional scales of social dysfunction (ADOS, SCQ), and/or differentially associated with particular subsets of low-level behaviors (sensory hyporesponsiveness, hyperresponsiveness, and seeking).
Results: Neither ADOS Social Affect Score nor SCQ Total Score were significantly correlated with any of the Positive, Negative, and Cognitive dimensions (all p's>.4), indicating that these scales tap new constructs overlooked in gold-standard scales for quantifying social dysfunction. Positive, Negative, and Cognitive scores were differentially associated with specific sensory responses: more positive symptoms correlated significantly with greater levels of social hyperresponsiveness (r=.610, p=.003), nonsocial hyperresponsiveness (r=.564, p=.006), and nonsocial hyporesponsiveness (r=.500, p=.018), whereas negative symptoms correlated positively and significantly only with nonsocial hyporesponsiveness (r=.512, p=.015), and cognitive symptoms correlated *negatively*and significantly with nonsocial hyporesponsiveness (r=-.494, p=.012).
Conclusions: Only 27 of 107 questions across the SRS and CELF-PP uniquely captured symptoms along Positive, Negative, and Cognitive dimensions, indicating that existing scales inadequately measure variability on these dimensions. Despite few suitable questions, our results support the notion that Positive, Negative, and Cognitive symptom scales capture variability in new ways that can begin to deconstruct the heterogeneity of ASD. Future work should move toward development of new measures that capture ASD symptomatology along these dimensions, which may then contribute to new ways of parsing heterogeneity, grouping subsets of ASD, understanding neurobiology of particular phenotypes, and informing targeted treatment.

136 **142.136** The Autism Diagnostic Observation Schedule Calibrated Severity Score Best Measures Autism Diagnostic Symptom Severity in Pre-School Children

L. D. Wiggins[1], *B. Barger*[2], *E. Moody*[3], *G. N. Soke*[1], *J. Pandey*[4] *and S. E. Levy*[5], *(1)Centers for Disease Control and Prevention, Atlanta, GA, (2)Georgia State University, Atlanta, GA, (3)University of Colorado, Denver, Aurora, CO, (4)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: The severity of autism spectrum disorder (ASD) is often measured by co-occurring conditions, such as intellectual disability or language delay, rather than deficits in social interaction, and restricted interests and repetitive behaviors (RRB). The Autism Diagnostic Observation Schedule calibrated severity score (ADOS CSS) was created to facilitate comparison of the diagnostic features of ASD independent of related conditions over time. Previous research found that, compared to the ADOS total score, the ADOS CSS was less influenced by factors such as cognitive and language abilities. Past studies did not include clinical judgment as a measure of ASD severity, nor explore the effect of other variables that may influence ASD severity, such as behavior problems and sleep disturbance.
Objectives: The objective for the current study was to determine whether the ADOS CSS, ADOS total score, or clinical rating of degree of impairment was least influenced by factors other than deficits in social interaction and RRB.
Â Methods: Children 2-5 years old were ascertained for the Study to Explore Early Development (SEED) through birth certificate records and multiple sources that serve children with developmental problems. All children were screened for ASD with the Social Communication Questionnaire upon enrollment. Children who demonstrated ASD risk were asked to complete an in-person developmental assessment that consisted of the ADOS and Mullen Scales of Early Learning (MSEL). Caregivers completed the Autism Diagnostic Interview – Revised (ADI-R), Child Behavior Checklist (CBCL), and Vineland Adaptive Behavior Scales. All children classified as ASD met ASD criteria on both the ADI-R and the ADOS, or met ASD criteria on the ADOS and one of three alternate criteria on the ADI-R.
The clinician who administered the ADOS noted his or her judgment of degree of impairment associated with ASD on a 7-point Likert scale (SEED DOI). The effect of child variables (i.e., CBCL externalizing behaviors, internalizing behaviors, and sleep problems; and MSEL expressive language, fine motor, receptive language, and visual reception skills) on measures of ASD severity (i.e., ADOS CSS, ADOS total score, and SEED DOI) were assessed with three separate linear regression models.
Results: 2,600 children completed a developmental evaluation and 707 met the SEED ASD case definition. The total amount of variance in ASD symptom severity accounted for by child characteristics was 9% for the ADOS CSS, 29% for the ADOS total score, and 38% for the SEED DOI. Higher ratings of autism symptom severity were significantly associated with more internalizing behavior problems and fewer expressive language and fine motor abilities for all three ASD severity outcomes. Expressive language ability contributed to ADOS total score and SEED DOI ratings more than any other variable.
Conclusions: Compared to the ADOS total score and clinical judgment, the ADOS CSS was the least influenced by the effects of co-occurring conditions on the severity of ASD diagnostic symptoms. Our findings are in agreement with past studies and suggest that, among the measures we evaluated, the ADOS CSS is the best measure of core features of ASD in pre-school children.

137 **142.137** The Broader Autism Phenotype in Parents of Children with ASD: A Systematic Review of Studies Reporting the Association Between Parent and Child Phenotype

***E. Rubenstein**, D. Chawla and J. L. Daniels, University of North Carolina, Chapel Hill, NC*

Background:
Broader autism phenotype (BAP) is elevated among parents of children with autism spectrum disorder (ASD). Identifying BAP in parents may help create subgroups of children with ASD that can improve efficiency in etiologic research. However, the literature on parental BAP is heterogeneous. Sources of heterogeneity include different measurement tools, varying informant types, which parent is assessed (mother, father, both), the source of the sample/population, and sample size. This variance has prevented clear understanding of the proportion of children with ASD that have parents with BAP and whether parental BAP impacts child ASD phenotype.
Objectives:
We aim to systematically review the literature to highlight and better understand heterogeneity of reported percentage of BAP in parents of children with ASD. Our secondary goal is to synthesize the literature on the association between parental BAP and child ASD phenotype. Better understanding of this relationship will be useful in identifying endophenotypes (specific traits genetic in origin that can parse heterogeneity) that can be used to refine etiologic analyses.
Methods:
We systematically searched Pubmed and Scopus databases in August 2016. Key search terms included ‘broader autism phenotype’, ‘quantitative autistic traits’ ‘parents’, ‘relatives’, and slight derivations of those phrases. Two independent reviewers examined 477 papers by title and abstract, resulting in a full text review of 97 papers. Studies were excluded if they did not measure BAP in parents of children with ASD or did not present dichotomized parental BAP status (BAP+ or BAP-).
Results:
Fifty-seven papers were identified that met criteria. Identified papers used eight different measurement tools, four types of informants, and three types of respondents. Sample sizes ranged from 4 to 3299. Thirty-nine papers reported proportion of parents with BAP, ranging from 3% to 73%. In most studies, the proportion of fathers with BAP was higher than mothers. The Family Health Interview was the most common measure and had the widest range in percentages, which may illustrate changes in the instrument over time or its use across clinical and population based samples. When sample size increased, the proportion of parents with BAP was less than in smaller samples, which may be a factor of sample population (clinic or population based) or difference in the type of measurement tools used depending on sample size. Fourteen studies assessed how parent BAP is associated with child ASD phenotype. These studies showed a relationship between parent restrictive and repetitive behavior and interests (RRBI) and child rigidity. There was also a positive association between parental BAP scores and child scores on ASD screeners. Father’s BAP tended to have a stronger association with child phenotype as compared to maternal BAP.
Conclusions:
BAP is prevalent in parents of children with ASD and there may be an association between BAP in parents and child ASD phenotype. Using BAP as a way to subgroup ASD may improve the efficiently of etiologic studies. Thoughtful consideration should be given when interpreting results of parental BAP studies, as sample type, measurement tool, and parent type may all play a role in effecting estimates.

138 **142.138** The Impact of the Audience Effect and Inattention on Online Vs in-Person IQ Assessment

***A. Zoltowski**[1], C. C. Clements[1], M. Henderson[1], L. Bateman[1], N. Stein[2] and R. T. Schultz[3], (1)The Center for Autism Research/CHOP, Philadelphia, PA, (2)Department of Statistics, Wharton School, University of Pennsylvania, Philadelphia, PA, (3)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: In order to facilitate collection of large samples of individuals with Autism Spectrum Disorder (ASD) and typically developing controls (TDCs), we developed an online, computer-adaptive IQ test based on item response theory - the Center for Autism Research Adaptive Test (CARAT; Clements et al., 2015). The online CARAT is self-administered; however, the absence of an examiner may affect performance in at least two meaningful ways for individuals with ASD and/or ADHD. First, individuals with ADHD may show periods of inattention without an examiner to help guide focus, missing some questions they ordinarily would have gotten correct. Second, the presence of another individual can affect one's behavior via the "audience effect," which is believed to be tied to a desire to positively manage one's reputation in front of others. Chevallier et al. (2014) found that examiner administration of a task benefited typically developing controls (TDCs) more than individuals with ASD compared to a computerized version of the test taken alone.
Objectives: Â Examine the effects of administration mode (in-person or computerized) on IQ test performance for individuals with ASD and/or ADHD.
Methods: Â Individuals ages 6-90 will complete both the online CARAT and the in-person WASI-II (n=50 ASD, 50 TDC). We expect a subset of both groups to have ADHD. We will detect "aberrant" responses due to inattention, meaning responses that are unexpectedly incorrect given the examinee's response pattern, by comparing the fit of two ability models that allow different levels of variability (Zoltowski et al., 2016). We previously used this method to successfully detect other types of aberrant responses (e.g., seeking help). We will compare the number of aberrant responses detected in individuals with and without ADHD. To test the impact of the audience effect, we will analyze the interaction between diagnostic group (ASD and TDC) and type of test (computerized CARAT or in-person WASI-II).
Results: Â To date, 24 TDC individuals between ages 7 and 53 (mean(sd) age = 24.7(12.6) years) have completed this testing, and WASI-II Full Scale IQ scores ranged from 86 to 136 (mean(sd) IQ score =114.1(15.6)). The remaining sample will be recruited in time for analysis and presentation by May 2017, and results in either direction will provide information about the appropriateness of online testing for different diagnostic groups.
Conclusions: As online tasks become increasingly popular in the field of ASD research, it is important to understand how different testing formats affect performance for people with autism and inattention. These analyses may help researchers determine how to interpret results from self-administered tasks and how to identify aberrant responses to items. The variability analysis may be able to detect individuals who have greater difficulty sustaining attention during online assessments so that researchers can implement supports for these situations, or rescore the measure removing aberrant responses. Furthermore, computerized testing may either provide a more equal testing environment, if we find that the audience effect boosts performance of TDC individuals, or may not affect group differences reported in examiner-administered tasks. Extensions of these approaches could be applied to other online tasks.

139 **142.139** Correspondence of Parent and Trained Observer Reports of Social Skills and Autism Symptoms

*M. Cornejo[1], J. J. Wood[2] and **K. Axthelm**[3], (1)UCLA Center for Autism Research and Treatment, Los Angeles, CA, (2)University of California Los Angeles, Los Angeles, CA, (3)Graduate Department of Education, University of California, Los Angeles, LA, CA*

Background:
It has been documented that in the child population, discrepancies often exist among different informant's ratings of child psychopathology and these discrepancies have an impact on assessment, classification, and treatment.Â Very little research has examined rater discrepancies, particularly in populations of children with developmental disorders.
Objectives:
The first objective of the study was to determine the consistency of parental reports of autism symptoms and social skills.Â This study also aimed to investigate the level of disparity between parent and trained observer reports of social skills and autism symptoms.
Methods:
The sample consisted of sixty-eight elementary school-aged children who were participating in a randomized treatment trial (M = 9.9 years, SD = 1.8) diagnosed with high functioning autism spectrum disorder (IQ above 85).
The parent report measures examined were the Autism Diagnostic Interview Revised (ADI-R) and the Social Responsiveness Scale (SRS). The ADI-R is an audio taped semi-structured interview organized around DSM-IV and ICD-10 diagnostic criteria for autism, and the SRS is a 65-item rating scale parent report measure of children's social impairments in naturalistic social settings.
The trained observer measures examined were the Autism Diagnostic Observation Schedule (ADOS) and the Playground Observation of Peer Engagement (POPE). The ADOS is a semi-structured autism diagnostic assessment tool and the POPE is a behaviorally based timed interval behavior coding system that measures peer engagement in natural environments.
Results:
Pearson correlations were performed between parent and trained observer ratings. There was a nonsignificant correlation (r = .08, p = .491) between measures of autism symptoms reported by parents (ADI-R) and those rated by trained observers (ADOS). Similarly, a nonsignificant correlation (r = -.175, p = .144) was found between measures of social skills reported by parents (SRS) and those rated by trained observers (POPE). In a secondary analysis, we found a significant correlation (r = .529, p < .001) between the parent report of autism symptoms (ADI-R) and parent report of social skills (SRS). At the subscale level, ADIR-restricted, repetitive, and stereotyped patterns of behavior significantly correlated with SRS-total (r=.264, p=.008), SRS-communication (r=.210, p=.035), SRS-motivation (r=.239, p=.016) and SRS-mannerisms (r=.382, p=.000).
Conclusions:
Parent and trained observer reports of autism symptomatology and social skills were not found to be consistent with one another. Greater child impairment reported by parents did not equate to worsened performance ratings granted by clinicians. Our findings provide support for the idea that parent report is not in line with eventual diagnostic outcome. Our results of the comparison between SRS and ADI-R indicate that parent report of ASD symptomatology and behaviors remained consistent across report type. Specifically, the information gathered during the semi-structured interview was reflected in the parent self-report measure. It is important to further investigate the lack of a relationship between parent and trained observer reports, given the need for accurate information to create clinical profiles and deliver effective treatments.

140 **142.140** The Predictive Value of AQ and SRS-a in Adults with Suspected ASD

*M. Meek-Heekelaar, M. L. Bezemer and **E. M. Blijd-Hoogewys**, INTER-PSY, Groningen, Netherlands*

Background:
ASD questionnaires are often used as screeners in the assessment of adults with suspected ASD. Their diagnostic value depends on their capability to properly assess the likelihood that the disorder is present (sensitivity: true positives) or not (specificity: true negatives).
In clinical practice, the AQ (Autism Quotient, open source) and the SRS-A (Social Responsiveness Scale - Adults, paid source) are most often used as tools for quantitative autism assessment. Their predictive value for diagnostic classification has seldom been compared.
Objectives:
The aim was to study the predictive value of the AQ and the SRS-A for diagnostic classification in a general mental health care population.
Methods:
The adult patients, who were referred for ASD assessment, filled in both an AQ (max score = 50) and a SRS-A (max score = 192) self-report at the beginning of the diagnostic process. An independent researcher scored these questionnaires. The results remained unknown to the diagnostician and the patient until after the ASD diagnosis was officially confirmed or rejected, resulting in an ASD-group and a non-ASD group. In total, there were 92 participants (M = 33.51 years, SD = 12.33), of which 68% received an ASD diagnosis. The ASD and non-ASD group did not differ on important characteristics, such as age (M = 33.68 vs. M = 33.14) and gender ratio (1.3:1 vs.1.4:1). T-tests and ROC-analyses were performed.
Results:
The ASD group had significant higher scores than the non-ASD group on both the AQ (M = 29.17, SD = 7.75; M = 20.97, SD = 8.13 respectively; t = 4.65, df = 90, p < .001, Cohen's d = 1.03) and SRS-A (M = 70.87, SD = 10.76; M = 63.59, SD = 12.56 respectively; t = 2.86, df = 90, p < .01 Cohen's d = 0.62). The correlation between both questionnaires was high (r = .80, p < .001).
The ROC-analysis for the AQ yielded an AUC of .78 (p < .001) for ASD vs. non-ASD. A cut-off score of 26 (as recommended for clinical use, but also determined by the best Youden's Index in this research) had a sensitivity of .76 and a specificity of .72 for ASD. The ROC analysis for the SRS-A yielded an AUC of .69 (p < .01) for ASD vs. non-ASD. A cut-off score of 70 (determined by the best Youden's Index) had a sensitivity of .63 and a specificity of .72 for ASD.
Conclusions:
Both questionnaires could differentiate between the ASD and the non-ASD group. However, the AQ had a higher effect size (large vs. medium), a better predictive reliability (moderate vs. poor) and a higher sensitivity. Thus, based on the current results, the AQ seems to be superior as a screening tool for general mental health care patients with suspected ASD. However, replication studies are needed before advising which one to use for clinical practice. Also, note that questionnaires are not intended to be diagnostic in itself. If there are clinically significant levels of autistic traits, a comprehensive diagnostic evaluation is warranted.

141 **142.141** The Predictive Value of the M-CHAT for ASD Screening Among Preterm Infants

E. Friedlander[1], *A. Harel*[1], *M. Yaari*[1], *B. Bar-Oz*[2], *S. Eventov-Friedman*[3], *D. Mankuta*[2] *and N. Yirmiya*[4], *(1)The Hebrew University of Jerusalem, Jerusalem, Israel, (2)Hadassah University Hospital, Jerusalem, Israel, (3)Neonatology, Hadassah University Hospital, Jerusalem, Israel, (4)Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel*

Background: The prevalence of Autism Spectrum Disorder (ASD) is 1% in the general population, whereas among preterm born children it is estimated as 1%-8%. Therefore, special attention has been given to early identification of social-communication deficiencies and ASD-symptoms in this high-risk population.
The Modified Checklist for Autism in Toddlers (M-CHAT) is a widely used screening instrument for ASD. The rate of positive screening for risk for ASD among preterm born children is 20%-41%, and is significantly higher compared to that of full-term infants.
Abnormal scores on the M-CHAT correlate with lower socio-economic status, male gender, low birth weight and gestational age, as well as with sensory, motor, social-communication, cognitive and emotional impairments. Given the association among the M-CHAT and the aforementioned characteristics, the predictive value of the M-CHAT should be carefully assessed utilizing gold standard measures.
Objectives: To examine the sensitivity and specificity of the M-CHAT administered at 18 months, concurrently at 18 months and predictively at 36 months among preterm born children.
Methods: One hundred and ten preterm infants (Demographic characteristics are presented in Table 1) participated in this longitudinal study. The Mullen Scales of Early Learning, the M-CHAT and the Autism Diagnostic Observation Schedule (ADOS) were administered at 18 and 36 months.
Among 110 infants in our sample, 3 infants were excluded from the analyses because of severe neurological impairments. Eighty-nine families completed the assessment at 18 months, and 81 completed the assessment at 36 months.
Results: Applying the recommended criteria for the M-CHAT at 18 months, 29 infants (32.6%) screened positive for risk for ASD whereas only 8 infants (9.0%) were identified at risk for ASD using the ADOS. At 36 months, only 2 (2.5%) infants passed the cutoff for ASD diagnosis using the ADOS.
The sensitivity of the M-CHAT conducted at the 18 months in comparison to the ADOS administered concurrently was 62.5%, and the specificity was 70.4%. Assessing the predictive value of the M-CHAT administered at 18 months in comparison to the ADOS administered at 36 months, the sensitivity was 100.0%, and the specificity was 69.6%. The sensitivity of the ADOS administered at the 18 months in comparison to the ADOS administered at 36 months was 100.0%, and the specificity was 93.7% (Table 2).
One-Way ANOVAs indicated that infants who screened positive for ASD by the M-CHAT at 18 months were more likely to be male, from lower income families, and had lower receptive and expressive language abilities at 18 months compared to infants who screened negative. At 36 months, infants who screened positive for ASD at 18 months, exhibited significantly lower fine-motor skills and receptive language abilities and a higher (worse) ADOS total score.
Conclusions: In line with previous reports, positive screening for risk for ASD by the M-CHAT was associated with characteristics not specific to ASD. Given the importance of early intervention, the M-CHAT may be useful in identifying infants who can benefit from intervention yet clinicians should be careful in suggesting risk for ASD, especially among high-risk groups such as preterm infants.

142 **142.142** The Primary Modification of the Chinese Version of Autism Spectrum Quotient- Children's Version (AQ-C)

F. Sun[1], *M. Dai*[1], *L. Lin*[1], *B. Auyeung*[2,3] *and J. Jing*[1], *(1)Department of Maternal and Child Health, Sun Yat-Sen University, Guangzhou, China, (2)Autism Research Centre, Cambridge, United Kingdom, (3)University of Edinburgh, Edinburgh, United Kingdom*

Background: The Autism Spectrum Quotient-Children's Version (AQ-C) is a parent-report instrument developed to measure autistic traits in children aged 4-11 years. A Mandarin Chinese translation of the AQ-C is needed for use in research in mainland China.
Objectives: Â To develop a Mandarin Chinese translation of the AQ-C, and to test its psychometric validity.
Methods: A total of 536 participants were assessed. A general population sample of 510 children (6.46±1.628 years of age) were recruited from kindergartens and primary schools. 26 autism spectrum conditions (ASCs) were recruited from hospital (5.85±1.434 years of age). Items were eliminated according to the critical ratioÂ and the change of Cronbach's alpha (α). The structure of the AQ-C was tested using exploratory factor analysis. The childhood autism spectrum test (CAST) and social responsiveness scale (SRS) were used for the validity of the AQ-C.
Results: Â A 31-item, 5-factor model achieved adequate goodness of psychometric characteristics, explaining 43.8% of the variance. The five factors were named mindreading, socialness, patterns, imagination and attention switching, respectively. The correlations between scores of the full scale and these factors were 0.776, 0.441, 0.475, 0.342 and 0.569. The Cronbach's α of the full scale was 0.742, and the five subscales' α ranged from 0.500 to 0.788. The total score was highly correlated with CAST and SRS (r=0.520, 0.587; *P*<0.001). ASCs scored significantly higher than the general population (ASCs: 53.58±9.97, general population: 34.18±9.15; *t*=10.49, *P*<0.001).
Conclusions: Â The Chinese AQ-C showed favorable reliability and validity in the preliminary analysis. Confirmatory factor analysis of a larger sample size is warranted.

143 **142.143** The Relationship Between Socialization and Externalizing Problems in ASD and VCFS

N. Shea[1], *E. Payne*[2], *E. P. McKernan*[1], *J. Kopec*[1], *E. A. Kaplan*[3], *K. Antshel*[3], *W. R. Kates*[4] *and N. Russo*[1], *(1)Syracuse University, Syracuse, NY, (2)Public Health, Johns Hopkins, Baltimore, MD, (3)Psychology, Syracuse University, Syracuse, NY, (4)Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY*

Background:
Addressing both core symptoms of autism spectrum disorder (ASD) and associated symptoms of ASD has become increasingly important (Lord & McGee, 2001). A commonly associated feature of ASD is that individuals often exhibit externalizing problems (Volker et al., 2010). It is important to understand the relationship between externalizing problems and core symptoms of ASD.
Objectives:
To examine whether social functioning uniquely predicts externalizing problems in ASD, in relation to typically and atypically developing populations.
Methods:
125 children and adolescents participated in this study: 34 with ASD, 34 typically developing (TD), and 58 with Velocardiofacial (VCFS / 22q11) syndrome. All diagnoses of ASD were confirmed using the ADOS-2, the ADI-R, and clinical judgment and VCFS diagnosis was confirmed with FISH analysis. Participants with VCFS did not have a comorbid diagnosis ASD, based on the ADI-R.
Externalizing behaviors were assessed with the BASC-2 Parent Rating Scale while social functioning was assessed with the socializations scores on the Vineland-II. IQ was measured by the WASI-II in the ASD and TD groups and by the WISC-III or the WAIS-IV in the VCFS group.
The ASD and TD groups were matched on chronological age (within 12 months) and Full Scale IQ scores (within one standard deviation) on the WASI-II.
Results:
Linear regressions assessed whether Socialization scores predicted Externalizing Problems. IQ was not significantly correlated with either measure in the ASD or TD groups and was thus not included in the regression. IQ was a significantly related to Socialization for the VCFS participants and was entered into the regression first.
For the ASD group, but not the TD group, socialization significantly predicted externalizing problems, $\beta = -.619$, $P < .001$, and socialization explained a significant proportion of variance (38.4%) in externalizing problems scores, $R^2 = .384$, $F(1,32) = 19.93$, $p < .001$.
For the VCS group socialization, but not IQ, significantly predicted externalizing problems $\beta = -.328$, $P < .001$, and socialization explained a significant proportion of variance (62.6%) in externalizing problems scores, $R^2 = .626$, $F(1,55) = 35.499$, $p < .001$.
Conclusions: Â
Socialization abilities significantly predicted externalizing behaviors in both participants with ASD and VCFS. These results can inform assessment and such that interventions targeting externalizing behaviors should focus on promoting social functioning as well. This relationship does not appear to be unique to ASD, as it also occurs in participants with VCFS.Â

144 **142.144** The Role of Feature Engineering in Developing Clinical Diagnostic Machine Learning Algorithms for ASD Screening

J. W. Wade[1], *A. Vehorn*[2] *and Z. Warren*[3], *(1)Autos Consulting, Murfreesboro, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN*

Background: Supervised machine learning (ML) methods are used to train models that map multi-dimensional numerical data to categorical target variables, given a labeled data set. This type of ML has been recently applied to the problem of predicting ASD diagnosis from gold standard measures such as the Autism Diagnostic Observation Schedule. However, these types of assessments are time- and resource-intensive. To demonstrate reasonably accurate predictions using ML methods on a reduced data set would provide immediate value for clinicians and families alike in the form of patient queue sorting and more rapid feedback.
Objectives: In this work, we present the design and performance of ML models trained on clinical diagnostic data to predict the presence or absence of ASD, using the labels *ASD* and *Non-ASD*, respectively. We first identify a small subset of features to be used in model training, thus reducing the number of items required to make predictions. Second, we use feature engineering methods to craft composite features that are more explanatory than their individual components. Finally, we train decision tree ML models and report on their performance for a variety of analyses.
Methods: Â A database of best-estimate clinical diagnoses for toddlers observed using the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2) was used for model training. This data set contained N=737 samples (514 *ASD* and *223 Non-ASD*) and 41 features. Dozens of engineered features were created based on exploratory analysis of the data. The most discriminating feature among these was the distance of the data point to the *Non-ASD* median centroid, which was composed of the medians of ADOS-2 codes A2, B1, and B5 for the *Non-ASD*subset.
Results: Â The metric unweighted average recall (UAR) has been suggested as a more robust measure of a model's reliability than true-positive rate (accuracy), particularly in the presence of unbalanced data. To compare the performance of our reduced feature set to the gold standard measures, we trained a model on the full set of ADOS-2 codes (accuracy=90.5%, UAR=0.89) and another model solely on the ADOS-2 total (accuracy=93.1%, UAR=0.92). Our best performing model using only 7 features (the three components of the *Non-ASD* median centroid and ADOS-2 codes A3, D1, D2, and D5) yielded comparable results (accuracy=92.4%, UAR=0.90), and an even simpler model using just 3 features (*Non-ASD* median centroid distance) demonstrated respectable results with just 7.3% of the available feature set (accuracy=91.32%, UAR=0.88).
Conclusions: Using the principles of feature engineering, we demonstrated that some composite feature (e.g., distance to Non-ASD median centroid) outperformed their component features in predicting best-estimate clinical diagnosis. Moreover, we showed that a small subset of ADOS-2 codes had comparable prediction power to the full set of codes, as well as to the ADOS-2 total score. These findings support the claim that a simplified clinical diagnostic tool may be used to facilitate faster turnaround times for clinicians, patients, and their families.

145 **142.145** The Role of Presence of ASD Symptoms in the Variability Between Parent and Teacher Ratings of Social Skills in School-Age Children Evaluated for ASD

S. W. Eldred[1], S. M. Ryan[2], T. Tomeny[2], J. A. Rankin[2] and L. K. Baker[1], (1)University of Alabama, Tuscaloosa, AL, (2)The University of Alabama, Tuscaloosa, AL

Background: When assessing children for autism spectrum disorder (ASD), clinicians often utilize measures from multiple informants to get a comprehensive picture of the child's functioning. Clinicians may gather information from both parents and teachers; however, variability may exist between informants due to factors such as informant bias and differences between settings (Ducekot et al., 2015). Whereas factors such as the child's age, gender, and IQ have been shown to predict variability between informant reports (Stratis & Lecavalier, 2015), little research has examined how high/low symptoms of ASD relates to this variability.
Objectives: The current study explores: 1) If parent- and teacher-reports of symptoms in school-age children evaluated for ASD are correlated; 2) If not, does presence of ASD symptoms (i.e., high; minimal-to-no) serve as a moderator of the relation between parent- and teacher-reports, after controlling for previously established covariates (i.e., child age, gender, IQ).
Methods: Parents, teachers and clinicians completed study measures for 43 children (ages = 3-16; 22 received an ASD diagnosis; 21 received other diagnoses) as part of an ASD evaluation at a university-based clinic. Parents and teachers completed the Social Responsiveness Scale (First or Second Edition; SRS), assessing social behavior deficits associated with ASD. Clinicians completed the Childhood Autism Rating Scale, Second Edition (CARS-2), assessing behaviors associated with ASD. Multiple regression was conducted using PROCESS for SPSS (Hayes, 2013) predicting teacher-reported SRS scores from parent-reported scores, while controlling for the child's age, gender, and IQ, and including CARS-2 scores as a moderating variable.
Results: Preliminary analyses revealed no significant correlation between parent- and teacher-reported social behavior deficits (SRS; r = .084, p = .592).Â When predicting teacher-reported SRS scores via multiple regression analysis, the addition of CARS-2 and parent-reported SRS scores in Step 2 did not account for significant variance over and above covariates, ΔR^2 = .13, $\Delta F(2, 37) = 2.99$, p = .06. However, the interaction term (parent-reported SRS scores X CARS-2 scores) entered in Step 3 accounted for significant variance in teacher-reported SRS scores, ΔR^2 = .10, $\Delta F(1, 36) = 5.68$, p = .02. Specifically, a significant positive relation emerged between parent- and teacher-reported SRS scores when high symptoms of ASD were present (high CARS-2), yet a non-significant relation emerged between parent- and teacher-reported SRS scores when minimal-to-no symptoms of ASD were present (low CARS-2; Figure 1).
Conclusions: Clinician-reported levels of ASD symptoms moderated the relation between parent- and teacher-reported deficits in social behavior. Although parent- and teacher-reports on the SRS are similar when symptoms are high, they are not related in children with minimal-to-no symptoms as observed by clinicians. This suggests that when ASD symptoms are more severe, agreement among raters is consistent; however, children with minimal-to-no symptoms are likely to have varying reports between parents and teachers. Identifying this non-significant relation present in reports of children with minimal-to-no symptoms helps to identify another potential predictor of report variability. Future studies will be needed to determine the potential reasons for this discrepancy in children with minimal-to-no symptoms.

146 **142.146** Unsupervised Data-Driven Stratification of Autism Based on ADI-R Symptom Domains

M. V. Lombardo[1,2], B. Auyeung[3], E. Loth[4], G. Dumas[5] and M. C. Lai[6], (1)University of Cambridge, Cambridge, United Kingdom, (2)University of Cyprus, Nicosia, Cyprus, (3)University of Edinburgh, Edinburgh, United Kingdom, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Institut Pasteur, Paris, France, (6)Psychiatry, University of Toronto, Toronto, ON, CANADA

Background:
Autism spectrum disorders (ASD) are clinically and etiologically heterogeneous. Pushing research forward towards precision medicine goals requires a deeper understanding of how individuals and subgroups within ASD are distinguished. Such distinctions within ASD may then point towards more precision in terms of clinical research and practice (e.g., aid in clinical practice for assessment, diagnosis, prognosis, planning treatment, monitoring, etc.) and may pave the way forward for translational research endeavors such as identifying etiological mechanisms and discovering novel targets for treatment.
Objectives:
To utilize unsupervised multivariate data-driven tools to aid in discovery of ASD subgroups defined by different patterning of symptom severity across social, nonverbal, verbal and repetitive restricted behavior (RRB) domains from ADI-R algorithm.
Methods:
ADI-R data was identified for n=3,380 ASD individuals across 72 independent datasets within the National Database for Autism Research (NDAR). Each individual had complete data across all algorithm items in the social, nonverbal, verbal, and repetitive restricted behavior domains. Domain totals were computed as the sum of all algorithm items within these domains. The dataset was split randomly in half within each of the 72 datasets to generate independent Discovery and Replication datasets (n=1,690 in each). We then utilized a hierarchical clustering tools commonly applied within genomics and systems biology analyses such as weighted gene co-expression network analysis (WGCNA), and applied it to the subject dimension of this dataset to identify ASD subgroups in an automated and unsupervised fashion (Lombardo et al., 2016, Scientific Reports). Euclidean distance was used as the distance metric and hierarchical clustering was implemented with the Ward linkage method. Subgroups were automatically identified using a dynamic hybrid tree-cut algorithm with a deepSplit parameter set at 1. Once subgroup clusters were identified we descriptively report symptom severity for each subgroup in each domain as a percentage of the maximum total score one could theoretically obtain across all items in that domain.
Results:
Across both independent Discovery and Replication datasets, we find evidence of 5 replicable ASD subgroups with near identical patterns of symptom severity across the domains. Four of the 5 subgroups could be differentiated on-average by degree of severity and had relatively similar levels of severity across domains. However, there was one subgroup that was distinctly different from all others, with a pattern of high levels of social and nonverbal symptom severity, but relatively large drop-offs in severity on verbal and RRB domains.
Conclusions:
Utilizing unsupervised data-driven tools for discovery of replicable ASD subgroups based on ADI-R symptom severity highlights 5 distinct subgroups. We will next examine how some of these subgroups may be identified and dissociated in further independent datasets (ABIDE, MRC AIMS, EU-AIMS LEAP), which have biological (e.g., resting state fMRI) and cognitive data collected on the same individuals.

147 **142.147** Use of Crowd-Sourcing to Assess Social Communicative Behavior in Toddlers with and without ASD

E. Myers[1], *W. L. Stone*[2], *T. S. Lendvay*[3], *B. A. Comstock*[4], *R. Bernier*[5] and ***C. A. Cowan***[1], (1)Developmental Medicine, Seattle Children's Hospital, Seattle, WA, (2)Psychology, University of Washington, Seattle, WA, (3)Urology, University of Washington, Seattle, WA, (4)Biostatistics, University of Washington, Seattle, WA, (5)University of Washington Autism Center, Seattle, WA

Background:
Social communication deficits are key behaviors associated with Autism Spectrum Disorders (ASDs). The assessment of these behaviors is complex and requires highly trained experts especially in very young children. Current practice standards assume that only experienced professionals can assess differences in social communication among young children. Consequently, waitlists are often long in most communities. The technique of crowd sourcing has been used to efficiently answer problems requiring human intelligence. It relies on the concepts of collective intelligence, i.e., that large groups of individuals can create solutions equal in quality to a few experts.
Objectives:
To compare ratings of toddlers' social-communicative behavior as judged by crowd-workers with those made by clinicians with expertise in ASD. We hypothesized that the crowd-sourced assessments would differentiate between varying abilities of social communication in a manner similar to expert-based assessments.
Methods:
A single video clip for each of eight, 18-month-old children participating in a longitudinal research study were selected for this study. All videos showed a child engaging with an adult during administration of the Screening Tool for Autism in Toddlers (STAT). The videos were chosen to show a range of typical and atypical behaviors during simple play-based activities. A 12-item Likert-based questionnaire was created to identify a range of behaviors that might be observed in 18 month old children, with the sum of the 12 items used as an aggregate score and higher scores indicative of more typical behavior. An additional question included a global judgement of whether or not the toddler's behavior was typical for his/her age. Each video was viewed by 3 experts and at least 68 crowd-workers. We assessed inter-rater reliability between expert ratings with an intra-class correlation coefficient (ICC). Rank order mean aggregate scores for each video clip were compared between crowd-workers and experts using a Spearman correlation coefficient. We used a Mann-Whitney U test to compare the aggregate score between clips that were rated as typical versus atypical.
Results:
Spearman correlation for rankings of total social communication behavior between crowd-workers and experts was very high (0.93; $p<0.001$) (See Fig.1). Inter-rater reliability between expert raters was excellent (ICC = 0.80. Crowd-workers completed 587 reviews in 6 hours and 50 minutes. Expert reviewers completed 24 reviews in 57 days. Aggregate summary scores were higher for videos rated as typical behavior than those rated as atypical for both crowd-workers (median score: 43 vs. 33; $p<0.001$) and experts (median score: 49 vs. 32; $p<0.001$).
Conclusions:
In this pilot study, we demonstrated the feasibility and validity of using a crowd-sourcing approach to measure social communication behaviors in very young children. Such a method may be a useful additional screening tool to discriminate typical from atypical behavior rapidly, with the goal of improving specificity of screening for developmental delays in social communication. Further studies with larger populations will be needed to confirm the utility of this approach.

148 **142.148** Use of the Systematic Observation of Red Flags (SORF) for Autism Spectrum Disorder in a Naturalistic Home Setting

D. Dow[1]*, T. N. Day*[2]*, C. Nottke*[1] *and A. M. Wetherby*[1]*, (1)Florida State University Autism Institute, Tallahassee, FL, (2)Clinical Psychology, Florida State University, Tallahassee, FL*

Background: While routine universal screening for autism spectrum disorder (ASD) is critical to allow timely initiation of intervention, some have expressed skepticism due to the lack of effective screening tools available (Al-Qabandi et al., 2007; Campos-Outcalt, 2011). Improved screeners are needed that not only effectively identify children at risk, but also offer increased feasibility for widespread use across community settings. The Systematic Observation of Red Flags (SORF) is an observational measure that has been shown to effectively detect risk for ASD when used with the Communication and Behavior Scales (CSBS) Behavior Sample (Dow et al., 2016). Because many children with developmental concerns do not receive a clinic evaluation, adapting this tool for use in the home could improve community-viable screening options accessible to more families, decreasing the age of diagnosis.
Objectives: To examine use of the SORF in the home for 16-24 month olds, including (1) diagnostic group differences and item-level performance of SORF items, and (2) sensitivity, specificity, and appropriate cutoff scores.
Methods: Preliminary analyses were conducted on the current sample of 32 participants (10 with ASD, 15 developmental delayed, 7 typically developing) recruited by the FIRST WORDS® Project at Florida State University. A sample size of 194 is estimated at the time of presentation, sufficient to achieve a medium effect size and power of 0.80. Children will be included if they have (1) a completed SORF based on behavior during a video-recorded home observation between 16-24 months, and (2) a concurrent diagnostic evaluation to confirm or rule out ASD.
Receiver operating characteristic (ROC) curves were used to evaluate individual items and summary scores, including the Total score of all summed items, Number of Red Flags (RF) score of the number of items indicating clear symptom presence, Social Communication (SC) score of SC items summed, and Restricted and Repetitive Behavior (RRB) score of RRB items summed. Area under the curve (AUC), sensitivity, specificity, and cutoffs were examined. Further analyses utilizing analysis of variance (ANOVA) will also be completed for the full sample to examine diagnostic group differences in items and summary scores, and a Composite score comprised of the best performing items will be created for optimal performance.
Results: Preliminary results suggest excellent discrimination between ASD and nonspectrum groups for the Total (AUC=.97), RF (AUC=.93), SC (AUC=.93), and RRB (AUC=.91) scores. High sensitivity and specificity was found for the Total, RF, and SC scores (sensitivity=.90, specificity≥.96) with appropriate cutoffs. The best performing items were poor directed eye gaze (AUC=.89), limited conventional gestures (AUC=.86), greater interest in objects than people (AUC=.86), repetitive speech/intonation (AUC=.83), limited coordinated nonverbal communication (AUC=.81), and limited consonant sounds (AUC=.80).
Conclusions: Preliminary results are promising indicating that the SORF may provide an effective observational screening tool in the home context, though the full sample is needed to support these findings. The Total and RF scores provided good discrimination, sensitivity, and specificity, and the SC domain may offer an abbreviated measure when used independently with similar effectiveness.

149 **142.149** Using Social Behavior Profiles to Predict Autism and Schizophrenia Diagnoses

K. E. Morrison[1]*, A. Pinkham*[1] *and N. J. Sasson*[2]*, (1)The University of Texas at Dallas, Richardson, TX, (2)University of Texas at Dallas, Richardson, TX*

Background: Overlapping social impairments in Autism Spectrum Disorder (ASD) and Schizophrenia (SCZ) contributed to decades of diagnostic confusion that continues to this day in some clinical settings. Our previous work used discriminant function analysis (DFA) to classify the social skills profiles of typically-developing (TD) adults and those with ASD and SCZ based upon their behavior during a 3 minute social interaction. Seven discrete social behaviors were coded: interactive behaviors (e.g., asking questions), nonverbal behaviors (e.g., gaze, affect expression), paralinguistic behaviors (e.g., verbal clarity), appropriate verbal content, repetitive movement, repetitive verbal content, and amount of time speaking. DFA profiles separated ASD ($p < .001$) and SCZ ($p = .041$) from the TD group, with ASD uniquely characterized by fewer interactive behaviors and more repetitive behaviors, and SCZ characterized by greater impaired gaze and flat/inappropriate affective responses.
Objectives: The current study tested our model's predictive accuracy in classifying both the original sample and a new sample of ASD, SCZ, and TD individuals based on their social behavior.
Methods: The original sample consisted of three adult groups: ASD (n=54), SCZ (n=54), and TD (n=56) comparable on age (group mean range: 25.69-28.67), gender (87% male), race (80-91% Caucasian), and IQ (group mean range: 103-106). DFA was used to classify a second unmatched sample (ASD n=28, TD n=31, SCZ n=16).
Results: Seventy percent of ASD and 70% of TD but only 33% of SCZ cases were correctly classified using the original sample. When applied to the second sample, TD classification accuracy increased to 87%, but decreased to 46% for ASD and 18% for SCZ. To explore this classification inaccuracy, we examined comparability in the two samples. The ASD cases in the second sample were younger than the initial sample (p=.010)—many were recruited from a university setting—and exhibited better interactive behaviors and poorer paralinguistic behaviors than the original sample ($p's$<.02). The second sample of SCZ individuals had more females and lower IQ ($p's$<.045) than the first sample, and demonstrated more repetitive movement (p=.01).
Conclusions: Group separation based on social behavior between ASD, TD, and SCZ individuals in an initial sample accurately predicted 70% of ASD cases but only 33% of SCZ cases. This disparity suggests that unique features of ASD (e.g., repetitive behavior) may aid in classifying ASD correctly, whereas differentiating SCZ from ASD based solely upon observable social behavior is less successful. Further, when the classification system was applied to a new sample, it proved accurate only at classifying TD individuals, with reduced classification accuracy for ASD and SCZ individuals. This may have occurred because the second sample of clinical participants was notably distinct from the original sample—ASD participants were younger and more skilled, and the SCZ group had lower IQ and more females. The failure of the model to predict clinical status within a novel sample suggests that social behavior within these clinical groups varies as a function of sample heterogeneity, and thus the model may be of limited utility in clinical settings, particularly those that evaluate diverse clinical populations.

150 **142.150** Using the Social Attention and Communication Surveillance Revised (SACS-R) in a Community Based Setting.

L. P. Hollier[1,2]*, C. Dissanayake*[3] *and J. Barbaro*[4]*, (1)Cooperative Research Centre for Living with Autism Spectrum Disorders (Autism CRC), Brisbane, Australia, (2)Olga Tennison Autism Research Centre, School of Psychology and Public Health, La Trobe University, Melbourne, Australia, (3)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (4)Olga Tennison Autism Research Centre, School of Psychology & Public Health, La Trobe University, Melbourne, Australia*

Background:
Social Attention and Communication Surveillance (SACS) was designed to prospectively identify children developing Autism Spectrum Disorder (ASD) between 12- to 24-months of age. This tool has 81% positive predictive value and an estimated 83.8% sensitivity and 99.8% specificity (Barbaro & Dissanayake, 2010). Five key behavioural markers identified at 12-, 18-, and 24-months of age as most predictive of an ASD diagnosis (Barbaro & Dissanayake, 2012) were incorporated into a revision of the SACS (SACS-R), where a child is considered as having a high-likelihood of developing ASD if s/he is noted as 'atypical' on three out of five key behavioural markers.
Objectives:
The aim in this study was to examine the effectiveness of key SACS-R items in differentiating children with/without autism in a community based setting.
Methods:
The SACS-R was implemented by Maternal and Child Health (MCH) nurses across eight councils in Melbourne, Australia. Children identified as having a high-likelihood of developing ASD on SACS-R were assessed by clinical experts at La Trobe University using the ADOS, ADI-R, and Mullen Scales of Early Learning. Of the 273 children referred and assessed to date, 199 met criteria for ASD. Nurse completed SACS-R data was available for 96 children at 12-months (24 high-likelihood), 159 children at 18-months (76 high-likelihood), and 204 children at 24-months (115 high-likelihood). Fisher's exact test was used to determine whether the key items at each age point were able to discriminate between children with/without ASD. Binary logistic regression analyses were used to determine whether scoring above the SACS-R cut-off predicted a diagnosis of ASD after controlling for gender and age.
Results:
No significant differences were found at 12-months of age between children with/without ASD on the frequency of atypical responses on the key items, and there was no significant association between scoring above the SACS-R cut-off and receiving a diagnosis of ASD. At 18-months of age, a significantly higher proportion of children with ASD than those without were rated as 'atypical' on all five of the key items (i.e. pointing, eye contact, waving, showing, and pretend play), and those scoring above cut-off were 3.5 times more likely to receive an ASD diagnosis. A higher proportion of children with ASD were given 'atypical' scores on four out of five of the key items (i.e. pointing, eye contact, waving, and pretend play) at 24 months of age, and those above cut-off were 3.4 times more likely to receive an ASD diagnosis.
Conclusions:
Previous clinical research has identified SACS as the most accurate and sensitive method for the early detection of ASD. The results from this study illustrate that when rated by community based clinicians, SACS-R does differentiate between children with/without ASD at the 18- and 24-month assessments. However, administration by nurses at 12-months did not significantly discriminate children with/without ASD. As these items were previously shown to differentiate between children with/without ASD when rated by a clinical expert (Barbaro & Dissanayake, 2013), additional education is required on the administration and accurate scoring of these items at 12-months for community-based professionals.

151 **142.151** Utility of Early Communication Assessment within ASD Diagnostic Evaluations in the Second Year of Life

N. Brane[1]*, R. Dailey*[1]*, M. Lewis*[1]*, H. Grosman*[1] *and S. Gillespie*[2]*, (1)Marcus Autism Center, Atlanta, GA, (2)Emory University School of Medicine, Atlanta, GA*

Background:
The AAP continues to support screening, early diagnosis, and timely referral for intervention, yet there is a lack of readily used standardized assessment instruments specific and sensitive enough to detect ASD red flags and inform intervention prior to comprehensive ASD evaluation. Parents often cite speech concerns early on, leading many families to seek a speech-language evaluation prior to comprehensive ASD evaluation (Chawarska, Paul, Klin et al., 2007), positioning speech-language pathologists (SLPs) at the front lines for detecting and quantifying ASD red flags in toddlers. Paul (2014) emphasizes that measuring frequency, range, and means of communication is necessary to capture a child's current communication abilities at the prelinguistic phase, while simultaneously measuring unusual communicative patterns (echolalia, significant deficits in pragmatics and receptive language). Further, the ASHA Ad hoc Committee on ASD (2006) states that SLPs play a critical role in screening, early detection of children at-risk for ASD, and referrals for further evaluation, while also formulating intervention specific to social communication delays. Additionally, given the complexity of ASD, varied levels of functioning, and need to distinguish ASD from other disorders, interdisciplinary collaboration within the diagnostic process is considered best practice.
Objectives:
To examine how early communication assessment, using the CSBS-DP, correlates to the ADOS-2 Toddler Comparison Score within an ASD diagnostic evaluation, among 2 diagnostic groups: ASD and language delay (LD).
Methods:
54 toddlers, ages 14-24 months, participated in a study evaluating toddlers suspected of ASD. Clinicians assessed participants at a single visit (Mean Age=21.44 months, SD=2.33), 40 received an ASD diagnosis [77.5% male (n=31), 22.5% female (n=9)] and 14 received a language delay (LD) diagnosis [64.3% male (n=9) and 35.7% female (n=5)]. Assessment battery included Communication Symbolic Behavior Scales-Developmental Profile *(CSBS-DP;* social, speech, symbolic composites), Mullen Scales of Early Learning, and ADOS-2. The standardized calibrated severity score (CSS) was generated as a metric of relative severity of ASD symptoms for each ADOS-2. Differences in CSBS-DP composite scores and CSS among the two diagnostic outcome groups were assessed using two-sample t-tests. Age-adjusted tests and gender by diagnosis interactions for each measure were assessed using linear regression and two-way ANOVAs.
Results:
Results revealed significant differences on CSBS-DP composites between the two diagnoses, ASD and LD, with LD toddlers receiving higher scores across all three composites (Speech: p<.001, Social: p<.001, Symbolic: p<.001). ASD toddlers received significantly higher CSS scores than LD toddlers (p<.001). Analyses revealed age-adjusted results as complimentary to the t-tests for all measure outcomes. However, a significant interaction between gender and diagnosis for Symbolic composite was observed (p=0.016), with ASD males receiving higher scores than ASD females and LD females receiving higher scores than LD males. All other interactions between gender and diagnosis were not significant.
Conclusions: The results contrast and differentiate communication skills of ASD and LD toddlers as measured by the CSBS-DP. These findings support the use of the CSBS-DP within a comprehensive ASD evaluation, by capturing verbal and nonverbal communication, highlighting social communication vulnerabilities, and leading SLPs to make informed decisions regarding further evaluation and treatment planning.

152 **142.152** Validity of the SRS in Minimally Verbal Children

C. Farmer[1], *V. Hus Bal*[2] *and A. Thurm*[1], *(1)National Institute of Mental Health, Bethesda, MD, (2)STAR Center for ASD & NDD; Dept of Psychiatry, University of California, San Francisco, San Francisco, CA*

Background: Implicit in any comparison of scores between groups is the assumption that an instrument is measuring the construct in the same way across groups; when this assumption is tested and confirmed, the instrument is said to have the property of measurement invariance (MI). Despite being an essential psychometric property, MI is often overlooked. This property is especially important for a measure of ASD symptoms, given the heterogeneity in presentation of this condition.
Objectives: The goal of this analysis was to test MI of the Social Responsiveness Scale, Second Edition across minimally verbal (MV) and verbal (V) children with ASD. Several items on the SRS-2 relate to verbal abilities, suggesting that scores for MV children should be interpreted with caution. Although considerably information on the concurrent/predictive validity of the SRS exists, neither the Total Score nor the Treatment Subscales of the SRS-2 were empirically derived, giving rise to the possibility that initial model fit may be poor and MI irrelevant. Thus, we first assessed the Total Score and the Treatment Subscales, but followed with evaluation of two empirically derived solutions: the SCI and RRB two-factor solution specified in the SRS-2 manual and the five-factor solution proposed by Frazier et al. (2014).
Methods: Â Data were drawn from the Simons Simplex Collection, comprising children with nonverbal IQ less than 70 and no phrase speech (MV; *n*=298) and children with nonverbal IQ greater than 70 and phrase speech (V; *n*=2,338). Invariance was tested in a multiple group confirmatory factor analytic framework. Model fit, and change in model fit as a result of increasing parameter constraints, was assessed with several complementary statistics (only RMSEA and ΔMcNCI are reported here).
Results: Â Fit statistics are shown in Table 1. Neither the Total Score nor the Treatment Subscale factor models fit the data, with the exception of the Awareness factor, which had adequate fit. Configural and metric invariance were also supported for the Awareness factor, but scalar was not. The fit of both the two-factor model and the Frazier model to the data were adequate; configural and metric invariance were supported, but not scalar.
Conclusions: These analyses demonstrated first that the Total Score and Treatment Subscales generally do not represent unidimensional constructs, and we were unable to produce psychometric support for their use, regardless of language level. Although we did find evidence for the adequate fit of the Awareness Treatment Subscale, mixed evidence for the fit of the two-factor model, and confirmed the adequacy of the Frazier et al. structure, scalar invariance of any organization was not supported across the MV and V subgroups. This means SRS-2 scores reflect both symptom severity and some unmeasured factor that differs between groups; functionally, this suggests that it is inappropriate to use these subscales without accounting for verbal ability, and that scores may not be combined or compared across groups.

153 **142.153** Cultural Differences in Symptom Recognition, Diagnosis, and Time Lag of Autism: A Comparison Between Japan and the US

N. Porter[1], *K. A. Loveland*[2], *Y. S. Posey*[3], *C. K. Carberry*[4] *and K. Morimoto*[5], *(1)Human Development, Washington State University, Lubbock, TX, (2)Psychiatry & Behavioral Sciences, University of Texas McGovern Medical School, Houston, TX, (3)Psychiatry and Behavioral Sciences, University of Texas Medical School, Houston, TX, (4)Educational Psychology, University of Texas at Austin, New York, NY, (5)Osaka Red Cross Hospital, Japan, Osaka, Japan*

Background:
The increase of autism is a global phenomenon, yet little research has examined whether cultural factors contribute to differential timelines for diagnosis of autism. Reasons for later diagnosis do not appear to be solely related to lower socioeconomic status or resources available in each country. Early markers of autism in one culture/country may be considered normal development in another, and may affect the timing of diagnosis (Matson et al. 2011). Cultural beliefs attached to disability can also create barriers to early identification (Saetermoe et al, 2001).
Objectives:
The current study compares factors associated with the first signs, first formal diagnosis, and the time lag between them, in U.S. and Japanese families.
Methods:
These data are from our ongoing cross-cultural research on mothers of children with autism. The study population included US and Japanese mothers of children ages 2-12 who had received a formal diagnosis of autism. Participants completed 5 questionnaires (Parenting Stress Index (PSI), Social Communication Questionnaire (SCQ), Social Responsiveness Scale (SRS-2), Child Behavior Checklist (CBCL), demographic questionnaire) and were interviewed regarding their experience of parenting their child with autism.
Results:
The data from fifty US and 50 Japanese mothers were analyzed. Mean age (months) of the first concern, the first formal diagnosis and the time between the two were earlier for the U.S. sample (18.7, 40.6, and 21.9) than those of the Japanese sample (20.6, 48.4, and 27.8). For both countries, 76% of participants indicated that parents (as opposed to professionals) were the first to recognize abnormalities of the child's behavior and development. Table 1 shows the comparison of the first symptoms to arouse concern between the US and Japan. In the ANOVA analysis, symptoms specific to autism, such as communication difficulties, fixation, and sensory issues, were more often referenced as the first symptom in the US sample compared to the Japanese sample. Interviews indicated the reasons for time lag as (1) long wait time, (2) medical and educational professionals' lack ofÂ knowledge about autism, (3) complex medical system, and (4) availability of intervention programs before formal diagnosis in the U.S ((1)(2) for Japan).
Correlations between early diagnosis and child/parent characteristics (Table 2) revealed that greater autistic characteristics were significantly correlated with earlier formal diagnosis for Japanese children, whereas greater autistic characteristics were significantly correlated with earlier age of first sign for U.S. children. Finally, child problem behavior, especially internalizing behavior, was positively associated with later recognition of child's abnormalities for the Japanese sample. There was no correlation between first sign/diagnosis and child problem behavior for the U.S. sample.
Conclusions:
Our preliminary findings indicate that children with greater autistic symptoms are noticed or diagnosed at earlier ages in both countries. Child behavior problems, especially internalizing behaviors, may delay parents or professionals from noticing abnormalities of development in Japan, but not the US. More research is needed on cultural and child/maternal factors associated with the timing of diagnosis.

154 **142.154** Who Goes Unseen? Race, Socio-Economics, and Autism Screening

C. Cordeaux[1], *D. A. Fein*[2] *and M. Barton*[2], *(1)University of Connecticut, Storrs, CT, (2)Psychological Sciences, University of Connecticut, Storrs, CT*

Background:
The American Academy of Pediatrics recommends all children be screened for ASD at 18 and 24 months of age. ASD screening tools allow clinicians to identify children at risk and provide diagnoses at younger ages. However, not all families engage with follow-up or evaluation services after screening. Historically, families of color and families of lower socio-economic status (SES) have lower rates of engagement with ASD services. While universal screening tools remove some barriers to access to intervention, racial and socioeconomic disparities may influence the extent to which screening is effective in population subgroups.
Objectives:
This study presents preliminary data from initial screening at 18-24 months of age, and examines patterns of attrition related to race, maternal education, and income.
Methods:
Participants were drawn from a sample of children who screened positive on the M-CHAT-R/F or the M-CHAT when screened at 18-24 months of age. Parents were invited to complete a follow-up phone interview to determine eligibility for a free diagnostic evaluation and offered an evaluation if appropriate. Participants lost to attrition who did not complete a phone interview for evaluation eligibility are the No Phone Interview (No-PI) group (n=310). Participants who completed a phone interview and were offered an evaluation are divided into two groups: the Evaluated group (n=634) and those lost to attrition before completing the evaluation (No-Evaluation group) (n=75).
Results:
At the 18-24 months screening, groups did not differ by age or gender. Groups differed significantly on years of maternal education, with the mothers in the No-PI group having significantly fewer years of education than mothers in the Evaluated group. There was also a significant difference between groups on median income such that the No-PI group had a lower median income than both the No-Evaluation and Evaluated groups. The groups also differed significantly on race/ethnicity. Those in the No-PI group were more likely to be children of color than children in the Evaluation and the No-Evaluation group. Those in the No-Evaluation group were also more likely to be children of color than children in the Evaluated group.
Conclusions:
This study presents preliminary data on a sample of participants who screened positive on an ASD screening tool but did not complete the follow-up or evaluation compared to peers who competed follow-up and evaluation. Children of color, lower income, and with mothers with less education were less likely to complete the diagnostic process. These data suggest universal screening removes some barriers in the early detection process. However, more minority and lower SES participants than White and higher SES participants were lost to attrition, and thus lost access to evaluations that made them eligible for treatment services. This is a notable pattern of disparate access for pediatricians and early interventionists who serve more vulnerable populations to consider.

155 **142.155** Novel Approaches to Parent-Reporting of Behaviors in Autism Spectrum Disorder

A. Bangerter[1], *N. V. Manyakov*[2], *D. Lewin*[3], *S. Jagannatha*[3], *M. Boice*[4], *A. Skalkin*[3], *W. Cioccia*[5], *G. Dawson*[6], *M. S. Goodwin*[7], *R. Hendren*[8], *B. Leventhal*[9], *F. Shic*[10], *G. Pandina*[4] *and S. Ness*[3], *(1)Janssen Research & Development, LLC, Pennington, NJ, (2)Computational Biology, Janssen Research & Development, LLC, Beerse, Belgium, (3)Janssen Research & Development, LLC, Titusville, NJ, (4)Janssen Research & Development, Titusville, NJ, (5)Janssen, Long Valley, NJ, (6)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (7)Northeastern University, Boston, MA, (8)University of California San Francisco, San Francisco, CA, (9)UCSF, San Francisco, CA, (10)Center for Child Health, Behavior and Development, Seattle Children's, Seattle, WA*

Background: Current autism spectrum disorder (ASD) interventions are mainly evaluated using retrospective parent-reported measures. While useful for describing general clinical presentation, this methodology often requires recall of specific behaviors weeks after they occurred, which can reduce accuracy of ratings. Furthermore, these measures are typically only administered before and after an intervention, limiting the ability to assess stability or dynamic change during an intervention. Emerging technologies are making it increasingly feasible to administer validated scales repeatedly in a simple and efficient format that can that can both improve parental experience and help enhance the validity and reliability of their reports.
Objectives: Validate MyJAKE - a web and mobile application – that allows parents to complete a new online rating scale (The Autism Behavior Inventory, ABI) about their child. The ABI contains 5 domains: Social Communication, Repetitive Behaviors, Mental Health, Self- Regulation and Challenging Behaviors. In addition, parents report significant behaviors such as affect and sleep and other events as they occur. Comparisons were made between these measures, other scales, and data from biosensors which individuals with ASD wore in the home.
Methods: Parents of individuals with ASD aged six years to adult completed the ABI online alongside commonly used paper-and-pencil scales at regular 4-week intervals during an observational clinical study (n=127). They also used the JAKE app to make daily reports on their child's sleep quality, affect, and other self-selected specific behaviors across an 8-week observational study. Individuals with ASD wore an actigraphy device each night for the duration of the study. Correlations between all parent-reported measures were calculated. Actigraphy sleep features were also compared to parent-reported measures of sleep and other behaviors.
Results: The ABI showed good internal consistency (Cronbach's alpha >0.80 for all 5 domains) and convergent validity with other rating scales: ABI/ABI-Short(S) social communication domain with Social Responsiveness Scale (SRS) social communication domain (r=0.73/0.62); ABI/ABI-S restricted or repetitive behavior (RRB) domain with SRS RRB domain (r=0.76 /0.71). Daily JAKE report measures correlated with scales (average daily report of overall type of day correlated with 4 weekly reports of caregiver burden (r=-0.30 p=0.02 n=88) and with ASD symptoms (r=-0.50 p<0.001); average valence on mood report correlated with daily reports of sleep (r=0.43, p<0.001). Actigraphy recordings correlated with parent measures of sleep and other behaviors: average sleep start time correlated with average daily tracker sleep report (r= -0.23 p=0.04 n=85); average sleep duration correlated with ABI core symptoms (r=-0.44, p<0.01).
Conclusions: The ABI is performing well, showing high internal consistency and moderate-to-high associations with standardized paper-and-pencil measures. Daily measures of behavior also showed statistically significant correlations with the ABI and other scales. The use of daily tracking of symptoms by parents could be a useful way of identifying early change in response to intervention. Sleep features measured by actigraphy showed some correlation with parent reports of sleep and with other parent-reported behaviors, demonstrating potential use of a more objective measure to accompany parental report of change over the course of an intervention.

156 **142.156** Eye-Tracking Features As Diagnostic Markers of Autism Spectrum Disorder, Symptom Severity, and Change over Time

G. Pandina[1], *S. Ness*[2], *A. Bangerter*[3], *N. V. Manyakov*[4], *D. Lewin*[2], *S. Jagannatha*[2], *M. Boice*[1], *A. Skalkin*[2], *W. Cioccia*[5], *G. Dawson*[6], *M. S. Goodwin*[7], *R. Hendren*[8], *B. Leventhal*[9] *and F. Shic*[10], *(1)Janssen Research & Development, Titusville, NJ, (2)Janssen Research & Development, LLC, Titusville, NJ, (3)Janssen Research & Development, LLC, Pennington, NJ, (4)Computational Biology, Janssen Research & Development, LLC, Beerse, Belgium, (5)Janssen, Long Valley, NJ, (6)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (7)Northeastern University, Boston, MA, (8)University of California San Francisco, San Francisco, CA, (9)UCSF, San Francisco, CA, (10)Center for Child Health, Behavior and Development, Seattle Children's, Seattle, WA*

Background: Research in eye-tracking has indicated that individuals with autism spectrum disorder (ASD) may differ from typically developing (TD) individuals in relation to allocation of attention to social and non-social stimuli. Though not conclusive, there is evidence of reduced attention to faces, eyes, and mouths, and increased attention to bodies and non-social elements in ASD. However, large-scale replication of these results is warranted, as is a deeper exploration of underlying relationships between eye tracking measures and clinically-relevant features of autism as well as applicability of these measures across the lifespan.
Objectives: To examine the discriminant validity (ASD vs TD) of different eye-tracking paradigms including dynamic, naturalistic, and static stimuli reported in literature broadly across development (childhood to adult); and to examine the relationship between ASD symptoms in ASD and performance on eye tracking tasks.
Methods: 127 ASD participants between six years and adulthood (mean [SD] age: 14.6 [7.91]) were monitored for attention to screen and pre-identified regions of interest using the Tobii X2-30 Eyetracker. A range of stimuli was presented, including Dynamic videos (Plesa-Skwerer, Chu, Brukilaachio, & Tager-Flusberg, 2016), Biological Motion, and a Visual Exploration Task. Stimuli were viewed at three time points during the course of the observational study. Parent reports on behavior rating scales were obtained at the same time points (0, 4, 8 weeks). Also, 41 TD individuals between six years and adulthood (mean [SD] age= 16.2 [13.18]) were presented with the same stimuli at baseline (0 weeks) only.
Results: Multiple eye-tracking stimuli discriminated between ASD and TD groups. Statistically significant findings included Biological Motion: Time spent looking at biological motion (n=108/38;[ASD/TD] d= -0.93, p<0.001); Dynamic Videos: Time spent looking at screen overall (n=82/38 d=-0.47; p=0.015),time spent looking at faces (n=82/38d= -0.72; p=0.001); and Visual Exploration Task: ASD participants explored less images per total time while looking at the screen (n=108/41); d= -0.63 p<0.001).
Many features across eye-tracking stimuli also correlated with increased ASD symptomology. Statistically significant findings included: reduced attention to screens during videos (n=52; r= -0.50, p<0.001); reduced attention to object of joint attention (moving toy) (n=81; r=0.34, p<0.001);
Finally, there were statistically significant correlations between change in biosensors from baseline with change in reported symptoms; Dynamic videos; change in attention to faces during the opening segment of videos statistically significantly correlated with change in ASD symptoms between baseline and endpoint (n=41; r= -0.42, p<0.01); visual exploration task; change from baseline in amount of time spent looking at images of high autism interest correlated with change ASD symptoms (n=75, r=0.37 p<0.001).
Conclusions: It was possible to discriminate between ASD and TD groups across a broad developmental range on eye-tracking measures that have previously been reported in the literature. For some of these features, there was also a statistically significant correlation with behavior rating scales. Finally, change in eye-tracking features over time was significantly correlated with reported change in behaviors during the same period. Taken together, these findings demonstrate the potential utility of eye-tracking measures as meaningful biomarkers and sensitive outcomes for use in clinical trials.

157 **142.157** Identifying EEG Biomarkers As Potential Change Indicators in Autism Spectrum Disorder Clinical Studies

N. V. Manyakov[1], *G. Pandina*[2], *S. Ness*[3], *A. Bangerter*[4], *D. Lewin*[3], *S. Jagannatha*[3], *M. Boice*[2], *A. Skalkin*[3], *W. Cioccia*[5], *M. S. Goodwin*[6], *R. Hendren*[7], *B. Leventhal*[8], *F. Shic*[9] *and G. Dawson*[10], *(1)Computational Biology, Janssen Research & Development, LLC, Beerse, Belgium, (2)Janssen Research & Development, Titusville, NJ, (3)Janssen Research & Development, LLC, Titusville, NJ, (4)Janssen Research & Development, LLC, Pennington, NJ, (5)Janssen, Long Valley, NJ, (6)Northeastern University, Boston, MA, (7)University of California San Francisco, San Francisco, CA, (8)UCSF, San Francisco, CA, (9)Center for Child Health, Behavior and Development, Seattle Children's, Seattle, WA, (10)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC*

Background: Autism spectrum disorder (ASD) is a neurological condition, thus it is expected that correlates of brain functioning can discriminate between ASD and typically developing (TD) populations, and furthermore these EEG-derived measures may account for variation in core and associated symptoms of ASD. Based on existing research, abnormal hemispherical asymmetry and differences in attentional allocation may be detected using EEG in ASD. Moreover, GABAergic dysfunction may lead to associated changes in related frequency bands. Identification of relationships between EEG correlates of brain activity and reported symptoms can contribute to the development of potential targets and novel outcome measures.
Objectives: Identify differences between TD and ASD in EEG recordings and relation of these measures to symptom severity.
Methods: JAKESense – a set of biosensors and experimental tasks – was administered to individuals with ASD (n=127, mean [SD] age: 14.6 [7.91]) and TD participants (n=41, mean [SD] age: 16.3 [13.18]). EEG was recorded according to 10-20 system during resting state condition (eyes closed or viewing hourglass), social vs non-social videos, and point-light displays of biological vs non-biological motions. Experiments were performed at 9 different geographical locations, ranging from research sites professional with EEG to clinical sites with no prior EEG experience. EEG was recorded simultaneously with eye-tracking, and only data, when participants were looking at stimuli, where considered for analysis. Age and gender was considered as covariates during analysis.
Results: During resting state, significantly ($p<0.05$) smaller alpha power at posterior regions were found in ASD in comparison to TD participants primary during eyes closed condition. Posterior alpha power correlated negatively, while frontal gamma correlated positively with symptom severity (e.g. occipital, eyes closed α vs ABC lethargy social withdrawal r=-0.4, p=0.001, frontal gamma vs SRS total r=0.35, p=0.011). Ratio in power between left and right hemispheres, characterizing functional brain asymmetry, were found significantly ($p<0.05$) smaller in ASD than TD for eyes opened and closed conditions for many brain regions and frequency bands. Coherence between frontal and other regions was significantly ($p<0.05$) higher in delta, theta and alpha and smaller in gamma in ASD than TD. During observation of social videos, suppression in alpha in comparison to non-social videos was significantly more prominent in TD than ASD in frontal, central and temporal regions ($p<0.01$), while no significant difference in theta ratio between two conditions of videos was found. Ratio in frontal alpha between biological and non-biological motion conditions correlated positively with social communication skills (e.g., r=0.23, p=0.073 at Fz)
Conclusions: EEG measures show potential for discriminating between ASD and TD individuals, and correlate with core and associated ASD symptoms. Difficulties obtaining reliable EEG recordings across a number of novice sites suggest that careful training and recording processes are needed, as well as use of stimuli that is engaging and reduces participant discomfort. Such instruction, processes, and stimuli have been established throughout these observational studies to enhance future use of EEG and enable continued understanding of this biosensor's contribution to the development of sensitive outcome measures in ASD.

158 **142.158** Cardiovascular Indices As Outcome Measures in Autism Spectrum Disorder Clinical Trials

M. S. Goodwin[1], *S. Ness*[2], *A. Bangerter*[3], *N. V. Manyakov*[4], *D. Lewin*[2], *S. Jagannatha*[2], *M. Boice*[5], *A. Skalkin*[2], *W. Cioccia*[6], *G. Dawson*[7], *R. Hendren*[8], *B. Leventhal*[9], *F. Shic*[10] *and G. Pandina*[5], *(1)Northeastern University, Boston, MA, (2)Janssen Research & Development, LLC, Titusville, NJ, (3)Janssen Research & Development, LLC, Pennington, NJ, (4)Computational Biology, Janssen Research & Development, LLC, Beerse, Belgium, (5)Janssen Research & Development, Titusville, NJ, (6)Janssen, Long Valley, NJ, (7)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (8)University of California San Francisco, San Francisco, CA, (9)UCSF, San Francisco, CA, (10)Center for Child Health, Behavior and Development, Seattle Children's, Seattle, WA*

Background: Heart rate (HR) and heart rate variability (HRV) are regulated by the autonomic nervous system (ANS). Several prior studies have reported elevated HR and reduced HRV in individuals with autism spectrum disorder (ASD) in comparison to typically developing (TD) controls and other clinical populations. However, less is known about these cardiovascular indices in response to social and non-social stimuli within ASD, and how they associate with reported symptomology over time.
Objectives: Evaluate HR and HRV between ASD and TD groups at rest, and within individuals with ASD in response to presentation of a range of social and non-social stimuli, including correlation with reported symptomology over time.
Methods: Cardiovascular data was collected using Actiwave Cardio Single-Channel Electrocardiogram while participants (ASD: n=127, mean [SD] age=14.6 [7.91]; TD: n=41, mean [SD] age=16.27 [13.18]) were at rest while observing a range of dynamic and static social and non-social stimuli across three blocks lasting approximately 15 minutes each. Baseline HR was calculated during a resting state task, both eyes open (where participants watched sand flow through an hourglass) and eyes closed. ASD participants repeated the task battery at four and eight weeks during a non-interventional trial. ASD and TD participants were approximately matched for age and gender.
Results: HR and RMSSD (a time-domain measure of HRV) were distributed non-normally (Kolgomorov-Smirnov $p < 0.05$) and analyzed non-parametrically. Data are reported as median [IQR].

At baseline, HR in ASD participants was statistically significantly higher than TD controls for both eyes open [88.38 BPM [79.35-96.23] vs. 73.14 BPM [65.81-84.37]) and eyes closed (89.32 BPM [79.32-97.62] vs 74.18 BPM [65.68-84.72]), both $p < 0.001$). RMSSD in ASD participants was statistically significantly lower than TD controls eyes open (43.43ms [27.41-72.26] vs. 61.28ms [38.41-93.16], p=0.024) and eyes closed (42.17ms [26.95-70.44] vs. 62.13ms [41.66-108.6], p=0.022).
The following findings between baseline assessment and endpoint assessment periods were also observed: HR during the passive viewing of social and non-social dynamic visual stimuli (Kanwisher task) was statistically significantly correlated with the ABI Social Communication subscale (Spearman's rho = -0.23, p=-0.043); RMSSD during the passive viewing of social and non-social dynamic visual stimuli (Tager-Flusberg task) statistically significantly correlated with the SRS Social Communication and Interaction subscale (Spearman's rho =-0.25, p=0.02); and RMSSD during both the Kanwisher and Tager-Flusberg tasks statistically significantly associated with the ABI Restrictive and Repetitive Behavior subscale (rho=0.30, p=0.008; rho=0.30, p=0.009).
Â Conclusions: Results confirm previous findings of statistically significant differences in cardiovascular indices between ASD and TD populations at rest. Changes in these indices between time points also significantly correlated with changes in reported symptom severity, indicating the potential of cardiovascular indices as sensitive outcome measures of clinical trial interventions.

Background:
In the wake of dramatic increases in ASD prevalence in recent decades, parent organizations are advocating for better services in many national governments across the European Union (EU). It is expected that over the next few years, the increase in political pressure will oblige governments to respond appropriately to this demand. Currently, however, there is no system for measuring ASD prevalence in the EU to provide baseline public health information. An important feature of such a baseline system would be a standardized method applicable across EU sites that would yield comparable prevalence rates across geographic areas.
Objectives:
The main objective of the presentation is to describe the strategy of the Autism Spectrum Disorder in the European Union (ASDEU) project to estimate the prevalence of ASD in school-aged children across Europe. The focus is on the novel field study methods and aims to be a reflexion on what we have learned regarding standardization of study methods across sites, what has worked well and what could be done differently in the future.
Methods:
A cross-sectional field study was implemented in the ASDEU project to ascertain ASD cases in 8 European countries: Austria, Bulgaria, Ireland, Italy, Poland, Portugal, Romania, Spain. The field study is based on a 3-stage screening strategy in primary schools including 1) Teacher Nomination (TN); 2) screening of nominated children using the Social Communication Questionnaire (SCQ); 3) clinical evaluation of SCQ positive children using ADOS and psychometric measures. A target population of 200000 children aged 7-9 years residing within the selected areas during 2016 is expected to be screened (8,000-10,000 per country).
Results:
The main challenges in the cross-sectional field study were common across sites and related to the adjustment of the study timeframe to school calendar years, the harmonization of screening methods to different educational/health systems and country-specific authorization requirements. Piloting of the TN method in schools known to have ASD children indicated that the number and type of issues signalled by teachers for nominated children are different for children with ASD or with other neurodevelopmental problems. A total of over 13,000 school children have already been screened in 5 countries, with 2,035 children (approximately 15%) nominated by teachers. The TN method, after translation and adaptation in 8 countries, was generally well received by teachers. The overall school participation rate was 92.5% in 5 sites, ranging from 42.5% to 100%, indicating that some countries require additional efforts to promote the study in schools. Initial findings regarding SCQ and clinical assessments across sites will be presented.
Conclusions:
ASDEU is the first study to estimate ASD prevalence across European countries using a common methodology. Analysis of early results indicates the field study is feasible and challenges related to cultural and educational systems diversity can be overcome. This method will be compared with population-registry screening approaches in Iceland, Finland, France and Denmark. The final ASD prevalence estimated across Europe will be fundamental to establish an evidence-based, EU-wide response to the growing societal needs of individuals with autism.

160 **143.160** ATN Longitudinal Study: 3-Year Follow-up of 575 Youth with ASD

***D. S. Murray**[1], P. Wang[2], D. L. Coury[3], K. Kuhlthau[4], J. Chan[5], E. A. Macklin[5] and A. Fedele[6], (1)Autism Speaks, Boston, MA, (2)Autism Speaks, New York, NY, (3)Nationwide Children's Hospital, Columbus, OH, (4)Massachusetts General Hospital, Boston, MA, (5)Biostatistics, Massachusetts General Hospital, Boston, MA, (6)Autism Speaks, Mullica Hill, NJ*

Background: Â This abstract introduces the ATN Longitudinal Study, a large-scale effort to describe behavioral, functional, and medical outcomes in children and adolescents with ASD. Comprehensive longitudinal data for youth with ASD are extremely limited, and few large-scale longitudinal cohorts exist. The Autism Speaks Autism Treatment Network (ATN) is a collaboration between Autism Speaks and 14 children's hospitals and medical institutions across North America. The ATN has established an open-access registry of data from almost 7000 youth with ASD, containing diagnostic, behavioral, functional, and medical data, and biospecimens in a limited subset. The ATN Longitudinal Study was designed to collect data 3-4 years after initial enrollment in the ATN Registry in a cohort that is broadly representative of the ATN Registry participants.
Objectives:
To describe the trajectory of behavioral, functional, and medical symptoms of ASD over 3-4 years, and the associations across these symptom domains.
Methods:
Subjects were randomly selected from among those who enrolled in the ATN Registry in 2011-13. These families were re-contacted for follow-up assessment on a battery of measures that were administered at enrollment, including the Vineland-II, CBCL, Aberrant Behavior Checklist, Pediatric Quality of Life scale (PedsQL), Children's Sleep Habits Questionnaire (CSHQ), a standardized medical history form, and limited physical examination. Families who were not able to schedule an in-person assessment were evaluated remotely by phone, internet, and mail. In this first abstract, we report on functional outcomes from the Vineland.
Results:
1275 subjects were contacted, and 575 consented to participate. Consented subjects were 83% male; 81% White, 7% AA, 5% Asian, and 92% non-Hispanic. Age was 5.9 years ± 3.2 (mean ± SD, range 2y0m to 16y10m) at initial assessment, and 9.7 ± 3.2 at follow-up. Consenters and non-consenters showed no differences in race, ethnicity, or sex and had similar baseline scores for ADOS severity, Vineland-II, and frequency of sleep, GI and seizure disorders. Non-consenters scored worse on measures of hyperactivity, on the CSHQ, and had trend worse scores on the PedsQL.
Among 571 participants who completed follow-up Vineland-II assessments, Composite scores showed little change: 71.6 ± 11.6 at baseline, and 70.5 ± 14.6 at follow-up. Domain scores also showed little change in the full cohort. However, while the mean Composite and Domain scores were steady or showed small increases among subjects <6 y.o. at baseline, they tended to decrease among those who were 6-12 y.o. at baseline (Figure 1). Among subjects whose baseline Composite scores were <80, mean scores were steady or increased slightly, but among those whose baseline scores were >=80, scores decreased (Figure 2).
Conclusions:
Mean changes in Vineland score seen among participants in the ATN Longitudinal Study were largely congruent with previous reports in smaller cohorts. Future analyses will examine the relationships between the Vineland and other measures and the association of medical co-morbidities and these outcomes in our ongoing study.

161 **143.161** Age of Earliest Evaluation Among Linguistically Diverse 8-Year-Old Children with Autism Spectrum Disorder, Denver Metropolitan Area, 2010 - 2012

K. R. Kast[1], *B. Harris*[2], *T. Hall*[3], *P. D. LaVesser*[3], *T. White*[4] *and C. Wells*[4], *(1)CO Dept. of Public Health and Environment, Denver, CO, (2)School of Education and Human Development, University of Colorado Denver, Denver, CO, (3)JFK Partners, University of Colorado Denver, Denver, CO, (4)Colorado Department of Public Health and Environment, Denver, CO*

Background: The prevalence of autism spectrum disorder (ASD) among surveillance sites in the United States is 14.6 per 1,000 8-year-old children. This prevalence varies significantly by race and ethnicity with more white, non-Hispanic children identified with ASD compared with black or Hispanic children. Compounding the understanding of prevalence among different racial and ethnic groups is the role of culture and linguistic diversity (CLD) on healthcare seeking behavior of families of persons with ASD. Children from CLD backgrounds within the US are more likely to be misdiagnosed and often diagnosed later than children who are white.
Objectives: The purpose of this analysis is to understand linguistic diversity among children with ASD in the Denver metropolitan area and understand its role on the age children are evaluated for developmental concerns.
Methods: Data were collected by the Colorado Autism and Developmental Disabilities Monitoring (ADDM) Project as part of the Centers for Disease Control and Prevention's ADDM Network – a population-based surveillance system of ASD among 8-year-old children. Participants are children born in 2002 and 2004 who met the ADDM Network case definition for ASD in the 2010 and 2012 surveillance years, respectively, and resided in Adams, Arapahoe, Boulder, Broomfield, Denver, Douglas, or Jefferson counties.Â A child is linguistically diverse if a qualified examiner in a developmental evaluation describes the child as speaking a language other than English, lives in a household where a language other than English is spoken, or was internationally adopted at greater than 12 months of age. A child was determined to be English-speaking only when the qualified examiner did not mention another language other than English in a comprehensive evaluation.
Results: Â The CO ADDM Project identified 820 children who met the ASD case definition during the 2010 and 2012 surveillance years. Among these children 85.6% were English-speaking only and 14.2% were considered linguistically diverse. Two children had an unknown language status. Compared with children who spoke English only, children who were linguistically diverse were first evaluated for developmental concerns at a younger median age (41.5 months compared with 46 months, respectively) and were more likely to have intellectual disability (IQ ≤ 70) (25.9% compared with 17.0%, respectively). When controlling for race, cognitive ability, and maternal education, linguistic diversity does not appear to effect the age at which a child is first evaluated. Rather, having intellectual disability significantly contributes to a child being seen for a developmental evaluation at earlier ages.
Conclusions: Â This analysis presents a deeper understanding of linguistic diversity's role in public health outcomes. Although linguistically diverse children are seen for a developmental evaluation at younger ages compared with English-only speaking children, this difference can be explained by the greater proportion of intellectual disability among linguistically diverse children with ASD in this surveillance dataset. Our findings suggest that linguistically diverse families may be less likely to seek an evaluation for children unless they have cognitive impairment. Further research is needed to better understand healthcare seeking behaviors of diverse families of children with ASD – with and without intellectual disability.

162 **143.162** An Exploratory Study on the Epidemiology of Autism Spectrum Disorder in Nepal

R. Shrestha[1], *C. Dissanayake*[2] *and J. Barbaro*[3], *(1)La Trobe University, Melbourne, Australia, (2)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (3)Olga Tennison Autism Research Centre, School of Psychology & Public Health, La Trobe University, Melbourne, Australia*

An Exploratory Study on the Epidemiology of Autism Spectrum Disorder in Nepal

Background: Early markers of Autism Spectrum Disorder (ASD) are present within the first 2 years of life making diagnoses possible by 24 months. Early diagnosis enables access to early intervention, known to promote better developmental outcomes in young children. However, there is limited research regarding the age of diagnosis (AoD) of ASD in low and middle-income countries (LMIC). Moreover, lack of awareness, cultural differences in interpreting ASD symptoms, delayed or alternative modes of help-seeking behaviours, limited access to intervention services and stigma associated with the disorder have led to delayed diagnosis of ASD in LMIC.

Objectives: The average AoD of ASD between 2010 and 2015 in Nepal was examined for males and females. The frequency of children diagnosed with ASD was also studied according to ethnicity, ecological zones, and districts. Finally, any change in AoD across the 6 years of sampling was examined.

Methods: De-identified data of 246 children registered at AutismCare Nepal Society (ACNS) from January 2010 to December 2015 and with a diagnosis of ASD as determined by paediatricians, child psychiatrists, and psychologists, were included in the study. The age of ASD diagnosis (in months) of children, gender, ethnicity and postcodes were extracted. Ethnic codes defined by Health Management Information System, Department of Health Services, Nepal were utilised to classify ethnicity. The postcodes were categorised into the types of ecological regions and districts according to Nepal Central Bureau of Statistics, 2011.

Results: The average AoD in children registered at ACNS between 2010 and 2015 in Nepal was 58 months ranging from 14 to 187 months. The ratio of a 1:3 Male (n-187): Females (n=59) diagnosed with ASD confirmed previous studies. There was no difference in AoD between males and females. The majority of the children (80 %, n=153) were from Upper caste groups. On the contrary, there were only 62 children from relatively advantaged group whereas 31 from a disadvantaged group. There was no significant statistical difference in AoD across three ethnic groups. But, Upper caste groups were diagnosed 7 months earlier than “Relatively Advantaged” and 17 months earlier than “Disadvantaged Group”. In addition, the hill region had the highest number of diagnosed children (n= 211) in contrast to Terai (n=33) and Mountain regions (n=2). In particular, 76 % of the children from the hill region were living in Kathmandu Valley. Finally, there was an increase in the number of children registered at ACNS between 2010 to 2015, with a decreasing trend in the AoD from 2013.

Conclusions: The findings show wide variability in the AoD of children with ASD in Nepal, with a decrease in diagnostic age over time. This decrease from 2013 coincides with the introduction of the DSM-5. The findings also illustrate a significant ethnic inequality and regional disparities in the number of children diagnosed with ASD. In conclusion, there is a great need to reduce the disparity in available services to promote early diagnosis of ASD across the population in Nepal.

163 **143.163** Association Between Breastfeeding and Autism Spectrum Disorder in Preschool Children: An Analysis of Data from the Study to Explore Early Development (SEED)

G. N. Soke[1], *M. J. Maenner*[1], *E. Moody*[2], *G. C. Windham*[3], *C. DiGuiseppi*[4] *and L. A. Schieve*[1], *(1)Centers for Disease Control and Prevention, Atlanta, GA, (2)University of Colorado, Denver, Aurora, CO, (3)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (4)University of Colorado - Denver, Aurora, CO*

Background: Most causes of autism spectrum disorder (ASD) are not well understood. The potential effect of breastfeeding is of interest because breastmilk provides key nutrients for physical and cognitive development of the child, and breastfeeding contributes to maternal-child bonding. However, breastmilk may also contain environmental pollutants or other substances with potential negative effects on cognitive development. Conflicting results have been reported in past studies on the relationship between breastfeeding and ASD, and few studies have examined a possible association with its duration. Methodological limitations noted in past studies include small samples, use of parental report to document ASD diagnosis, lack of a comparison group, and incomplete adjustment for confounding factors.

Objectives: To evaluate possible associations between ASD and (1) breastfeeding and (2) breastfeeding duration, and to identify factors associated with breastfeeding and its duration in cases and typically-developing controls.

Methods: We used data from the Study to Explore Early Development (SEED), a multi-site case-control study that includes children aged 2-5 years ascertained through birth certificates (controls) and clinical and educational sources providing services to children with developmental disabilities (cases). Enrolled children underwent an extensive assessment by expert clinicians using standardized instruments. The diagnosis of ASD was based on the Autism Diagnostic Observation Schedule and the Autism Diagnostic Interview-Revised. Mothers participated in a telephone interview about their pregnancy, including whether the child was ever breastfed and if “yes,” then how old the child was when breastfeeding stopped. We compared cases and controls using logistic regression to assess any association with breastfeeding and multinomial logistic regression to compare child age (tertiles) at breastfeeding cessation. These analyses were adjusted for a variety of child and maternal characteristics.

Results: The sample included 707 cases and 1223 controls. Overall, 75% of children were “ever breastfed.” The mean child age (in months) at breastfeeding cessation was 7.3 in cases and 9.2 in controls. There was no independent association between breastfeeding and ASD (adjusted odds ratio [aOR]: 0.92 (95 CI: 0.65, 1.30). Compared to controls, cases were younger at the time of breastfeeding cessation: aOR comparing highest age tertile (> 12 months) to lowest age tertile (<=3 months) in cases versus controls was 0.60 (95%CI 0.42, 0.87). In both cases and controls, higher maternal education attainment was associated with breastfeeding and its longer duration. In cases, higher family income and having a mother born outside of the United States were each associated with breastfeeding, and older maternal age was associated with longer breastfeeding duration. In controls, white race was associated with breastfeeding and longer breastfeeding duration; cesarean birth, mother with a psychiatric condition, and lower family income were each associated with shorter breastfeeding duration (p-values <0.05).

Conclusions: Although initiation of breastfeeding was not significantly different between groups, its duration was shorter among ASD cases compared to controls. These results document the importance of assessing duration of breastfeeding rather than initiation alone. Multiple factors were associated with both the initiation and duration of breastfeeding, and should be taken in account when assessing the relationship between breastfeeding and ASD.

164 **143.164** Association Between Maternal Pre-Pregnancy Body Mass Index, Gestational Weight Gain and the Risk of Autism in Han Chinese Population

Y. Shen*, H. Dong, J. Ou and J. Zhao, Institute of Mental Health, the Second Xiangya Hospital, Central South University, Changsha, China*

Background: Autism is a neurodevelopment disorder with unclear etiology. Some previous studies suggested that maternal pre-pregnancy body mass index (BMI) and gestational weight gain (GWG) might involve in the etiology of autism. However, the studies are still limited, and the findings need further replications. Furthermore, there are obvious ethnic disparities in BMI and GWG for the different genetic backgrounds, living environments and lifestyle. So it is necessary to validate in populations from different backgrounds.
Objectives: The goal of this study is to explore the association between maternal pre-pregnancy BMI, GWG and the risk of autism in Han Chinese population.
Methods: 697 Han Chinese autistic children(599 male and 98 female,mean age 4.97±1.19 years) and their parents were recruited through a face to face interview,2200 age-matched unrelated typically developing (TD) children(1187 male and 1013 female,mean age 5.17±1.82 years) were recruited by using a web-based survey.
After removing the outliers, Student's t-test and Chi square test were adapted to compare the demographic characteristics, the maternal BMI and GWG between case and control groups. Then we conducted binary logistic regressions to calculate the Odds Ratio (OR) for the relationship between pre-pregnancy BMI, GWG and the occurrence of autism.
All mothers of the enrolled children were classified as underweight, normal weight, overweight and obese according to the adult BMI classification standards for Chinese population. According to Chinese GWG recommendation, they were classified into inadequate weight gain, adequate weight gain and excessive weight gain based on their GWG.
Results: Â The mean BMI of mothers with TD children was 20.30±2.27, and the mean BMI of mothers with autistic children was 20.50±2.25. The mean GWG of mothers with TD children was 15.04±5.81 kg , while 15.70±6.21kg of mothers with autism. There was a significant group difference in GWG (t=-2.526, p=0.012) and a minor but significant difference in maternal pre-pregnancy BMI (t=-2.015, p=0.044).
The results of logistic regression analyses showed that excessive weight gain during pregnancy was associated with autism risk in the whole samples (OR=1.475, 95%CI: 1.107-1.965) after controlling for the cofoundings. However, the inadequate gestational weight gain was not significantly associated with autism risk (OR=0.875, 95%CI: 0.690-1.110). One the other hand, the relationship between maternal pre-pregnancy BMI and autism was not found to be significant (normal weight was set as reference, underweight group: OR=0.901, 95%CI: 0.679-1.195; overweight group: OR=0.680, 95%CI: 0.445-1.038).
We further analyses the interaction between pre-pregnancy BMI and GWG by adapting stratification analyses with logistic model. And the results showed that neither inadequate (OR=1.225, 95%CI: 0.716-2.097) nor excessive GWG was significantly associated with autism risk for lean mothers. Excessive GWG would increase the risk of autism (OR=1.479, 95%CI: 1.059-2.066) for the normal pre-pregnancy weight mothers, might also significantly but more obviously increase the risk of autism (OR=2.479, 95%CI: 1.059-2.066) for overweight mothers.
Conclusions: To our knowledge, this is the largest scale study in Chinese Han population. Our present study reported that maternal pre-pregnancy BMI might not be associated with autism risk, but excessive GWG might increase offspring autism risk among normal weight and overweight mothers

165 **143.165** Associations of Autism Spectrum Disorder with Residential Air Pollution Exposure in a Large Southern California Pregnancy Cohort

H. Jo[1], *A. Xiang*[2], *M. Cockburn*[1], *J. C. Chen*[3] *and R. McConnell*[1], *(1)Department of Preventive Medicine, University of Southern California, Los Angeles, CA, (2)Department of Research & Evaluation, Kaiser Permanente Southern California, Pasadena, CA, (3)University of North Carolina, Chapel Hill, NC*

Background: Â Autism spectrum disorder (ASD) prevalence has increased over several decades to its currently estimated 1 in 68 children in the United States. Recent research suggests that adverse child neurodevelopmental outcomes, including ASD, may occur in association with regional and near-roadway air pollution exposures. There have been limited longitudinal analyses of population-based cohort studies that have addressed the relationship between air pollution and ASD, and results from previous case-control studies have not been consistent.
Objectives: Â This retrospective cohort study evaluated the associations of ASD risk with prenatal exposure to regional air pollutants, including particulate matter (PM) ≤2.5 µm in aerodynamic diameter ($PM_{2.5}$), ≤10 µm (PM_{10}), nitrogen dioxide (NO_2), and ozone (O_3).
Methods: Â We retrospectively identified a cohort of children born in Kaiser Permanente Southern California (KPSC) hospitals between 1995 and 2009 (n=294,637), reviewing electronic medical records from birth until the first date of clinical diagnosis of ASD, last date of continuous KPSC health plan membership, death from any cause, or age 5. Birth certificate addresses were geocoded and used as the residential locations where birth-year annual average exposure to regional particulate and gaseous air pollutants ($PM_{2.5}$, PM_{10}, NO_2, and O3) were estimated by inverse distance weighting to the network of Southern California monitoring stations, and distances to major roadways and freeways were calculated for 294,637 mother-child pairs. ASD diagnosis was defined based on ICD-9 diagnostic codes from at least 2 separate KPSC hospital visits. Relative risks of ASD were estimated by hazard ratios (HRs) using Cox regression models adjusted for potential confounders.
Results: There were 2414 children with a diagnosis of ASD by age 5. After adjusting birth year, for maternal age, parity, education, household income, race/ethnicity, history of comorbidities (≥1 diagnosis of heart, lung, kidney, or liver disease; cancer), sex of the child, and KPSC medical center service areas, HRs scaled to interquartile range of the distribution of each pollutant were 1.18 (95% confidence interval [CI], 1.05-1.34) per 8.74 µg/m^3 $PM_{2.5}$ 1.10 (95% CI, 1.00-1.21) per 11.3 µg/m^3 PM_{10}; 0.95 (95% CI, 0.85-1.07) per 11.9 ppb NO_2; and 0.79 (95% CI, 0.71-0.88) per 10.8 ppb O_3. No associations of residential distance to major roadways and freeways were observed. HRs for air pollutants did not change substantially after additionally adjusting for preeclampsia, maternal diabetes, and preterm birth.
Conclusions: Â Prenatal exposure to $PM_{2.5}$ and PM_{10}, were associated with risk of ASD in children from a large, prospectively analyzed birth cohort in Southern California. Inverse associations with O_3 merit further investigation.

166 **143.166** Autism Features and Gender-Specific Eating Behaviour Problems throughout Childhood: The Generation R Study

M. van 't Hof[1,2,3], *W. A. Ester*[2,3], *H. W. Hoek*[3,4] *and H. Tiemeier*[5,6,7], *(1)The Generation R Study Group, Erasmus University Medical Center, Rotterdam, Netherlands, (2)Sarr Expert Centre for Autism, Lucertis Child and Adolescence Psychiatry, Rotterdam, Netherlands, (3)Parnassia Psychiatric Institute, The Hague, Netherlands, (4)Department of Psychiatry, University Medical Center Groningen, University of Groningen, Groningen, Netherlands, (5)Department of Child and Adolescent Psychiatry / Psychology, Erasmus MC-University Medical Center, Rotterdam, Netherlands, (6)Department of Epidemiology, Erasmus MC-University Medical Center, Rotterdam, Netherlands, (7)Department of Psychiatry, Erasmus MC-University Medical Center, Rotterdam, Netherlands*

Background: The odds of having eating problems is five time higher for children with autism compared to children without autism [1] and can create medical problems like gastrointestinal dysfunction [2, 3] which is a serious concern for parents [4]. Restricted interests [5], over-sensory and -responsivity to taste, texture and smell of foods [6] may underlie these eating problems. A recent general population study [7] suggests that picky eating is more common in children with autism features. However, it is unknown whether autism features relate to broader eating behaviour problems in the general population.
Objectives: To examine the relationship between autism features and eating behaviour throughout chilhood in a general population sample.
Methods: In this subset (N=3066) of the Generation R study [8] we assessed autism features by the Child Behavior Checklist (CBCL) at age 3 and the Social Responsiveness Scale (SRS) at age 6. Parental report of eating behavior was assembled at age 4 by the Child Eating Behavior Questionnaire (CEBQ) and at age 9 with the CEBQ and one scale of the Dutch Eating Behavior Questionnaire (DEBQ).
Results: Per each 1-point increase in autism features at age 3 (CBCL), children scored 0.06 points higher on Emotional Undereating (95%CI: 0.04; 0.08), 0.05 points higher on Food Fussiness (95%CI: 0.03; 0.08), 0.03 points higher on Slow Eating (95%CI: 0.01; 0.05), 0.04 points higher on Emotional Overeating (95%CI: 0.02; 0.06) and 0.02 points lower on Enjoyment of Food (95%CI: -0.04;-0.00) at age 4 in adjusted models. No gender differences were found.
Children scored per 1-point increase in autism features at age 3 years (CBCL), 0.04 points higher on Emotional Undereating (95%CI: 0.01; 0.06) and 0.03 points higher on Emotional Overeating (95%CI: 0.01; 0.05) at 9 years in adjusted models. In girls, autism features related with increased Emotional Overeating at age 9 years, in contrast to boys.
Each 1-point increase in autism features at age 6 years (SRS), associated with a 0.23 points higher score on Emotional Undereating (95%CI: 0.03; 0.43), 0.30 points higher on Emotional Overeating (95%CI: 0.11; 0.50), 0.29 points lower on Enjoyment of Food (95%CI: -0.47; -0.10), and 0.48 points higher on Food Responsiveness (95%CI: 0.29; 0.76) at age 9 in adjusted models. Whereas in girls, autism features associated with increased Emotional Undereating, Emotional Overeating and reduced Enjoyment of Food, this relation was absent in boys.
Conclusions: This study indicates that autism features in the general population are associated with eating behavior problems throughout childhood, thus not only in clinical populations. Early childhood autism features may predispose eating behavior difficulties, especially in girls.

167 **143.167** Autism Risk Associated with Parents' Age and Educational Status?

F. Duque[1,2], *J. Almeida*[1], *S. Mouga*[1,3], *C. Café*[1], *M. Patrício*[4] *and G. Oliveira*[1,2,3], *(1)Unidade de Neurodesenvolvimento e Autismo, Pediatric Hospital, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal, (2)University Clinic of Pediatrics, Faculty of Medicine, University of Coimbra, Coimbra, Portugal, (3)Institute for Biomedical Imaging and Life Science, Faculty of Medicine, University of Coimbra, Coimbra, Portugal, (4)Laboratory of Biostatistics and Medical Informatics and IBILI, Faculty of Medicine, University of Coimbra, Coimbra, Portugal*

Background: Advanced parental age has attracted attention as a potential risk factor for Autism spectrum disorder (ASD), since the beginning of this trend of delayed reproduction. Studies have reported increased risk of ASD when both parents are of older ages, when there are older fathers but not older mothers and vice versa, or neither. According to National Portugal Statistic, mean age of mother at birth, in 2010, was 28.6 years, reflecting a two years delay in motherhood compared to 2000. In 2014, it stood in 31.5 years. Increased prevalence of ASD is a phenomenon without complete explanation. Examining effects of interactions of parental age on ASD risk is important and if it represents independent risk factors. Moreover, the association between parental educational status and ASD is poorly understood.
Objectives: To characterize the role of advanced parental age at birth in ASD comparing with a group of other neurodevelopmental disorders (OND) without ASD.
Methods: *Participants*included 1973 children and adolescents, ranging in age from 2 to 18 years old. They were divided into two clinical main groups: ASD (N=1202; Male/Female ratio – 5/1) versus OND (N=771; Male/Female ratio – 2.5/1). Participants were seen as part of an outpatient clinic in a tertiary Pediatric Hospital between 1995 and 2015. To be included, all participants had to have registered both parental date of birth; ASD was diagnosed according to positive score for both ADI-R and ADOS, and fulfilment of DSM-5 criteria. Parents of OND group completed the Social Communication Questionnaire to exclude comorbidity with ASD. Parental age was categorized into: < 25; 25 – 29; 30 – 34 and ≥ 35 years of age. To enhance comparability covariates were included: gender; parental educational status categorized according to International Standard Classification of Education – ISCED; birth order; gestational age; Apgar score and pregnancy complications. All statistical computations were performed resorting to IBM SPSS Statistics version 23. We considered the significance level (α) = 0.05
Results: Mean age of mothers at the time of birth was 30.8 ± 5.2 years for ASD and 29.8 ± 5.7 for OND. Mean age of fathers was 33.2 ± 6.0 and 32.7 ± 6.4 years among ASD and OND group, respectively. Significant differences were found between maternal ages of children with ASD and children with OND, $t(1533.486)= -3.927$, $p<0.001$ but not between the corresponding paternal ages, $t(1562.170)= -1.840$, $p=0.066$.
In addition, a significant difference between the two groups was found for parental education (Mann-WhitneyU, $p<0.001$) for ASD group, median parental education was level 3 and for OND group was level 2. In ASD subjects 75% of all fathers and mothers had a level of education equal or less than 4 and 6, respectively; in OND group 75% of all fathers and mothers obtained lowest level of educational (level 3).
Conclusions: In a large sample comparing parental age and educational level of ASD *versus* OND population we can state that older maternal age at birth and higher parental education was independently associated with increased odds of ASD than other neurodevelopmental disorders.

168 **143.168** Autism Spectrum Disorder (ASD) in Qatar:Profiles and Correlates of a Large Clinical Sample

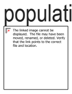
F. Alshaban[1], *M. Aldosari*[2], *E. Fombonne*[3] *and I. Ghazal*[4], *(1)Qatar Biomedical Research Instutute, Doha, Qatar, (2)Cleveland Clinic, Cleveland, OH, (3)Oregon Health & Science University, Portland, OR, (4)King Faisal Specialist Hospital and Research Center, Riyadh, SAUDI ARABIA*

Background: There is a paucity of studies on ASD in Qatar, mostly in the form of case reports and genetic causes. To date, no studies have explored the characteristics, environmental and genetic factors in the ASD population in Qatar.The current study was designed to describe the clinical characteristic of ASD and its correlates in Qatar.
Objectives: Â The aim of the current study was to describe cases within one of the country's largest special needs centers, the Shafallah Center for Children with Special Needs. The current study evaluated clinical profiles of ASD and their correlates.
Methods: The methodology of the current study was designed to review cases of ASD within Shafallah Center for Individuals with Special Needs between the years of 2011-2015.A total of 171 cases of ASD were identified,Â The analysis included the following factors; nationality, age, gender, socio-economic status, consanguinity, prenatal/postnatal complications, and comorbidities. Â
Results:
80% of the identified cases were males, with a 4:1 male to female ratio. Additionally, 83% of the families had one proband, 9.9% had 2 probands, and 7.1% more than two. Comorbid conditions included; Intellectual Disabilities (ID) in 83% and Epilepsy in 18.8%. 76.6% of subjects were non-verbal. There were 3 (1.8%) children with Rett's Syndrome, 3 (1.8%) with Fragile X, and 1 (0.6%) with Tuberous Sclerosis. The effect of consanguinity as a risk factor was not found to be significant as only 40% of the participant's parents were consanguineous compared to 54% consanguinity rate among general population in Qatar.
Conclusions: In conclusion, the current study is the first attempt at the clinical characterization of ASD in Qatar. This study provides insights to the similarities and discrepancies to what has been noted in other parts of the world and supports the need for a prospective epidemiological study in this population, such a study might contribute to expanding our knowledge of ASD.

169 **143.169** Autism Spectrum Disorder: Mortality and Healthcare Implications from the National Mortality Files

K. Y. Graves[1], *H. J. Carretta*[2] *and T. W. Benevides*[3,4], *(1)Behavioral Sciences and Social Medicine, Florida State University College of Medicine, Tallahassee, FL, (2)Florida State University College of Medicine, Tallahassee, FL, (3)Thomas Jefferson University, Philadelphia, PA, (4)Occupational Therapy, Augusta University, Augusta, GA*

Background:
Autism spectrum disorder (ASD) is a pervasive developmental disorder that globally impacts functioning, and its prevalence is increasing among children (Bukstein & Cornelius, 2006; Baxter et al., 2015). The prevalence of ASD in adults is also increasing as these diagnosed children grow up, yet there is limited information on ASD beyond childhood. The limited literature suggests a poor prognosis for adults with ASD, citing high levels of disability, poor health, low likelihood of independent functioning, and increased mortality risk (Modre et al., 2012). Previous large cohort studies on mortality risk for ASD adults have been largely focused outside of the United States, and more research is needed to determine specific causes of early mortality risk in the ASD population (Hirvikoski et al., 2016). Quantifying frequently occurring, potentially preventable causes of death in the ASD population is imperative to increasing awareness for families, care-takers, policy-makers, and practitioners.
Objectives:
The purpose of this presentation is to describe underlying causes of death for ASD individuals compared to individuals with intellectual disability (ID) and to the general population. A secondary purpose is to quantify mortality rates by age, race/ethnicity, and gender to identify vulnerable sub-populations.
Methods:
This study used national Multiple Cause-of-Death Mortality Data for years 2011-2013. These data sets are created using information from death certificates provided to the National Vital Statistics System (NVSS). The International Classification of Diseases, Tenth Revision (ICD-10) was used to code underlying causes of death. The multiple cause of death codes are classified by NVSS to identify the underlying cause of death from up to 20 multiple causes of death listed. Using ICD-10 codes, individuals with ASD and ID were identified, and cross-tabulations were run to: (1) compare ASD deaths to the ID and typical populations, and (2) compare mortality rates among sub-populations of the ASD group.
Results:
Preliminary analyses of 2011 mortality files, presented in Tables 1 and 2 attached, show 3.3% of deaths in the typical population occur before age 30, compared with 41.1% in the ASD population and 7.8% in the ID population. For the typical under 30 population, 15.5% of deaths are due to non-motor vehicle accidents, compared with 24.5% for ASD, and 2.7% ID. The ASD population under 30 also has a greater proportion of deaths (15.1%) due to ischemic or other heart disease than the typical (4.0%) or ID (1.7%) populations.
Conclusions:
Describing causes of death for the ASD population is a crucial first step in eliminating premature mortality for this group. Results show that deaths in the ASD population are to a disproportionate number of young people under age 30, which could be a reflection of the lower prevalence of ASD among older cohorts. Further, ASD individuals appear to be at increased risk of early mortality due to non-motor vehicle accidents and ischemic heart disease compared with the typical and ID populations. Analyses of the 2011 mortality files are complete, and these analyses will be replicated for 2012 and 2013 in order to substantiate these findings.



170 **143.170** Autism Symptom Severity in Males and Females: An Exploration of Gender Differences Using Item Response Theory

A. Sturm[1] *and M. Kuhfeld*[2], *(1)UCLA, Los Angeles, CA, (2)University of Texas Austin, Austin, TX*

Background:
Studies examining the role of gender in autism have found inconsistent support for phenotypic differences between boys and girls. However, few studies have systematically tested gender differences in autism symptomatology using gold-standard measures in large samples.
Objectives:
This study aimed to systematically explore gender differences in the phenotype of ASD in a large sample of clinic- or research-referred youth and adults (N = 9697). Specifically, the present study explored symptom bias, mean and variance differences, and the potential moderating role of nonverbal IQ for each of the four ADOS modules.
Methods:
Participants included cross-sectional data compiled from the National Database for Autism Research, Autism Genetic Resource Exchange, and Simons Simplex Collection. Multigroup unidimensional confirmatory factor models were fit to each ADOS module using revised scoring algorithm items to determine differences in factor means and variances between males and females. Fitted models included Module 1 no words (N = 1496) and some words (N = 1792), Module 2 less than age 5 (N = 1076) and greater than or equal to age 5 (N = 1162), Module 3 (N = 3170) and Module 4 (N = 1001). Items were then evaluated for significant item bias by gender using differential item functioning. Finally, to test whether gender differences are moderated by nonverbal IQ, each unidimensional model was estimated including gender, NVIQ, and their interaction as latent predictors.
Results:
None of the items currently included in the ADOS scoring algorithm showed significant DIF (wABC > .35) by gender. Only Module 2 less than 5 years (z = 19.1, p < .001) and Module 4 (z = 9.22, p < .001) showed significant differences between males and females on factor means, such that males scored significantly higher than females. In addition, only Module 2 less than 5 years (σ_{female} = 1, σ_{Male} = .18) and Module 4 (σ_{female} = 1, σ_{Male} = .4) showed pronounced differences in factor variability. Finally, the interaction between gender and nonverbal IQ significantly predicted ADOS severity for all Modules (β_{range}=-0.006 to – 0.002, p < .01) excluding Module 2 greater than or equal to age 5 (β = -0.001, p= .24).
Conclusions:
Males and females who have the same autism severity are nearly equally likely to receive a particular score on a specific item of each module and show similar autism severity and variability in severity. While males scored significantly higher than females when assessed using Module 2 less than 5 years and Module 4, there were also the fewest number of individuals in these groups which highlights the importance of investigating symptom and phenotypic differences in large samples and thus these two populations should be further explored. Finally, although NVIQ impacted ADOS scores for males more so than females, parameter estimates were so small that these results are not likely substantively meaningful. In the absence of phenotypic differences, factors aside from ASD core features, such as associated features and comorbid disorders, must be explored to develop a better understanding of the disparity in prevalence.

171 **143.171** Comparison of Parental Concerns Around Child's Food Intake Between Children with ASD and Typically Developing Children

L. G. Bandini[1,2], *C. Curtin*[1], *S. Phillips*[3] *and A. Must*[4], *(1)Eunice Kennedy Shriver Center, University of Massachusetts Medical School, Worcester, MA, (2)Department of Health Sciences, Boston University, Boston, MA, (3)Department of Public Health and Community Medicine, Tufts University School of Medicine, Boston, MA, (4)Department of Public Health and Community Medicine, Tufts University School of Medicine, Boston, MA*

Background: Â Background: Food selectivity is a common feeding problem in children with autism spectrum disorder (ASD). In previous reports from our Children's Activity and Mealtimes Patterns (CHAMPS) study we found that children with ASD exhibit more food selectivity and mealtime behavior problems than typically developing (TD) children. Despite the high prevalence of feeding problems among children with ASD, there are few reports about the extent to which parents are concerned about the quality of their child's diet.
Objectives: Â To determine parental concern around eating and diet among children with ASD and TD children.
Methods: Â 53 children with ASD and 58 TD children between the ages of 3-11 years participated in the CHAMPS study. Parents completed several questionnaires including the Meals In Our Household Questionnaire, which we used to assess parental concern about their child's nutritional intake. We focused on 8 questions related to diet quality. We dichotomized the 6-tiered response categories into 2 groups as follows: not concerned, a little concerned and somewhat concerned comprised one category ('Not Concerned') and the responses of quite concerned, very concerned and extremely concerned comprised the other category ('Concerned'). Chi square analyses were used to compare the frequency of parental responses between children with ASD and TD children.
Results: Â We found that parents of children with ASD were significantly more likely to be concerned than parents of TD children that their child was not eating enough (15% vs 2% p<0.013); eating too much junk food (26% vs 7% p<0.005); eating only a few types of food (57% vs 10% p<0.001); not eating enough vegetables (43% vs 10% p<0.001); and not eating enough fruit (32% vs 2% p<0.001). No significant differences were found in response to questions about eating too much (11%vs 3% p<0.15; eating too much fat (13% vs 7%, p<.27) and eating too much sugar (9% vs 5%, p<.48). We did not observe any significant changes in the findings when these analyses were repeated using logistic regression that adjusted for age and sex.
Conclusions: Â These findings suggest that parents of children with ASD have elevated concerns compared to parents of TD children regarding their children's nutritional status. The findings also support the need for professionals to include inquiries about these concerns when working with parents of children with ASD and to develop and test strategies for parents to promote their children's healthy eating.

172 **143.172** Congenital Abnormalities of the Male Reproductive System and Risk of ASD

R. S. Rotem[1]*, G. Chodick*[2]*, M. Weisskopf*[1]*, M. Davidovitch*[2]*, B. Coull*[1] *and R. Hauser*[1]*, (1)Harvard School of Public Health, Boston, MA, (2)Maccabi Healthcare Services, Tel Aviv, Israel*

Background:
Autism spectrum disorder (ASD) is a developmental disorder with increasing prevalence reported worldwide. While the specific mechanisms driving ASD pathogenesis remain largely unknown, accumulating evidence suggests that androgens have extensive influence on structural and functional brain development in regions that are relevant for ASD, and that atypical in-utero androgens levels or actions is a potential risk factor for ASD. Direct evidence, however, remains scarce, owing in part to the difficulty of obtaining direct measurements of fetal androgens levels during pregnancy. Hypospadias (abnormal positioning of the urethral opening) and cryptorchidism (undescended testis) are two of the most common birth defects in newborn boys, are strongly associated with deficiencies in prenatal androgens, and are readily recognizable at birth. Thus, having cryptorchidism or hypospadias is a proxy indicator of atypical androgen actions during pregnancy, but the association between these two disorders and ASD has not been extensively studied on an individual level.
Objectives:
To evaluate whether male newborns diagnosed with either hypospadias or cryptorchidism at birth were at a higher risk of receiving ASD diagnosis later in life, compared with children born without these conditions.
Methods:
We analyzed all male singleton live births (n=147,324) from January 1, 1999 through December 31, 2008 occurring in a large Israeli healthcare organization. Boys with cryptorchidism (n=3,650) or hypospadias (n=2,343) were identified via ICD-9 codes. ASD cases (n=1,329) were identified by ICD-9 code and verified by review of medical records. Analyses were conducted using logistic mixed effect models with random component accounting for family clusters, and adjusted for covariates.
Results:
In multivariable-adjusted analyses, the odds ratio (OR) for ASD among boys with hypospadias or cryptorchidism was 1.31 (95% confidence interval (CI): 1.03-1.65). For cryptorchidism only the OR was 1.39 (95% CI: 1.04-1.86) and for hypospadias only was 1.16 (95% CI: 0.79-1.71). Restricting to boys who underwent surgical correction strengthened the results for cryptorchidism (OR: 1.63, 95% C.I 1.08-2.45), but not hypospadias.
Conclusions:
Boys with cryptorchidism were at higher risk of ASD, but we did not observe an increased risk among boys with hypospadias. Differences in ASD risk between the disorders may reflect variations in critical windows of exposure to a hypoandrogenic in-utero environment, or effects of other signaling systems involved in the etiology of the disorders. Understanding the links between cryptorchidism and ASD could shed light on mechanisms of ASD pathogenesis.

173 **143.173** Enrollment and Participant Characteristics of SPARK, a National, Web-Based Cohort of Individuals with ASD and Their Family Members

H. Zaydens[1]*, V. J. Myers*[1]*, A. M. Daniels*[2]*, L. Snyder*[1]*, A. Amatya*[1]*, L. Grosvenor*[1]*, P. Feliciano*[1] *and W. Chung*[1]*, (1)Simons Foundation, New York, NY, (2)SPARK, New York, NY*

Background: The heterogeneity of autism spectrum disorders (ASD) and the burden of large-scale phenotyping and genotyping [2] have historically been significant obstacles to the study of this group of neurodevelopmental disorders. Initiatives such as the Interactive Autism Network's (IAN) pioneered efforts in creating large web-based autism registries and have successfully demonstrated the validity of parent-reported ASD diagnosis [3] and the phenotypic data provided [1]. To date, however, no studies of this scale have combined large scale parent-reported data with genetic data to rapidly advance ASD research.
Objectives: The aim of the current study is to describe SPARK and to summarize preliminary demographic and clinical characteristics of SPARK participants <18 years.
Methods: Â Enrollment in SPARK occurs entirely online at SPARKforAutism.org. Participants are asked to indicate their ASD status and relationship to the individual in the family with ASD and to enter basic demographic information. After consenting to share medical, and optional genetic data, participants are then asked to provide the following additional information on the individual(s) with ASD: ASD diagnosis type, age at diagnosis, individual who diagnosed ASD, language ability, ever/never ASD-related services used, ever/never individualized educational plan for ASD, and ever/never intellectual disability diagnosis. Data collected through SPARKforAutism.org also includes a brief medical history and the Social Communication Questionnaire – Lifetime (SCQ) for children age 2 – 18 years. Participants who consent to share genetic data are then asked to provide a shipping address for saliva collection and are also given the option of inviting the other biological family members to participate.
Results: From the launch of SPARK's pilot in December 22, 2015 through October 13, 2016, a total of 8,650 children with ASD enrolled in SPARK. Among child participants, the mean age at enrollment was 8.6 years (SD 4.1), and 80% were male. Mean age at diagnosis was 49.5 months (SD 30.8), and the most commonly assigned diagnosis was ASD (68%). Children were most commonly diagnosed by a clinical psychologist (24%), and the most common language level was use of longer sentences (57%). The majority of parents reported that children received ASD services (89%) and had an IEP (83%). 17% of participants received a diagnosis of ID, and the mean SCQ score was 22.5 (7.1 SD).
Conclusions: Initial enrollment supports the feasibility of implementing a large-scale, web-based registry for ASD that collects both phenotypic and genetic information. Characteristics of the participants <18 years recruited to SPARK are consistent with those described in both CDC's Autism and Developmental Disabilities Monitoring Network study cohorts and IAN samples. Future research on the SPARK cohort will provide more in-depth examination of adults with ASD, evaluate the effectiveness of saliva collection for DNA analysis and examine the associated genetic findings.

174 **143.174** Familial Confounding of the Association Between Maternal Smoking in Pregnancy and Autism in Offspring

A. Kalkbrenner[1]*, S. M. Meier*[2]*, C. Ladd-Acosta*[3]*, M. D. Fallin*[4]*, E. Parner*[5] *and D. E. Schendel*[6]*, (1)University of Wisconsin-Milwaukee, Milwaukee, WI, (2)Child and Adolescent Mental Health Centre, Copenhagen, Denmark, (3)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)Department of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD, (5)University of Aarhus, DK-8000 Århus C, DENMARK, (6)Aarhus University, Aarhus, DENMARK*

Background: Maternal smoking in pregnancy is a preventable but common exposure thought to lead to neurodevelopmental problems in offspring such as attention deficit hyperactivity disorder (ADHD). Epidemiological studies have evaluated its role in autism with inconsistent findings. Resolving links between maternal smoking and autism is especially difficult because of strong confounding by social class and genetic factors that influence smoking behavior and autism occurrence.
Objectives: To examine whether maternal smoking in pregnancy increases the risk of autism spectrum disorder (ASD), with a focus on disentangling individual and familial effects to account for confounding.
Methods: The study cohort comprised all children born in Denmark in 1991 through 2012 with complete parent and maternal smoking information. The cohort (1,294,906 persons, including 993,301 siblings nested within 728,271 families) was followed from 1 year of age until an ASD diagnosis (13,547), death, emigration, or December 31, 2012. Diagnoses of ASD and the presence of co-occurring ADHD (3319 ASD+ADHD and 10,228 ASD-ADHD) were based on ICD-8 and ICD-10 codes from psychiatric and patient register databases. Maternal smoking data were obtained from the birth register as reported by the mother to her midwife at the first prenatal care visit.Â We estimated adjusted hazard ratios (aHR) and 95% confidence intervals (95% CI) between any maternal smoking and ASD using Cox survival models and robust standard errors to account for familial clustering, adjusting for child sex, parity, parental age, education, income, psychiatric case history, and calendar year. To separate familial from individual effects, we constructed similar models that included a term for the mean level of maternal smoking in the family and the individual's deviance from the family mean (maternal propensity model). A third modeling approach stratified on maternal siblings and considered siblings discordant for maternal smoking in pregnancy to account for unmeasured confounding at the family level.
Results: In the cohort, 21.5% of individuals had a report of maternal smoking in pregnancy. In standard adjusted models, the risk for ASD was slightly elevated for maternal smoking: aHR 1.17 (95% 1.13-1.22). The risk for ASD from smoking was attenuated, however, based on either the maternal propensity model, aHR 0.98 (95% CI 0.88-1.09) or the discordant sibling analysis, aHR 0.86 (95% CI 0.64-1.15). In standard adjusted models of case subgroups, the risk for ASD+ADHD from smoking was higher: aHR 1.54 (95% CI 1.40-1.68) than for ASD-ADHD: aHR 1.09 (95% CI 1.03-1.16), and both were attenuated in the maternal propensity model: ASD+ADHD aHR 1.15 (95% CI, 0.89-1.40) and ASD-ADHD aHR 0.93 (95% CI, 0.82-1.06).
Conclusions: An association between maternal smoking in pregnancy and ASD diagnosis was observed after adjusting for a range of confounding variables, but was attenuated following designs that more fully accounted for unmeasured factors at the family-level, with similar effects observed for ASD with and without co-occurring ADHD. These results suggest that maternal smoking in pregnancy is not a risk factor for ASD and that elevated associations reported in previous studies may arise in part from not fully accounting for confounding influences at the family level.

175 **143.175** Geographic Differences Among Children with Autism Spectrum Disorders

B. Zablotsky *and S. J. Blumberg, National Center for Health Statistics, Hyattsville, MD*

Background: There have been few nationally representative surveys that have explored geographic differences among children with autism spectrum disorder (ASD). Yet, regional differences may provide insight into what factors influence the likelihood that a child is diagnosed with ASD and whether the child is able to receive necessary services and treatments. In fact, previous studies have found varying rates of unmet needs and service utilization by geographic region (Chiri & Warfield, 2012; Lokhandwala, Khanna, & West-Strum, 2012). The current study expands the limited literature by analyzing regional differences in ASD prevalence and service utilization within a nationally representative sample of children.
Objectives: 1) Calculate the prevalence of ASD in four geographic regions (Northeast, Midwest, South, West), 2) Explore child and household demographic characteristics and the service utilization of children with ASD in each of these four geographic regions.
Methods: Data were drawn from the 2014-2015 National Health Interview Survey (NHIS). NHIS is a nationally representative household survey of the noninstitutionalized US population. Respondents (usually parents) provided information on receipt of an ASD diagnosis and service utilization (among other topics) for one randomly selected child in each family. Children aged 3-17 years were included in this analysis.
Prevalence estimates were calculated using Stata 13.1 SE, which accounted for the complex survey design of the NHIS. Differences between geographic regions were compared using logistic and linear regressions with and without adjustment for child and household characteristics.
Results: The prevalence of ASD was highest in the Northeast (3.14%), followed by the Midwest (2.57%), South (2.15%) and West (1.86%). Without adjustment, children in the Northeast were significantly more likely to be diagnosed with ASD than children in the South and West. After adjusting for child and household demographics, children in the Northeast remained significantly more likely to be diagnosed with ASD than children in the West, but not the South.
Children with ASD living in the Northeast were the most likely to live in households with an annual income 400% or higher than the federal poverty level and live in two parent households. The majority of children with ASD in the Northeast lived in a large metropolitan statistical area (69.4%) and were non-Hispanic white (70.5%). Children with ASD located in the Northeast were younger than children with ASD in the Midwest.
Overall, the frequency of service utilization (number of office visits, ER visits, home visits) was highest among children with ASD in the Northeast, but this difference was not significant after adjusting for child and household demographics. However, even after adjustment, children with ASD in the Northeast were significantly more likely to have seen a specialist, therapist, or mental health professional in the past twelve months.
Conclusions: There were notable demographic differences among children with ASD between regions. These differences accounted for observed differences in the frequency of service use, but regional differences in specialized service use remained significant.

176 **143.176** Improving the Identification of ASD Cases from Claims Data Using Machine Learning and Latent Class Analysis

M. Brucato[1], *C. Ladd-Acosta*[2], *R. Musci*[3], *X. Hong*[1], *D. M. Caruso*[4], *M. D. Fallin*[5], *X. Wang*[6] *and E. Stuart*[7], *(1)Johns Hopkins University School of Public Health, Baltimore, MD, (2)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)Johns Hopkins University, Baltimore, MD, (5)Department of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD, (6)Johns Hopkins University School of Public Health, Baltimore, MD, (7)Johns Hopkins School of Public Health, Baltimore, MD*

Background: Current methods for identifying ASD cases in electronic medical records, particularly when restricted to claims data and without access to notes or laboratory results, rely on the presence of specific diagnostic codes (299 and its children for ICD-9-CM). Claims datasets are a potential source of data for establishing studies with large sample sizes, but ICD-9-CM diagnoses are prone to error and are limited in their sensitivity and specificity when compared to gold standard diagnostic measures. However, the considerable co-morbidity in ASD may allow the utilization of other, non-ASD diagnoses to improve identification of potential ASD cases in claims datasets, in addition to distinguishing clinically relevant ASD subtypes.
Objectives: We aim to improve our ability to identify ASD cases from claims data, exploiting the full amount of variability in ICD-9-CM diagnoses, using machine learning and latent class analysis.
Methods: We used data from the Boston Birth Cohort (BBC), a prospective birth cohort that enrolls predominantly urban, low-income minority mothers and their children. We restricted our analysis to the 2992 children with claims data available from the era of ICD-9-CM (1 Oct 2003 – 30 Sept 2015). Of these children, 771 were given the Social Communication Questionnaire (SCQ) by research staff.
In the 771 patients with SCQ data, random forests were used to identify the specific ICD-9-CM codes, out of over 2500 unique codes present in the claims data, most predictive of the continuous SCQ score. The codes with the highest importance criteria in the random forest were used as indicators in a Latent Class Analysis (LCA) of the full dataset (n=2992).
We compared the LCA-based diagnostic results to using the simple presence of ASD-specific ICD-9-CM hospital diagnosis codes (299.00, 299.80, 299.90) from pediatric outpatient, inpatient, and emergency room visits, which is the current standard in studies that are limited to claims data.
Results: Â Using random forests, we identified the 14 ICD-9-CM codes most predictive of SCQ score. These codes were used as indicators in LCA of the full dataset (2992 children). LCA identified four classes among the subjects; one class (93% of the sample) had a low probability of a 299 code or other developmental diagnoses (normal class), while one class (4% of the sample) had a high probability of carrying a 299 diagnosis (ASD-type class). When compared to the standard ASD definitions (n=120), the ASD-type class derived from LCA was smaller (n=113). There were 9 children who carried a 299 code but did not cluster within the ASD-type class; and there were 2 children who did not carry a 299 code but were assigned to the ASD-type class on the basis of other characteristics. These children may represent false positive and false negative ASD cases, respectively, when using the standard ICD-9-CM-based identification.
Conclusions: Machine learning and LCA show promise in improving ICD-9-CM-based ASD case identification. This may also help in identifying subgroups of children with ASD based on their clinical heterogeneity.

177 **143.177** In Utero Pyrethroid Pesticide Exposure and Child Cognitive Development from 6 to 36 Months in the Marbles Longitudinal Cohort

J. Barkoski[1], *D. Bennett*[1], *S. Ozonoff*[2], *D. J. Tancredi*[3], *D. Barr*[4] *and I. Hertz-Picciotto*[5], *(1)University of California, Davis, Davis, CA, (2)Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (3)UC Davis School of Medicine, Sacramento, CA, (4)Rollins School of Public Health, Emory University, Atlanta, GA, (5)University of California at Davis, Davis, CA*

Background: Associations between prenatal pesticide exposure and both autism spectrum disorder (ASD) and cognitive delays have been reported. Pyrethroid pesticides have neurotoxicological properties but little is known about the effects of *in utero* exposure on child development.
Objectives: Assess the relationship between pyrethroid pesticide exposure during pregnancy and child cognitive development from 6 - 36 months.
Methods: Mother-child pairs (n=134) in the MARBLES (Markers of Autism Risk in Babies-Learning Early Signs) longitudinal birth cohort were examined. This cohort enrolled pregnant women who already had a child with ASD and, therefore are at increased risk (up to 20%) for having another child who will develop ASD. Maternal urine samples comprising an individual spot urine and a pooled sample of 3 individual spot urine samples (each at least a week apart), from each of the latter 2 trimesters were analyzed for pyrethroid metabolite 3-phenoxybenzoic acid (3PBA). To adjust for urine dilution 3-PBA concentrations were specific gravity (SG) corrected. To assess average exposure during the pregnancy period concentrations of 3-PBA from urine samples collected during each trimester of pregnancy were averaged and the intraclass correlation coefficient (ICC) and total number of urine samples for each pregnancy were used to compute weights for linear regression models of average 3-PBA concentration during pregnancy and Mullen Scales of Early Learning (MSEL) scores.
Results: Subjects had median SG-adjusted 3-PBA concentration= 0.78 ng/ml and ICC = 0.34. After applying weights to 3PBA concentrations and adjusting for SG, child's sex, prenatal vitamin use and maternal education, we found significantly lower MSEL Composite (β= -0.79, *p*=0.003), Visual Reception (β= -0.80, *p*=0.001), and Fine Motor (β= -0.32, *p*=0.02) scores at 6 months.
Conclusions: This may be the first study to assess a biomarker of pyrethroid exposure, with the use of multiple urine samples, from both the 2nd and 3rd trimesters during pregnancy in relation to child cognitive development from 6-36 months. We observed lower scores on the MSEL at 6 months however this effect was attenuated by 12 months. These findings suggest *in utero* 3-PBA concentrations are not strongly related to child cognitive development. Previous literature on this topic is inconsistent, which in part could be due to exposure misclassification because previous studies used a single spot urine sample to assess exposure. A single urine sample from pregnancy will not capture long-term exposure for pyrethroids due to their quick metabolism. *A priori* we had expected that if prenatal pyrethroid exposure affected child cognition, this effect would be consistent across ages. The 6-month results could be a chance finding and/or the lack of association at 12 months or older could reflect confounding factors that are influential at later ages. These are preliminary findings from an ongoing study. Results will be updated with a larger sample, more rigorous measurement error modeling approaches, results from additional urine samples, and analyses of trimester specific 3-PBA concentrations.

178 **143.178** Infections in Children with Autism Spectrum Disorder: Study to Explore Early Development

K. R. Sabourin[1], *A. M. Reynolds*[2], *D. E. Schendel*[3], *S. Rosenberg*[4], *L. A. Croen*[5], *J. Pinto-Martin*[6], *L. A. Schieve*[7] *and C. DiGuiseppi*[8], *(1)Epidemiology, Colorado School of Public Health, Aurora, CO, (2)University of Colorado Denver, Aurora, CO, (3)Aarhus University, Aarhus, DENMARK, (4)University of Colorado, Aurroa, CO, (5)Kaiser Permanente Division of Research, Oakland, CA, (6)University of Pennsylvania, Philadelphia, PA, (7)Centers for Disease Control and Prevention, Atlanta, GA, (8)University of Colorado - Denver, Aurora, CO*

Background:
Immune system abnormalities have been widely reported as a component of autism spectrum disorder (ASD); childhood infections may be an expected outcome of these abnormalities. In addition, there have been some limited studies linking childhood infections, including ear infections and specific viral infections, to autism. However, these studies have provided mixed results. Further, potential differences in infection risk in regressive versus non-regressive ASD have not been extensively examined.
Objectives:
We examined caregiver report of clinically diagnosed infections in (1) children with ASD compared to non-ASD developmentally delayed/disordered (DD) controls and to non-ASD population (POP) controls and (2) children with regressive ASD compared to children with non-regressive ASD.
Methods:
The Study to Explore Early Development is a multi-site case-control study of ASD that enrolled children aged 30-68 months. ASD cases (n=707) were determined using standardized diagnostic instruments including the Autism Diagnostic Observation Schedule and the Autism Diagnostic Interview, Revised. DD controls (n=690) were recruited from educational or clinical settings. POP controls (n=898) were ascertained from birth certificates. Children with regressive ASD (n=310) were identified using Early Development Questionnaire (EDQ) scores. Whether the child ever had a clinically diagnosed infection in the first 3 years of life was reported by the child's primary caregiver. Associations between ASD and having ever had an infection were examined using multivariable logistic regression models adjusted for child sex, birthweight and gestational age, maternal race/ethnicity and education, and number of children in the home. Associations between regressive ASD and having ever had an infection were examined using multivariable logistic regression models, adjusted for child sex and maternal race/ethnicity and education. All analyses included a random intercept for enrollment site.
Results:
At least one clinically diagnosed infection in the first 3 years of life was reported for 51.5% of children with ASD, 40.3% of POP controls and 49.2% of DD controls; 34.6%, 33.4% and 37.2% of ASD, POP, and DD children, respectively, had more than one such infection. The odds of ever having had a clinically diagnosed infection were 1.6 times higher in ASD cases compared to POP controls (adjusted OR [aOR] = 1.6 [95% CI: 1.3, 2.0]). ASD cases and DD controls did not differ in their odds of ever having a clinically diagnosed infection before the age of 3 (aOR = 1.9 [0.9, 1.4]).
Among ASD cases, 50.9% of those with regressive ASD had ever had an infection compared to 53.9% of those with non-regressive ASD, while 33.1% and 37.1% of regressive ASD cases and non-regressive ASD cases, respectively, had more than one infection in the first 3 years of life. Those with regressive ASD did not differ in their odds of ever having an infection compared to those without non-regressive ASD (aOR = 1.2 [0.9, 1.6]).
Conclusions:
These results support earlier reports of greater infectious disease risk in children with ASD, but the risk does not appear to be unique to ASD overall, or regressive ASD specifically. An increased risk for childhood infections may be a shared feature among children with adverse neurodevelopmental outcomes.

179 **143.179** Investigating Polychlorinated Biphenyls and Cytokines in Autism Spectrum Disorder

E. M. Kauffman[1], *N. L. Lee*[2], *L. A. Croen*[3], *K. Lyall*[1], *M. D. Fallin*[4], *I. Hertz-Picciotto*[5] *and C. J. Newschaffer*[6], *(1)AJ Drexel Autism Institute, Philadelphia, PA, (2)Drexel University School of Public Health, Philadelphia, PA, (3)Kaiser Permanente Division of Research, Oakland, CA, (4)Department of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD, (5)University of California at Davis, Davis, CA, (6)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Polychlorinated biphenyls (PCBs) are persistent organic pollutants known to adversely affect neurodevelopment. Both cytokines and PCBs have independently been hypothesized to play a role in etiologic pathways of ASD, and PCBs have been shown to alter cytokine profiles. However, no study has examined the potential for cytokines to act as an effect modifier of the association between PCBs and ASD.
Objectives: This study examined whether there is an association between prenatal exposure to PCBs and ASD in a risk-enriched pregnancy cohort. This study also assessed whether levels of selected maternal circulating cytokines altered associations between PCBs and ASD.
Methods: Data are from the Early Autism Risk Longitudinal Investigation (EARLI) study, a risk-enriched longitudinal cohort in which women who had a child with ASD were enrolled during a subsequent pregnancy and followed through the sibling's third year of life. Based on clinical assessment at 36 months using DSM-5 criteria, 37 children were diagnosed with ASD, and 127 were non-cases and included in these analyses (n=164). Concentrations of 37 PCB congeners were measured in second trimester maternal serum samples; 29 cytokines and chemokines were measured in first available maternal plasma samples. Twelve PCB congeners (28, 74, 99, 118, 138/158, 153, 170, 180, 187, 194, 196/203, 199), a summed measure of all 12 congeners, and six cytokines (IL-1β, IL-2, IL-4, IL6, IL-8, and IFN-λ) had >60% of measures above limits of detection and were included in further analyses examining odds of ASD relative to typical development. Multivariable logistic regression analyses adjusting for maternal race and education, parity, smoking during pregnancy, and gender of child were run to assess the association between PCB congeners and ASD, parameterizing PCB concentrations in tertiles. The potential for effect modification by cytokine concentration was explored by comparing PCB levels in ASD cases and non-cases in subgroups defined by cytokine concentration above or below the median.
Results: PCB congeners 138/158 and 153 had the highest concentration in the total study population. There were no statistically significant differences in geometric means of individual prenatal PCB concentrations in ASD cases and non-cases. Adjusted associations were also not statistically significant. PCB 99 had the largest odds ratio estimate, OR=3.66, but the associated 95% C.I. was very wide (0.84-15.84) and two congeners, PCB 28 and 153, had adjusted OR point estimates below 1.0, also with wide confidence intervals. There was no suggestion of potential effect modification of PCB and ASD associations by cytokine level in our preliminary explorations.
Conclusions: The results of these analyses with prospectively collected biomarkers do not provide evidence supporting an association between prenatal PCB exposure and ASD risk. However, these results were based on only 164 subjects, and further investigation of prenatal exposure to these and other persistent organic pollutants is needed.

180 **143.180** Linking Department of Children's Services Records with ADDM Population Surveillance Methods

H. Dyer[1], *A. Vehorn*[2], *R. Brewster*[1], *M. Santulli*[1], *N. Bardett*[2], *Z. Warren*[3] *and R. Epstein*[4], *(1)Department of Pediatrics, Vanderbilt University Medical Center/Vanderbilt Kennedy Center, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Chapin Hall at the University of Chicago, Chicago, IL*

Background: Â Children with Autism Spectrum Disorder (ASD) and Intellectual Disability (ID) are thought (1) to be at increased risk for maltreatment and (2) to encounter the juvenile justice system at higher rates than children without these specific neurodevelopmental conditions. While previous work has linked educational classifications of developmental disabilities to child maltreatment concerns (Sullivan & Knutson, 2000), larger epidemiological studies specifically addressing ASD within child protection systems are more limited.
Objectives: Â The objectives of the current work were to utilize (1) identify potential ASD/ID cases in the Vanderbilt University Medical Center's (VUMC) electronic medical system using Centers for Disease Control and Prevention (CDC) Autism and Developmental Disabilities Monitoring network methodology (2) link identified children through Tennessee's Department of Children's Services database of encounters related to maltreatment and the juvenile justice system.
Methods: Â Tennessee's current ADDM surveillance cycle population includes 11 counties within middle Tennessee region; 28,414 postcensal estimate of eight-year olds born in 2006. Potential ASD/ID cases were identified by searching specific ASD/ID-related ICD codes and identifying behavioral triggers within comprehensive developmental evaluations in the VUMC medical record. Using an algorithm based on SSNs, names, and dates of birth these records were then linked to Tennessee's Department of Children's Services database (TFACTS) for evidence of any DCS involvement among this group of potential ASD/ID cases.
Results: Â This initial search through the VUMC medical records using ADDM methodology resulted in 421 potential ASD/ID cases. 153 of these children were also identified in the DCS system. This suggests individuals with ASD/ID symptomatology have a greater than 1 in 3 chance of having an encounter with DCS.
Conclusions: Â Past work on the prevalence of youth with psychiatric disorders in the juvenile justice system and in state custody (e.g., foster/adoptive placements) has consistently documented high rates of behavioral challenges. However, several methodological hurdles have limited understanding of the prevalence of children with ASD and ID within these care systems. Specifically, such investigations have often relied on reporter and/or survey strategies, focused on selected subsamples of convenience, and relied on small sample sizes. By using ADDM surveillance methodology we have been able to suggest that over 36% of identified potential ASD/ID cases have also had encounters with DCS.

181 **143.181** Is There Evidence of Intergenerational Influences on Autism?

M. E. Pembrey[1,2], *D. Rai*[3], *S. Gregory*[4], *K. Birmingham*[1], *J. Golding*[3] *and A. M. Emond*[5], *(1)Centre for Child and Adolescent Health, University of Bristol, Bristol, United Kingdom, (2)University College London, London, United Kingdom, (3)School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom, (4)Centre for Child and Adolescent Health, University of Bristol, Bristol, United Kingdom, (5)Centre of Child and Adolescent Health, University of Bristol, Bristol, United Kingdom*

Background: Mammalian experiments and human observations indicate that population variation in development and health is influenced by the early-life experience of parents and ancestors (Pembrey et al J Med Genet 2014; 51:563). For example, smoking in pregnancy by either grandmother is associated with the grandchildren's growth patterns in a sex-specific manner (Golding et al Am J Hum Biol. 2014; 26:731).
Objectives: We aimed to determine whether similar intergenerational effects of prenatal smoking could be demonstrated for autism.
Methods: We have used grandmothers' smoking behavior to test for associations with autism and autistic traits in their grandchildren. The Avon Longitudinal Study of Parents and Children (ALSPAC), which enrolled pregnant women in 1990-1992 has information on prenatal exposure of father (n=9677) and mother (n=12,707). Follow up of their offspring includes four traits independently predictive of autism, plus autism diagnosis itself. Trait measures used, identified in ALSPAC (Steer et al PLoS One 2010; 5(9):e12633), cover Social Communication, Speech Coherence, Repetitive Behaviour, and Sociability Temperament. The most extreme ~15% of each were used as outcomes in the analysis. Adjusted analyses took account of various features of the grandparents including years of birth, ethnic origin, ages, social categorisation and education level; separate analyses subdivided the data according to the sex of the child, and whether or not the study mother herself smoked prenatally.
Results: Three of the four traits tested showed an association with maternal grandmother smoking when pregnant. For two traits the effect sizes were greatest if the study child was a girl and the mother did not smoke e.g. for Social Communication the adjusted odds ratio (AOR) was 1.67 [95% CI 1.25, 2.25] (P= 0.001) and for Repetitive Behaviour 1.48 [1.12, 1.94] (P=0.005). The trait Speech Coherence showed a marginal effect with grandsons AOR 1.24 [1.02, 1.50] (P=0.030) but not granddaughters. 170 children monitored through pregnancy had a diagnosis of autism, again associated with maternal grandmother smoking in pregnancy when the mother did not smoke; AOR 1.53 [1.06, 2.20], (P=0.022). There were no associations with prenatal exposure of the study father.
Conclusions: There is evidence that some of the more extreme levels of behaviour traits predictive of a high risk of autism have an association with mothers (but not fathers) who have been exposed to their own mother smoking during pregnancy. Assuming that these findings are replicated in other studies, they raise the possibility that transgenerational exposures of other substances may influence the risk of traits leading to autism.

182 **143.182** Mercury Exposure in Pregnancy and Diagnosed Autism and Autistic Traits in the Offspring: Results from a Prospective Birth Cohort

J. Golding[1], *D. Rai*[2], *S. Gregory*[3], *K. Birmingham*[4], *C. M. Taylor*[3] *and A. M. Emond*[1,5], *(1)University of Bristol, Bristol, United Kingdom, (2)School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom, (3)Centre for Child and Adolescent Health, University of Bristol, Bristol, United Kingdom, (4)Centre for Child and Adolescent Health, University of Bristol, Bristol, United Kingdom, (5)Centre of Child and Adolescent Health, University of Bristol, Bristol, United Kingdom*

Background: For several decades mercury has been suspected of causing autism, leading to alarm over thiomersal-containing vaccinations and eating fish during pregnancy. Reviews of the literature have found few robust studies. The only prospective longitudinal study, based in the Seychelle islands, found no association between prenatal mercury levels and an autistic trait measure. Numbers were too small to assess relationships with diagnosed autism. Thus there is a need to determine whether there is prospective evidence of links between fetal exposure to mercury and autism or autistic traits.
Objectives: To determine the association between 1) prenatal exposure to mercury and 2) indirect measures of mercury levels during pregnancy, and the risk of diagnosed autism and of autistic traits in the offspring.
Methods: In the Avon Longitudinal Study of Parents and Children (ALSPAC), a large prebirth cohort in England, we used three strategies: (1) direct comparison of prenatal mercury levels in 48 cases of autism with 3837 controls; (2) comparison of prenatal mercury levels in those with high scores on each of four autistic traits with the rest of the population at risk (n~2800); (3) indirect measures of association of these outcomes with proxies for increased mercury levels such as frequency of fish consumption, and exposure to dental amalgam (n > 8000). We used logistic regression models adjusted for various potential confounders including maternal age, housing circumstances, maternal education and parity.
Results: The mean maternal whole blood mercury in the pregnancies resulting in an offspring with diagnosed autism was 2.10µg/L [SD 0.95] compared with 2.08[1.09]µg/L for the rest of the population. There was no evidence of an adverse effect of rising mercury levels on diagnosed autism [adjusted odds ratio (AOR) 0.89; 95% CI 0.65, 1.22] per SD of mercury (P = 0.485) or on any of the autistic trait measures. The proxy measures of exposure to mercury reported by the mothers also gave no indication of adverse associations with any of the autistic traits or of diagnosed autism.
Conclusions: There was no evidence that maternal prenatal blood mercury levels, or proxies for increased mercury exposure were associated with autism or autistic traits in this large population based study with prospective data.

183 **143.183** Maternal Height in Relation to Autism Spectrum Disorders in Offspring

L. Granillo *and R. J. Schmidt, University of California at Davis, Davis, CA*

Background: Increased testosterone levels and hyper-masculine physical traits have consistently been identified in individuals diagnosed with autism spectrum disorder (ASD); however, if parental risk factors such as increased testosterone are identified, then earlier prevention could be implemented.
Objectives: This project's aim is to examine whether maternal height, as a surrogate exposure variable for maternal testosterone, has an association with risk of bearing a child with ASD.
Methods: A subset of 121 children from the MARBLES cohort was included in a crude regression model. The MARBLES cohort, established in 2006 at the UC Davis MIND Institute in Sacramento, CA, is an ongoing prospective pregnancy cohort study. The cohort population is comprised of the younger sibling in high-risk families having at least one previous child with ASD, residing within 2.5 hours driving distance of the MIND Institute. The diagnostic criteria for an outcome of ASD or typical development was derived from an algorithm including scores on Mullen Scales of Early Learning and Autism Diagnostic Observation Schedule (ADOS) assessments at 36-months of age. Maternal height (cm) was collected and verified through medical records, maternal medical abstraction forms, environmental exposure questionnaires, and food frequency questionnaires. Logistic regression was performed to estimate the association between maternal height and ASD risk.
Results: No association between maternal height and ASD risk was found (OR=1.018, 95% CI: 0.967-1.072).
Conclusions: Â Crude evaluation of the relationship between maternal height and ASD did not find a link. Further analysis will be conducted to adjust for possible confounding and verify this lack of association. In addition, future work includes determining the validity of using maternal height as a surrogate variable for maternal testosterone by comparing height with measured testosterone, and studying the relationship between gestational testosterone concentrations and the child's ASD risk.

184 **143.184** Maternal Smoking during Pregnancy and Autism: Applying Genetic and Epigenetic Approaches in a Birth Cohort Study.

D. Caramaschi[1,2], *A. E. Taylor*[1,3], *R. C. Richmond*[1,2], *J. Golding*[2], *C. L. Relton*[1,2], *M. R. Munafò*[1,3], *G. Davey Smith*[1,2] *and D. Rai*[2], *(1)Medical Research Council Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom, (2)School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom, (3)School of Experimental Psychology, University of Bristol, Bristol, United Kingdom*

Background: An association between maternal smoking in pregnancy and autism may be biologically plausible, but the evidence to date is inconsistent. In particular, it is difficult to rule out the possibility of unobserved or residual confounding when investigating causal effects in observational studies. One way to address this is by using genetic variants as proxies of exposure in a Mendelian randomization framework. Furthermore, the possibility of measurement error in self reports of smoking is difficult to address. Since smoking during pregnancy is robustly associated with changes in DNA methylation, using this information by means of an 'epigenetic score' for smoking may be more reliable than self-reported smoking.
Objectives: We aimed to investigate the causal relationship between maternal smoking during pregnancy (measured by self-report and by a DNA-methylation score) and offspring autism and autistic traits using conventional analysis, Mendelian randomization and paternal smoking as a negative control.
Methods: We used data from the Avon Longitudinal Study of Parents and Children (ALSPAC), a large birth cohort study in the Bristol and surrounding areas of the UK. We investigated the effect of maternal smoking during pregnancy (exposure) on autism diagnosis and high scores on four autistic traits (outcomes) including the Social and Communication Disorders Checklist (SCDC) score, the Childhood Communication Checklist (CCC) coherence score, a score for repetitive behavior, and sociability subscale of the Emotionality Activity and Sociability temperament score. Maternal prenatal smoking was self-reported and also identified by computing a well-characterized DNA methylation score for adult smoking in the mothers when they were pregnant. Partners' smoking during pregnancy was used as a negative control for intrauterine exposure. Mendelian randomization was carried out using the genetic variation at the *CHRNA3*locus in maternal DNA, as a proxy for heaviness of smoking.
Results: In conventional analysis, there was an association between smoking during pregnancy and impairments in social cognition [OR=1.52, 95% CI=1.20,1.92] and repetitive behaviors after adjusting for sex, maternal age, parity, maternal education, social class and financial difficulties. There was no evidence of such associations for the other traits or a diagnosis of autism. Paternal smoking was also associated with similar odds as for mothers, of impairments in social cognition [OR=1.44, 95% CI=1.15,1.81] and repetitive behaviors suggesting shared confounding. There was no evidence of an association of smoking exposure measured through DNA methylation on the autism traits. Genetic variation at *CHRNA3* for heaviness of smoking was not associated with ASD or any of the autistic traits.
Conclusions: Our results do not support a causal association between maternal smoking during pregnancy and offspring autism or autistic traits. Previous studies finding such an association may have been prone to residual confounding.

185 **143.185** Medical History of Discordant Twins Indicates Environmental Etiologies of Autism

C. Willfors[1], *T. Carlsson*[2,3], *B. M. Anderlid*[4,5], *A. Nordgren*[5,6], *E. Kostrzewa*[7], *S. Berggren*[8], *A. Ronald*[9], *R. Kuja-Halkola*[10], *K. Tammimies*[8] *and S. Bolte*[11], *(1)Karolinska Institute Center for Neurodevelopmental Disorders, Stockholm, Sweden, (2)Karolinska Institutet Center for Neurodevelopmental Disorders, Pediatric Neuropsychiatry Unit, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (3)Prima Child and Adult Psychiatry, Stockholm, Sweden, (4)3Department of Molecular Medicine and Surgery, Center of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden, (5)Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden, (6)Department of Molecular Medicine and Surgery, Center of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden, (7)1Karolinska Institutet Center for Neurodevelopmental Disorders, Pediatric Neuropsychiatry Unit, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (8)Karolinska Institutet, Stockholm, SWEDEN, (9)Birkbeck College, London, UNITED KINGDOM, (10)Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden, (11)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Institutionen för kvinnors och barns hälsa (KBH), Karolinska Institutet, Stockholm, Sweden*

Background: The environmental contributions to Autism Spectrum Disorder (ASD) and their informative content for diagnosing the condition are still largely unknown. The assessment of monozygotic (MZ) twin pairs discordant for a phenotype, is a powerful design for exploration of environmental components in the etiology.
Objectives: The objective of this study was to investigate associations between ASD and early medical events and characteristics, in twins. In particular, the aim was to test the hypothesis of an environmental cumulative effect on ASD risk.
Methods: A total of 80 MZ twin pairs (13 were discordant for clinical ASD diagnosis) and 46 dizygotic (DZ) twin pairs, were examined for intra-pair differences in early medical events (e.g., obstetric and neonatal factors, first year infections) using anamnestic survey data. First, differences in early medical events were investigated using multisource medical records in the rare subsample of MZ twin pairs qualitatively discordant for ASD and matched typically developing (TD) pairs (N=52). Second, identified intra-pair differences specific to ASD diagnoses were tested in relation to autistic traits inÂ an independentÂ sample of quantitative discordant pairs (N=200), applying generalized estimating equations analyses.
Results: Intra-pair differences in both clinical ASD (Z=-2.85, p= .004) and autistic traits (β=78.18, p=.002) were associated with the cumulative load of early medical events when controlling for IQ and ADHD comorbidity in MZ pairs. This association wasÂ particularly drivenÂ by increased infant dysregulation (feeding, sleeping abnormalities, excessive crying and worriedness). NoÂ significant association were found in DZ pairs.
Conclusions: Â Early dysregulation, and foremost the cumulative load of early medical events, may index children at risk of ASDÂ owing to non-shared environmental contributions. Findings could facilitate screening and early detection of ASD.

186 **143.186** Is the Prevalence of Autism Associated with Maternal Ethnicity and Nativity?

R. Bruno[1], *M. Khalil*[2] *and M. Elsabbagh*[2], *(1)Research Institute of the McGill University Health Centre, Montreal, QC, CANADA, (2)McGill University, Montreal, QC, Canada*

Background:
The prevalence of autism is highly variable within and across geographic regions (Elsabbagh et al., 2012 Aut Res). Several factors have been proposed to explain this variability. Among these factors are differences in level of awareness and recognition as well as the availability of services in different communities. Previous research has suggested that socio-demographic factors such as maternal ethnicity and nativity are associated with prevalence, which may in turn explain some of the variability in estimates.
Objectives:
We conducted a systematic review to establish the reliability of association between sociodemographic factors and autism prevalence.
Methods:
We searched Medline and PsychInfo for manuscripts where association between autism prevalence and sociodemographic factors was investigated. We included research articles exploring ethnicity and nativity or immigration in relation to autism regardless of their design. By following PRISMA guidelines, this approach allowed for inclusion of large population studies from which quantitative data can be extracted to compare relative risk between groups as defined by these sociodemographic variables. Non-original articles and those not reporting prevalence estimates were excluded.
Results:
Our search identified 130 records, from which we retained 44 full text articles after screening and application of inclusion and exclusion criteria. Of these 16 original articles reported sufficient data on the association between prevalence and sociodemographic risk factors to be included in the final analysis. A meta-analysis was possible to conduct only for immigration status, where data extraction provided clearly differentiated risk estimates for immigrants vs. non-immigrants. The total population included in the analysis was 76.7 Million (321,188 individuals with ASD). Relative risk was 0.947 in immigrant group versus non-immigrant (CI- 0.66- 1.35, P<0.001). However, we also found significant heterogeneity in the estimates (Q = 1518.04, p < .0001), limiting confidence in the findings of the meta-analysis.
Conclusions:
Several strong claims have been made in the literature regarding the association between socio-demographic factors and autism prevalence. Our finding, using a systematic review methodology, suggests that the number of studies and their quality limits the validity of these claims. Our review also identified sampling biases where risk factors like ethnicity and immigration are more often than not confounded by other socio-demographic factors. Future studies need to also shift from post-hoc accounts and toward specific and biologically plausible hypotheses explaining how sociodemographic factors might impact autism prevalence.

187 **143.187** Metabolic Programming of Child Gastrointestinal Symptoms in Children with Autism Spectrum Disorder

P. Krakowiak[1], *C. K. Walker*[2], *R. Hansen*[3] *and I. Hertz-Picciotto*[4], *(1)2825 50th Street, UC Davis, Sacramento, CA, (2)University of California, Sacramento, CA, (3)UCD MIND Institute, Sacramento, CA, (4)University of California at Davis, Davis, CA*

Background: Gastrointestinal (GI) symptoms are highly prevalent in children with autism spectrum disorder (ASD), and growing evidence suggests that their etiology involves alterations in gut microflora, intestinal permeability, and activation of specific immune and metabolic pathways.
Objectives: Our goal was to explore whether fetal programming via maternal dysmetabolism during gestation might be associated with GI symptoms in child participants in the CHARGE (CHildhood Autism Risks from Genetics and the Environment) study.
Methods: The CHARGE Study is a population-based case-control investigation of ASD etiology. Children aged 24-60 months and living in catchment areas with a biological parent fluent in English or Spanish were enrolled 1/29/2013-5/7/2013. Children with ASD (n=550) and delayed development (DD, n=218) were recruited through the California Department of Developmental Services, the Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, and referrals. Controls with typical development (TD) (n=425) were randomly selected from birth records and frequency-matched on age, sex, and broad geographic region. Diagnoses of maternal metabolic conditions – including prepregnancy obesity, diabetes and chronic hypertension; maternal irritable bowel syndrome (IBS); mode of delivery and duration of breastfeeding were drawn from medical records and responses to structured interviews. Child GI symptoms of interest were drawn from maternal report, and included frequent diarrhea or constipation within three months of enrollment or at any time in the past. The Autism Diagnostic Observation Schedule and Autism Diagnostic Interview-Revised were used to confirm ASD, whereas children with DD and TD were confirmed by Mullen Scales of Early Learning and Vineland Adaptive Behavior Scales and were free of ASD symptoms.Â Preliminary analyses of symptom frequencies were compared across groups using Chi-square tests.
Results: Â As reported previously, both past and recent diarrhea and constipation frequency were 4-6 times more common in children with ASD and DD compared to TD controls (26.0%, 18.8% vs. 4.7%; p<0.0001). Current and past GI symptoms were more common in children born to mothers diagnosed with metabolic conditions (23.7% vs. 16.7%; p=0.07). Statistically significant differences were seen in children born by cesarean (19.5% vs. 14.7%; p=0.04), and whose mothers had IBS (28.7% vs. 15.1%; p=0.002). In analyses stratified by diagnostic group, current GI symptoms remained more prevalent in all children whose mothers had IBS (ASD: 34.1% vs. 24.1% p=0.15; DD: 40.0% vs. 18.2% p=0.04; 14.3% vs. 3.4% p=0.01).
Conclusions: Our findings support a relationship between maternal dysmetabolism during pregnancy and increased frequency of GI symptoms in children, suggesting a disruption in the development of beneficial gut microflora in the offspring. Metabolic conditions are associated with both IBS and labor complications that increase risk for cesarean delivery. Children of mothers with IBS or birth by cesarean were likely to have frequent GI symptoms. It has been postulated that cesarean birth alters "seeding" of the intestinal microbiome, leading to long-term changes in colonization and immune development.Â Other environmental and genetic factors likely play a role in GI disturbances particularly prevalent among children with ASD or DD. Further efforts are needed to characterize mechanisms underlying the relationship between maternal dysmetabolism and GI symptoms in the offspring.

188 **143.188** Neonatal Jaundice in Association with Autism Spectrum Disorder in the Child

C. Cordero[1], *L. A. Schieve*[2], *L. A. Croen*[3], *C. Seashore*[4] *and J. L. Daniels*[5], *(1)The University of North Carolina-Chapel Hill, Carrboro, NC, (2)Centers for Disease Control and Prevention, Atlanta, GA, (3)Kaiser Permanente Division of Research, Oakland, CA, (4)Pediatrics, UNC Chapel Hill, Chapel Hill, NC, (5)University of North Carolina, Chapel Hill, NC*

Background: Several neonatal complications have been studied in association with autism spectrum disorder (ASD). The most common complication, neonatal jaundice, is inconsistently defined across studies and is also inconsistent in showing an association with ASD. However, neonatal jaundice can be indicative of high bilirubin levels that may result in neurological damage and should be appropriately investigated in association with ASD.
Objectives: To examine associations between neonatal jaundice or hyperbilirubinemia and ASD in 2-5 year old children.
Methods: Our analysis uses the Study to Explore Early Development (SEED), a multi-site, case-control study. Children born from 2003-2006 were enrolled in SEED at 2 to 5 years of age. Developmental assessment in the clinic was used to classify children into three groups based on presence of ASD (n=702), a wide-range of non-ASD developmental delays or disorders (DD; n= 891), or non-ASD controls drawn from the general population (POP; n=983). Infants with jaundice in the first 28 days of life were identified from neonatal medical records and maternal interviews. A diagnosis was classified as definite if the infant received treatment for jaundice, as probable if there was no treatment but a diagnosis was available in the medical record, or possible if the mother reported jaundice, but there was no medical record (16%), it was not complete (19%), or it was complete but no jaundice or treatment reported (65%). Hyperbilirubinemia was classified using bilirubin levels, when available in the medical record. We examined the associations between neonatal jaundice and case status (ASD and DD groups to POP), as well as hyperbilirubinemia and case status, using adjusted multivariable logistic regression models. Odds ratios were adjusted (aOR) for sex, race/ethnicity, gestational age, maternal age, maternal education, maternal diabetes, and parity.
Results: From a sample of 2,576, we identified 1,239 infants (48.1%) with neonatal jaundice, of which 626 (50.5%) were definite, 378 (30.5%) were probable, and 235 (19%) were possible. Of 1,419 infants born ≥35 weeks gestation with bilirubin levels available, 88 (6%) were classified as having hyperbilirubinemia (bilirubin levels in the 95thpercentile). For neonatal jaundice in association with ASD vs. POP, we obtained an aOR=1.17 (95% confidence interval (CI) 0.93, 1.47). A slightly stronger, non-significant association with ASD vs. POP was observed for definite jaundice (aOR=1.29; 95% CI 0.95, 1.75). No associations were found for probable or possible jaundice and ASD. Significant associations were present when comparing DD vs. POP for neonatal jaundice (aOR=1.34; 95% CI 1.09, 1.65) and for definite jaundice (aOR=1.73; 95% CI 1.32, 2.27). A significant association was also observed for hyperbilirubinemia comparing DD vs. POP (aOR=1.87; 95% CI 1.03, 3.40), but non-significant comparing ASD vs. POP (aOR=1.28; 95% CI 0.65, 2.53).
Conclusions: Our results did not show a statistically significant association between neonatal jaundice and ASD or between hyperbilirubinemia and ASD. However, neonatal jaundice and hyperbilirubinemia were each significantly associated with an increased odds of DD. Further investigations are needed to confirm the association between high bilirubin levels and DD, and if there is a higher risk for any specific developmental disorder.

189 **143.189** Newborn Vitamin D Levels in Relation to Autism Spectrum Disorders; A Case-Control Study in California

G. C. Windham[1], *M. Anderson*[2], *D. Eyles*[3], *L. Weiss*[4], *M. Traglia*[4], *K. Lyall*[5], *M. Kharrazi*[1] *and L. A. Croen*[6], *(1)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (2)Impact Assessment, Inc., Richmond, CA, (3)Queensland Brain Institute, University of Queensland, Brisbane, Australia, (4)Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, San Francisco, CA, (5)AJ Drexel Autism Institute, Philadelphia, PA, (6)Kaiser Permanente Division of Research, Oakland, CA*

Background: Explanations for the continuing rise in the prevalence of Autism Spectrum Disorder (ASD) are urgently needed, so environmental factors are important to consider, as well as gene-environment (GxE) interactions. Vitamin D deficiency/insufficiency also appears to be increasing over recent decades. Emerging evidence suggests vitamin D may be related to risk of ASD, given advances in the understanding of its role in brain and immune function. Prior studies of ASD have generally examined surrogates of vitamin D (e.g. latitude, season) or levels in children already diagnosed, rather than the more likely susceptibility period during early development.
Objectives: To investigate the association between measured perinatal vitamin D deficiency/insufficiency and ASD in the Early Markers for Autism (EMA) study.
Methods: We conducted a population-based case-control study among children born in 2000-2003 in Southern California whose mothers had participated in prenatal and newborn screening and had banked biospecimens available. Autism (N=563) was identified from the Department of Developmental Services (DDS) and confirmed by expert clinician record review. General population controls (N=436) were randomly selected from birth certificates of children not served by DDS born in the same region and years. 25-Hydroxyvitamin D (25OHD) metabolites were measured in newborn dried blood spots by a sensitive assay, and hematocrit-corrected. The distribution of total 25OHD was compared between ASD cases and controls, and by potential confounding factors. For this presentation we categorized vitamin D levels as deficient (<50nmol/L), insufficient (50-74 nmol/L) and sufficient (≥75 nmol/L). Crude and adjusted odds ratios (AOR) and 95% confidence intervals (CI) were calculated by logistic regression. Further, we examined associations by newborn genotype for SNPs associated with vitamin D levels, and in subgroups defined by maternal race/ethnicity, parity, and child sex.
Results: Â The median OHD level was 85.3 nmol/L; 14% of infants were classified deficient and 26% insufficient. OHD levels were lower (or deficiency more frequent) for winter births, higher birth order, non-White maternal race/ethnicity, and lower maternal education, as well as shorter time to blood draw. OHD levels were similar between cases and controls. Adjusting for a number of potential confounders did not change these patterns; the AOR (95%CI) for deficiency was 0.95 (0.64-1.4) and for insufficiency was 1.2 (0.86-1.6). While some variation in effect estimates were observed among the sub-groups examined, including the genotype at missense SNP rs4588 in vitamin D transport gene *GC,* confidence intervals were relatively wide and overlapped.
Conclusions: This is the first large study to examine newborn vitamin D in relation to autism, with no association seen. The relatively low rate of Vitamin D deficiency limited small sub-group analyses. Prior studies reporting lower Vitamin D levels in children with autism or their mothers, after diagnosis, may reflect current lifestyle and diet. In the more developmentally relevant time period, studies have found lower prenatal maternal OHD levels associated with language difficulties and mental and psychomotor outcomes in offspring, supporting the need for additional research on autism. We plan to examine second trimester maternal vitamin D levels in this study population in the future.

190 **143.190** Patterns of Service Utilization Among Children with Autism Spectrum Disorder: A Cluster-Analysis of the 2011 Pathways to Diagnosis and Services Survey

A. E. Epstein[1], *S. E. O'Kelley*[2] *and M. Wingate*[1], *(1)Health Care Organization and Policy, University of Alabama at Birmingham, Birmingham, AL, (2)University of Alabama at Birmingham, Birmingham, AL*

Background:
Despite extensive examination of demographic factors such as race-ethnicity and socio-economic status and how they are related to ASD identification, severity, and access to services, research has not been conducted at a nationally-representative level. In addition, cluster analysis as a method has only rarely been applied to this topic. When cluster analysis has been used, it has examined symptoms and phenotypes.
Objectives:
The objective of this project is to determine whether there are groups of children with ASD that have similar patterns of service utilization, access, or treatment type. Subsequent analysis will determine whether these clusters differ with regards to functional status, race, ethnicity, sex, and/or insurance coverage.
Methods:
Data from the 2011 Survey of Pathways to Diagnosis and Services (Pathways) were used in this analysis. Developed as a follow-up to the 2009/10 National Survey of Children with Special Health Care Needs, Pathways measures parental report of the emergence of symptoms, diagnosis, and use of services among children with intellectual disability, developmental disability, and ASD. The sample for this analysis was limited to include only children with complete data on variables of interest in the principal components analysis (n=324). Principal component analysis (PCA) was performed on 39 items from the Pathways Survey related to types of services and medication utilized and services not covered by health insurance. Once factors were determined, summated scores were calculated using the items that comprised each factor. These scores were used to develop a cluster analysis identifying groups of individuals whose service utilization and treatment represent similar, meaningful patterns. Post-hoc analyses were performed to name and describe distinct clusters. Analyses will be performed to examine potential differences between clusters with regards to functional status, race, ethnicity, sex, and/or insurance coverage.
Results:
The PCA revealed four factors related to utilization of medication, school-based, and non-school-based services, as well as report of services not covered by insurance. Four clusters emerged based on these factors. The largest cluster included 36.4% of the sample and was defined by high use of both school-based and non-school-based services with low medication use. One quarter (25.3%) of the sample was characterized by high utilization of both medications and services. The smallest cluster (15.7%) was characterized by high medication usage and low service utilization. The remaining cluster (22.5% of the sample) is characterized by higher levels of "not covered" services according to parents, though there do not appear to be remarkable patterns of lower utilization.
Conclusions:
Results show that there are distinct patterns of how children in the Pathways survey access services. Although the majority of the population in this analysis was defined as having high utilization of services and low medication usage, there were other segments of the population that varied in the utilization of service and medication usage. This suggests that the access issues may be related to demographics, access to care, and severity. Subsequent analyses studies will explore differences between clusters and potential disparities.

191 **143.191** Prenatal Air Pollution Exposures, Maternal Cytokine/Chemokines, and Risk of Autism Spectrum Disorder: The Early Markers for Autism (EMA) Study

H. E. Volk[1], *L. A. Croen*[2], *G. C. Windham*[3], *D. B. Campbell*[4], *K. L. Jones*[5], *J. Van de Water*[5], *B. Y. Park*[6], *F. Lurmann*[7] *and P. Ashwood*[8], *(1)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Kaiser Permanente Division of Research, Oakland, CA, (3)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (4)University of Southern California, Los Angeles, CA, (5)University of California at Davis MIND Institute, Davis, CA, (6)Johns Hopkins Bloomberg School of Public Health, Philadelphia, PA, (7)Sonoma Technology Inc, Petaluma, CA, (8)UC Davis, Sacramento, CA*

Background: Increasing evidence suggests that both air pollutants and immune system dysregulation may be associated with adverse neurodevelopmental outcomes, including autism spectrum disorder (ASD). The relationship between these two risk factors has not been studied prenatally.
Objectives: In this study, we examined the relationship between mid-gestational air pollution exposures and levels of maternal serum cytokines/chemokines to determine their potential combined associations with risk of ASD.
Methods: Study participants were from a large population-based, nested case-control study of archived maternal mid-pregnancy specimens from the same mother-infant pairs from Southern California. Study groups were identified through the linkage of California birth records, Department of Developmental Services (DDS) records, and the California Prenatal and Newborn Screening Program records. This study includes mothers of children with ASD (n=378), intellectual disability (ID) but not ASD (ID; n=165),or children with no known neurodevelopmental disability from the general population (GP; n=416). The ASD group was further divided into those with ID (DQ<70) (ASD+ID; n=181) and those without (DQ ≥70) (ASD-noID; n=197). To estimate air pollutant exposure during the second trimester of pregnancy, maternal residential addresses reported during prenatal screening visits and on the infant's birth certificate were used. Regional air pollutant measures (NO_2, PM_{10}, $PM_{2.5}$, Ozone, NO) based on the Environmental Protection Agency's Air Quality System data were averaged for one month before the maternal serum sample collection date. Stored maternal serum samples, collected during weeks 15-19 of gestation for routine prenatal screening, were quantified for 22 cytokines/chemokines using Luminex multiplex analysis technology. Correlations between prenatal levels of air pollutants and maternal cytokines/chemokines were examined separately for each case group using Spearman's correlation. Resulting correlations were then compared between each diagnostic group and GP controls using Fisher's z-transformation to assess whether correlations between exposures and cytokine/chemokines differed across groups.
Results: The correlation between measured air pollutants and maternal cytokines/chemokines were generally weak (<0.2 in absolute value). Distinct patterns of correlation between cytokines/chemokines and air pollutants were observed for each diagnostic group. For example, the correlations between the allergy and asthma-associated cytokine IL-4 and NO_2 (p=0.03) and PM_{10} (p=0.01) differed significantly between the ID and GP groups, and were greater in magnitude among ID, while a significant difference in the magnitude of correlation between ozone and IL-4 showed an inverse relationship in ID (p=0.01). The magnitude of association between IL-4 and ozone was significantly different for ASD+ID than for GP (p=0.04) and showed inverse association among ASD+ID. No significant differences in the magnitude of correlation between air pollutants and cytokines/chemokines were found between ASD-noID and GP groups. Additional analyses will quantify relationships between ASD risk and joint effects of air pollution and maternal immune markers, as well as explore potential mediation.
Conclusions: Correlations between mid-gestational maternal cytokines/chemokines and air pollutants varied in direction and magnitude across the different diagnostic groupups. The observed relationships between prenatal air pollutant exposures and maternal cytokines/chemokines may thus provide further insight of their potential role(s) in neurodevelopment, particularly in the context of risk of ASD and ID.

192 **143.192** Prenatal Polybrominated Diphenyl Ether (PBDE) Exposure and Social Cognition at Age 14

M. H. Harris*, S. Sagiv, K. G. Harley, K. Kogut, J. Deardorff, A. Bradman and B. Eskenazi, UC Berkeley School of Public Health, Berkeley, CA*

Background: An accumulating body of literature has linked prenatal exposure to polybrominated diphenyl ethers (PBDEs), chemicals used as flame retardants in furniture, electronics, textiles and other consumer products, to behavior problems in childhood, suggesting that PBDEs may act as developmental neurotoxicants in humans. Epidemiologic findings to date on PBDE exposure and autism spectrum disorder (ASD) are very limited. In the CHAMACOS (Center for the Health Assessment of Mothers and Children of Salinas) study, a birth cohort of predominantly Mexican-Americans in an agricultural region of California, prenatal PBDE exposure was associated with poorer attention, fine motor coordination, and cognition at ages 5-7 and poorer attention and executive function at ages 9-12.
Objectives: To examine the influence of prenatal exposure to PBDEs on social cognition, a trait impaired in individuals with ASD, in early adolescence.
Methods: We measured concentrations of 4 common PBDE congeners (BDE-47, 99, 100, 153) in blood contributed by CHAMACOS mothers during the second half of pregnancy (in 2000-2002). When children were aged 14 years, parents completed the Social Responsiveness Scale, Second Edition (SRS-2), a rating scale of traits related to ASD. Using generalized additive models, we examined associations of serum lipid-adjusted PBDE concentrations in relation to sex-standardized SRS-2 T-scores (population standard mean=50, standard deviation=10), with adjustment for child's age at SRS-2, breastfeeding duration, household income, maternal characteristics (age, parity, education, country of origin, years in the United States, pre-pregnancy body mass index, and IQ), and measures of maternal depression and support for cognitive development in the home.
Results: 147 children with SRS-2 scores, prenatal PBDE measures, and relevant covariates were included. Median (25%—75%) serum lipid-adjusted PBDE concentrations were: 15.0 ng/g lipid (8.7—24.5) [BDE-47], 3.7 (2.4—6.9) [BDE-99], 2.4 (1.6—4.2) [BDE-100], 2.0 (1.4—3.6) [BDE-153]. SRS-2 T-scores ranged from 41—88 with a mean (standard deviation) of 55.3 (7.8). Relationships of SRS-2 T-scores with log10-tranformed PBDE concentrations appeared linear, and scores were higher (representing more autistic behaviors) among children whose mothers had higher concentrations of BDE-153 in pregnancy (β=3.5; 95% confidence interval (CI): -0.5, 7.5 per 10-fold increase in maternal BDE-153 concentration). SRS-2 scores did not appear associated with the other measured PBDE congeners or the sum of the four PBDE congeners (β=0.7; 95% CI: -3.0, 4.4).
Conclusions: Among young adolescents living in a low-income agricultural community, behaviors related to ASD appeared somewhat elevated in those with higher prenatal exposure to BDE-153, but not other measured PBDEs. BDE-153 is a component of the commercial flame retardants penta- and octabromodiphenyl ethers (penta- and octaBDEs), which were phased out of production in the United States in 2004 due to concerns about potential toxicity, but remain present in older consumer products.

193 **143.193** Prenatal Serum Levels of Brominated Flame Retardants in Association with Autism Spectrum Disorder and Intellectual Disability: Potential Sex Differences

K. Lyall[1], *L. A. Croen*[2], *L. Weiss*[3], *M. Kharrazi*[4], *M. Traglia*[3], *G. N. Delorenze*[2] *and G. C. Windham*[4], *(1)AJ Drexel Autism Institute, Philadelphia, PA, (2)Kaiser Permanente Division of Research, Oakland, CA, (3)Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, San Francisco, CA, (4)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA*

Background: Prior work suggests prenatal exposure to polybrominated diphenyl ethers (PBDEs) may have neurodevelopmental impacts. However, few human studies have prospectively examined levels of these chemicals during suspected critical windows of neurodevelopment in association with autism and other developmental disorders.
Objectives: To determine whether prenatal exposure to brominated flame retardants influences risk of autism spectrum disorder (ASD) or intellectual disability without autism (ID).
Methods: We conducted a population-based case-control study. Participants were from the Early Markers of Autism (EMA) study. Children with ASD (n=545) and ID (n=181) were identified from the Department of Developmental Services (DDS), with diagnoses confirmed by expert clinician review, and ASD cases meeting Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV-TR criteria. General population (GP) controls (n=418) were randomly selected from birth certificates of the same birth years as cases (2000-2003) after excluding those served by DDS. Concentrations of nine PBDE congeners and 2,2',4,4',5,5'-hexabromobiphenyl were measured in maternal 2nd trimester serum samples. Logistic regression was used to calculate crude and adjusted odds ratios (AOR) for associations with ASD, and separately for ID, compared to GP controls, by quartiles of analyte concentrations in primary analyses. Stratified analyses examined potential effect modification by offspring sex as well as potential differences by ASD with and without comorbid ID. Sensitivity analyses were conducted to test the robustness of results to a number of alternate modeling strategies.
Results: Six congeners were frequently detected in this study population and evaluated in further analysis. Levels of most PBDE congeners were lower in children with ASD or ID relative to GP controls. In adjusted analyses, inverse associations were found for ASD relative to GP, comparing the highest quartile of concentration to the lowest (AOR=0.56, 95% CI 0.38, 0.84 for BDE-153, and AOR=0.54; 95% CI 0.36, 0.80 for the sum of detected congeners). Results differed for odds of ASD when stratified by child sex, with estimates above the null in girls, and confidence intervals closely overlapping 1.0 for BDE-28 and -47. Similar patterns were observed for ID. No differences in risk were noted for ASD with or without ID. Sensitivity analyses did not alter findings.
Conclusions: Contrary to expectation, results did not suggest increased risk of ASD or ID with higher levels of prenatal PBDEs. However, these findings suggest potential sexual dimorphism in neurodevelopmental effects of prenatal exposure to brominated flame retardants.

194 **143.194** Prevalence and Comorbidities of Autism Spectrum Disorder and Study of the Method of the Developmental Health Checkup in a Japanese Community-Based Population Sample of Five-Year-Old Children

Y. Sakamoto[1], *M. Saito*[2], *S. Yoshida*[3], *M. Adachi*[4], *N. Takayanagi*[4], *S. Yasuda*[5], *M. Kuribayashi*[6] *and K. Nakamura*[7], *(1)Graduate School of Medicine, Hirosaki University, Hirosaki, JAPAN, Hirosaki, Japan, (2)Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, Hirosaki, JAPAN, (3)Research Centre for Child Mental Developmenta Hirosaki University Graduate School of Medicine, Hirosaki, JAPAN, (4)Hirosaki University, Hirosaki, JAPAN, (5)Research Center for Child Mental Development Graduate School of Medicine, Hirosaki University, Hirosaki, JAPAN, (6)Hirosaki University Research Center for Child Mental Development, Hirosaki, Aomori, JAPAN, (7)Hirosaki University, Aomori-Ken, JAPAN*

Background: In Japan, local governments perform pregnant women and infants' health check-up as a fundamental maternal-and-child-health service. However, it cannot completely pick up developmental disabilities, especially ASD at 18 months and 36 months old. Therefore, we have conducted five-year-olds developmental health check-up since 2013, and directly diagnosed developmental disorders using DSM-5. It allows investigating the prevalence of developmental disorders, andÂ proposing early identification and intervention.
Objectives: The purpose of this study is to investigate the prevalence and Comorbidities of ASD in a community-based population sample of five-year-old children. We also clarify the difference of clinical data between children with ASD or other developmental disorders and healthy controls.
Methods: This study was conducted as Hirosaki Five years check-up (HFC) study-assessing mental health among children in Hirosaki. Subjects are 3804 children who become 5 years old between April 2013 and March 2016 in Hirosaki city. 2923 children responded to the first screening (parents and teacher filled out ASSQ, SDQ, ADHD-RS, DCDQ, PSI-C). 607 children were above the cutoff point of the screenings. Finally, 440 children and their parents visited to the developmental health check-up including 31 applicants. Pediatricians and psychiatrists diagnosed neurodevelopmental disorder directly using DSM-5 criteria (ASD, ADHD, ID/BI) and EACD criteria (DCD), in addition, psychologists and Occupational therapists evaluated not only ASD symptoms but also cognitive and motor function using WISC-4, MABC-2, SCQ, AQ, PARS-TR short version. We estimated the rate of prevalence and comorbidities. In addition, we verified the availability of the screening and assessment tools.
Results: The prevalence rate of ASD was estimated at 3.20%. The comorbidities of ASD were ADHD (60.0%), DCD (61.1%) and ID/BI (40.0%). In the logistic regression analysis, the primary screenings which are combination of parent-ASSQ, ADHD-RS, PSI-C and teacher's SDQ showed 96.9% prediction diagnostic rate (R^2=.559). Similarly, the secondary assessment tools which are combination of MABC Total, AQ Total and PARS-TR short-version showed 86.2% prediction diagnostic rate (R^2=.479).
Conclusions: This is the first epidemiological study of a community-based population sample in Japan. These findings suggest that ASD children have plural comorbidities, in other words, ASD children suffer from severe disabilities than other disorders. ASSQ, ADHD-RS, PSI-C, SDQ is useful for screening and MABC-2, AQ, PARS-TR is available for diagnosis of 5-year-old ASD children.

195 **143.195** Prevalence of Autism Spectrum Disorders in the Public Schools

L. Dilly[1,2,3] *and K. Sargent*[1,2,4]*, (1)Marcus Autism Center, Atlanta, GA, (2)Children's Healthcare of Atlanta, Atlanta, GA, (3)Emory University School of Medicine, Atlanta, GA, (4)Georgia State University, Atlanta, GA*

Background: Current estimates of the prevalence of autism spectrum disorders (ASD) in the U.S. are 1 in 68 (1.5%) (Christensen, 2016). However, studies indicate that many children with an ASD health diagnosis do not have an ASD special education eligibility classification within the public schools (Pinborough-Zimmerman et. al, 2012). In the past, identification of ASD within the population has been shown to vary across geographic location and race (Daniels & Mandell, 2014; OSERS, 2016).
Objectives: The purpose of this study was to examine the prevalence rates of children classified as having autism spectrum disorders in special education in the 50 states. Differences in prevalence will be considered across ages groups (i.e., ages 3-5 and 6-12) to determine if older children are more likely to be classified as having ASD within the public schools. In addition, differences across US geographic regions were considered.
Methods: Publically accessible state level Child Count and Educational Environments data from the 2014-2015 school year collected by the US Department of Education (2016) through the *Individuals with Disabilities Education Act* (*IDEA*) Section 618 was used. Data related to the number of children with eligibilities in the areas of autism spectrum disorder and significant developmental delay from the 50 states and the District of Columbia were analyzed (Age 3-5 Autism N = 66,059; age 3-5 Significant Developmental Delay N = 278,194; age 6-11 Autism N= 255,505). In addition, 2014 state population estimates for children ages 3-5 years and 6-11 years were accessed through the US Census Bureau State Characteristics Datasets (US Census Bureau, 2014).
Results: The prevalence rate for children age 3-5 with an autism eligibility was .4% and with a SDD eligibility was 2.9%. There was a significant difference between the ASD eligibility prevalence for children age 3-5 and those age 6-11 (M = .95%; p <.001). For children age 3-5 years, prevalence rates of ASD special education eligibilities are higher in the Northeast as compared to those in the Midwest (p = .015) and South (p = .016). Similarly, for children age 6-11 years, prevalence rates of ASD special education eligibilities are higher in the Northeast as compared to those in the Midwest (p = .020), South (p = .006), and West (p = .013).
Conclusions: Considering the prevalence of ASD is 1.5% of the population and only .4% of young children were found to be receiving ASD specific services in the public schools, there is considerable room for improvement in the early detection of ASD through the public school system. This is of considerable importance as young children with ASD primarily receive intervention services through the public schools (Bilaver et al., 2016). As the public schools in the Northeast US are identifying more children with ASD, it would be beneficial to further explore their processes and resource allocation in order to determine if it could be generalized.

196 **143.196** Puberty Timing and Sexual Attraction in Autism Using a Nationally Representative Sample

T. May[1]*, K. Pang*[2]*, M. O'Connell*[2] *and K. Williams*[3]*, (1)Paediatrics, The University of Melbourne, Parkville, VIC, Australia, (2)Royal Children's Hospital, Parkville, Australia, (3)Developmental Medicine, The Royal Children's Hospital, Parkville, VIC, Australia*

Background:
Past research suggests there is more variation in sexual attraction and puberty timing in individuals with Autism Spectrum Disorder (ASD) using clinical and community samples, however, population representative data is lacking. Both sexual attraction and puberty timing are associated with sex hormones and may therefore inform on the androgen theory of ASD which proposes that excess androgens may cause ASD.
Objectives:
The present study utilised a population representative sample to explore sexual attraction at 14-15 years of age and indicators of puberty timing using data collected over four time points from ages 8-9 to 14-15 years in adolescents with and without ASD.
Methods:
Secondary analyses were undertaken using data from the Kindergarten (K) cohort from the Longitudinal Study of Australian Children (LSAC) which included 94 adolescents (73 males, 21 females) with parent reported ASD and 3,454 adolescents (1,685 males, 1,675 females) without ASD. Adolescents self-reported on sexual attraction. Timing of androgen and oestrogen driven pubertal events included facial hair growth, growth spurt, breast development, body hair, menstruation, and maternal puberty collected by parent report at ages 8-9, 10-11, 12-13, and child self-report at 14-15, were compared in those with and without ASD adjusting for demographic and child factors.
Results:
Adolescent males with ASD reported lower rates of heterosexual attraction (adjusted odds ratio: 0.384, p=.002), and a trend toward higher rates of not feeling any attraction to others (adjusted odds ratio: 2.79, p=.06) compared to non-ASD males. Females adolescents with ASD also reported lower rates of heterosexual preference (adjusted odds ratio: 0.14, p<.001), higher rates of bisexuality (adjusted odds ratio: 6.05, p<.001) and uncertainty in whom they were attracted to (adjusted odds ratio: 10.44, p<.001) compared with non-ASD females. Oestrogen driven puberty indicators (breast development, growth spurt, menstruation) completed earlier in girls with ASD (100% completed by 10-11 years) according to parent report. There was no difference in the timing of androgen driven puberty indicators in adolescent boys and girls with ASD relative to those without ASD. There was no difference in the age of menarche in mothers of girls (p=.71) and boys (p=.59) with or without ASD.
Conclusions:
The findings confirm in a population ascertained sample that adolescents with ASD have differences in sexual attraction compared with non-ASD peers and that these are present by early adolescence. The increased rate of bisexuality in females with ASD is consistent with the androgen theory of ASD, but the decreased rate of heterosexuality in males with ASD and the similarities in androgen driven puberty timing do not support the androgen theory of ASD.

197 **143.197** Record-Based ASD Annual Prevalence for Children Ages 0-8 in Taiwan, 2004-2013

Y. T. Wu[1], *Y. J. Li*[2] *and L. C. Lee*[3], *(1)School and Graduate Institute of Physical Therapy, National Taiwan University College of Medicine, Taipei, Taiwan, (2)Center of Genomic Medicine, National Taiwan University, Taipei, Taiwan, (3)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*

Background: In the past decade, global prevalence estimates of Autism Spectrum Disorder (ASD) are between 1-2% among children of all ages. Since higher recognition and changes in diagnostic practice and service availability, the number of people with ASD in Taiwan increased 10-20% as compared to a decade ago. However, the data were from the National Disability Registry system in Taiwan only includes children who are eligible for social assistance payments. Taiwan implements a National Health Insurance (NHI) program since 1995. NHI offers comprehensive and universal health insurance to all citizens.
Objectives: The objective of the study was to calculate the annual prevalence of ASD among 0 to 8-year-old children based on the National Health Insurance data from 2004 to 2013.
Methods: The study utilized the NHI database that includes 96% medical claims of all citizens. The diagnosis coding of the national data follows the International Classification of Diseases, Ninth Revision, Clinical Modification diagnostic criteria. Children who were 0 to 8 years old at each year and had an outpatient service claim with a diagnosis of ASD during 2004 to 2013 were defined as the case. The denominator of calculating the prevalence rate was the total number of 0 to 8 years-old children in the database each year. Annual percentage change of prevalence which is the change in rates yearly over 2004 to 2013 was calculated.
Results: The prevalent cases under 8 years of age were increasing from 5,455 cases in 2004 to 7,884 cases in 2013, whereas the total population for the children under 8 years of age were decreasing from 2,437,948 in 2004 to 1,763,147 in 2013. The prevalent rate of ASD increased from 2.24 in 2004 to 4.47 per 1,000 in 2013 (Table 1). The annual percentage change in ASD prevalence was 8.3% per year on average from 2004-2013, with a 99.5% increase from 2004 to 2013.
Conclusions: Â Using NHI claim data in Taiwan, the results showed that ASD prevalence increases over time from 2004–2013. The increasing trends we found is in line with reports from existingÂ studies. The increase of prevalence over the years could be in part due to the increase of awareness of the public. More investigation on potential factors that contribute to the increase of ASD diagnosis in children is warranted.

198 **143.198** Record-Based ASD Prevalence Estimates of 2004-2005 Birth Cohort in Taiwan

Y. T. Wu[1], *Y. J. Li*[2] *and L. C. Lee*[3], *(1)School and Graduate Institute of Physical Therapy, National Taiwan University College of Medicine, Taipei, Taiwan, (2)Center of Genomic Medicine, National Taiwan University, Taipei, Taiwan, (3)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*

Background: Â Previous studies in Taiwan reported the prevalence of autism spectrum disorder (ASD) among 3- to 17-year-olds was 2.1 per 1000 in 2011, with cumulative prevalence increased from 0.18 in 1996 to 2.87 in 2005 per 1000. However, these studies included children who were eligible for social assistance payments and retrospectively collected diagnostic information from clinical samples. The figures are therefore likely under-estimated the "true" prevalence. Prospective studies on ASD prevalence estimate, and the association between potential risk factors (e.g., prematurity, gender, geographical region, and urbanization) and ASD are limited.
Objectives: Â The objectives of the study are 1) to calculate the prevalent rate of ASD for children ages 0-8 in 2004-2005 birth cohorts; and 2) to examine the birth and demographic factors associated with the prevalence of ASD.
Methods: Â The study is a population-based cohort study with children born in Taiwan between 1 January 2004 and 31 December 2005, and had a claim documented in the National Health Insurance (NHI) database. NHI convers 96% of citizens of Taiwan. The prevalence of ASD was defined as those children who were born in the defined birth cohorts and have been diagnosed as ASD less than 8 years of age (before 2013). The denominator of calculating the prevalent rate was the total number of live births during 2004-2005. In addition, prematurity (gestational age < 37 weeks) and demographic characteristics (gender, region of residency, and urbanization) were also obtained from the database. Geographical distributions were classified into northern, central, southern, and eastern region. Urbanization was divided into urban and rural categories. Cox regression analysis was used to analyze the predictive factors for occurrence of ASD.
Results: The total number of children who were live birth in 2004-2005 were 424,299, and 6,086 of them were diagnosed as ASD between 2005 and 2013. The prevalent rate was 14.3 per 1,000 among 1- to 8-year-old children. Higher prevalent rates were shown in males (HR, 4.58; 95% CI, 3.28-6.38), premature babies (HR, 2.11; 95% CI, 1.80-2.47) and in those who lived in northern area compared to central area (HR, 2.21; 95% CI, 2.06-2.37); and in urban areas compared to rural areas (HR, 1.72; 95% CI, 1.62-1.83) (Table 1). Southern (HR, 1.20; 95% CI, 1.11-1.30), and eastern (HR, 1.26; 95% CI, 1.10-1.46) regions showed slightly higher prevalence of ASD than central area.
Conclusions: Using NHI claim data, our prevalence estimate for children under 8 years old in 2004/05 birth cohort is supported by reports from other countries. Factors of premature birth, male children, place of residence in northern and urban areas were associated with higher ASD prevalence. Our results indicated that the prevalence of ASD existed difference between urban and rural areas, and may be the consequence of uneven distribution of medical resources. Further researches may need to elaborate the association of distribution of medical care and ASD.

199 **143.199** Reliability and Validity of Self-Reported Home Environment in Autism Studies

P. Krakowiak[1]*, D. Bennett*[2]*, D. J. Tancredi*[3]*, I. Hertz-Picciotto*[4]*, C. K. Walker*[5] *and R. J. Schmidt*[4]*, (1)2825 50th Street, UC Davis, Sacramento, CA, (2)University of California, Davis, Davis, CA, (3)UC Davis School of Medicine, Sacramento, CA, (4)University of California at Davis, Davis, CA, (5)University of California, Sacramento, CA*

Background: Â Questionnaires can help advance research on environmental risk factors for autism when more detailed measurements are too expensive or not feasible, but only when these data are reliable and valid compared with gold standard measures.
Objectives: Â To compare maternal retrospective report of home characteristics that can be used to assess environmental exposures during pregnancy and until child's first birthday on the ELEAT (Early Life Exposure Assessment Tool) with prospectively collected responses, prenatal and postpartum home walkthrough visits, and public records in ASD-affected families.
Methods: Â Participants (n=120) from the MARBLES (Markers of Autism Risk in Babies-Learning Early Signs) prospective cohort study of high-risk younger siblings of children with autism completed a structured telephone interview during the 1st half of pregnancy (Environmental Exposures Questionnaire [EQ1]) and then again with the ELEAT, a shorter instrument administered 2 or more years postpartum. MARBLES Study also conducted a home walkthrough visit at the homes of participating families during mid-pregnancy and again at 6 months postpartum. Additional information about the home was obtained from public records (Zillow.com). Home characteristics compared with the EEQ included type of residence, tap water source, and whether the residence was near an agricultural field or golf course. Home square footage reported on ELEAT was compared with public records. Planned analyses for comparisons with home walkthroughs will include type of residence, year/decade the home was built, heat and air conditioning sources, and type of flooring. Reliability was assessed with Cohen's Kappa statistic (K); and validity with sensitivity (Se), specificity (Sp) and Youden's index (Y=Se+Sp-1) for each home characteristic for matched addresses from the index time period (conception until child's 1st birthday). Analyses were restricted to one address per family if more than one was reported during the index period.
Results: Â Ninety-two families were included in analyses comparing ELEAT responses with EQ1. Over 80% of families lived in a single family home. Mothers recalled the type of residence (single family home vs. multiplex/apartment/condo) with 100% accuracy (K=1.00). Agreement coefficients for water supply (public supply, private well) and ¼ mile proximity to agricultural field or golf course were fair (K=0.30 and 0.38, respectively). Eighty-one families were included in the home square footage analysis, compared with public records. Home area was divided into 4 categories: <1000 sq. ft., 1000-1999, 2000-3000, and >3000. However, very few families lived in homes <1000 or >3000 sq. ft. and we used collapsed categories <2000 and ≥2000 instead. Agreement was substantial (K=0.77).
Conclusions: Â Mothers of children with autism tended to recall information about the home they lived in during pregnancy and the child's first year reliably, and their responses to home size were highly valid. However responses on proximity of their homes to agricultural fields and golf courses, which can be used to assess likelihood for drift pesticide exposure, were not as reliable, suggesting other methods of drift pesticide exposure are likely needed.

200 **143.200** Risk of Epilepsy and Autism in Full- and Half-Siblings: A Population-Based Cohort Study

J. Christensen[1]*, M. Overgaard*[2]*, E. Parner*[3]*, M. Vestergaard*[2] *and* ***D. E. Schendel***[4]*, (1)Aarhus University Hospital, Aarhus, Denmark, (2)Aarhus University, Aarhus, Denmark, (3)University of Aarhus, DK-8000 Århus C, DENMARK, (4)Aarhus University, Aarhus, DENMARK*

Background: Epilepsy and autism spectrum disorder (ASD) frequently co-occur in the same individual and they may share common etiological factors. The sibling recurrence risk in both ASD and epilepsy is higher than expected which suggests that genes or environmental factors shared by family members play an important causal role in each disorder. However, no studies have previously evaluated the cross-disorder sibling risk for ASD and epilepsy.
Objectives: In a large population-based study, estimate the cross-disorder sibling risk for epilepsy and ASD in full and half-siblings of children with these conditions.
Methods: The study population comprised all Danish births, 1 January 1980 through 31 December 2006, and followed through 2012 (N=1,663,302) for reported ASD (N=17,145), epilepsy (N=22,531), death or immigration. All births were linked to parents and full and half siblings born in the birth cohort. The oldest child in a sibling set defined the exposure for all younger siblings. We used Cox regression to calculate the adjusted hazard ratio (aHR; risk for ASD or epilepsy in younger sibling given older sibling diagnosis) and the Kaplan-Meier method to calculate the cumulative incidence. Cox models adjusted for child's sex, parental age, and parental psychiatric or epilepsy history. Sensitivity analyses included analyses by birth year group, childhood autism specifically, epilepsy subtype, and considering intellectual disability in the younger sibling.
Results: Â The aHR of epilepsy in younger siblings increased by 70% (aHR = 1.70 (95% CI: 1.34-2.16%)) if the older sibling had ASD (64 events) compared with siblings where the older sibling did not; the aHR was 4.56 if the older sibling had both disorders. The cumulative incidence of epilepsy at 20 years of age was 2.54% (95% CI: 1.97-2.32%) if the older sibling had ASD and 1.63% (95% CI: 1.60-1.66%) if the older sibling did not. The aHR of ASD in younger siblings increased by 54% if the older sibling had epilepsy (159 events; aHR = 1.54 (95% CI: 1.32-1.80)) compared with siblings where the older sibling did not; the aHR was 4.44 if the older sibling had both disorders. The cumulative incidence of ASD at 20 years of age was 2.06% (95% CI: 1.84-2.32%) if the older sibling had epilepsy and 1.27% (95% CI: 1.25-1.29%) if the older sibling did not. Cross-disorder risks were increased in both full and half siblings. Similar results were found considering cross-disorder risk between epilepsy and autistic disorder; after excluding younger siblings with intellectual disability; and by birth year group of older sibling. ASD risks in the younger sibling by epilepsy subtype in the older sibling were similar to overall results. Risks for epilepsy subtype in the younger sibling from an older sibling with ASD were somewhat lower than overall results and not statistically significant.
Conclusions: The cross-disorder sibling risks of epilepsy and ASD suggest that genes or environmental factors shared by family members may play a causal role in the co-occurrence of ASD and epilepsy. The results may also inform developmental follow-up practices for healthcare professionals and parents.

201 **143.201** Screening for Autism Spectrum Disorder with the SCQ and SRS: Variation Across Demographic and Developmental Factors

E. Moody[1], *N. M. Reyes*[2], *C. Ledbetter*[3], *L. D. Wiggins*[4], *C. DiGuiseppi*[2], *A. Alexander*[5], *S. Jackson*[6], *L. C. Lee*[7], *S. E. Levy*[8] *and S. Rosenberg*[9], *(1)13121 E 17th Avenue, University of Colorado, Denver, Aurora, CO, (2)University of Colorado - Denver, Aurora, CO, (3)School of Public Health, University of Colorado, Aurora, CO, (4)Centers for Disease Control and Prevention, Atlanta, GA, (5)University of Colorado, Aurora, CO, (6)CDC, Atanta, GA, (7)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (8)The Children's Hospital of Philadelphia, Philadelphia, PA, (9)University of Colorado, Aurroa, CO*

Background: The American Academy of Pediatrics recommends that all children be screened for autism spectrum disorder (ASD) at an early age. Early identification of children with ASD is critical for referral to early intervention services, which improve outcomes and reduce long term care costs. To date, the performance of ASD screeners has not been comprehensively examined across demographic, behavioral, and developmental characteristics in young children.
Objectives: To determine how two widely used ASD screeners, the Social Communication Questionnaire (SCQ) and Social Responsiveness Scale (SRS), perform across a variety of demographic and child characteristics.
Methods: Data for this analysis come from The Study to Explore Early Development. SCQ and SRS were collected by phone interview and paper questionnaire, respectively. All parents completed the Child Behavior Checklist (CBCL) and all children completed the Mullen Scales of Early Learning (MSEL). The Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview–Revised (ADI-R) were administered to children who screened above 10 on the SCQ, or if the clinician observed behaviors sufficient to warrant an ASD evaluation. Following the evaluation, the clinician scored his or her global impression that the child has ASD using the Ohio State University Autism Rating Scale-4 (OARS-4), which served as our gold standard for all calculations. Additional demographic data were collected via a standardized parent interview. Sensitivity and specificity were calculated for the SCQ using cut-offs of 11, 13 and 15, and the SRS using a T score cut-off of 60 relative to the OARS-4. Sensitivity and specificity were then stratified by demographics (maternal race, ethnicity and education; household income; and MSEL and CBCL subscales.
Results: This analysis included 2317 children with a completed developmental evaluation, and OARS, CBCL, SCQ, and SRS assessments; 616 had ASD and 1701 were non-ASD, with 852 identified with developmental disability from educational and clinical settings and 849 population controls identified from state vital records. There was a significant difference in proportion of children with ASD and non-ASD who had below average cognitive functioning (74% versus 30% respectively). Overall, sensitivity and specificity were acceptable for the SCQ with a cut-off of 11 (0.87 and 0.81) and 13 (0.75 and 0.86), and for the SRS (0.85 and 0.77, respectively); however, specificity was considerably lower for African American and Hispanic mothers. Both the SCQ and SRS became less specific and more sensitive as maternal education and household income decreased. Specificity also decreased by as much as 50% when the child had below average scores on the MSEL or borderline to clinical scores on the CBCL.
Conclusions: These findings suggest that the SCQ and SRS cannot accurately differentiate many children with developmental delay from ASD within a diverse sample of children. Screening individuals from minority and lower socioeconomic backgrounds increases false positive rates. Refining these screeners to be more effective regardless of the child's behavioral presentation and across cultures could help reduce the impact of false positives. When used clinically, additional testing with standardized instruments, such as the ADI-R and ADOS, is needed to inform the differential diagnosis.

202 **143.202** Self-Reported Pregnancy Exposures and Placental DNA Methylation in the Marbles Prospective Autism Sibling Study

R. J. Schmidt[1], *D. I. Schroeder*[2], *F. K. Crary*[2], *J. Barkoski*[3], *D. J. Tancredi*[4], *C. K. Walker*[5], *S. Ozonoff*[6], *I. Hertz-Picciotto*[1] *and J. M. LaSalle*[1], *(1)University of California at Davis, Davis, CA, (2)University of California Davis, Davis, CA, (3)University of California, Davis, Davis, CA, (4)UC Davis School of Medicine, Sacramento, CA, (5)University of California, Sacramento, CA, (6)Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA*

Background:
Human placenta is a fetal-derived tissue that offers a unique sample of epigenetic and environmental exposures present in utero.
Objectives:
Â In the MARBLES prospective pregnancy study of high-risk younger siblings of children with autism spectrum disorder (ASD), pregnancy and environmental factors collected by maternal interviews were examined as predictors of placental DNA methylation, including partially methylated domains, an embryonic feature of the placental methylome.
Methods:
DNA methylation data from MethylC-seq analysis of 47 placentas of children clinically diagnosed at 3 years with ASD or typical development (TD) using standardized assessments were examined in relation to: child's gestational age, birthweight, and diagnosis; maternal pre-pregnancy body mass index, smoking, education, parity, height, prenatal vitamin and folate intake; home ownership; pesticides professionally applied to lawns or gardens or inside homes, pet flea/tick pouches, collars, or soaps/shampoos used in the 3 months prior to or during pregnancy. Sequencing run, order, and coverage, and child race and sex were considered as potential confounders. Akaike information criterion was used to select the most parsimonious among candidate models. Final prediction models used sandwich estimators to produce homoscadisticity-robust estimates of the 95% confidence interval (CI) and p-values controlled the false discovery rate (FDR) at 5%.
Results:
The strongest, most robust associations were between pesticides professionally applied outside the home and higher average methylation over partially methylated domains (0.45 (95% CI: 0.17, 0.72), P=0.03) and a reduced proportion of the genome in partially methylated domains (-0.42 (95% CI: -0.67, -0.17), P=0.03).
Conclusions:
Pesticide exposures could alter placental DNA methylation more than other factors.

203 **143.203** Study on Prevalence of Autism in Rural Bangladesh

***J. shefa**, Institute of Nutrition & Food Science, Dhaka university, Dhaka, Bangladesh; Paediatric Neurodisorder, Institute of Paediatric Neurodisorder & Autism (IPNA), BSMMU, Dhaka, Bangladesh*

Background:
In Bangladesh, autism has already been identified as burden of diseases and it has been assumed that the magnitude is high and majority cases, is undetermined. Especially in the rural settings, Autism has been found as neglected disease. However, there was no epidemiological strong evidence on autism prevalence in rural Bangladesh. In the Institute of Pediatric Neurodisorder& Autism in Children, at Bangabandhu Sheikh Mujib Medical University data shown that higher rate of children with autism at urban settings are seeking treatment from the facility.
Objectives:
To observed the prevalence of Autism Spectrum Disorder in rural community of Bangladesh.
Methods: A cross sectional study has been performed in where quantitative data was collected from the household level by door to door visit in rural community of Bangladesh. A four stage diagnosis process was applied to confirm autism. This study findings shown that among 5286 children of 18moths to 36 months aged group in one upazilas (six unions).
Results:
04 cases were found with autism spectrum disorder (ASD). Prevalence of the ASD in rural community was found 0.075%. Among the four ASD cases three were boys and one was girl and age range is between 20- 30 months.
Conclusions:
The findings also shown the parents in the rural community still not much aware about the disease, mostly treatment in government facilities or at local level. However, children were not received treatment from specialized facilities where ASD treatment/ counseling are in practice. Social stigma and barriers are also found as one of the key challenge in rural Bangladesh.

204 **143.204** Testosterone and Steroids in Meconium: Differences By Sex of the Offspring

***N. Snyder**[1], B. Y. Park[2], L. A. Croen[3], M. D. Fallin[4], I. Hertz-Picciotto[5] and C. J. Newschaffer[6], (1)Drexel University, Philadelphia, PA, (2)Johns Hopkins Bloomberg School of Public Health, Philadelphia, PA, (3)Kaiser Permanente Division of Research, Oakland, CA, (4)Department of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD, (5)University of California at Davis, Davis, CA, (6)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Prenatal metabolism exerts profound effects on development. The first stool of the newborn, meconium, provides a window into the prenatal metabolic environment.
Objectives: The objective of this study was to examine the feasibility of meconium as a novel matrix to quantify prenatal steroid levels. We quantified parameters of analytical interest regarding the use of meconium, including sample stability. We hypothesized that meconium steroid content would differ by sex, prompting analysis of meconium to test effects of prenatal steroid metabolism.
Methods: Meconium from 193 newborns enrolled in the Early Autism Risk Longitudinal Investigation (EARLI) study, including 107 males, and 86 females, were analyzed by stable isotope dilution-liquid chromatography-high resolution mass spectrometry (ID-LC-HRMS) while blinded to identity for testosterone (T), androstenedione (AD), and dehydroepiandrosterone (DHEA). Steroids levels were compared by sex, and investigations of potential trends resulting from sample storage or processing was conducted.
Results: The unconjugated steroid content of meconium in ng/g (mean, standard deviation) was for males: T (2.67, 8.99), AD (20.01, 28.12), DHEA (13.96, 23.57) and for females: T (0.82, 1.63), AD (22.32, 24.38), DHEA (21.06, 43.49). T was higher in meconium from males (p = 0.0333), and DHEA was higher in meconium from females (p = 0.0202). 6 female and 3 male T values were below the limit of detection. No extreme variability in hydration or trend in steroid levels by storage time was detected.
Conclusions: Sexually dimorphic levels of hormones may reflect gestational differentiation, and future studies should consider meconium analysis.

205 **143.205** The ATN Longitudinal Study: Changes in Behavior, Sleep and Quality of Life over Time

***D. L. Coury**[1], D. S. Murray[2], P. Wang[3], K. Kuhlthau[4], J. Chan[5], E. A. Macklin[5] and A. Fedele[6], (1)Nationwide Children's Hospital, Columbus, OH, (2)Autism Speaks, Boston, MA, (3)Autism Speaks, New York, NY, (4)Massachusetts General Hospital, Boston, MA, (5)Biostatistics, Massachusetts General Hospital, Boston, MA, (6)Autism Speaks, Mullica Hill, NJ*

Background:
Longitudinal data for autism spectrum disorders (ASD) are limited. The Autism Speaks Autism Treatment Network (ATN) Longitudinal Study tracks behavioral, functional and medical data on youth with ASD to better understand the natural course of ASD and their comorbid symptoms and behaviors. Objectives:
To describe the trajectory of behavioral, functional, and medical symptoms of ASD over 3-4 years, and the associations across these symptom domains in a large cohort of youth with ASD.
Methods:
A random sample of subjects originally enrolled in the ATN Registry between 2011-13 were contacted at each of 14 ATN sites to participate in follow-up behavioral and medical assessments on measures collected at baseline enrollment. We report here results from the initial follow-up visit completed in 2015-2016.
Results:
Of 1275 subjects contacted, 575 consented to participate. Consented subjects were 83% male; 81% White, 7% AA, 5% Asian; 92% Non-Hispanic. Age at baseline was 5.9 years ± 3.2 (mean ± SD, range 4.5 to 20.9), and follow-up interval was 3.7 years ± 0.6. There were no differences in sex, race, or ethnicity between consenters & non-consenters. ADOS severity, Vineland Adaptive Behavior Scales (VABS), sleep, GI and seizure disorders were the same in both groups, while non-consenters scored worse on Children's Sleep Habits Questionnaire (CSHQ), Child Behavior Checklist ADHD scale (CBCL-ADHD), with a trend toward worse scores on the Aberrant Behavior Checklist (ABC) Hyperactivity scale and Pediatric Quality of Life (Peds QL). From baseline to follow-up, the CBCL Total Problems t-scores improved 2.7 points and the ABC Irritability scale improved 2.5 points. Improvements on the CBCL and ABC were greatest for those with higher baseline scores (Figures 1 and 2). Scores on the PedsQL improved 1.8 points over the same interval. Scores on the CSHQ improved a mean of 0.7 points with the greatest improvement seen in those with higher scores at baseline.
Conclusions:
While only 45% of targeted subjects completed a follow-up visit, the sample enrolled appears to be largely free of bias and represents one of the largest longitudinal cohorts of youth with ASD reported. The longitudinal changes seen are largely congruent with previous reports in smaller cohorts. Behavioral problems as measured by the CBCL Total Problems scale and the ABC-Irritability scale show modest improvement over the 3-4 year interval. These findings may overestimate long-term trends as the non-consenting group demonstrated slightly worse behavioral problems at baseline. Overall quality of life as measured by the PedsQL and parent reported sleep problems measured by the CSHQ improved minimally on average. Future analyses will examine relationships between measures, changes in medical conditions, and the relationship between medical conditions and behavioral and functional outcomes.

206 **143.206** The Association of Maternal Lipid Levels and Autism Spectrum Disorder Risk.

B. Y. Park[1], *M. Brucato*[2], *E. Tierney*[3], *G. Wang*[4], *X. Hong*[2], *M. D. Fallin*[5], *X. Wang*[6] *and H. E. Volk*[7], *(1)Johns Hopkins Bloomberg School of Public Health, Baltimore,, MD, (2)Johns Hopkins University School of Public Health, Baltimore, MD, (3)Kennedy Krieger Institute, Baltimore, MD, (4)Johns Hopkins University School of Public Health, Balktimore, MD, (5)Department of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD, (6)Johns Hopkins University School of Public Health, Baltimore, MD, (7)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*

Background: Maternal obesity and gestational diabetes are conditions of increasing concern among pregnant women in the United States. Emerging evidence also links these metabolic dysregulations with risk of autism spectrum disorder (ASD), which affects more than 1% of children in the United States. Recent research identified maternal obesity and gestational diabetes as ASD risk factors. However, little is known about how the biological indicators of metabolic dysregulations are associated with ASD risk.
Objectives: We measured maternal serum lipid levels to examine the association with ASD risk stratified by maternal BMI categories.
Methods: We performed a nested case-control study drawing on the Boston Birth Cohort (BBC), an urban minority prospective birth cohort. BBC children with at least 1 inpatient, outpatient, or emergency room visit to the Boston Medical Center between 2003 and 2015 were eligible for inclusion in our analysis. Electronic medical record ICD-9-CM diagnosis codes were used to identify ASD cases and neurotypical controls among BBC participants. Maternal non-fasting serum lipids (triglyceride (TG), high density lipoprotein (HDL), total cholesterol, and calculated low density lipoprotein (LDL)) were obtained from blood samples collected after delivery. Logistic regression was used to assess the association between ASD risk and lipid measurement. Maternal lipid quantiles were use to examine non-linear associations. Models were also stratified by maternal pre-pregnancy BMI groups (normal, overweight and obese) to assess interaction.
Results: A total of 99 children with ASD and 698 neurotypical children were identified among mother-child dyads with lipid measurements. There was no association between maternal total cholesterol, HDL and TG with ASD risk. However maternal LDL level was associated with increased ASD risk in both the lowest (<92 mg/dL; OR 2.4 [CI: 1.3-4.4]) and highest (>250 mg/dL; OR 1.9 [CI: 1.1-3.6]) tertiles compared to the middle tertile (92-250 mg/dL) after adjusting for gestational age, sex, maternal age, education and birthweight. When stratified by maternal BMI groups, maternal LDL association with ASD risk did not persist in the normal and overweight groups but was still seen among obese mothers. Interestingly a similar U-shaped pattern of ASD risk was observed among children born to obese mothers (Lowest tertile OR 5.2 [CI: 1.4-25.2], Highest tertile OR 5.3 [CI: 1.4-26.9]).
Conclusions: Our study shows that both low and high maternal LDL levels are associated with ASD risk compare to the middle LDL range, particularly among obese mothers. Optimal maternal lipid levels during pregnancy are not well established and more study is needed to better understand the role of maternal LDL and ASD risk.

207 **143.207** The Influence of Clinical Judgment in a Record-Review Surveillance System on Autism Spectrum Disorder Prevalence Estimates

L. D. Wiggins[1], *J. Baio*[1], *K. R. Kast*[2], *R. S. Kirby*[3], *M. J. Maenner*[1], *C. E. Rice*[4], *K. Van Naarden Braun*[5], *W. W. Zahorodny*[6] *and M. Wingate*[7], *(1)Centers for Disease Control and Prevention, Atlanta, GA, (2)CO Dept. of Public Health and Environment, Denver, CO, (3)University of South Florida, Tampa, FL, (4)Emory Autism Center, Decatur, GA, (5)National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA, (6)New Jersey Medical School, Westfield, NJ, (7)Health Care Organization and Policy, University of Alabama at Birmingham, Birmingham, AL*

Background: Symptoms of autism spectrum disorder (ASD) overlap with other conditions in early childhood (e.g., attention deficit hyperactivity disorder). Differential diagnosis by a clinician is important to distinguish ASD from other disorders. One way to estimate ASD prevalence while mitigating resources needed for in-person evaluations is to have clinicians apply professional judgment to abstracted service (educational and health) records to determine case status. Clinical judgment applied to service records may exclude children who meet a standardized definition of ASD, but have symptoms that are better accounted for by another disorder.
Objectives: The objectives of this analysis were to (1) identify the number of children in a population-based surveillance system who met a standardized definition of ASD, but were disqualified as having ASD by a clinician who reviewed service records, (2) assess associations between ASD status determined by a clinician who reviewed the service records and the clinician who examined the child and authored the service record, and (3) estimate the change in ASD prevalence if children who were disqualified by a clinician who reviewed service records were included in ASD prevalence estimates.
Methods: Participants were children who met the Autism and Developmental Disabilities Monitoring Network (ADDM) case definition for ASD in surveillance year 2012. Education and health records were abstracted by project personnel and sent to clinicians for comprehensive review. Clinicians applied a standardized coding scheme based on DSM-IV-TR criteria to abstracted information to determine ASD case status. A child was “disqualified” if he or she met standardized coding criteria for ASD, but the clinician felt that symptoms were better accounted for by another disorder or any other reason. Children who were disqualified were not included in ASD prevalence estimates.
Results: 6,112 children met ADDM coding criteria for ASD; 5,063 (83%) were not disqualified and 1,049 (17%) were disqualified after record review. Logistic regression found that children who were disqualified were less likely than children who were not disqualified to have 1) a diagnosis of autistic disorder, pervasive developmental disorder – not otherwise specified, or Asperger disorder (9.1% versus 73.8%); 2) a special education classification of autism (1.0% versus 23.9%); and ASD characteristics noted in service records (16% versus 67.1%). However, children who were disqualified were more likely than children who were not disqualified to have ASD excluded by the clinician who evaluated the child and authored the service record (28.4% versus 10.0%). ASD prevalence increased from 14.6 per 1,000 to 17.6 per 1,000 when children who were disqualified were included in prevalence estimates.
Conclusions: The estimated prevalence of ASD is higher when clinical judgment is not applied to surveillance case definitions. More children who do not have ASD noted in service records – and who do have ASD excluded by a clinician who evaluated the child – are omitted from surveillance counts when clinicians disqualify children based on professional judgment. More research is needed to determine the influence of clinical judgment on ASD prevalence estimates, and the clinical characteristics that are associated with disqualification of ASD surveillance case status.

208 **143.208** The Negev Hospital-University-Based (HUB) Database of Autism

I. Menashe[1], *A. Michaelovski*[2], *H. Fluser*[2], *M. Faroy*[2], *M. Ilan*[1], *A. Bar-Sinai*[1], *D. Stolowicz*[1], *L. Manelis*[3], *L. Yosef*[1], *N. Davidovitch*[1], *H. Golan*[1], *S. Arbel*[2], *I. Dinstein*[4] *and G. Meiri*[5,6], *(1)Ben-Gurion University of the Negev, Beer Sheva, Israel, (2)Soroka University Medical Center, Beer Sheva, Israel, (3)Department of Psychology, Ben Gurion University of the Negev, Beer-Sheva, Israel, (4)Department of Cognitive and Brain Sciences, Ben Gurion University of the Negev, Beer-Sheva, Israel, (5)Pre-School Psychiatry Unit, Soroka University Medical Center, Beer-Sheva, Israel, (6)Ben-Gurion University of the Negev, Beersheva, Israel*

Background:
In the last decade, research into the etiologies of autism is shifting from small-scale studies often focusing on one or several biological/clinical measures in a small sample, to more extensive studies that examine multiple types of data in larger cohorts. Nevertheless, many of these studies have relatively limited pre-diagnostic data, and usually do not collect sufficient follow-up data that enables connecting the etiological dots from risk factors through biological mechanisms to precise phenotypic manifestations.
Objectives:
We have established a hospital-university-based (HUB) database of autism at the Soroka University Medical Center (SUMC) and Ben-Gurion University (BGU) in the Negev. This database contains a wide variety of unique clinical and behavioral information regarding each participating child and his/her family members.
Methods:
Children who are referred to SUMC with suspected social communication difficulties go through a rigorous clinical assessment that includes a comprehensive intake interview regarding the clinical and sociodemographic background of the diagnosed child, cognitive evaluation by either the Bayley-III or the WPPSI-III test and assessment by ADOS-2. Autism diagnosis is determined by a pediatric psychiatrist or a pediatric neurologist according to DSM-V criteria. Parents or the legal guardian of all referred children are asked to enroll in the study and sign a consent form. Children with a positive diagnosis of autism return to the clinic for follow-up visits every 6 to 12 months until the age six. During these visits, their diagnosis is re-evaluated and additional data are collected through other ongoing studies (e.g. genetics, sleep and sensory questionnaires, overnight EEG exams, and eye-tracking experiments). All these data are organized and stored in a designated secured computerized database.
Results:
During the first eighteen months of the study, 296 children were referred to SUMC with suspected social communication difficulties. Autism diagnosis was confirmed in 188 of these children (63.5%), and 133 of these (70.4%) were successfully recruited to our study. Interestingly, the rate of positive autism diagnoses was significantly higher among Jewish children than among Bedouin children (68.3% vs 51.3%; P = 0.0077). Significant ethnic differences (P<0.05) were also seen in mother’s age at birth (Bedouin mothers were 5-years younger), ADOS module, and cognitive test utilization (suggesting more language impairments among Bedouins at time of diagnosis), and cognitive level (Bedouin had lower cognitive scores). Other unique characteristics of our cohort include: complete birth records for >90% of the children; a high frequency of consanguineous families (especially of Bedouin origin); and multiple follow-up meetings with participating families that facilitate recruitment to additional studies.
Conclusions:
The Negev hospital-university-based (HUB) database of autism contains a wide variety of demographic, clinical and behavioral measures that are collected both retrospectively and prospectively from a population with unique ethnic composition. Thus, it comprises a remarkably rich resource to study different aspects of autism.

209 **143.209** The Parental Stress and Externalizing Behavior in Children with Autism Spectrum Disorder in Oman: A Case-Control Study

O. A. Al-Farsi[1], *Y. Alfarsi*[2], *M. M. Al-Sharbati*[3] *and S. H. Al-Adawi*[4], *(1)P.O. Box 34, PC 123, Sultan Qaboos University, Muscat, Oman, (2)Sultan Qaboos University, Al-Khoud, OMAN, (3)Sultan Qaboos University, Muscat-Al-Khod, OMAN, (4)Behavioral Medicine, Sultan Qaboos University, Muscat, Oman*

Background:
Parental stress has been widely documented in the literature on children with developmental disorders such as autism spectrum disorder (ASD). These studies have demonstrated a linear relationship between co-occurring cognitive, emotional and behavior problems in children with ASD and parental stress. With the rising tide of ASD in emerging economies such as Oman, studies relevant for psychosocial issues relevant to ASD are warranted.
Objectives:
This study aims to compare the performance indices of externalizing behavior in children with ASD as solicited by the Strengths and Difficulties Questionnaire (SDQ), .the parental reactivity as tapped by Parental Stress Scale (PSC) as well socio-demographic factors contribute to parental stress
Methods:
A case control study has been conducted on 122 ASD children, 81 intellectual disabilities, children and 90 typically developing children and their parents. Children with ASD were selected from the Sultan Qaboos University Hospital (SQUH) by convenience sampling method whereas control groups were recruited by the same method from social centers and schools. Parenting stress was tapped into by ***Parental Stress Scale*** (PSC) while co-occurring cognitive, emotional and behavior functioning was evaluated using ***the Strengths and Difficulties Questionnaire*** (SDQ).
Results:
,8 .16=is greater than the total mean score of intellectual disabilities are typically developed children (m (20=The total mean score of SDQ for children with ASD (m The study found out a linear association between behavior problems in children with ASD and parental stress, in other words, whenever behavior problems .(3 .13=m .48=The mean score of PSC for parents who caring for children with ASD (m .(0.001 =p-value ,54 .0=^{2}in children with ASD increase, parental stress also increases (r Mothers of children with ASD experienced stress more than fathers. .(35=and TD (m (3 .36=was higher than the mean score of parents with children with ID (m (4 .There was also trend on trajectory of socio-economic status on parental stress
Conclusions:
The parents of children with ASD are marked with higher indices of stress, a feat that has been observed from elsewhere. Secondly, externalizing behaviors are more common in children with ASD than the control. The mothers are more likely to experience higher stress compared to fathers. Moreover, income appears to play an important role in such trajectories. Concerted efforts are needed to introduce mechanisms to help parents with ASD in Oman in coping with the challenge of nurturing .children with ASD

210 **143.210** The Prevalence of Autism Spectrum Disorder in School Aged Children: Population Based Screening and Direct Assessment

L. A. Carpenter[1], *A. D. Boan*[1], *A. Wahlquist*[2], *A. Cohen*[1], *J. Charles*[1], *W. Jenner*[1], *C. C. Bradley*[1] *and E. G. Hill*[3], *(1)Medical University of South Carolina, Charleston, SC, (2)MUSC, Charleston, SC, (3)Department of Public Health Sciences, Medical University of South Carolina, Charleston, SC*

Background: The South Carolina Children's Educational Surveillance Study (SUCCESS) evaluated the prevalence of autism spectrum disorder (ASD).
Objectives: To determine prevalence of ASD in school-aged children born in 2004 using population-based screening and direct assessment.
Methods: Â Children born in 2004 and living in a contiguous geographic region (census derived n=8780) were screened for ASD using the Social Communication Questionnaire. The demographics of the catchment area for the target age group are 57% Non-Hispanic White, 33% Non-Hispanic Black, 8% Hispanic, and 2% other. Screening was conducted in partnership with 123/127 private and public elementary schools. Partnerships were also established with 25 home-school associations and three virtual schools in the area. All children at risk for ASD, as well as a subset of those falling below the threshold for risk, were invited to participate in a developmental assessment to determine ASD case status. Diagnostic assessment procedures included parent interview, parent and teacher behavior checklists, IQ and adaptive measures, and the Autism Diagnostic Observation Schedule, Second Edition. Clinical diagnoses were assigned by doctoral level clinicians, and were based on lifetime history of ASD symptoms. Prevalence estimates with 95% CI were calculated based on the NCHS vintage 2014 census population estimates. To account for the complex multi-phase design, multiple sampling weights with raking procedures were computed to account for the differentials in the probability of selection between strata, differences in non-response, and sampling frame adjustments in the final weighted estimate.
Results: Approximately 48% of eligible children participated in the screening process (n=4185). Of children with complete screening data (n=3,698), 7.4% screened positive for ASD risk, and 23% fell in a sub-threshold range for ASD risk. Of eligible children invited for a diagnostic assessment (n=704), 41.5% completed this assessment (n =292). ASD prevalence in this sample is 3.62%. Males were more likely to have ASD than females (6.77:1). ASD prevalence was higher among white children (3.92%) than black children (2.52%). Among those diagnosed, 21% had cognitive functioning falling in the Intellectually Disabled range, and 70% had delays in adaptive skill development (Vineland ABC<85). The majority of children meeting criteria for ASD (36/52; 69%) had received a formal clinical ASD diagnosis prior to entering the study. Of the 16 children newly identified via participation in the study, 14 had a prior neurodevelopmental/behavioral diagnosis such as ADHD, anxiety, language delay, etc. Six children (6/52; 12%) had a clear developmental history of ASD but did not display clinically significant symptoms at the time of participation in this study.
Conclusions: ASD prevalence in this study was substantially higher than has been previously reported by studies using records-based or administrative count methods to ascertain prevalence. Our study also revealed substantial functional impairment in the ASD group during the later elementary school years. Results suggest that some individuals with ASD may not be formally identified as such and may not be receiving the appropriate supports. However, 12% with a history of ASD no longer had significant ASD-related symptoms, providing further support for the potential for optimal outcomes in some individuals.

211 **143.211** The Use of Psychoactive and Complementary Alternative Medicine (CAM) in Autism Spectrum Disorder (ASD) in Minors in the Province of Antwerp, Belgium

M. Dhar[1,2], *E. Heyde*[3], *H. Hellemans*[4], *E. Schoentjes*[5] *and D. van West*[1,2,4], *(1)Department of Clinical and Lifespan Psychology, Vrije Universiteit Brussel, Brussels, Belgium, (2)Collaborative Antwerp Psychiatric Research Institute (CAPRI), University of Antwerp, Antwerp, Belgium, (3)University of Antwerp, Antwerp, Belgium, (4)Antwerp Hospital Network-University Center for Child and Adolescent Psychiatry, Antwerp, Belgium, (5)Ghent University Hospital, Ghent, Belgium*

Background: Â To date, particularly in European countries, relatively little is known regarding the prevalence of medication use for treatment of individuals with ASD. Previous international studies suggested that that an ever-increasing number of patients with ASD use at least one psychoactive drug. Even studies in the nineties suggested that frequent use of psychoactive medication was widespread although evidence for this assumption was limited at the time.
Objectives: The main aim of this study was to gauge the use of psychoactive medication and complementary and alternative medicine (CAM) in the province of Antwerp, Belgium. A second aim was to investigate the relationship between medication use and 'predisposing', 'enabling', and 'need' factors included in the Behavioral Model of Health Service Use (Andersen, 2008).
Methods: Respondents, consisting of parents of children aged 0-17 years diagnosed with ASD, were recruited in the province of Antwerp, Belgium. All completed a Dutch translation of the Survey of Medications in persons with autism (Aman et al., 1995).
Results: Results showed that 42.6% of the children (n=263) were reported to use at least one psychoactive drug. Over 12.2% were reported to use more than one drug. ADHD medication was most frequently reported (31.6%), followed by antipsychotics (16.7%). Some form of CAM was used by 14%. There was a positive relationship between the use of medication and psychiatric comorbidity and/or epilepsy, severity of autism and housing arrangements.
Conclusions: Compared to North American studies there was a relatively low use of antipsychotics, antidepressants, mood stabilizers and sedatives. Our findings do not provide evidence of overmedication and suggest that the use of medication in ASD in at least the studied province in Belgium is in accordance with current clinical guidelines.

212 **143.212** Understanding Prevalence and Kindergarten Behavioural Profiles of Children with Autism Spectrum Disorder

M. Janus[1], *A. Siddiqua*[1,2], *S. Taylor*[1], *M. Brownell*[3] *and E. Duku*[1], *(1)Offord Centre for Child Studies, Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, ON, Canada, (2)Department of Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, ON, Canada, (3)Manitoba Centre for Health Policy, University of Manitoba, Winnipeg, MB, Canada*

Background: Health disorder such as Autism Spectrum Disorder (ASD) in early childhood can impact the developmental trajectory of the child. Early identification can facilitate access to information and resources that will assist the family and child to achieve the most optimal developmental outcomes. Identification of behavioural profiles common to children with ASD in preschool and kindergarten can provide helpful information for educational professionals in managing classrooms and promote inclusion. Building on our previous work investigating kindergarten behavioural profiles of children who were later diagnosed with Autism Spectrum Disorder, we have linked the data reported by teachers in kindergarten on child's diagnosis and an assessment of child development in five domains with administrative data. In this study we are using the data from one Canadian province, Manitoba, to explore prevalence on ASD in kindergarten, teachers' knowledge (determined by linking), and behaviour of those children.
Objectives: This study aims to 1) determine the concordance of EDI and administrative data when identifying children with ASD in Manitoba, and 2) examine differences in behavioural profiles of children in five developmental domains by child's diagnosis and teacher's knowledge. We expect that there will be no difference in teachers' ratings of children with the confirmed (through linkage) ASD diagnosis between those for whom teacher reported the diagnosis and for whom s/he did not.
Methods: The Early Development Instrument (EDI) has been used in Manitoba since 2005 and has included the option to identify children that fall on the autism spectrum since 2011. Combining this population-level data with health and educational administrative data provides a powerful opportunity to explore the identification of ASD in Manitoba.
EDI data including indication of ASD were collected in Manitoba in academic years 2010-2011 and 2012-2013. Health and education administrative data have been collected on an ongoing basis in Manitoba and are housed through the Manitoba Centre for Health Policy (MCHP). These data include, but are not limited to, prescription information, hospitalization records, and codes for diagnoses.
Results: Results show good concordance between the administrative and EDI data. The administrative data show an overall prevalence rate of ASD in kindergarten at 0.9% (n=229) and the EDI data estimates ASD prevalence at 0.8% (n=191). Fifty-eight percent (n=177) of ASD cases were identified by both the administrative data and the EDI, 37% (n=112) of ASD cases were identified prior to kindergarten only by the administrative data, and 5% (n=14) of cases were identified only by the EDI data. Comparison of behavioural profiles between the groups is ongoing.
Conclusions: The EDI and administrative data in Manitoba show good concordance in identifying children with ASD at school entry. Our investigation takes into consideration details such as the age of first diagnosis and post-kindergarten diagnoses. We also examine associated child vulnerability at school entry as determined by the EDI, which has implications for practices, procedures, and policy surrounding identification and assistance of children with ASD in the school system.

213 **143.213** Using Health, Education and Research Administrative Databases to Better Understand Autism Prevalence in Australia

T. May[1] *and K. Williams*[2], *(1)Murdoch Childrens Research Institute, Parkville, VIC, Australia, (2)Developmental Medicine, The Royal Children's Hospital, Parkville, VIC, Australia*

Background:
Autism Spectrum Disorder (ASD) prevalence has been increasing worldwide. In Australia varied prevalence estimates have been reported from under 1% to more recently 2.5%. Exploring different administrative and research databases with varied criteria for the classification of ASD may provide insight into factors influencing prevalence.
Objectives:
To explore the prevalence of ASD in Australia using research and administrative databases from health, education and research systems using data collected in 2014.
Methods:
Secondary analyses of health, education and research databases were performed. The Victorian Department of Education and Training program for students with disability data was used to explore ASD prevalence in school aged children (5-18 years). To be classified under the ASD category, in addition to a confirmed medical diagnosis of ASD, children required a severe language impairment. Health data from the Australian Medicare Benefits Scheme items used by paediatricians and psychiatrists for the diagnosis of children with ASD aged 0-12 years was also explored. This required a paediatrician or child psychiatrist confirmed ASD diagnosis. Secondary analysis of the Longitudinal Study of Australian Children (LSAC) were also performed. LSAC is a nationally representative sample of Australian children. Parent reported ASD diagnoses from the Birth cohort (born in 2003/2004) collected in 2014 when the children were aged 10-11 years were used. Medicare ASD diagnostic items linked to LSAC data were also explored.
Results:
Education data showed the prevalence of ASD in the Victorian state school aged population (5-18 years) was 0.87% (95% CI 0.84-0.89). Health data using Medicare diagnostic items showed a preliminary prevalence of 2.81% (95% CI 2.80-2.83) in children aged 0-12 years. The parent reported prevalence of ASD diagnoses in 2014 using LSAC research data from the Birth cohort was 3.86% (95% CI 3.17-4.55) in 10-11 year old children. Medicare linked ASD diagnostic items in the LSAC Birth cohort were lower than parent report at 1.73% (95% CI 1.36-2.21).
Conclusions: No one administrative source will present a complete picture of service need and administrative sources are often thought to underestimate true prevalence. Large differences in prevalence depending on the data source were not expected nor were higher prevalence estimates than have been reported in other study designs and settings. Factors driving high estimates and differences need to be understood, as does appropriateness of service access.

214 **143.214** Validation of the Utah Registry of Autism and Developmental Disabilities: A State-Wide Registry for Autism Spectrum Disorder

A. V. Bakian[1], *C. M. Kingsbury*[2], *W. M. McMahon*[1], *N. Taxin*[2] *and D. Bilder*[1], *(1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Children with Special Health Care Needs, Utah Department of Health, Salt Lake City, UT*

Background: State-based autism spectrum disorder (ASD) registries are becoming more common in the U.S. and provide an important public health surveillance service. Eight state-level ASD registries currently exist including the Utah Registry of Autism and Developmental Disabilities (URADD). URADD, established in 2002, tracks changes in ASD prevalence in Utah, investigates ASD epidemiology, informs public policy, and supports ASD-related service planning. The multiple uses of ASD registry data necessitate validation of information acquired by these registries, especially ASD case status.
Objectives: 1) Validate URADD's ascertainment of children with ASD against the Utah Autism and Developmental Disabilities Monitoring (UT-ADDM) project's ascertainment of children with ASD. 2) Determine the impact of imposing a more stringent definition of ASD on URADD prevalence estimates, sensitivity, and specificity.
Methods: URADD uses two ascertainment methods. The first is a passive surveillance system in which individuals with ASD are identified by birth cohort based on a community medical ASD diagnosis and/or autism special education eligibility (URADD method). Second, URADD previously participated in the CDC's ADDM Network in surveillance years (SY) 2002, 2008, 2010, and 2012. ADDM uses a retrospective record review approach to identify children who meet ASD case definition based on DSM-IV-TR criteria (UT-ADDM method). For this study, eight-year-old children identified with ASD, residing in the three county UT-ADDM surveillance area in SY2010 or SY2012 were categorized by ascertainment method: URADD, UT-ADDM, or both. ASD prevalence was estimated by ascertainment method and compared using a chi-square test. The sensitivity and specificity of URADD ASD case status was estimated using UT-ADDM as the gold standard. A more stringent URADD definition was subsequently imposed by limiting ascertainment to children with ≥ 2 medical ASD diagnoses and/or an autism special education eligibility.Â URADD-based ASD prevalence, sensitivity, and specificity analyses were subsequently repeated.
Results: Â Collectively, 872 and 1141 eight-year-old children were identified with ASD by UT-ADDM and URADD, respectively for SYs 2010/2012. 74% of eight-year-old children identified with ASD in SYs 2010/2010 were ascertained by both UT-ADDM and URADD (N=647). URADD's ASD prevalence estimate (23/1,000 eight-year-old children (95% Confidence Interval (CI)): 22.1-24.8) was statistically significantly higher than UT-ADDM's (18/1,000 eight-year-old children (95% CI: 16.8-19.1); p-value < 0.0001). Sensitivity and specificity of URADD case ascertainment was 81.7% and 96.4%, respectively. After removing the 263 cases ascertained by URADD based on a single medical diagnosis, URADD's prevalence was reduced to 14.0/1,000 (95% CI: 12.9-14.9) eight-year-old children, and sensitivity and specificity of URADD versus UT-ADDM changed to 58.5% and 98.6%, respectively.
Conclusions: Â URADD's high sensitivity and specificity compared with UT-ADDM validates URADD's community-based approach to ASD case ascertainment. URADD's approach results in higher ASD prevalence estimates than the UT-ADDM method suggesting that the URADD approach may be more susceptible to identifying persons who are false-positive for ASD. However, imposing a stricter definition of ASD on URADD resulted in a marked decrease in sensitivity and only a minimal increase in specificity. From a public health perspective, URADD's capacity to conduct complete population-wide ASD ascertainment outweighs the risk of mis-classifying a small proportion of unaffected persons.

Poster Session
144 - Family Issues and Stakeholder Experiences I
12:00 PM - 1:40 PM - Golden Gate Ballroom

215 **144.215** Oral Health and Dental Care Among Children with and without an Autism Spectrum Disorder in Australia: A Comparative Study

J. Granich[1], *A. Lin*[2], *A. Dass*[2], *L. G. Do*[3], *L. Luzzi*[4], *M. Y. Rayner*[2] *and A. J. Whitehouse*[1], *(1)Telethon Kids Institute, University of Western Australia, Perth, Australia, (2)Telethon Kids Institute, The University of Western Australia, West Perth, Australia, (3)Australian Research Centre for Population Oral Health, School of Dentistry, The University of Adelaide, Adelaide, Australia, (4)Australian Research Centre for Population Oral Health (ARCPOH), The University of Adelaide, Adelaide, Australia*

Background: Impairments associated with autism spectrum disorders (ASD) may limit children with ASD ability to engage in self-care and healthcare. Oral health is empirically linked with general health whilst dental health-care is fundamentally required across the life-course. Health behaviours are usually formed during the childhood years. However, little is known about oral health behaviours of children with ASD in the world and there are no published dental health reports for Australian children with ASD.
Objectives:
This study aimed to better understand oral and dental health of children with ASD in Australia. The objectives were:

1. To examine dental health status and oral hygiene practices in children with ASD, in comparison with the general paediatric population.
2. To identify oral health factors that may impact on dental health status of children with ASD.
3. To examine dental visits experience of children with ASD.
4. To identify barriers to dental care at home and at the dentist.

Methods:
An online survey asked parents about their child with ASD oral health status, oral hygiene practices and barriers to dental care. The survey data of 5-14 year olds with ASD (n = 57) was compared with the 2012-2014 Australian National Child Oral Health Survey (NCOHS) (n = 24, 664) on a range of socio-demographics and dental health factors. The NCOHS questionnaire data was parent-reported and child oral clinical examinations were performed by dental practitioners.
Results:
Children with ASD had a higher rate of deciduous dental decay and permanent filled teeth compared with NCOHS children ($p < .001$) (Figure 1). Children with ASD were more likely to visit the dentist for a dental problem or when in pain compared with NCOHS children ($p < .001$). Children with ASD were more likely to be older than NCOHS children at their first dental visit ($p < .001$) (Table 1). Nearly 20% of children with ASD had a negative experience during their last dental visit. Sixteen percent of children with ASD had conscious sedation or general anaesthesia for routine preventive treatments. Children with ASD had moderate-to-severe levels of oral (78.1%), taste (82.9%), light (72.3%) and sound (84.1%) sensitivities. Most parents (67.7%) of children with ASD had difficulties with children's oral care. Over 40% of parents had little/quite a bit of difficulty locating a dentist willing to provide dental care for their child with ASD.
Conclusions:
This study provides information about oral and dental health problems among children with ASD, in Australia. It also adds value to the emerging worldwide evidence about oral health needs and barriers to dental care for children with ASD. Findings showed that children with ASD have more dental decay compared with the general paediatric population. This study highlights difficulties with oral care for children with ASD. Sensory sensitivities pose challenges to effective dental hygiene and dental care visits. This study has research and clinical implications focused on preventive strategies that can assist both, parents and children with ASD to overcome dental care problems in an effort to prevent or reduce dental disease.

216 **144.216** Parent Concerns and Screen-Based Media: Teens with ASD and Typically-Developing Peers

C. A. Cohen[1] *and A. R. Marvin*[2]*, (1)Kennedy Krieger Institute, Baltimore, MD, (2)Painter Bldg 1st Fl, Kennedy Krieger Institute, Baltimore, MD*

Background:
With the ubiquitous use of technology among teens with autism spectrum disorder (ASD), their gaming and video viewing habits have become an important concern to parents. Given that restricted, repetitive patterns of behavior, interests, and activities are diagnostic of ASD, researchers are beginning to investigate the excessive and inappropriate use of screen-based media by people with ASD.
Objectives:

- To understand parents' concerns with the video and gaming behaviors of their teens with ASD
- To determine whether parents' concerns are different for teens with ASD and typically-developing (TD) teens

Methods:
An anonymous 80-question survey was administered online to parents/guardians of children ages 13-17 living in the US with and without ASD. Participants were recruited using the Interactive Autism Network (IAN) and social media. The survey ran in October and November 2015.
348 survey instances were completed: ASD=264 (76%); TD=84(24%). Male-to-female gender ratios for TD (1:1) and ASD (5.87:1) were in the expected range.
Results:
Three groups were used for analysis: ASD with normal-or-above intellectual ability (ASD-Average; n=131); ASD with lower-than-normal intellectual ability (ASD-Low; n=133); and typically-developing teens (TD; n=84). No TD teens were attributed with lower-than-normal intellectual ability. Logistic regression was used to compare parental concern across groups, controlling for child's age, gender, race, and ethnicity.
Video-viewing behavior. Nearly all teens in our sample viewed videos. The ASD-Average teens' viewing habits were of the greatest concern (58.7%) as compared to ASD-Low (44.6%) and TD (34.5%). The difference between the groups was statistically significant ($\chi^2(6)=13.88$, $p=.031$).
Parents were asked to describe their main concerns. A thematic content analysis revealed the following themes for the ASD groups, in order of frequency: inappropriate/violent content; excessive viewing time; need for parental controls/monitoring; and safety.
Gaming behavior. A majority of teens were gaming, with the ASD-Average group gaming significantly more than the other groups at 91% ($\chi^2(2)=7.10$, $p=.029$). Many parents expressed concern; however, the logistical regression model demonstrated that gender was the key factor, with parents of boys being far more concerned than parents of girls across all groups ($\chi^2(6)=18.61$, $p=.005$; gender male, $p=.005$).
A thematic content analysis of parental concerns revealed the following themes for the ASD groups, in order of frequency: excessive time spent gaming; bad content/content that overexcites (including sexual, profane, inane, and violent); problems with other gamers in social gaming; frustration with gameplay; safety; and behavioral issues, including oppositional behaviors, violent behavioral, and meltdowns.
Conclusions:
Parents of teens with ASD were worried about their teens' judgment and the excessive amount of time spent watching videos and playing games to the exclusion of other activities. Given recent research on the relationship between the excessive use of screen-based media and issues including oppositional behavior and sleep problems, more research needs to be done to clarify these associations so that interventions can be developed.

217 **144.217** Parent Experiences of Raising an Adolescent with Autism Spectrum Disorder

H. S. Ho[1] *and A. Perry*[2]*, (1)Psychology, York University, Toronto, ON, Canada, (2)Psychology, York University, Toronto, ON, CANADA*

Background: Although autism spectrum disorder (ASD) is a lifelong disorder, much of the current literature has been focused on the experiences of families with young children. As the child matures, the research becomes sparser and the experiences, needs, and outcomes of individuals and their families during the period of adolescence and adulthood have remained largely unexamined. The limited number of studies on this population suggest that adolescence is a challenging and resource-intensive time for families.
Objectives: To describe and compare the lived experiences of parents raising an adolescent with ASD in three different outcome groups: poor, medium, and good
Methods: This study was conducted as part of a larger study following the outcomes of adolescents who previously received early intervention. The adolescent participants in this sample were 14 to 20 years old and were being assessed on their cognitive ability, adaptive behaviour, academic skills, autism symptom severity, and social-emotional functioning. Semi-structured in-depth interviews ranging from 1 to 1.5 hours long were conducted with 9 families with adolescents diagnosed with ASD and variable cognitive ability. Thematic analysis was used to analyze the parents' perspectives and feelings about the meaning of ASD, current experience with raising an adolescent with ASD, changes from childhood to adolescence, and expectations for the future.
Results: Four themes were constructed to represent the parents' narratives of their caregiving journey: 1) Rippling Effect of Loss; 2) Becoming a Parent-Professional; 3) One Size Fits None; and 4) Preparing for "The Future". Parental narratives reflect the tension they experience with the school system and the frustration with dealing with services that do not grow with their child's needs. Findings also indicate that, over the years, parents develop a specialized skill set that helps them navigate the ever-changing ASD landscape.
Â Conclusions: Â Many parents reported more positive experiences from childhood to adolescence. Parents found that they felt more empowered and confident with their knowledge of ASD to better advocate for their adolescent. The results of this study have several important implications, including the need for service and education providers to actively involve parents in the treatment of their child, as well as to increase appropriate services for adolescents that target both ASD and comorbid mental health challenges.

218 **144.218** Parent Perceptions of Self-Determination for Adolescents with ASD

L. Corona[1]*, C. Janicki*[2] *and K. V. Christodulu*[3]*, (1)Center for Autism and Related Disabilities, Albany, NY, (2)Center for Autism and Related Disabilities - University at Albany SUNY, Albany, NY, (3)Center for Autsim and Related Disabilities, Albany, NY*

Background: Self-determination refers to the concept of acting as a causal agent in one's life and includes skills such as setting goals, making decisions, problem-solving, and self-advocacy (Wehmeyer et al., 2010). Self-determination and self-advocacy skills have been linked to positive outcomes for individuals with disabilities generally, including greater likelihood of postsecondary education (Test, Fowler, & Kohler, 2013). However, documentation of self-determination skills among youth with ASD is only beginning. Carter et al. (2013) examined parent ratings of self-determination skills for their children with ASD or intellectual disability, noting that parents rated self-determination skills as important but indicated that their children did not perform these skills well. The present study sought to further document parents' perceptions of self-determination for their children with ASD.
Objectives: The primary objectives of the present study were to document parents' awareness of the concept of self-determination and examine ratings of child self-determination skills. A further objective was to preliminarily examine variables associated with self-determination, including child age, degree of school inclusion, and parent familiarity with self-determination.
Methods: Data for the present study came from an anonymous online survey distributed to parents through the mailing list of a university-affiliated autism center. Parents completed demographic questions and measures assessing child self-determination. Parent perceptions of child self-determination were assessed using the AIR Self-Determination Scale (Wolman et al., 1994) and a set of questions regarding self-determination component skills developed by Carter et al. (2013).
Results: Survey participants included 56 parents with a child between the ages of 11 and 21 (M = 15.6, SD = 2.7) diagnosed with ASD by a pediatrician, psychologist, or other specialist. (See Table 1 for demographic information.) Nearly one third (30%) of parents reported that they were not at all familiar with the concept of self-determination; 50% reported that they were somewhat familiar; and 20% indicated that they were very familiar with the concept. Most parents rated each self-determination component skill to be very important, but less than 20% indicated that their children performed any of the self-determination skills very well (See Table 2). Multiple linear regression was used to examine predictors of parents' ratings of child self-determination on the AIR Self-Determination Scale. Child age, degree of inclusion in integrated school settings, and parent familiarity with self-determination were entered as predictors. The full model was significant (F = 5.06, p < .01) and accounted for 24% of the variance in global self-determination ratings. Only degree of inclusion emerged as a significant predictor (t = 3.69, p < .01), with higher self-determination ratings for youth who spent more time in integrated educational settings (r = .48, p < .01).
Conclusions: Though self-determination skills are increasingly identified as important for youth with ASD, nearly one third of parents in the current study were unfamiliar with the concept. Consistent with prior research, parents rated self-determination skills as important for their children but indicated that their children did not perform the skills well as present. Future research should continue to examine potential predictors of self-determination for adolescents with ASD.

219 **144.219** Parent Perspectives on Participating in Intervention Research with Their High-Risk Toddler

E. A. Karp[1]*, K. Pickard*[2]*, K. Ragsdale*[1]*, B. Ingersoll*[2]*, P. J. Yoder*[3] *and W. L. Stone*[1]*, (1)Psychology, University of Washington, Seattle, WA, (2)Michigan State University, East Lansing, MI, (3)Vanderbilt University, Nashville, TN*

Background: The research community is increasingly using randomized-controlled trials (RCT) with high-risk (HR) siblings of children with autism spectrum disorder (ASD) to examine the extent to which early intervention ameliorates ASD symptomatology. However, to date, few studies have solicited parents' perspectives regarding their decisions and experiences related to participating in intervention research with their HR toddlers. Understanding the perceptions of stakeholders (i.e., parents) who participate in research, often before ASD symptoms have emerged, will provide valuable information regarding best practices related to research with HR toddlers.
Objectives: To understand parents': 1) motivation to participate in and experience during intervention research with their HR toddler; and 2) opinion about the conceptualization of providing preventative intervention to HR toddlers.
Methods: Parents enrolled in an RCT examining the efficacy of ImPACT, a parent-mediated social communication intervention, were invited to participate in an interview regarding their experiences in this study. Consenting parents assigned to both the intervention and control groups completed a semi-structured interview at time points corresponding to 3 or 6 months after the intervention group completed the 12-week intervention. Interviewers and coders were independent of the main study. Parents were asked about what motivated them to participate in the study, their experience participating in the study, and what they think about the concept of intervention or prevention for HR toddlers. All interviews were recorded, transcribed and checked for accuracy. Grounded theory and mixed method analysis were used. Data collection is ongoing.
Results: Preliminary results are presented for parents in the intervention (*n*=9) and control group (*n*=5) who completed interviews. Categories and subcategories of responses were generated using grounded theory (Table 1). Parents from both groups felt positively about their group assignment and were motivated to enroll in the study to track their child's development. Fewer than half reported being concerned about their child's development at the time of enrollment. Both groups felt that the assessment process was educational, either because it enabled them to monitor their child's progress or because they learned about interacting with their child based on the assessor's style. When asked about the concept of preventative research, approximately 20% of parents described feeling torn between not wanting to change their child with ASD or wanting to prevent challenges associated with ASD.
Conclusions: This study revealed novel information related to parents' decisions to enroll in research with their HR toddler, their experience participating in research, and their perceptions about preventative research. Of particular note is that not all parents were concerned about their child's development when enrolling, and that parents in both groups were satisfied with their group assignments. These results emphasize that though parents are enrolling in an RCT which includes an intervention condition, many parents may be motivated and satisfied by assessments offered. Results also suggest that a minority of parents feel conflicted about preventative interventions as it relates to their older child. This information has implications for future HR studies, both for understanding what motivates parents to participate in research and for conceptualization of these projects.

220 **144.220** Parent Reported Child Attention Problems and Depression Related to Parenting Stress in ASD

R. Kramer[1]*, T. Ward*[2]*, A. J. Lee*[1]*, E. A. Bisi*[1]*, T. Estrada*[1] *and B. J. Wilson*[1]*, (1)Seattle Pacific University, Seattle, WA, (2)University of Washington Autism Center, Seattle, WA*

Background: It is well established that parents of children with autism spectrum disorder (ASD) report more stress than parents of typically developing (TD) children (Hayes & Watson, 2013). Common parent-reported stressors include child externalizing behaviors (Baker et al., 2003), social communication impairment, and restrictive and repetitive interests (Hastings & Johnson, 2001). A less studied factor related to parenting stress may be the presence of comorbid symptoms (Simonoff et al., 2008). Research over the past decade has confirmed comorbidities between ASD and a wide array of psychiatric disorders, of which attention difficulties (Matson & Nebel-Schwalm, 2005) and depressive symptoms (Kim et al., 2000) are commonly noted. Understanding the various mechanisms underlying parental stress is crucial as it informs future interventions to better support families.
Objectives: The objective of our study was to investigate how attention difficulties and child depression symptoms influence frequency of stress events in parents of children with ASD.
Methods: Our sample included 100 children (ages 3:0 to 6:11) and their parents.Â Sixty-one TD children (37.7% female) and 39 children with ASD (25.6% female) participated. Parents' ratings from the Behavior Assessment System for Children—Second Edition (BASC-2; Reynolds & Kamphaus, 2004) were used to evaluate children's attention problems and depression symptoms. Frequency of parenting stress was measured using the parent-reported Parenting Events Questionnaire (Crnic & Greenberg, 1990).
Results: A serial mediation model was conducted using the SPSS 24 macro PROCESS (Hayes, 2008), which provided bootstrapped estimates of the indirect effects based on 5000 resamples. The results indicated that status was positively associated with attention-related problem behaviors (B = 14.64, p < .001), child attention problems was positively associated with child depression symptoms (B = .70, p < .001), and depression symptoms were positively associated with frequency of parenting stress (B = .30, p = .003). The direct effect was significant (B = 8.21, p < .001). Results of the bootstrapping analysis supported the mediational role of child's depression symptoms (B = .27, CI95 = .10 to.45) in the association between status and frequency of parental stress. The role of attention problems was not significantly associated with frequency of parental stress (B = .08, CI95 = -.15 to .32). The results support a serial indirect effect in the relation between status and frequency of parenting stress such that when compared to TD children, children with ASD had higher attention problems, which was associated with higher depression symptoms, which predicted greater frequency of parenting stress (B = 2.76, CI95 = .96 to 5.60). Additionally, this model accounted for 35% of the variance in predicting frequency of parenting stress in our sample.
Conclusions: Our results suggest that compared to TD children, children with ASD have higher levels of attention problems predicting more depressive symptoms which is associated with greater parental stress. These findings suggest that targeting interventions to decrease child attention difficulties and depressive symptoms may play a role in decreasing parenting stress. Future research should explore the relations between parenting stress and other common comorbid psychiatric symptoms.

221 **144.221** Parent Responsive Direction in Play and Children's Language and Social Development in ASD

B. Caplan[1]*, A. Eisenhower*[2] *and J. Blacher*[3]*, (1)Psychology, UCLA, Los Angeles, CA, (2)University of Massachusetts Boston, Boston, MA, (3)University of California - Riverside, Riverside, CA*

Background: Parent responsive communication, or that which is contingent on a child's interest and focus of attention, predicts gains in language and social functioning for children with typical development (Tamis-LaMonda, Bornstein & Baumwell, 2001). Children with autism, who demonstrate difficulties in understanding social-pragmatic cues such as joint attention (Mundy, Sigman, Ungerer & Sherman, 1986), may be particularly dependent on parenting that is responsive to their current interest and focus. In a study of 28 preschool-aged children with autism, Siller and Sigman (2008), demonstrated that early maternal responsiveness predicted language acquisition across three years. However, in studies of youth without ASD, parent responsiveness has shown to differentially impact young children as a product of cognitively ability (Green, Caplan & Baker, 2014), with parenting having a greater impact for children with lower cognitive ability. It is unclear what role cognitive ability plays in the influence of parent responsiveness in ASD.
Objectives: (1) To examine how parental responsive direction during parent-child play relates to concurrent and prospective child language and social skills. (2) To assess cognitive ability as a moderator of the relationship between parent responsive direction and child functioning.
Methods: This study examined language and social skills in 4- to 7-year-old children with a confirmed ASD diagnosis (*N*=170) using data obtained from a multi-site longitudinal study collected at three time-points across 1.5 years. All eligible children met clinical criteria for ASD diagnoses according the ADOS-2 and exhibited IQ ≥ 50 as assessed by the WPPSI-III (Weschler, 2002). A coding system of parent verbal direction that coincided with (*responsive* direction) or deterred from (*interfering*direction) child ongoing activity was implemented during a 10-minute parent-child free play interaction. Children's language abilities were assessed using a standardized assessment of spoken language (CASL; Carrow-Woolfolk, 1999) at time-points 1 and 3, and children's social skills were assessed using parent and teacher report of the SSiS (Gresham & Elliott, 2008) at all three time-points.
Results: Preliminary analysis with a subsample (*n*=100), reveals positive associations between parent *responsive* direction and concurrent child spoken language (*r*= .32, p<.05) but not child social skills. Parent *interfering* direction was negatively associated with child spoken language (*r*= -.36, p<.05) and social skills (*r*= -.24, p<.05). Future analyses will utilize multiple regression and latent growth modeling in MPLUS to assess parent direction (*responsive, interfering*) as it predicts change in child language and social skills, respectively, over time. Analyses will control for child negativity and engagement with toys during the interaction. Child cognitive ability will be assessed as a moderator by adding the appropriate interaction terms to the model.
Conclusions: Parental responsive and interfering direction demonstrate concurrent relationships with child language and/or social skills. However, given evidence that child behavior predicts later parenting in ASD (Markus et al., 2000), it will be important to employ longitudinal methods to predict downstream child development while controlling for prior levels of child functioning. Findings will serve to characterize dyadic interaction styles that are predictive of positive developmental outcomes in ASD, and may inform family-focused interventions.

222 **144.222** Parent Strategies to Support Mealtime Participation for Children with Autism Spectrum Disorders: Integration of Behavior and Narrative Data

K. K. Ausderau[1] *and B. St. John*[2]*, (1)University of Wisconsin-Madison, Madison, WI, (2)University of WI - Madison, Madison, WI*

Background: Â Mealtime is significantly affected in families with children with autism spectrum disorders (ASD) as they report significant mealtime behaviors, increased focus on the child with ASD, disrupted eating patterns, and an overall increased level of stress. Families use a number of strategies to support their child with ASD's engagement in mealtime, but these strategies have not yet been clearly identified within natural mealtime contexts.
Objectives: Â The purpose of this study was to identify and triangulate parent reported and observed strategies used to support their child's mealtime participation.
Methods: Twelve families with a child between the ages of 2 and 7 years with ASD were recruited to participate in 1 to 2 videotaped mealtime observations and 1 to 3 semi-structured interviews. Videos were reviewed to identify strategies families used during mealtimes to facilitate participation. The strategies were identified, defined, and arranged into categories using qualitative conventional content analysis. The categories were used to develop coding schemes with detailed definitions that were used to code family mealtime videos with each video being coded independently by two research team members. Agreement measures of inter-rater reliability were calculated. Thematic analysis was used on the transcribed parent interviews to identify strategies parents reported using during child eating experiences and family mealtimes. Categories of observed behavioral strategies were compared to the themes of reported parent strategies.
Results: Six categories of observed parental strategies were identified through the mealtime video data: 1) Parent Intervening and Ignoring, 2) Meal Preparation and Adaptability, 3) Positive Reinforcements, 4) Play and Imagination, 5) Distractions, and 6) Modeling. In contrast, only four primary themes of parent reported strategies were identified through the parent interview data: 1) Setting the Mealtime Stage, 2) Essential Food Modifications, 3) Social Strategies, and 4) Letting Go. When describing mealtime strategies, parents consistently discussed the importance of the environmental and child context in determining when and what strategies they may use to support their child. Families were observed to and reported using multiple strategies within and across mealtimes with variable success, highlighting the individualistic nature of feeding challenges in children with ASD. However, the observed and reported family strategies were not necessarily the same.
Conclusions: Similarities and differences were found when comparing the observed and parent-reported mealtime strategies to support their child with ASD. For example, parents described the strategies they used to prepare and create an environment to promote food acceptance during mealtime (Setting the Mealtime Stage), which was clearly confirmed through their behaviors during the observed mealtimes (Mealtime Preparation/Adaptability). However, multiple direct strategies were observed during mealtime (i.e., Parent Intervening/Ignoring and Distractions) that were absent in the parent interviews. Identifying the relationship between parent-reported and observed mealtime strategies will allow for a richer understanding of the context and motivation leading to parent behaviors during family mealtimes that will support the development of family-centered interventions to promote mealtime participation for children with ASD.

223 **144.223** Parent-Mediated Training for Behavior Problems in Children with ASD: We Have Miles to Go

A. P. Ables[1]*, A. D. Rodgers*[2]*, L. A. Ruble*[2]*, R. J. Reese*[3]*, G. M. Kuravackel*[4] *and J. H. McGrew*[5]*, (1)Department of Pediatrics, University of Louisville, Louisville, KY, (2)University of Kentucky, Lexington, KY, (3)Educational, School and Counseling Psychology, University of Kentucky, Lexington, KY, (4)University of Louisville, Louisville, KY, (5)Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN*

Background:
Estimates suggest more than 90% of children and youth with ASD experience challenging and disruptive behaviors some time during their life (Matson, Wilkins, & Macken, 2009). Children with ASD display more challenging behaviors compared to children with other disabilities and those behaviors are associated with a variety of negative outcomes. Caregivers of children with ASD report higher stress compared to parents of neuro-typical children and parents of children from other disability groups (Baker-Ericzen, Brookman-Frazee, & Stahmer, 2005; Hayes & Watson, 2013). Family-centered care, specifically parent support and training, is imperative for these families. Numerous studies demonstrate the positive impact of parent training for improving developmental skills such as social communication in children with ASD, however, few have specifically addressed problem behaviors and even fewer have examined parental factors, such as stress or competency. **Objectives**: The current analysis represents part of a comprehensive meta-analysis concerning parent mediated interventions specifically targeting parents of children with Autism Spectrum Disorder and behavioral challenges. Conference participants should expect to gain knowledge of the current research base concerning parent-mediated interventions for problem behaviors in children with Autism Spectrum Disorder, specifically highlighting the large gaps in this research to date. The current research base, as well as its effectiveness in addressing parent concerns and characteristics will be discussed. **Methods:** Computer-based database and ancestry searches, and manual searches of peer-reviewed articles and dissertations were used to identify studies meeting inclusion criteria. To be included studies had to: (1) use a group design to evaluate the outcomes of a parent training or intervention for parents/caregivers of children with ASD, (2) report original data, (3) be published in English, (4) include five or more participants in their experimental groups, and (5) specifically be designed to address problem behaviors.
Â **Results:**
Â Review of the literature only produced seven group design studies that included parents as the key implementers of interventions designed to decrease disruptive behavior of their child with ASD. Of those studies, only three measured parent variables. Although effect sizes for children's behavior based outcomes were positive, ranging from -0.73 to 2.02, direct comparison of outcomes was not possible because only 3 studies used the same outcome measures for child problem behavior. Overall, sample sizes were modest (range = 16 to 64) and dropout rates ranged from 5.1 to 48.5%. Neither implementation variables nor mechanisms of change variables were considered or mentioned in any of the seven studies.
Â **Conclusions:**
Â The current analysis clearly highlights a need for parent-mediated interventions to address the needs of families of children with Autism Spectrum Disorder, specifically for problem behaviors. While discussion of a "need" persists, the current analysis would suggest we are much further behind in actually "doing" something to address that need. This review highlights both the dearth of studies and research investigating parent-based problem behavior intervention for ASD, as well as the large gaps in our knowledge about these interventions. Recommendations and directions for future research will be discussed.

224 **144.224** Parental Attributions of Behavior in Toddlers with ASD-Related Concerns

A. R. Kurup[1]*, R. Baharloo*[1]*, W. L. Stone*[1] *and L. V. Ibanez*[2]*, (1)Psychology, University of Washington, Seattle, WA, (2)UW READi Lab, Seattle, WA*

Background:
Parental attributions of their children's behaviors have important implications for parent-child interactions and expectations. For typically developing (TD) children, parents generally attribute good behaviors as internal, stable, and controllable, while misbehaviors are perceived as external, temporary, and uncontrollable (Morrissey-Kane & Prinz, 1999). Conversely, parents of children with autism spectrum disorder (ASD) perceive misbehavior as more internal and controllable than good behavior (Wittingham et al., 2008). However, little is known about the behavioral attributions of parents who have ASD-related concerns about their toddlers. This study compares parental attributions about their toddler's behavior across three groups: parents with developmental concerns, ASD concerns, or no concerns about their toddler.
Objectives:
Do parents in the three groups differ in: (1) behavioral examples they provide when describing their toddler's good behavior and misbehavior; and (2) their attributions for their toddler's good behavior and misbehavior?
Methods:
The sample comprises 101 parents/toddlers recruited from primary care practices and early intervention programs through a longitudinal community-based study. The groups comprise parents with either self-reported ASD-related concerns, other developmental concerns (e.g., language; motor), or no concerns about their toddler (Table 1). Data collection is ongoing.
Parent's descriptions and attributions of their toddler's behavior were collected via the Parental Attributions Questionnaire, which asks parents to describe two scenarios: one in which their child exhibited good behavior and another in which they exhibited misbehavior. In addition, parents rated (on a 5-point Likert scale) the degree to which they view these behaviors as internal, stable, and controllable. Two examiners independently coded parents' scenario descriptions for content related to social behavior and compliant behavior (see Table 2 for examples of behaviors coded for each scenario type). Interobserver agreement was excellent (Cohen's κ=.814).
Results:
A 3 (group) x 2 (scenario; good behavior or misbehavior) x 2 (behavior type; social or compliant) repeated-measures ANOVA indicated that: (1) across groups, parents provided more examples of behaviors for the misbehavior scenario than the good scenario, p=.014; and (2) regardless of scenario type, the ASD concerns group provided fewer social behavior examples than the developmental concerns group, p=.019.
A 3 (group) x 2 (scenario) repeated-measures ANOVA was conducted for each attributional domain. For the *internal* domain, good behaviors were rated as more internally driven than misbehaviors, p=.001. For the *stability* domain, (1) good behaviors were rated as more stable than misbehaviors, p<.001; and (2) the ASD concerns group rated misbehaviors as more stable than the developmental concerns group, p=.008. For the *control* domain, the ASD concerns group rated behaviors as less under their child's control than the developmental concerns group, p=.015.
Conclusions:
Relative to the developmental concerns group, parents of children with ASD-related concerns reported fewer social examples for both the good behavior and misbehavior scenarios. This likely reflects their toddler's limited socially-directed behavioral repertoire. Additionally, the parents with ASD concerns perceived their toddlers' good behavior and misbehavior as less under their child's control, and their misbehavior as a more stable characteristic. These findings have potential implications for parents' adoption of and adherence to intervention.

225 **144.225** Parental Involvement in Educational and Intervention Services for Young Children with Autism

R. K. Schuck *and L. A. Simpson, Special Education, San Jose State University, San Jose, CA*

Background: Parental involvement in autism intervention is encouraged by the National Research Council (2001); however, the specifics of involvement are unclear. Previous research has found that parents report being involved in many ways, such as applying educational principles outside of school/therapy, facilitating between different providers, attending conferences/meetings, and communicating with personnel (Granger, des Rivières-Pigeon, Sabourin, & Forget, 2012; Solish, Perry, & Shine, 2015; Stoner & Angell, 2006). Correlates of involvement have been investigated (e.g. Benson, Karlof, & Sipersetin, 2008; Solish & Perry, 2008), though correlates of each type of involvement remain unclear. Similarly, while involvement has been found to be positively related to parental satisfaction with educational services (Renty & Roeyers, 2006; Zablotsky, Boswell, & Smith, 2012), how each type of involvement is related to satisfaction has not yet been investigated.
Objectives: The current study aimed to determine how parents are involved in their child's services, factors related to involvement, and the relationship between involvement and service satisfaction.
Methods: Parents of children with autism between the ages of 3-8, recruited from parent support groups and autism organizations, were invited to participate in a survey. The survey examined parent involvement in and satisfaction with educational and behavioral intervention (BI) services.
Results: Twenty-nine parents of children with autism (average age: 5.7) completed the survey. The majority of parents reported wanting to be involved to know what their child was learning (93%) and generalize skills (86%). Sixty-two percent of participants reported at least two barriers to involvement. Child age was significantly negatively associated with amount of time spent trying to implement strategies learned at school (Spearman's r=-.584, p=.001), as was number of children in the house (r=-.503, p=.007). Number of hours worked outside the home was negatively correlated with attending BI meetings (r=-.515, p=.014). Ethnicity, income, and parent education were not related to any involvement type (ps>.05). Parents who reported spending more time implementing strategies learned from school were more likely to be satisfied with school (r=.760, p<.001). Parents who spent more time being directly involved in their child's BI sessions were less likely to be satisfied with those services (r=-.392, p=.048). Other school and BI involvement types were not significantly correlated with satisfaction.
Conclusions: This study demonstrates the importance of studying parental involvement in the context of different types of involvement, as different correlates were related to different aspects of involvement. Parents of older and multiple children, for example, may need unique methods to increase their school-based involvement. When assessing involvement, professionals may benefit from understanding that different involvement types may be especially impactful when it comes to parental satisfaction. Specifically, implementing school-based strategies in everyday life and participating directly in BI sessions were related to satisfaction, whereas other aspects of involvement were not. BI teams may want to assess whether parents who are heavily involved in BI sessions are satisfied with those services and whether other involvement types might better suit them. Future research should expand on these findings, for example by exploring child factors related to the various types of parental involvement.

226 **144.226** Parental Quality of Life in ASD Families: Influence of Autism Severity, Adaptive Functions, Availability of Public Health Services and Prospective Assessment of the IMPACT of Case Management Intervention on Parental Stress.

A. M. Persico[1], *R. Faggioli*[2], *M. Frittoli*[2], *B. Olivari*[2], *G. Turturo*[2] *and R. Sacco*[3], *(1)University of Messina, Messina, Italy, (2)Mafalda Luce Center for Pervasive Developmental Disorders, Milan, Italy, (3)Univ. Campus Bio-Medico, Rome, ITALY*

Background: Parents of autistic individuals are under great emotional pressure for multiple reasons. Autism spectrum disorder (ASD) in a child has a major negative impact on the quality of life (QoL) of his/her parents. "Case management" intervention should indirectly improve parental QoL by coordinating the diagnostic assessments, therapeutic interventions, school- or work-related programs, and daily life assistance provided by "care managers" to autistic individuals and their families.
Objectives: (1) To assess the QoL in parents of autistic individuals and to characterize its relationship with the severity of their child's autism and the availability of public services; (2) To measure the impact of one year of case management intervention (T1) on the QoL recorded prior to treatment (T0). The present communication is focused on objective n.1.
Methods: Parents of 39 autistic individuals consecutively recruited for the Case Management Program supported by Regione Lombardia were assessed at T0 for quality of life (QoL) using both the WHOQOL and the recently developed QOLA (subscale A=general QoL, subscale B=Autism-related QoL). Their autistic offspring was assessed using WISC-III, Leiter-R or Raven's matrices for IQ, ADOS, VABS, SRS, TRF and CBCL. Data were analysed by c^2 test and ANOVA, correlations by Pearsons's R statistics.
Results: Data are available on 29 patients (M:F=25:4) and their parents at T0. WHOQOL and QOLA-A provide superimposable measures of maternal and paternal QoL (mean scores are 84.58 and 82.05 for WHOQOL, 84.15 and 89.29 for the QOLA-A, respectively). Parental QoL is worsened by the child's ASD (maternal and paternal QoL scores are 66.70 and 68.85 for the QOLA-B, respectively). QoL is lower for both fathers and mothers if their autistic offspring is non-verbal, has co-morbid intellectual disability and intense mannerisms. Paternal QoL appears more sensitive to low imagination and creativity, and to intense stereotypic behaviors in the affected child, as recorded by the ADOS. VABS scores in the affected offspring and parental QoL are significantly correlated. Mothers appear especially sensitive to lack of verbal communication and fathers to lack of socialization. Strikingly, total WHOQOL scores display a significant positive correlation with QOLA-A scores for "availability of health services for ASD" in fathers (R=0.529, P<0.05), while mothers display the opposite trend (R=-0.326, P=0.104).
Conclusions: Overall, parents of individuals with ASD display sizable levels of autism-related stress. Parental QoL is especially hampered by the child's low functioning, comorbid intellectual disability and expressive language deficits, as compared to lack of social non-verbal communication. Motor stereotypies and mannerisms also have a major negative impact on QoL both for fathers and mothers. Fathers are strongly more reliant on social support and efficient health services as compared to mothers, who may actually feel worse if their autistic child is "taken over" by efficient health services without maternal involvement in the process. We are currently verifying the latter hypothesis in the entire data set of 39 families analyzed at T0, while the efficacy of case management intervention on improving parental QoL is also being prospectively assessed at T1 (i.e., after 12 months of intervention).

227 **144.227** Parental Stress, Parental Efficacy and Problem Behaviors in Children with Autism Spectrum Disorder: A Structural Equation Analysis

K. A. Smith[1,2], *M. Siegel*[3], *S. L. Santangelo*[4], *R. Gabriels*[5], *G. Righi*[6] *and W. L. Cook*[7], *(1)Maine Medical Center Research Institute, Portland, ME, (2)Tufts University School of Medicine, Boston, MA, (3)Maine Medical Center - Tufts School of Medicine - Spring Harbor Hospital, Westbrook, ME, (4)Maine Medical Center, Portland, ME, (5)Children's Hospital Colorado, Aurora, CO, (6)Alpert Medical School of Brown University, Rumford, RI, (7)Center for Excellence in the Neuroscience, University of New England, Biddeford, ME*

Background:
Several studies have examined the role of parental stress on child outcomes, however there is little research examining positive parental characteristics, such as self-efficacy, that may reduce the impact of stress on the family. The direction of effects between parental stress, parental efficacy, and child problem behavior is also unclear.
Objectives:
To develop and test a longitudinal model including the latent variables (LVs) parental stress, parental efficacy, and child problem behavior and estimate their effects on each other over time (cross-lagged effects) using structural equation modeling (SEM).
Methods:
The study included 350 hospitalized children and adolescents with an Autism Diagnostic Observation Schedule-2 (ADOS-2) confirmed ASD diagnosis admitted to six specialized inpatient psychiatry units and prospectively enrolled in the Autism Inpatient Collection (AIC) study. Parents (N=323) were administered the Aberrant Behavior Checklist Irritability (ABC-I) subscale, Parent Stress Index Short Form (PSI-SF-4) and Difficult Behavior Self-efficacy Scale (DBSS) at admission, discharge, and 2-month follow-up. The hypothesized model was specified to have both measurement and path model components to make up the overall structural model composite. The measurement model contained three LVs – Parental Stress, Parental Efficacy, and Child Problem Behavior – which were measured using observed variables of each as indicators. The substantive part of the model involved the correlations and possible causal paths between the LVs (see Figure 1).Â Each LV was specified to be correlated with the other two LVs within a given time period, to predict itself at all later points in time (stability), and to be a predictor of the other two LVs measured at the immediately following time period (cross-lagged effects). Structural equation modeling was conducted using AMOS software version 20.
Results:
There were no significant differences between males and females on any of the demographic (age, ethnicity, race) or clinical variables (length of stay, non-verbal IQ, intellectual disability, expressive communication, adaptive behavior, or self-injurious behavior) (see Table 1). The majority of parents were mothers (84%), married (58%), average age of 42 years old. SEM results indicated the three latent variables were significantly correlated with each other at each respective time point (all p-values < .005) in a manner that supported the validity of each.Â Parental efficacy was negatively correlated to both parental stress and child problem behavior and parental stress was positively correlated with child problem behavior. The overall model fit the data well, $\chi^2 = 229.2$, $df = 138$, $p = 0.001$; RMSEA = .04; CFI = 0.97. Two cross-lagged effects were found. Parental stress at admission predicted parent self-efficacy at discharge, $\beta = -0.33$, $p=0.002$, and parental stress at discharge predicted parental efficacy at follow up, $\beta = -0.34$, $p=0.001$. There were no other significant cross-lagged effects in this model.
Conclusions:
Results revealed a negative association between parental stress and parental efficacy which was consistent over time. Interventions to develop coping/behavioral management skills to reduce stress related disorders in parents may be important for mitigation of problem behaviors among children with ASD. Employing advanced statistical modeling methods (SEM) advances our knowledge in this field.

228 **144.228** Parenting Stress and Emotional Availability in the Families of Children with Autism Spectrum Disorder

*Y. Ozturk, A. Bentenuto, **N. Mazzoni** and P. Venuti, University of Trento, Rovereto, Italy*

Background: Â Rearing a child with Autism Spectrum Disorder (ASD) is a unique challenge for both parents. Parenting a child with ASD is stressful and impacting overall quality of life. In the last decades, a number of factors have been found as impacting parents' psychological well-being in the family of children with ASD. However, far too little attention has been paid to the dyadic quality of emotional availability in parent-child interactions, considering the perspectives of both the adult and child.
Objectives: Our main goal was to explore the association among parenting stress, observed behaviors of children and parents during interaction and a number of child and family characteristics, including autism severity, cognitive functioning, age and SES.
Methods: Â Participants were 40 mothers and 40 fathers of children with ASD (Range chronological age = 18 - 48 months). Data were collected using The Emotional Availability Scale (EAS), the Parenting Stress Index-Short Form (PSI-SF), theÂ Autism Diagnostic Observation ScheduleÂ (ADOS) and theÂ GriffithÂ Mental Development Scales (GMDS). EA in parent-child dyads was coded using the EAS which includes four scales reflecting parents' sensitivity, structuring, non-intrusiveness and non-hostility, and two scales reflecting child's responsiveness and involvement. The data were collected during 10-min play sessions for mother-child and father-child dyads.
Results: Â Parenting stress and emotional availability scales were found to be associated in the present study. In particular, parenting stress scores were negatively correlated withÂ the scores for Emotional Availability. The preliminary results showed that the Parent-Child Dysfunctional Interaction and the Parenting Distress scales of the PSI-SF were negatively correlated with the Sensitivity scale of the EAS for mothers.
Conclusions: These results suggest that the emotional availability and the psychological well-being of parents are connected. In the family of children with ASD, it is important to measure the emotional exchange of mothers and fathers to assess parent-child interactions and to explore parents' distress. This study might be useful to implement treatments for children with ASD focusing on parent-child interaction and on supporting the development of high-quality dyadic relationship.

229 **144.229** Portrayal of ASD in Canadian Media: A Framing Analysis

*S. Chiu and **S. Hodgetts**, University of Alberta, Edmonton, AB, Canada*

Background: How media stories are framed can significantly influence societal perceptions of issues, influence demand for health services, shape decisions related to health care and education, and inform policy. Previous framing analyses of media representations of ASD from the United States (Kang, 2013), the United Kingdom (Huws, 2010), Australia (Jones & Harwood, 2009), and China (Bie & Tang, 2015), were often inaccurate and negative in focus, perpetuating misconceptions and stereotypes of ASD. However, Canada is recognized as being relatively well resourced for health care and other services for people with ASD and their families. Therefore, the Canadian media may portray ASD differently, leading to different perceptions of ASD in Canada than in other countries.
Objectives: We used frame analysis to investigate how newspapers across Canada covered ASD over a 5-year period (2011-2015). Specific research questions related to the coverage of ASD included: (1) What were the main issues? (2) Who were the primary sources cited or quoted? (3) What discourse was used? (4) What tone was used?
Methods: The Canadian Newsstand Complete database was used to collect print news articles from two national and 8 regional Canadian broadsheet newspapers representing all geographic regions. Search terms were autis* OR ASD OR Asperger* in the article headline. Working frames were derived based on an in-depth content analysis of the articles, and a codebook was developed for data extraction. Inter-coder reliability for 10% of articles for each coding category was moderate to very strong (Cohen's Kappa = 0.60-0.88 across categories).
Results: A total of 397 unique articles were found. The main issues covered were (1) infrastructure (e.g., services, funding; n=128), science (n=80), family story (n=70), victimization of/by the person with ASD (n=35), and advocacy (i.e., awareness/acceptance of ASD; n=33). Primary sources cited were family members (n=128) and academics/scientists (n=106). Persons with ASD were infrequently cited (n=24). Human-interest discourse was most common (n=332), followed by scientific (n=50) and policy (n=15) discourse. All articles coded as scientific discourse focused on research, but 10% of scientific topics (research findings) were framed within human-interest discourse. Most articles presented neutral information, including both positive and negative sides (n=167) or descriptive information (n=110). Eighty articles were exclusively positive in tone, dominated by advocacy, family story, and infrastructure topics; 41 were negative in tone, dominated by victimization and family story topics. The word "suffer" was included 98 times within 70 articles, and the word "burden" was included 42 times in 36 articles.
Conclusions: Increased understanding of media portrayal of ASD can provide context for societal understanding of ASD, and resulting acceptance and inclusion, or stigma and discrimination. Portrayals of ASD in Canadian newspapers were more neutral or positive than previous frame analyses from other countries. However, the words "suffer" and "burden" were frequently used, even in positively framed articles. Infrastructure was a more frequent topic compared to other jurisdictions, perhaps due to the amount and variety of programs in Canada. Similar to previous studies, the voices of people diagnosed with ASD were largely unheard.

230 **144.230** Predicting Anxiety in Autism Spectrum Disorder: The Roles of Parenting and Emotion Regulation

E. M. McRae[1]*, S. E. O'Kelley*[2] *and L. Stoppelbein*[2]*, (1)Psychology, University of Alabama at Birmingham, Birmingham, AL, (2)University of Alabama at Birmingham, Birmingham, AL*

Background:
Positive parenting is characterized as above average levels of warmth, affection, responsiveness, and involvement and is positively associated with healthy child adjustment and lower levels of internalizing behaviors in children, including those associated with anxiety. Because children with Autism Spectrum Disorder (ASD) are at an increased risk of experiencing higher levels of anxiety than their typically developing peers, positive parenting might be particularly important for this population. Another potential predictor of high anxiety in children with ASD might be emotion regulation and emotional coping skills. Individuals with ASD have been shown to have differences in and difficulties with emotion regulation compared to their typically developing peers which might further explain some of the increased levels of anxiety.
Objectives:
In the present study, we sought to elucidate the relations between positive parenting, emotion regulation and coping skills, and anxiety-related child behavior in children with ASD. We hypothesized that both positive parenting behaviors and emotion regulation and coping skills would significantly predict anxiety-related behaviors in children with ASD. Specifically, higher levels of positive parenting and higher levels of emotion regulation and coping skills would both predict lower levels of anxiety-related behaviors.
Methods: Parent reports of anxiety-related child behavior and parenting behavior and child self-reports of emotion regulation and coping strategies were obtained from a sample of parent-child dyads in which the child has a diagnosis of ASD (*N*=23). We examined the ways in which positive parenting behaviors and the child's emotion regulation and coping skills predict anxiety-related behavior in the child.
Results:
Results of a simple linear regression indicated that positive parenting behaviors (b(21)= -.799, p <.001) and the child's emotion regulation and coping skills (b(21) =-.295, p <.05) both significantly predicted anxiety-related child behavior. The overall model (F(2,20) = 10.67,Â pÂ = .001) accounted for 52% of the variance (R^2=.516) in anxiety-related behaviors in children with ASD.
Conclusions:
These findings further evidence the importance of providing positive parenting based interventions to parents of children with ASD and interventions focused on emotion regulation and coping skills to children with ASD in order to decrease the levels of anxiety experienced. It might also be that increased emotion regulation and coping skills are a mechanism through which positive parenting behaviors decrease child anxiety-related behaviors. Preliminary analyses indicate a trend towards mediation and further analyses will be conducted when expected sample size is reached to determine if the child's emotion regulation and coping skills are acting as a mediating variable between positive parenting behaviors and the child's anxiety-related behaviors.

231 **144.231** Predictors for Parent Wellbeing Around the Time of Young Child ASD Diagnosis

M. J. Grant[1] *and K. Hudry*[2]*, (1)Olga Tennison Autism Research Centre, La Trobe Univeristy, Melbourne, Australia, (2)Olga Tennison Autism Research Centre, Melbourne, AUSTRALIA*

Background: Research has established that the stress associated with raising a child with an Autism Spectrum Disorder (ASD) has considerable impact upon parent wellbeing (Karst, 2012). However, there is a relative paucity of studies investigating parent wellbeing specifically around the time a child is diagnosed, resulting in a limited understanding of the factors that have the greatest impact upon parent wellbeing at this particular point in time. Stress around diagnosis is reported to trigger uncertainty and helplessness in parents (Bruey, 2004; Schall, 2000), and acute psychological distress (i.e., anxiety, depression symptoms), which risks becoming stable and ingrained over time (Estes et al., 2013). Therefore, further investigation of factors which contribute to parent wellbeing during this time will develop current understanding and propensity to support parent wellbeing.
Objectives: This study investigated a variety of factors as potential predictors of concurrent parental wellbeing around the time their child was assessed for an ASD. It was predicted that parents at increased vulnerability would use poorer coping mechanisms and have poorer wellbeing outcomes.Â
Methods: Forty-seven parents with children aged 2-4 years who were recently diagnosed/assessed for an ASD participated in the study. Parents completed questionnaires regarding vulnerability factors (i.e., parenting self-efficacy, ASD trait expression, and socioeconomic status), coping styles (i.e., use of social support, engagement with stressors, distraction/disengage from the issue), and current wellbeing (i.e., depression, anxiety, affect). Children were assessed using ADOS-2 to confirm the appropriateness of their community-assigned ASD diagnosis.
Results: Parents who reported more symptoms of depression and stress around the time of their child's ASD diagnosis were those also reporting greater vulnerability in terms of lower parenting self-efficacy, and those who more often used distraction/disengagement as a method of coping. Furthermore, parents who reported more symptoms of anxiety and more negative affect around this time were also those who reported increased vulnerability in terms of greater ASD trait expression, and also more often used distraction/disengagement coping. By contrast, parents who reported more positive affect around the time of their child's ASD diagnosis were those who also reported greater parenting self-efficacy and used reframing of stressors as an adaptive coping style.
Conclusions: The clear patterns of concurrent association between elevated vulnerability factors, the use of less adaptive coping styles, and poorer wellbeing among parents of young children with recent ASD diagnoses highlight the need to target aspects of parent functioning directly at this point in the family's journey with ASD. Given that the focus of practitioners and parents is often highly focused on the child, it is particularly important that focus during the diagnostic period incorporates parent support. Professional support that increases parenting confidence may promote more adaptive styles of coping, both of which are clearly indicated in order to improve parent wellbeing.

232 **144.232** Predictors of Anxiety in Parents of Adolescents and Young Adults with Autism Spectrum Disorder (ASD)

M. Uljarevic[1,2]*, A. L. Richdale*[1,2] *and R. Y. Cai*[1,2]*, (1)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia*

Background:
Previous research has suggested that parents of children with autism spectrum disorder (ASD) have higher levels of stress and higher prevalence of anxiety than both parents of typically developing children and other disabilities. During transition from secondary school into adulthood, individuals with ASD lose their entitlements to many services they have received while in school, and parents often must take on increased responsibility for service coordination. Therefore it can be expected that this period will be particularly stressful for parents and might lead to increased levels of anxiety. There are however, notable individual differences in the way individuals respond to stress. It has been shown that particular individual characteristics, as well as environmental characteristics, can on one hand prolong the effects of negative life events, making individuals more susceptible to the negative psychological effects of chronic stress, and on other hand serve as resilience factors. However, factors that might put these parents at increased risk for developing anxiety are currently under-researched.
Objectives:
To identify factors associated with higher levels of anxiety in parents of adolescents and young adults with ASD, in particular focusing on intolerance of uncertainty (IU), mindfulness, and broader autism phenotype traits (BAP) as parental characteristics, and social support, as characteristic of the environment.
Methods:
Ninety-three parents of adolescents and young adults with ASD (Parents: M_{age}= 50.19 years, SD_{age}= 5.78; 86 females; Children: M_{age}= 19.14 years, SD_{age}= 2.53, range) completed questionnaires assessing anxiety (DSM-5 Dimensional Anxiety Scales; DSM-5 DAS), BAP traits (Autism Quotient-10; AQ-10), mindfulness (Mindful Awareness Scale; MAAS), social support (Social Support Questionaire-6; SSQ-6), and IU (Intolerance of Uncertainty scale-12; IUS-12). Both parents and young people with ASD were participants in the Australian Autism CRC longitudinal School Leavers study.
Results:
No statistically significant association was found between chronological age, gender, BAP traits and anxiety. IU (r= .59, p < .001), mindfulness (r= -.54, p < .001) and level of social support (r= -.42, p < .001) were all associated with anxiety. A multiple regression model was conducted in order to examine relative contribution of these variables in predicting anxiety. The final model accounted for 54% of variance in anxiety, with IU, mindfulness and social support all unique, independent predictors, t = 5.30, p < .001, β = .265; t = -4.31, p < .001, β = -.480; and t = 3.12, p = .002, β = .272, respectively.
Conclusions:
This study identified lower mindfulness, lower levels of social support and higher levels of IU as independent, contributing factors to elevated levels of anxiety in parents of adolescents and young adults with autism. Identifying these risk and resilience factors is of particular importance for informing the effective parental support programs.

233 **144.233** Predictors of Maternal Stress in Pre-School and School Aged Children on the Autism Spectrum

L. Zheng[1,2]*, R. Grove*[2,3] *and V. Eapen*[1,2,4]*, (1)The University of New South Wales, Randwick, Australia, (2)The Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)The University of New South Wales, Sydney, Australia, (4)Academic Unit of Child Psychiatry South West Sydney (AUCS), Liverpool, Australia*

Background: Mothers of children on the autism spectrum have been shown to experience higher levels of stress than mothers of typically developing children and children with other developmental disabilities (Dumas et al. 1991; Schieve, et al. 2007; Estes et al. 2009; Dabrowska & Pisula 2010). However little is known about whether maternal stressors differ across childhood. Given that that parent stress can have a large impact intervention outcomes (see Osborne et al. 2007 and Strauss et al. 2012), it is important to investigate the factors that influence stress levels in the mothers of young children on the autism spectrum in order to understand how best to minimise parental stress levels and in turn help maximised intervention efficiency.
Objectives: This study aimed to (1) determine if maternal stress levels differ between pre-school aged and school aged children on the autism spectrum, (2) analyse the relationship between family and child characteristics and maternal stress, and (3) identify any differences between the variables that predict maternal stress in pre-school aged children compared to school aged children on the autism spectrum.
Methods: This study investigated maternal stressors in 29 pre-school aged and 27 school aged children on the autism spectrum. Correlation and regression analysis were used to determine the impact of maternal age, family income and various child related factors on maternal stress levels. Specific child related factors used in the investigation were cognitive ability (measured using the WISC-IV and Mullen Scales of Early Learning), autism severity (measured using the ADOS-2), problematic behaviours (measured using the Child Behaviour Checklist), adaptive behaviours (measured using the Vineland Adaptive Behavioural Scales), repetitive behaviours (measured using the Repetitive Behaviour Scale-Revised), and sensory processing challenges (measured using the Short Sensory Profile). Maternal stress was measured using the Parental Stress Index (PSI-SF).
Results: No differences in overall maternal stress levels were found between the two age groups. Correlation analysis revealed that while several child related factors were associated with maternal stress in each age group, maternal age and family income were not correlated with any of the PSI-SF subscales. Hierarchical regression analysis was used to determine which correlates predicted maternal stress after controlling for each child's age, sex, and cognitive ability. Results revealed that maternal stressors differed between the groups. Specifically stressors in the school aged group were found to be related to repetitive behaviours, sensory sensitivities and problematic behaviours, while stressors in the pre-school aged group were mainly associated with adaptive behaviours.
Conclusions: These results indicate that while overall maternal stress levels remain stable over time, mothers' stress levels are impacted by different child-related factors throughout their child's development. These results draw attention to the need to identify the unique factors that have an impact on maternal stress levels at different stages of childhood. In doing so, these findings can help inform clinical practice and provide insight into targeted and effective supports that will enhance the wellbeing in mothers of children on the autism spectrum.

234 **144.234** Predictors of Parent Expectations within an Intervention for Children with Autism

L. Hauptman[1]*, C. K. Toolan*[1]*, T. Carr*[2] *and C. Kasari*[1]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)Autism Discovery Institute, Rady Children's Hospital San Diego, San Diego, CA*

Background: Â Past literature has emphasized the influence that family and child factors can have on parent expectations. Child variables, such as symptom severity, and family variables, such as ethnicity and socioeconomic status (SES), predicted parent expectations for children with oppositional behavior (Nock & Kazdin, 2001). These variables may be even more salient within ASD, as diagnosis rates and treatment access have been lower among ethnic minority families and families with low resources (Bhasin & Scendel, 2006; CDC, 2014; Liptak et al., 2008). Furthermore, parent expectations regarding the benefit of therapy can influence parent attendance and adherence (Nock et al., 2006;Â Nock & Kazdin, 2001). Therefore, understanding factors that may influence parents' expectations may inform support strategies.
Objectives: The purpose of this study was to investigate how family characteristics (e.g., ethnicity, SES, intervention history) and child characteristics (e.g., ASD symptom severity) predict parent expectations at the start of intervention.
Methods:
Participants. Of 147 preschool children with ASD and their caregivers who were randomized into a larger intervention trial (Kasari et al., 2014), 113 with complete Parent Expectancies Questionnaire (PEQ: Kasari et al., 2015, adapted for this study from Nock & Kazdin, 2001) data were included in the present study (see demographics in Table1).
Measure. The *PEQ*is a caregiver questionnaire that assesses parent expectations on a 5-point scale. Two outcome variables were derived based on factor analyses (Toolan, in prep) including: (a) belief in child improvement (BCI) including 3 items, and (b) treatment credibility (TC) including 8 items. Both BCI and TC are percentage scores where 100%=expectations for timely child improvement (BCI), and the treatment will lead to gains for my child (TC), while 0%=no expectation my child can improve (BCI), and the treatment will not lead to gains for my child (TC). One linear multiple regression model was conducted for each factor. The following parameters were included: SES score (Hollingshead Two-Factor Index of Social Position), ethnicity (dummy coded, white as reference group), MSEL developmental quotient, ADOS severity score, child's early intervention experience (yes/no), and Parenting Daily Hassles frequency percentage score, controlling for site.
Results: Participants entered the intervention with high expectations for both BCI (*M*=72.27%, *SD*=15.65%) and TC (*M*=89.62%, *SD*=10.41%). No variables were found to predict TC scores. All racial groups demonstrated higher mean expectations scores than White participants. Participants reporting as African American or mixed/other had significantly higher BCI expectations than White participants (β=0.28, *p*=.030; β=0.35, *p*=.004 respectively). Early intervention experience was significantly and negatively related to BCI (β=-0.28, *p*=.010). There was no interaction between intervention experience and race/ethnicity.
Conclusions:
African American and mixed/other parents had higher expectations for intervention than White parents. Future research should not only examine factors that may influence these underlying differences, but also how these differences are related to treatment outcomes. Early intervention experience negatively predicted parents' BCI. Future research may investigate the influence of parent satisfaction with intervention, type of service, and duration on expectancies.

235 **144.235** Predictors of Parent Scaffolding in Children with Autism Spectrum Disorder

V. Chan (Ting)[1] *and J. A. Weiss*[2]*, (1)Psychology, York University, Toronto, ON, Canada, (2)York University, Toronto, ON, CANADA*

Background: Children with autism spectrum disorder (ASD) often have externalizing (e.g., aggression) and internalizing (e.g., anxiety) emotional and behavioural problems (Ooi et al., 2011; Totsika et al., 2011). Parents can support children's emotional development through scaffolding (i.e., motivational or emotional scaffolding), which in turn may help improve psychopathology (Hooven et al., 1995; Wilson et al., 2013). Although parent scaffolding may be an important aspect of parent involvement in their children's mental health treatment, little is known about the predictors of parent scaffolding
Objectives: The purpose of this study was to investigate the predictors of parent scaffolding in children with ASD, 8 to 12 years of age. We examined both child factors (i.e., age, IQ, ASD severity, emotion regulation, psychopathology) and parent factors (i.e., emotion regulation, depression, anxiety) in relation to parent scaffolding.
Methods: Fifty-two children with ASD (89% male) and their parents (79% mothers) participated in a larger treatment trial to improve emotion regulation. Children were 8 to 12 years of age (*M*=9.63, *SD*=1.31), with average IQ (*M*=103.08, *SD*=13.57, Range=79-140). Parent scaffolding was measured using a behavioural coding scheme (Gulsrud et al., 2010), applied to parent behaviours during a standardized *Emotion Discussion Task.* We used a parent report measure (*Emotion Regulation Checklist*; Shields & Cicchetti, 1997), and two open-ended measures (*Dylan is Being Teased* and *James and the Math Test*; Attwood, 2004b) to assess child emotion regulation. Child psychopathology was measured using the *Anxiety Disorders Interview Schedule for DSM-IV* (Silverman & Albano, 1996), and via parent report on the *Behavior Assessment System for Children, Second Edition – Parent Rating Scales* (Externalizing and Internalizing subscales; Reynolds & Kamphaus, 2004). We measured parent emotion regulation using a self-report questionnaire (*Cognitive Emotion Regulation Questionnaire – Short Version*; Garnefski & Kraaij, 2006). Parent depression and anxiety was measured using the *Depression, Anxiety, and Stress Scales-21* (Lovibond & Lovibond, 1995).
Results: The majority of parents had scaffolding ratings in the "acceptable" to "good" range (*M*=3.73, *SD*=.83). Pearson correlations were conducted to examine the parent and child correlates of parent scaffolding. Of the child factors, age (*r*=-.29, *p*=.04), emotion lability and negativity (*r*=-.31, *p*=.03), and externalizing problems (*r*=-.28, *p*=.05) were correlated with parent scaffolding. Of the parent factors, depression (*r*=-.38, *p*=.007) and anxiety (*r*=-.45, *p*=.001) were correlated. The overall model accounted for 39% of the variance in parent scaffolding, $F(7,44)=3.36$, *p*=.007, and parent anxiety emerged as the only significant independent predictor (*t*=-2.64, *p*=.01).
Conclusions: This is the first study to investigate the predictors of parent scaffolding in school-age children with ASD. Parent depression and anxiety are more highly associated with parent scaffolding than child factors, suggesting that parents with better mental health are more likely to provide higher quality support of their children's emotional development. Clinicians may consider assessing the emotional needs of parents when involving parents in their children's mental health treatment.

236 **144.236** Profile of Access and Satisfaction with Health and Educational Services for People with Autism Spectrum Disorders in Latin America

G. Garrido[1], *R. A. Garcia*[2], *C. Montiel-Nava*[3], *C. S. Paula*[4], *S. H. Cukier*[5], *A. Rosoli*[6], *D. Valdez*[7], *M. Irarrazaval*[8,9], *V. Besio*[1], *F. Prieto*[8,9], *M. Koolhaas*[1] *and A. Rattazzi*[5], *(1)Universidad de la República, Montevideo, Uruguay, (2)Universidad de Chile, Santiago, CHILE, (3)La Universidad del Zulia, Gainesville, GA, (4)Developmental Disorder Program, Mackenzie Presbyterian Univesrsity, Sao Paulo, BRAZIL, (5)PANAACEA, Programa Argentino para Niños, Adolescentes y Adultos con Condiciones del Espectro Autista, Buenos Aires, Argentina, (6)OEI, Santo Domingo, Dominican Republic, (7)FLACSO, Buenos Aires, Argentina, (8)Universidad de Chile, Santiago de Chile, Chile, (9)Millenium Institute for Research in Depression and Personality, Santiago de Chile, Chile*

Background: People with Autism Spectrum Disorders (ASD) require multiple and different treatments throughout life and have special needs for inclusion in educational services. There is limited research available about access and level of satisfaction with these treatments in Latin America.
Objectives: Understand and analyze the access to health and education services and satisfaction with these services in families affected by ASD in order to enhance awareness, improve services and develop long term policy solutions.
Methods: This study is part of a larger one based on the needs of caregivers of people with ASD carried out in six Latin American countries (Argentina, Brazil, Chile, Uruguay, Panama, Dominican Republic) by the Red Espectro Autista Latinoamerica (REAL). Data was collected by a online survey (n=2965) during 4 months, which assessed the health and educational services that families had received, their costs (for the governments and for the families), and type of services, considering demographic characteristics by country.
Results: There are differences between countries in terms of support and treatment received by subjects with ASD. In terms of access to health services, subjects have low to moderate access, depending on the country (Language therapy 3.8-43.1%; CBT 3.8-43.2%; Neurologist 3.8-43.7%). Among all countries, language delay treatment is the most frequently received. There is a high representation of psychodynamic therapies in Argentina (30%) compared to other countries (4% Venezuela, 7% Dominican Republic). In Uruguay physical therapies (motor skills) are the most prevalent (73%), while in other countries is 30%. Some countries like Chile, Dominican Republic and Argentina have a frequency of almost 40% of Sensory Integration Therapy, while in Uruguay it is only 11%. Chile has 27% of biomedical approaches. In other countries, biomedical treatments were received in a range of 11-20%. Treatments with the lowest percentage of satisfaction in all countries were biomedical and medication. Regarding the support subjects receive in the educational setting, only Brazil reports medium to high rates (42 to 55.9%). The other countries have rates from 3 to 28.6%. Only 5.0-42.1% of parents have received training or help with their children needs or treatment.
Conclusions: There are similarities between countries in access to certain treatments, but profiles show significant differences that may be linked to the existence of different professional profiles by country and easier access of households according to socioeconomic status and level of education of parents. There is inequity in the access to educational services and support depending on socioeconomic level in all countries. These data are potentially useful for the development of human resources and health policies that promote and support access to treatment.

237 **144.237** Profiles of Parental Personal/Social Coping Resources during Children's Early School Years: Implication for Psychological Distress

A. Zaidman-Zait[1], ***P. Mirenda***[2], *P. Szatmari*[3], *I. M. Smith*[4], *J. Volden*[5], *L. Zwaigenbaum*[6], *T. Bennett*[7], *E. Duku*[8], *M. Elsabbagh*[9], *S. Georgiades*[8] *and W. Ungar*[10], *(1)Tel-Aviv University, Tel-Aviv, ISRAEL, (2)University of British Columbia, Vancouver, BC, Canada, (3)Centre for Addiction and Mental Health, Toronto, ON, CANADA, (4)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (5)University of Alberta, University of Alberta, AB, CANADA, (6)University of Alberta, Edmonton, AB, CANADA, (7)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (8)McMaster University, Hamilton, ON, CANADA, (9)McGill University, Montreal, CANADA, (10)Sick Kids Research Institute, Toronto, ON, Canada*

Background: Â Many parents of children with ASD experience high levels of stress and/or depression. The Conservation of Resources theory (Hobfoll, 1989) posits that people mobilize resources in the face of stressful events to maintain well-being and adjust successfully to stressors. Increased personal and coping resources enhance an individual's ability to overcome the threat of a stressor, while resource loss has the opposite effect.
Objectives: This study examined (1) patterns of personal and social coping resources among parents of children diagnosed with ASD around the time of the children's school entry; and (2) how these patterns were related to parenting stress and depression symptoms 2 years later.
Methods: Parents of 203 children from the Canadian Pathways in ASD study were included, based on availability of relevant data. At Time 1 (T1) data collection, shortly after school entry, children's mean age was 6.6 years. Parents completed a demographic survey; the Ways of Coping Scales; a Family Functioning Questionnaire; a Social Support Survey; and the Child Behavior Checklist 1.5-5. In addition, within the subsequent 12 months, parents also completed the Measure of Processes of Care to reflect their experience of family-centered care in the school system. Two years later (T2), when the children's mean age was 8.7 years, parents completed the Parenting Stress Index-Short Form and the Symptom Checklist-90-R,used to assess depression symptoms. Latent profile analysis was used to identify profiles of parents' personal and social resources at T1, with socioeconomic (SES) cumulative risk indicators, utilization of coping strategies, family functioning, social support, perception of family-centered care, and child behavior demands entered into the model. Latent GOLD's Step3 module (Vermunt & Magidson, 2013) was used to examine associations between T1 profile membership, and T2 parenting stress and parental depression.
Results: A four-profile model of parent resources showed the best fit and was also the most parsimonious (Fig. 1). Profile 1 (38%) was characterized by elevated active coping, average resources, and average child behavior demands. Profile 2 (28%) had the lowest SES risk and child behavior demands, average active coping, and elevated resources. Profile 3 (21%) displayed the lowest utilization of coping strategies, and low levels of both social resources and child behavior demands. Finally, Profile 4 (13%) had the lowest level of social resources, the highest levels of both SES risk and child behavior-related demands, and the highest level of disengaged coping strategies. At T2, profile membership significantly predicted both parenting stress and depression symptoms, $p<.001$. In particular, parents in Profile 2 reported significantly lower parenting stress and fewer depression symptoms compared to all other profiles, whereas parents in Profile 4 reported the highest symptoms.
Conclusions: Parents of children with ASD who reported low social resources, including poor family functioning, low social supports, and low levels of family-centered care, were at greater risk for experiencing later psychological distress. Professionals providing interventions to school-age children with ASD should endeavor to build collaborative relationships with families, as such relationships may help to ameliorate parenting stress and depression.

238 **144.238** Psychosocial Well-Being and Treatment Access in High Risk Families of Individuals with ASD

L. A. Pepa[1] *and S. L. Harris*[2]*, (1)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY, (2)Rutgers University, Piscataway, NJ*

Background: Research suggests that a diagnosis of ASD has a profound psychosocial impact on the entire family unit (Baker-Ericzen et al., 2005). ASD- specific social communication and behavioral impairments introduce a pervasive family stress that is maintained over a lifetime (Conway & Meyer, 2008; Hastings, 2003). While the salience may change over time, both parents and siblings of individuals with ASD are considered more vulnerable to negative psychosocial outcomes, including symptoms of anxiety and depression (Dunn et al., 2001; Tudor & Lerner, 2015). In this way, all families are at some level of risk, and are in need of individualized treatment and support. While the literature has begun to identify factors that predict family member outcome, little attention has been paid to the interaction between an ASD diagnosis and a family history of psychosocial risk. Risk may include, for example, family members with a concurrent or pre-existing psychiatric condition. Given the prevalence of these behavioral diagnoses in the general population, it is crucial for researchers and service providers to better characterize the needs of this high risk group.
Objectives: This study aims to identify 1) the psychosocial functioning of "high risk" families, 2) the treatment wants and needs of this population, and 3) factors that may contribute to further risk or difficulty accessing treatment.
Methods: Families of individuals with ASD were distributed an online survey through the Qualtrics platform. Participants in the survey were parents across the U.S. who had one child with ASD and at least one typically developing child. ASD diagnosis was confirmed by the GARS-3 (Gilliam, 1995), and typical sibling development was confirmed by parent report. Parents were also asked to rate their own psychosocial well-being (GHQ-28; Goldberg, 1978), parent stress (PSI-4-SF; Abidin, 1995), and perceived social support (ISSB; Barrera et al., 1981). Participants were also given a treatment questionnaire, inquiring about past service access, future service interest, and barriers to treatment for parents and siblings. Importantly, parents reported service access on behalf of their TD child.
Results: Of the 158 total families who completed the survey, 32 were considered to be "high risk," defined by parent endorsement of a developmental or learning disability, or major psychiatric condition in themselves or their TD child. Several group-based differences were identified between the "high risk (HR)" and "low risk (LR)" groups. Families in the HR group were significantly more diverse with regard to racial and ethnic identification. Further, these parents reported significantly lower ISSB scores and higher GARS-3 severity scores than the LR group. While parents in the overall sample reported a generally positive view of treatment services aimed at families, individuals in the HR group endorsed less service engagement in the past, and less interest in future support services than LR families. Groups also differed with regard to factors that facilitate treatment access, with the HR families citing time and financial resources as significant barriers to treatment, while these factors were not significant predictors in the LR group.
Conclusions: Implications of these differences will be discussed further.

239 **144.239** Quality of Life of Caregivers of Children with Autism Spectrum Disorders in Nigeria

I. I. Adeosun[1]*, O. Ogunderu*[2] *and O. Ogun*[2]*, (1)Mental Health Unit, Babcock University, Ilishan-Remo, Nigeria, (2)Federal Neuro-Psychiatric Hospital Yaba, Lagos, Nigeria*

Background:
Autism Spectrum Disorder (ASD) is a disabling neuro-developmental disorder. In resource-poor countries with dearth of specialised services and formal support for children with disabilities, informal caregivers have little or no respite in caring for children with ASD. The impact of caring for a child with ASD may negatively impact the mental health and quality of life of caregivers, which may subsequently jeopardise the continuity of informal care available for children with ASD. Since, the well being of the informal caregiver is inextricably linked to that of the child with ASD, it is pertinent to determine the mental health of the caregivers, in order to inform relevant interventions.
Objectives:
1. To assess the Quality of life of informal caregivers of children with ASD.
2. To compare the QOL of the caregivers with that of a control group, matched for age and gender
3. To determine the correlates of Quality of life and depression among the study group
Methods:
The study group consisted of caregivers (n=42) of children with ASD attending a tertiary mental health care facility in Lagos, Nigeria. The control group consist of age and gender matched individuals from the same community who were involved in caring for children without chronic disease. The study instruments consisted of a socio-demographic questionnaire, World Health Organisation Quality of Life Questionnaire Brief form (WHOQOL- Bref), Mini International Neuropsychiatric Interview (MINI version 5.0) and the Oslo-3 Support Scale (OSS-3). Qualify of life (QOL) of the participants was assessed across four domains namely physical health, psychological health, social relationships and environment. Participants were assessed for depression using the MINI. The level of social supports available to the caregiver was determined using the OSS-3. The data was analysed using SPSS-IBM version 20.
Results: The majority (76.2%) of the caregivers were females, and 61.9% were mothers of the children with ASD. More than half (54.8%) of caregivers reported quitting their jobs due to the demands of care-giving. None of the caregivers had any form of formal social or financial welfare support outside the family. Nearly half (47.6%) of the caregivers rated the support received within the family as poor. Caregivers of children with ASD had significantly poorer overall Quality of life scores in comparison with the control group (t=2.089, p=0.041).Â Quality of life of the caregivers was also significantly lower in the psychological domain (t= 3.233, p=0.002) and environmental domain of WHOQOL-Bref (t=4.032, p=<0.001). Caregivers who had to quit their jobs to care for children with ASD reported significantly lower QOL in the physical domain (t=2.168, p=0.036) and social relationships domain (t=5.475, p=0.008). Caregivers had higher prevalence of depression (23.8%) compared with 14.2% in the control group (p=0.266). Caregivers with poorer quality of life were more likely to be depressed (p<0.005). Caregivers with depression reported lower levels of social support (p<0.005).
Conclusions: The findings highlights the need for formal support and other interventions targeted at improving the quality of life and addressing the mental health needs of caregivers of children with ASD.

240 **144.240** Quality of Life of Parents of Children with ASD: From Adolescence to Early Adulthood.

C. Rattaz[1] *and A. Baghdadli*[2]*, (1)Centre de Ressources Autisme, Montpellier, FRANCE, (2)CHU MONTPELLIER, MONTPELLIER, France*

Background: Autism spectrum disorders (ASD) are lifelong disorders, potentially impacting the parental quality of life (QoL) in a persistent manner. The transition period from adolescence to adulthood has been reported as a time of confusion and stress for families of people with developmental disabilities. When entering adulthood, most people with ASD still need a consequent support in their daily life and parents have to face significant life adjustments such as finding new services and a place of living for their child with ASD. However, there are very few studies about the transition from adolescence to adulthood in ASD and its impact on parental QoL.
Objectives: The goals of this study were to describe parental QoL in the EpiTED cohort and its related risk factors at early adulthood. We also examined the determinants and predictors of QoL in the subgroup of parents who experienced an improvement or a decline in their QoL from adolescence to adulthood ASD and its impact on parental QoL.
Methods: One hundred and six mothers or fathers of young adults with ASD completed the Par-DD-QoL scale at two time points: during adolescence (mean age = 15 years) and young adulthood (mean age = 20 years). This scale assesses the following dimensions: emotional, daily disturbance and global QoL. Adaptive skills, aberrant behaviors, symptom severity, as well as environmental variables (social support, type of interventions, scholarship) were also assessed at the two collection time points. This cross sectional study uses a subset of data collected at the last two times of a follow-up study (EpiTED cohort).
Results: Â Results show that parental QoL is altered or moderately altered in two third of parents, suggesting that the impact of ASD on families remains strong even when children become adults. The perceived impact of ASD on parental QoL at adulthood was related to their children's characteristics, namely the level of adaptive skills, the severity of symptomatology and the presence of challenging behaviors. The polytomic regression demonstrated that challenging behaviors were the main risk factors for a decreased parental QoL, particularly the lethargy/withdrawal, irritability, and hyperactivity domains. Among the 106 parents, 54 experienced a gain or a loss in their global QoL over the 5 years period. Results showed that parents whose children had a decrease in challenging behaviors experienced a gain in their QoL, suggesting that, when entering adulthood, challenging behaviors are the strongest predictor of parental QoL. Another interesting result is that parents who experienced a gain in their QoL were more likely to be members of a parental association, which is a substantial form of social support.
Conclusions: Overall, the changes in parental QoL from adolescence to adulthood were mainly predicted by the presence of challenging behaviors in their children and the social support they can find. These results argue for the importance to propose specific interventions to target associated challenging behaviors in ASD and to provide social support to families.

241 **144.241** Relation Between Socioeconomic Status and Symptom Severity, Cognitive, and Language Ability in ASD

L. Olson[1,2]*, S. Reynolds*[1,3]*, Y. Gao*[1,2]*, S. Punyamurthula*[1]*, N. Witkowska*[1]*, R. A. Müller*[1,2] *and I. Fishman*[1,2]*, (1)Brain Development Imaging Laboratory, Department of Psychology, San Diego State University, San Diego, CA, (2)Joint Doctoral Program in Clinical Psychology, SDSU / UC San Diego, San Diego, CA, (3)Department of Psychological Sciences, University of San Diego, San Diego, CA*

Background: The factors associated with low socioeconomic status (SES) are known to have negative impacts on language and cognitive development (Hart & Risley, 1995). While the negative effects of poverty on typical development have been widely documented, little is known about how socioeconomic factors may influence developmental outcomes in children with ASD. There is some evidence that low SES is associated with later age of diagnosis and reduced access to intervention services in ASD (Dickerson et al., 2016). Examining the relationship between SES and developmental outcomes in ASD is critical for understanding the impact of socio-contextual factors on symptom presentation in ASD. Knowledge thereof also has the potential to inform intervention efforts in vulnerable populations.
Objectives: To investigate the relationship between SES, cognitive ability, and ASD symptomatology in a cohort of children and adolescents with ASD taking part in brain imaging studies.
Methods: 96 participants (80 males) ages 7 – 18 (mean ±SD = 13.6 ± 2.7) with confirmed ASD diagnoses completed neuropsychological and diagnostic assessment as part of an ongoing study of brain development and ASD. Participants completed the CELF-4, WASI-II, ADOS-2 and the ADI-R. Additionally, primary caregivers of 37 participants (30 males) provided information on both maternal and paternal income and education level. SES variables were submitted to Principal Component Analysis (PCA), which yielded two principal components (PCs) accounting for 49% and 28% of the variance, respectively. PC1 and PC2 were then used as predictors in multiple linear regression models to test for associations between SES, ASD symptomatology, and cognitive ability.
Results: Maternal income and education both loaded positively onto PC1 (rs = 0.88 and 0.44, respectively), whereas paternal education loaded positively onto PC2 (r = 0.80). Thus, PC1 and PC2 were interpreted to represent maternal SES and paternal education, respectively. Consistent with previous findings on the effects of maternal SES factors on language ability, maternal SES (PC1) was significantly associated with language skills (r = 0.47, ß = 4.41, t_{22} = 2.52, p = 0.02), and cognitive ability (r = 0.43, ß = 4.04, t_{29} = 2.56, p = 0.01) (see Figure 1). Notably, PC1 scores were negatively associated with ASD symptom severity on the ADI-R (r = -0.41, ß =Â -1.64, t_{28} = -2.38, p = 0.02) (see Figure 1). Paternal SES factors were not associated with any outcome measures.
Conclusions: Â Consistent with findings in the general population, we found that lower maternal income and education were associated with lower cognitive ability and weaker language skills in children and adolescents with ASD. Lower maternal SES was associated with increased symptom severity on the ADI-R, a parent report of the child's symptoms at age 4-5 years. Intriguingly, this association was not significant on the ADOS-2, a clinician-rated measure. This discrepancy merits further research on the use of parent-report and clinician-rated diagnostic tools in low-SES populations. Paternal SES factors were not associated with any clinical or cognitive outcomes, corroborating previous findings that maternal SES factors have a greater effect on developmental outcomes than paternal factors.

242 **144.242** Results of a Patient-Centered Outcomes Research Institute (PCORI) Approach to Engaging ASD Stakeholders in Rural Underserved Areas

J. Elder[1]*, S. N. Brasher*[2] *and C. Kreider*[3]*, (1)FCH, College of Nursing University of Florida, Gainesville, FL, (2)Emory University, Atlanta, GA, (3)University of Florida, Gainesville, FL*

Background: The Patient Centered Outcome Institute (PCORI) has identified the critical need to address health disparities that exist among patients and connect researchers with stakeholders to focus on what is most important to patients and their families. Building on our initial work with families of children with Autism Spectrum Disorders (ASD), we have been awarded two PCORI grants (Tier 1 and II) to engage and build capacity for families and other stakeholders living in rural areas who are more likely to have reduced access to proper care and use alternative, unproven, and potentially harmful treatments.
Objectives: To describe the 2-tiered process of implementing the PCORI mechanism and report stakeholder generated comparative effectiveness research priorities related to families of individuals with ASD living in underserved rural areas
Methods: In 2014 our team was funded by the Clinical Translational Research Institute ar our university to establish a Community Advisory Board (CAB) of major stakeholders (e.g., parents of individuals with ASD, community-based healthcare service providers, school teachers) and we conducted a series of focus groups. Results from this study informed two subsequent PCORI funded applications (Tier I and II, 2015-2017), the second of which is currently in progress. This work demonstrates how the PCORI mechanism can be implemented in a systematic manner to engage stakeholders in rural underserved areas and position researchers to conduct comparative effectiveness research studies that are of most interest to the stakeholders.
Results: Following the completion of the initial study that engaged focus group participants to identify barriers to early diagnosis and treatment, we have greatly increased our capacity to reach and engage stakeholders in three rural underserved areas of our state. These vibrant and highly engaged groups are led by community stakeholders and include parents, educators, and community service providers who meet monthly in their rural locations. The group leaders also meet monthly with our centrally located Community Advisory Board (CAB) to discuss their progress and receive professional consultation as needed. These groups have each established their own names, functions, and priorities that will, in the spirit of PCORI, inform subsequent comparative effective research that is most meaningful to them. While several topics have emerged, of most interest is future research evaluating the effects of distance delivered ABA, PRT interventions and remote data capture using state of the art technology
Conclusions: Â As noted, the Patient Centered Outcome Institute (PCORI) approach is well-suited to address the needs of underserved and rural ASD stakeholders. Engaging stakeholders from the beginning of the research process (i.e., formulating the comparative effectiveness research questions) is critically important to remove "the mystique" that stakeholders may perceive related to autism research and facilitate their involvement throughout the process of conducting comparative effectiveness studies.

243 **144.243** Role of Externalizing Children Problem Behaviors in the Relationship between Autism and Parenting Stress: A Primary School Based Case-Control Study

Q. K. Y. Siu[1]*, H. Yi*[1]*, F. Y. D. Chan*[2]*, J. Greenberg*[3]*, W. W. S. Mak*[4] *and S. M. Griffiths*[1]*, (1)JC School of Public Health and Primary Care, The Chinese University of Hong Kong, Shatin, Hong Kong, (2)Department of Pediatrics, The Chinese University of Hong Kong, Shatin, Hong Kong, (3)The Children's Institute of Hong Kong, Kenndy Town, Hong Kong, (4)Department of Psychology, The Chinese University of Hong Kong, Shatin, Hong Kong*

Background: Identifying the sources of parenting stress (PS) is important to improve well being of parents and their child. Although PS has been consistently reported higher among parents of children with autism spectrum disorders (ASD) than parents of typically developing (TD) children, the findings of the relationship between severity of ASD and PS among parents of children with ASD are not consistent suggesting PS can be independent from ASD. While children problem behaviors (CPB) are known to be a major source of PS, little is known about the relationship between ASD, CPB, and PS.
Objectives: (1) To compare PS between parents of children with ASD and TD children; (2) To examine factors associated with PS; and (3) To examine the role of CPB, including externalizing and internalizing problem behaviors, in the relationship between the symptoms and severity of ASD and PS.
Methods: A cross-sectional survey was conducted in 5 public primary schools and 2 special education programs in 2015. A total of 731 parents (177 ASD children and 554 TD) completed the survey (M=41.5 years old, SD=6.4). Age by gender of children was matched between the children with ASD and TD children groups (M=8.6 years old, SD=1.6). The measures included parent and child characteristics, Childhood Autism Spectrum Test (CAST) assessing symptoms and severity of autism characteristics, Strengths and Difficulties Questionnaire (SDQ) assessing externalizing and internalizing CPB, pro-social behavior, and parenting stress (PS; the Parental Distress subscale of Parenting Stress Index Short Form). Pilot survey checked preliminary validity and reliability in the study sample. Multiple regression models were used to examine the associations between the study variables and outcome variable of PS, direct and indirect effects of CAST on PS mediated by SDQ, controlling for diagnosis of ASD (i.e., children with ASD and TD children groups).
Results: Compared to parents of TD children, those of children with ASD reported higher scores on CAST, externalizing and internalizing CPB, and PS and lower score on pro-social behavior (all p<.001). In multiple regression models, in the sample of ASD cases, PS was significantly associated with the number of children with ASD, externalizing CPB and less pro-social behaviors. In TD controls, PS was significantly associated with lower household income, larger household size, lower birth order, externalizing and internalizing CBP. The significant indirect effect was found between CAST and PS, mediated by SDQ in both groups: .34* (.12) in ASD case and .50***(.066) in TD control. In examining the both groups in one model, the effect of externalizing CPB was found as well: .42***(.081), and diagnosis of ASD entered but was not significant for PS.
Conclusions: The mediation effect of CPB on the association between CAST and PS suggests a primary stress source for PS was not the severity and symptoms of ASD but externalizing problem behaviors. Children's labeling with ASD was not a primary parenting stressor either. Psychological interventions should focus on skills and efficacy in coping with their children's externalizing behaviors rather than autism-oriented characteristics in order to alleviate PS.

244 **144.244** Should We Tell? Parents' Perspectives on Disclosing an Autism Diagnosis

S. Hodgetts[1], *L. G. Rogers*[2], *L. Acheampong*[1] *and S. Phelan*[3], *(1)University of Alberta, Edmonton, AB, Canada, (2)University of Alberta, Edmonton, AB, CANADA, (3)Department of Occupational Therapy, University of Alberta, Edmonton, AB, Canada*

Background: Deciding to disclose their child'sÂ diagnosis of autism spectrum disorder (ASD) to others is a major life decision for parents. Limited research has investigated the implications of disclosure or non-disclosure, leaving families without evidence to help guide or inform their decision-making processes. It also leaves professionals, to whom parents often turn for advice and support, with little evidence to inform their recommendations to families.
Objectives: Â To better understand: (1) The decision-making processes by which parents of a child diagnosed with ASD chose to disclose their child's diagnosis to others; for example, family, peers, educators, healthcare professionals, and community members. We explored decision-making related to if, to whom, when, how, and why parents choose to disclose, or not disclose. (2) Parents' perspectives of the outcomes of disclosure or non-disclosure.
Methods: Using a constructivist grounded theory methodological approach (Charmaz, 2006), we interviewed parents of 3-16 year old children with ASD (N=10 to date). Purposive and theoretical sampling were used for diversity in child and family factors (e.g., age, symptom severity, ethnicity), and families who have chosen to disclose and not disclose. Recruitment, data collection and analysis will continue until saturation. Consistent with grounded theory methodology, data collection and analysis are being conducted concurrently to inform theoretical sampling, emerging codes, and the development of theoretical categories. Data, consisting of verbatim transcripts, field notes, and memos, are being analyzed using constant comparative analysis and initial, focused, and theoretical coding strategies (Charmaz, 2006).
Results: Based on preliminary data analysis, decisions to disclose were related to parent's acceptance of the ASD diagnosis, their perceived knowledge about ASD, their perceptions of stigma and blame, and parent's desire for informal and formal supports. Perceived disadvantages of disclosure included reluctance to have their child labeled, especially when young, concern about a lack of control over who the child's diagnosis may be shared with once disclosed, and fear of stigmatization and blame by spouses, relatives, and society in general. Benefits of disclosure included increased safety of their child and others, parent social support, affirmation of concerns about their child, and access to funding and services. However, some parent's felt that disclosure was a necessity, not a choice, to access funding and services.
Conclusions: These analyses will be used to generate a theoretical model representing the decision-making processes of disclosure, including parents' perceived decision making points and outcomes. Findings may help increase sensitivity and understanding, and decreasing stigma and judgment for professionals and the public, related to parents' decisions of whether or not to disclose their child's diagnosis of ASD.
Charmaz, K. (2006). *Constructing Grounded Theory*. London: Sage.

245 **144.245** Sibling Status (TD or ASD) Is Associated with Parent Reports of Adaptive Skills in Children with ASD

R. Bakhtiari[1], ***B. Thompson***[2] *and G. Iarocci*[3], *(1)Simon Fraser University, Burnaby, BC, Canada, (2)Autism Developmental Disorder Lab, Burnaby, BC, CANADA, (3)Simon Fraser University, Burnaby, BC, CANADA*

Background: Previous research has focused on the impact of having a sibling with autism spectrum disorder (ASD) on typically developing (TD) children. Findings suggest that having an ASD sibling is associated with increased adjustment problems, peer problems, internalizing and externalizing behaviours and less prosocial behaviour in TD children (Hastings, 2003; Ozonoff et al., 2010). However, little research exists on how the effect siblings have on the behaviour of children with ASD. In the current study we examined adaptive skills of children with ASD who had a TD sibling vs. a sibling with ASD. Children with ASD generally show poor adaptive skills (Gillberg, 2002), even those with average intellectual functioning show adaptive behaviour in the "at risk" range (Volker et al., 2010). In this study we assessed adaptive skills including adaptability, social skills, leadership, activities of daily living, and functional communication in children with ASD who had a TD sibling and inthose who had an ASD sibling.
Objectives: To investigate whether sibling status (i.e., TD or ASD) is associated with different levels of adaptive skills in children with ASD
Methods: Â Participants were 40 children with ASD between the ages of 6 and 17 years old (*M*=11.4; SD=2.4) who have one sibling (agerange = 6–21 years; M=12.1; SD=2.4) with ASD (n=12), or one TD sibling (n=27). The parents ratedtheir children's adaptive skills on the Behaviour Assessment System for Children Second Edition (BASC-2), and ASD symptoms on the Social Responsiveness Scale (SRS). Children's IQ scores were assessed using the Wechsler Abbreviated Scale of Intelligence (WASI-II), or Stanford-Binet Intelligence Scales, abbreviated version (SB5).
Results: Â Hierarchical multiple linear regression analyses indicated that sibling status was a significant predictor of Adaptive Skills in children with ASD, above and beyond ASD symptoms, IQ, siblings age, and participants age. Specifically, having a TD sibling accounted for a significant additional 19% of the variance in adaptive skills (.To further explore this relationship we examined the subscales of the Adaptive Skills. Certain subscales remained significant, Adaptability(, Activities of Daily Living (,and Functional Communication (. In contrast, social skills and leadership subscales did not reach significance.
Conclusions: In children with ASD, having a TD sibling is a significant predictor of higher scores on Adaptive Skills including Adaptability, Activities of Daily Living and Functional Communication. These results suggest that TD siblings may have an important role to play in the daily functioning of children with ASD. Having a TD sibling may provide opportunities for modeling of adaptive behaviour in children with ASD and sibling mediated interventionsmay be a potentially powerful tool for teaching adaptive skills to children with ASD.

246 **144.246** Sleep Problems in Children with Autism Spectrum Disorders: Impact on Caregiver Quality of Life.

***B. Cuomo**, T. Falkmer, S. Vaz and J. Rogerson, School of Occupational Therapy and Social Work, Curtin University, Perth, Australia*

Background:
Children with autism spectrum disorder (ASD) frequently experience sleep problems, with previous research indicating prevalence rates of between 50 to 80%. Due to the negative impact of prolonged sleep problems on developmental outcomes and general health and wellbeing, this is a major cause for concern. Research suggests that sleep problems in children with ASD also have a wider negative impact on their caregivers, particularly in relation to parent stress. The relationship to the phenomenon of parent quality of life (QOL) however has not been explored; despite literature finding associations between parental QOL and behavioural problems in children with ASD, the impact of child sleep has not been explicitly investigated.
Objectives:
The study aimed to establish a profile of sleep problems in children with ASD in a Western Australian population, and subsequently examine the relationship between sleep problems in children with ASD and parent QOL, with consideration of the impact of other child factors.
Methods:
A cross-sectional survey was conducted with 204 caregivers of 219 children with ASD aged 2-18 years living in Western Australia, with data collected over an 18-month period from January 2015-July 2016. Outcome measures were all parent-reported and included the Children's Sleep Habits Questionnaire (CSHQ), World Health Organisation Quality of Life (WHOQOL) - BREF version, the DSM-IV-TR/ICD-10 checklist of ASD diagnostic criteria, and general demographic questions. A sleep profile was generated based on established 'cut offs' indicative of clinically significant sleep problems. General linear modelling was conducted to examine the presence of a relationship between parent QOL and child factors, including sleep problems.
Results:
Results from the CSHQ indicated that over 85% of the children experience clinically significant sleep problems. Key areas of concern were poor sleep duration, sleep onset delay, night wakings and parasomnias. Sleep problems were found to be significant predictors for two of the three QOL domains. Sleep-disordered breathing, daytime sleepiness and sleep duration were found to be predictors of poorer parental physical QOL, while bedtime resistance predicted poorer social relationships QOL. Sleep was not a significant predictor of parent psychological QOL. Other significant child factors included communication difficulties, sensitivity to sensory input, behaviours relating to distress over environmental change, and taking melatonin supplements (a common sleep intervention). Factors of child age, gender, diagnosis, and presence of other co-morbidities were not significant predictors.
Conclusions:
Findings confirm the high presence of sleep problems in a sample of Western Australian children with ASD, highlighting the need for greater clinical attention including assessment and intervention of sleep problems in this population. The presence of significant relationships between child sleep problems and parent QOL demonstrates the significant negative impact these problems have, not only on the child, but on their caregivers. This emphasises the need to consider the family as a unit in paediatric clinical practice, and draws attention to the need for recommendations to be considered on the basis of effectiveness for the child, as well as whole-of-family feasibility and 'fit'.

247 **144.247** Stigma and Social Perception of Mothers of Children with Autism Spectrum Disorder

***E. Baker**[1], C. Ponting[2], T. Hutman[3], M. Dapretto[4] and S. S. Jeste[5], (1)UCLA Center for Autism Research and Treatment, Los Angeles, CA, (2)Clinical Psychology, UCLA, Los Angeles, CA, (3)University of California Los Angeles, Los Angeles, CA, (4)University of California, Los Angeles, Los Angeles, CA, (5)UCLA, Los Angeles, CA*

Background:
Mothers of children with autism spectrum disorder (ASD) report higher levels of parental stress related to community responses to their children's behavior and their parenting strategies. These experiences may contribute to high levels of anxiety and depression that have been reported in mothers of children with ASD. Stigmatized individuals "possess a quality that others perceive as negative, unfavorable, or in some way unacceptable" (Shtayermman, 2009). Goffman (1963) first used the expression "courtesy stigma" to describe the distinctive burden of association with a stigmatized individual. Mothers of children with ASD, in the role of primary caregivers, are especially vulnerable to stigmatizing behavior in their community (Nealy, 2012). Characterizing mothers' experience of stigma is critical, as experiences of prejudice, rejection, and discrimination increase the risk for psychopathologies such as anxiety and depression (Farrugia, 2009).
Objectives:
We aimed to understand mothers' experiences of stigmatization associated with raising one or more children with ASD. Using a qualitative approach, we examined two different types of courtesy stigma: (1) Felt Stigma (feelings of shame or rejection) and (2) Enacted Stigma (overt acts of discrimination) triggered by mothers' peer groups, families, or strangers. We also examined whether mothers developed coping mechanisms to counteract these acts of stigma.
Methods:
We conducted in-depth, semi-structured interviews (lasting 27-83 min) with 20 mothers with at least one child with ASD (age range: 3-10 years). Mothers were asked about experiences related to raising children with ASD, including quality of the relationship between their children and shifts in family dynamics after receiving an ASD diagnosis.Â Interviews were transcribed and double coded for accuracy, and a codebook consisting of 60 codes was established using a thematic analysis approach (Braun & Clark, 2006). We focused on the following three sub-themes: (1) Mother's Feelings of Shame (2) Invisibility of ASD and (3) Misconceptions of ASD, to identify instances of enacted and felt stigma.
Results:
All 20 participants reported personal accounts of distinct challenges related to parenting a child with ASD. Effects of felt stigma were reported by 80% of mothers.Â The fact that ASD is not overtly recognizable made it harder for parents to connect with friends and family, and in some cases, led to the destruction of relationships. Cases of enacted stigma, endorsed by 30% of mothers, were experienced through categorization by use of labels and negative judgment regarding parental decisions.Â One mother reported excommunication from her church congregation due to her child being disruptive during services. Generally, effects of courtesy stigma are negative. Still, mothers developed coping styles that allowed them to view stigmatizing reactions of others as acts of ignorance, rather than malice.
Conclusions:
Courtesy stigma is conveyed in public reactions to mothers' parenting choices and has damaging effects on social relationships and well-being. Mothers' coping strategies are self-protective and they also safeguard the family unit by defending against critical judgments about the child and the family. Further exploration of courtesy stigma will consider if severity of a child's symptomatology is related to the degree of stigma that a family experiences.

248 **144.248** Strategies for Successful Dental Encounters for Children with ASD: A Qualitative Study

L. I. Duker (Stein)[1]*, L. I. Florindez*[1]*, B. F. Henwood*[2]*, D. Como*[1]*, J. C. Polido*[3] *and S. A. Cermak*[4]*, (1)Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)School of Social Work, University of Southern California, Los Angeles, CA, (3)Children's Hospital Los Angeles, Los Angeles, CA, (4)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA*

Background: It is well established that oral care is an important component of pediatric healthcare. Many barriers to treatment have been identified for the ASD population, but few high-quality interventions have been designed and implemented to improve care for this population.
Objectives: As the prevalence of ASD increases, dentists are increasingly more likely to encounter children with ASD in their practice. Therefore, the purpose of this study was to gather information on the current strategies implemented by dental professionals and by parents of children with ASD to facilitate successful oral care encounters.
Methods: To document dental practitioner and parent strategies utilized to facilitate oral care challenges in the dental office and home four focus groups were conducted, two with parents of children 5-18 years with ASD and two with dental practitioners who treat children with ASD. Each focus group lasted 2.5-3 hours in duration and were transcribed verbatim. Thematic analysis following a grounded theory approach was used to describe parent and dentist implemented strategies to address children's oral care challenges.
Results: In the parent focus groups, three themes emerged. The first theme, *What Makes a Good Dentist*, focused on dentist knowledge, understanding and experience, which were all reported to be essential to a positive dental care encounter. The second theme, *Tricks, Tactics, and Diversions,* described different techniques and strategies the dental practitioner could use to help make dental visits successful. These included: (1) the strategic use of scheduling for visits, (2) the coordination with other professionals, (3) the implementation of adaptations as needed, (4) the search for sugar bugs, (5) the use of positive reinforcement, (6) the creation of a child- and sensory-friendly dental environment, and (7) the utilization of drugs. The last theme, *Preparation, Preparation, Preparation,* explored strategies caregivers could implement to increase the chance of a successful dental encounter including: (1) how to "warn" the child about the visit, (2) how to practice for the dental visit, (3) how to use visual schedules and/or social stories, and (4) items to bring to the dental visit.
Dentist focus group data analysis is currently in progress.
Conclusions: Parent findings provide insight into the techniques perceived to lead to successful dental care encounters for children with ASD. Combined with the perspectives of dental care practitioners, this information has the potential to improve care for this population by identifying areas for accommodation to create the optimal experience for children with ASD and their parents.

249 **144.249** Support Intensity Scale Profile in Autism : A Proof of Concept Study

E. Grossi[1]*, T. Gomiero*[2] *and L. Croce*[3]*, (1)Villa Santa Maria scs, Tavernerio, Italy, (2)DAD© project group, ANFFAS Trentino, Trento, Italy, (3)Catholic University, Brescia, Italy*

Background:
Tailoring supports for individual needs in disability requires tools that reliably and validly measure those needs. That is the function of the Supports Intensity Scale for children (SIS-C) developed from the American Association on Intellectual and Developmental Disabilities. SIS-C measures the individual's support needs in personal, work-related and social activitiesÂ in order to identify and describe the types and intensity of the support an individual requires. SIS has been designed to be part of person-centered planning processes that help all individuals identify their unique preferences, skills and life goals.
Objectives:
The aim of the study is to assess the SIS-C profile in Autism in comparison withÂ Intellectual and Developmental Disability (IDD) not related to autism.
Methods:
We have applied the Italian Version of SIS, during the process of Italian psychometric validation, to a group of children and adolescents with different kinds of neuropsychiatric disorders in a multicenter study carried out in13 units throughout the Italian territory. This paperÂ presents the data concerning two specifics subgroup of 127 individuals with autism (mean age 9.76; range 4-17 years) and 62 persons with IDD not related to autism (mean age 11.33; range 5 – 16 years). Seven support need dominions have been explored through independently structured interviews, whereby the two principal caregivers for each subject in this study responded to a total of 61 items covering: home living, community and neighborhood, scholastic participation and learning, health and safety as well as social and advocacy activities. Results are expressed as a percentage of maximum theoretic support need in each dominion.
Results:
The score profiles obtained from the interview of two caregivers resulted highly correlated in all dominions of the scale (*r* values ranging from 0.85 to 0.95). Individuals with AUTISM, despite an average level of intellectual disability similar to that individuals without autism diagnosis showed degrees of support need that were significantly higher than subjects in the comparison group for all dominions (see figure 1), with absolute differences ranging from +33% to +61% (mean +42%). As expected, the difference was particularly evident for home living, social activity, and community and neighborhood dominions.
Conclusions:
Traditionally, a person's level of developmental disability has been measured by the skills the individual lacks. SIS-C shifts the focus from shortfalls to needs. The scale evaluates practical support people with developmental disabilities need to lead independent lives. The key message emerging from our study is that, given a similar level of intellectual function, special needs in individuals with AUTISM are around 40% higher than those in subjects with IDD not associated to autism.

250 **144.250** Teacher Self-Efficacy for Teaching Students with Autism Spectrum Disorder: A Study of Relationships with Stress, Engagement, and Student Outcomes

A. M. Love[1]*, J. A. Findley*[2] *and L. A. Ruble*[2]*, (1)Educational, School, and Counseling Psychology, University of Kentucky, Lexington, KY, (2)University of Kentucky, Lexington, KY*

Background: Â Teacher self-efficacy refers to the belief teachers hold about their ability to affect student learning (Bandura, 1997; Klassen, Tze, Betts, & Gordon, 2011) and has been shown to change teachers' motivation and work effort (Klassen & Chiu, 2010). Teachers' sense of their own efficacy (i.e., effectiveness as teachers) varies according to the diverse contexts and learners they face, however, little research has examined efficacy when teaching students with autism spectrum disorder (ASD; Ruble, Toland, Birdwhistell, McGrew, & Usher, 2013). White, Smith, Smith, and Stodden (2012) noted that ASD learners have become one of the most challenging groups to teach; therefore, investigating the interpersonal processes involved in teaching children with ASD is an important and relevant area of research. This study seeks to explore the potential associations between self-efficacy and related constructs using multiple measurement techniques and sources (i.e., observational data, self-report, and outside observer). By incorporating objective behavioral measures and not simply self-report, teacher self-efficacy can be considered in relation to student outcomes and achievement.
Objectives: This study investigated relationships among teacher self-efficacy for teaching students with ASD and linked variables including teacher stress, student outcomes, and teacher engagement.
Methods: Special education teachers (*N* = 44) were recruited as part of a larger randomized controlled study examining a consultation intervention with teachers of students with ASD. Data were collected over multiple time points, but this study focused solely on the final responses. Measures included a self-report instrument assessing teacher self-efficacy for teaching students with ASD (ASSET) and a standardized self-report instrument capturing teacher stress, the Index of Teaching Stress (ITS). In addition, blind observers reported on a measure of teacher engagement. Student achievement data was collected using direct videotape observation from an unaware rater using goal attainment scaling. Correlation analyses were used to determine the initial degree of relationships between the variables of interest.
Results: As predicted, scores from the ASSET were positively related to teacher engagement ($r = .36$, $p < .05$) and student achievement ($r = .39$, $p < .01$). This signals a degree of relationship between teachers who engage positively with their students with ASD and teachers who self-report higher levels of teacher self-efficacy. In addition, ASSET scores were negatively related to scores derived from the measure of teacher stress ($r = -.39$, $p < .01$), indicating that teachers who have low self-efficacy for teaching students with ASD also report higher levels of stress.
Conclusions: Teacher self-efficacy was positively related to indicators of good teaching quality (higher engagement and student outcomes) and protective against negative teacher outcomes (stress). Teacher self-beliefs are likely to have significant impact on teachers' decisions, teaching environment, and interactions with students. The results have potential applications in making professional development decisions, addressing areas of perceived incompetence, and improving teacher practice.

251 **144.251** The Autism Family Experience Questionnaire (AFEQ): An Ecologically-Valid, Parent-Nominated Measure of Family Experience of Autism, Quality of Life, and Prioritised Outcomes for Early Autism Interventions

K. Leadbitter[1]*, J. Green*[2]*, R. Emsley*[2]*, H. McConachie*[3]*, A. Le Couteur*[4]*, T. Charman*[5]*, V. Slonims*[6]*, P. Howlin*[7]*, C. R. Aldred*[1] *and .. PACT Consortium*[8]*, (1)University of Manchester, Manchester, UNITED KINGDOM, (2)University of Manchester, Manchester, United Kingdom, (3)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom, (4)Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle Upon Tyne, UNITED KINGDOM, (5)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)Evelina Children's Hospital Guy's and St Thomas' NHS Foundation Trust, London, UNITED KINGDOM, (7)King's College London, Institute of Psychiatry, London, UNITED KINGDOM, (8)United Kingdom*

Background:
A focus on patient-centred outcomes, such as quality of life (QoL), has become increasingly important to intervention research. Simultaneously, there has been increasing attention to user involvement in research design. Families of children with ASD have an important contribution to make in defining the metrics by which successful interventions are judged.
The Pre-school Autism Communication Trial (PACT) was a randomised controlled trial of a parent-mediated communication-focussed intervention for pre-schoolers with autism and their parents (Green et al., 2010), with an endpoint (1-year) and 5-year follow-up.
Objectives:
1) To consult with families to develop a parent-generated measure, the Autism Family Experience Questionnaire (AFEQ), which would reflect family experience of autism, quality of life, and family priorities for specific areas that might be changed by an effective intervention
2) Within the PACT trial, to check the external validity of the child development aspects of the AFEQ by testing for a strong association with the parent rated Vineland Adaptive Behavior Scales (VABS; Sparrow et al 2006);
3) To examine a treatment effect in the AFEQ, with the hypothesis that, compared to controls, the PACT intervention group would show relative improvements in the total AFEQ score and each of the subscale scores, at endpoint (1-year) and 5-year follow-up
Methods:
The AFEQ was developed from focus groups and a national web-based consultation which asked families of young children with autism to nominate key markers of an effective pre-school autism treatment. The AFEQ was then administered at baseline and follow-up to the 152 families involved in the PACT trial.
Results:
1) The AFEQ was developed from focus-group themes and consultation feedback. It contains 56 items and covers three domains: 1) experience of parenting their child; 2) quality of family life; 3) child development, social functioning and behaviour.
2) There were strong correlations between the AFEQ child development subscore and the VABS total score: baseline r = -0.46 ($p<0.001$, n=143); endpoint r = -0.57 ($p<0.001$, n=134; AFEQ low score = better outcome, VABS high score = better outcome).
3) We compared AFEQ total and subtotal scores between intervention and control groups using linear regression (analysis of covariance) including baseline measures of the outcome as a covariate. Summary statistics and treatment effect estimates are presented in the table. On the AFEQ total score, there was a statistically significant improvement of PACT over controls. Treatment effects on the AFEQ subscales were all non-significant, although showing a trend towards a more positive outcome for the intervention group. Findings from the 5-year follow-up data will also be presented.
Conclusions:
The AFEQ represents a viable, ecologically valid, parent-nominated measure of prioritised outcomes for a pre-school autism intervention. It shows association in the expected way with another parent rated measure, the VABS. It also shows evidence of sensitivity to change over time: a treatment effect in response to a parent-mediated intervention for autism. The AFEQ has the potential to enhance understanding of the external validity of early psycho-social interventions for children with autism.

252 **144.252** The Colorado Parent Mentoring Program: Parent-to-Parent Support Improves Family Functioning and Satisfaction with Care

B. Rigles[1], *E. Moody*[2], *K. E. Kaiser*[3], *L. Kubicek*[4], *J. Davis*[4] *and C. Robinson Rosenberg*[4], *(1)University of Colorado, Boulder, CO, (2)13121 E 17th Avenue, University of Colorado, Denver, Aurora, CO, (3)JFK Partners University of Colorado, Aurora, CO, (4)University of Colorado, Aurora, CO*

Background: Despite the increasing prevalence of autism (Baio, 2014) there is currently no standard of care for autism and systems of care remain highly fractured. The challenge of creating, financing, and maintaining treatment plans adds to the stress experienced by families of children with autism. As mothers are often designated as the caregiver for children with autism, much of this burden falls on them (Bouma & Schweitzer, 1990). Previous research has found that mothers and fathers deal with the stress associated with having a child with autism differently, with social support being key for mothers (Boyd, 2002). The Colorado Parent Mentoring (CPM) program was created to improve family quality of life, family functioning, and service use, as well as to help create social support networks for mothers of children with autism. CPM combines family centered action planning and education with ongoing parent-to-parent mentorship.
Objectives: This study was designed to measure family functioning and quality of life, service use, social support, and program acceptability outcomes of the CMP program for families of children newly diagnosed with autism.
Methods: In a randomized controlled trial, the CPM intervention was given to a group of parents (n=29) and compared to a waitlist group (n=32) on four main outcomes: 1) family quality of life (Family Quality of Life questionnaire; FQOL), 2) family functioning (Family Adaptation and Cohesion Scale IV; FACES), 3) service use, and 4) program acceptability. Qualitative interviews were also conducted with all participants to explore program benefits to social support.
Results: Linear mixed models were used to test the effect of group (active vs waitlist), time (pre vs post). The active group reported greater satisfaction with disability related supports following intervention (FQOL; t = 2.18, p=.03) and reduced family rigidity (FACES, t=2.15, p=.04). Services used outside of the school setting increased for all participants but did not meet the national standard; the program was highly acceptable to participants. Qualitative data suggest that once mothers were connected to other mothers, they experienced a sense of empowerment, which reduced stressful interactions with family members.
Conclusions: The CPM program prevented rigidity in the family system and reduced the level of importance parents held regarding involvement of other family members in their child's care.Â Family functioning and quality of life are complex following a child's diagnosis of autism. The CPM program positively impacts family functioning and quality of life, primarily due to the increased social support created through this program for mothers.

253 **144.253** The Development of a Family Support Package for Parents Following a Child's Diagnosis of Autism Spectrum Disorder: What Do Parents Want?

S. Rabba[1], *C. Dissanayake*[2] *and J. Barbaro*[3], *(1)La Trobe University, Melbourne, AUSTRALIA, (2)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (3)Olga Tennison Autism Research Centre, School of Psychology & Public Health, La Trobe University, Melbourne, Australia*

Background: Â Children with ASD are being diagnosed more than ever before. Unfortunately, the diagnostic process is distressing and difficult to understand for families.
Objectives: Â The objective in the proposed project is to develop and test the efficacy of a Family Support Package (FSP) to support parents soon after the diagnostic process.Â The specific aims include: 1) the development of a package that comprises parental education/information in the form of a post-diagnostic kit, and a Family Clinic (FC); 2) to investigate whether access to the FC improves parental well-being.
Methods: Â Focus groups were conducted with parents to inform the development of the FSP.Â This paper will present the qualitative results from the focus groups and the framework of the FSP.
Results: Â Mothers and fathers who received their child's diagnosis in the last 24 months were invited from the participant registry to the current study. Consenting participants attended a single focus group of approximately 60 to 90 minutes with four to six other parents. Audio recordings were transcribed with qualitative analyses conducted to draw key themes.
Conclusions: Parents of children diagnosed with ASD at a young age are often overwhelmed and uncertain about what to do at this critical time. Themes emerged from the focus groups that identified what parents really want and what is most helpful to them soon after the diagnosis. A central contact point was highlighted, as well as a step-by-step guide about who to contact and where to find more information. Parents also emphasised that education and awareness of ASD is key to their understanding and acceptance of the diagnosis.

254 **144.254** The Effect of Sibling Order on Communication in Individuals with and without ASD

E. Lecarie[1], *B. Lewis*[2], *J. Lei*[1], *H. Turner*[1], *J. Wolf*[1], *R. J. Jou*[3] *and J. McPartland*[4], *(1)Yale Child Study Center, New Haven, CT, (2)Yale School of Medicine, Darien, CT, (3)Yale University, New Haven, CT, (4)Child Study Center, Yale School of Medicine, New Haven, CT*

Background: Sibling interaction can be an important positive influence in the development of children with autism spectrum disorder (ASD; Jones & Carr, 2004; Knott et al., 2007). Social and communication difficulties are core components of ASD, with deficits in adaptive use of language being common. A recent study indicated that children with ASD who had at least one older sibling showed stronger communication skills than children with ASD who did not have siblings (Ben-Itzchak et al., 2016), suggesting that older siblings promote social interaction and foster the acquisition of communication in children with ASD. It is not known whether the influence of sibling order on communication and adaptive use of language is specific to ASD or common to other neurodevelopmental disorders.
Objectives: The present study evaluated whether sibling order has an impact on the adaptive use of language in individuals with ASD when compared to individuals with diagnoses other than autism.
Methods: The present study utilized a clinical sample of 25 individuals (Mean age: 8.62, Range: 3-25); data collection and retrospective analyses of additional historical cases are ongoing. Seventeen individuals had an ASD diagnosis (Mean age: 7.76, Range: 3-19; diagnosis confirmed with ADOS). Eight of the seventeen individuals in the ASD cohort were oldest children. The eight individuals who did not meet criteria for ASD (Mean age: 10.43, Range: 4-25) had other clinical diagnoses (e.g., anxiety, language disorder), as evaluated by a multi-disciplinary team. Four of the eight individuals with other diagnoses were oldest children. The Vineland II Adaptive Behavior Scales – Survey Interview (VABS-II) was administered to parents, and the communication domain was used to evaluate each subject's adaptive use of language.
Results: Â T-tests revealed no significant differences in the adaptive use of communication (VABS-II) between individuals with ASD and other psychological conditions (p=.945). In the ASD group, there was a marginal effect (p=.057) with regard to sibling order, such that those who were the oldest children in their families had higher communication standard scores, thus demonstrating greater adaptive use of language. No effects of sibling order on adaptive use of language were observed in the group with other diagnoses (p=.278).
Conclusions: The current study failed to replicate the finding that the availability of older siblings is associated with improved social communication in ASD. In contrast, preliminary results suggested that individuals with ASD may benefit from interactions with younger siblings. This may reflect conventional order effects in that oldest siblings with ASD may benefit from a developmental period with undivided parental attention. Results add to evidence indicating the benefits of siblings for the development of individuals with ASD (Shivers and Plavnick, 2015).

255 **144.255** The Effectiveness of a Group Brief Parent Training for Parents with the Developmental Disorders

M. Inoue[1], *D. Enomoto*[2,3] *and H. Murase*[2], *(1)Tottori University, Yonago-City, Tottori, Japan, (2)LITALICO Inc., Tokyo, Japan, (3)LITALICO Lab., Tokyo, Japan*

Background: Â Various types of Parent Training (PT) have been developed as a family support program to meet the needs of parents who have children with developmental disabilities. However, practical challenges have been studied, such as contents, amount and length of the program varies among types of disabilities and needs of parents. Brief parent training program was expected to be effective for various needs, can address these problems.
Objectives: Â The purpose of this study was to examine the effectiveness of a shortened version of Tottori University-PT program (S-TPT) by analyzing variability of parents' behavior and cognition, and child's behavior.
Methods: Â 80 parents of children with intellectual/developmental disabilities were participated. The children were 4.11 years old on average and were provided therapy 2 to 8 times a month. The participants were divided into PT group (N=40; 31 boys and 9 girls) and controlled group (N=40; 33 boys and 7 girls). The PT group attends S-TPT, which were 5 sessions in one time a week for 5 weeks. S-TPT was performed in groups of 8-10 mothers/fathers each. The sessions consisted following: Reinforcement, the token economy system, three-term contingency, effective instruction, and antecedent control. Beck Depression Inventory-Second Edition (BDI-Ⅱ) , Parenting Stress Index (PSI) Parenting Styles and Dimensions Questionnaire(PSDQ) and Eyberg Child Behavior Inventory(ECBI)Â were used. These measures were given at pre- and post-program, and at 2-month follow up.
Results: Â In PT group, there were improvements of all measurements. Effects on the PT group compared to the control group were tested with two-way factorial analysis of variance (ANOVA), using the pre- and posttest scores. There was a significant difference in the main effect and the interaction on PSI, PSDQ item "Rebuke", and "Difficulty of the Corresponding".
Conclusions: Â In comparison between controlled group and PT group, it suggested that shorter parent training give positive effect on stress of raising child and depression. And, both groups showed improvement over 2-month follow-up. We consider that the reasons might be that child of a parent who was in both groups was provided therapy. Further, as for the behavior variability of child, there was the improvement, but no significant difference between groups. We want to make clear that point in the future.

256 **144.256** The Experience of Stress in Caregivers of Children with ASD: An Examination of Stressors

R. G. Romanczyk[1], *R. N. Cavalari*[2], *J. Gillis*[1], *D. M. Noyes-Grosser*[3], *E. H. Callahan*[4], *B. Elbaum*[5] *and K. M. Siegenthaler*[6], *(1)State University of New York at Binghamton, Binghamton, NY, (2)Binghamton University - Institute for Child Development, Binghamton, NY, (3)NYS Department of Health, Averill Park, NY, (4)The Council of Autism Service Providers, Wakefield, MA, (5)University of Miami, Coral Gables, FL, (6)New York State Department of Health, Bureau of Early Intervention, Albany, NY*

Background:
The caregivers of children with autism spectrum disorder (ASD) have typically reported high levels of stress in previous research. The impact of stress is typically negative for the individual and in turn can impact therapeutic activities directed toward the child. The specific sources of stressors have received less attention than establishing the presence of stress.
Objectives:
To examine the utility of two low cost (caregiver completed) instruments to examine possible stressors in a large sample of caregivers of children with ASD and a comparison group of caregivers of children with other developmental delays. The research validated measures were chosen to represent the types of instruments needed for large scale screening in the public service, rather than for a research, setting. That is, instruments were chosen that caregivers complete, are inexpensive, and require modest professional training to score and interpret.
Methods:
A large state wide sample of children receiving early intervention services through the New York State Part C Early Intervention Program was utilized. The Parenting Stress Index (PSI) and the Pervasive Developmental Disorder Behavior Inventory (PDDBI) were administered at the time of entry to services.
Results:
266 caregivers responded and the average child age of the sample was 2.3 years. High levels of caregiver stress for the ASD group were recorded as has been reported in previous research. Significantly higher stress levels for the ASD group vs the comparison group were found. A significant proportion in the ASD group scored in the clinically elevated range. However, elevated stress level for the comparison group was also recorded. The PDDBI autism severity scores were positively correlated with PSI scores for both the ASD and comparison group, indicating a possible common composite source of stressors. However, analysis of the specific subscales of the PSI and PDDBI associated with child specific characteristics indicated complex interactions with group, such that there were both shared (such as problem behaviors) and separate (such as communication deficits) stressors.
Conclusions:
Appropriate emphasis has been placed on the necessity of early diagnosis and intervention for children with ASD. Less formal attention has been directed at caregiver needs and supports during this process. The use of the PSI as a low cost screener of caregivers to identify individuals experiencing elevated levels of stress in both ASD and other developmental delay groups is recommended. Such screening should be routine to allow caregivers to access appropriate services should they wish. The use of the PDDBI as a low cost instrument allows for identifying possible sources of stressors that can then form the basis of an appropriate caregiver-child assessment and intervention strategy. The present research indicates that there are shared and separate child characteristics that may affect caregiver stress in an ASD and non ASD population that may permit appropriate individualization of services. Results also affirm that caregiver stress is problematic not simply for caregivers of children with ASD.

257 **144.257** The Impact of Personality Traits on Outcomes in Caregivers of Individuals with Autism Spectrum Disorder in the Transition Period

Y. Yu[1] *and J. H. McGrew*[2]*, (1)Indiana University - Purdue University Indianapolis, Indianapolis, IN, (2)Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN*

Background:
Raising children with autism spectrum disorder (ASD) is a difficult challenge for primary caregivers. Previous studies have identified child (e.g., number of problem behaviors) and parent factors (e.g., social support) related to caregiving stress (Stuart & McGrew, 2009). However, few studies have examined the impact of the "big 5" personality traits (i.e., neuroticism, extraversion, conscientiousness, agreeableness, openness; Costa & McCrae, 1992) on caregiving stress and *how* they may affect caregiving stress, although this is an area of active research in understanding caregiving in other disorders (e.g., cancer caregiving).
Objectives:
The current study examined the potential impact of caregivers' personality traits on stress during the period when individuals with ASD transition out of high school. The study also examined potential mediators and moderators (e.g., coping skills, use of negative appraisals) to determine how personality traits affect caregiving stress. The Double ABCX model was used as a framework (McCubbin & Patterson, 1983), which views caregiving stress as the additive impact of several independent factors: stressors, internal resources, and external resources.
Methods:
A total of 117 participants, recruited via Amazon Mechanical Turk and other methods (e.g., parent support groups, autism listservs), were caregivers of individuals with ASD who either will graduate within two years or graduated from high school within the past two years. Caregivers completed questionnaires online measuring caregiver burden, stressors (i.e., ASD symptom severity, problem behaviors, pile-up demands), internal resources (i.e., personality traits, cognitive appraisals, and coping strategies), and external resources (i.e., social support).
Results:
Parents reported moderate levels of caregiving stress in the transition period (M = 2.06, SD = .75). Greater caregiving stress was associated with higher neuroticism (r = .52, p <.001), and lower levels of extraversion (r = -.31, p <.001), conscientiousness (r = -.32, p <.001), and agreeableness (r = -.22, p = .01). Parallel mediation analyses indicated that use of passive avoidance as a coping strategy was a significant mediator between caregiving stress and all four personality traits, neuroticism (Indirect effect = .02, SE = .01, 95% CI = .01, .03), extraversion (Indirect effect = -.02, SE = .01, 95% CI = -.04, -.01), conscientiousness (Indirect effect = -.03, SE = .01, 95% CI = -.05, -.01), and agreeableness (Indirect effect = -.03, SE = .01, 95% CI = -.04, -.01). Social support mediated the link between agreeableness and caregiver burden (Indirect effect = -.01, SE = .01, 95% CI = -.03, -.001).
Conclusions:
The results demonstrate the potential importance of personality traits in explaining differences in caregiving stress in families of those with ASD. Specifically, parents high in neuroticism reported greater stress, whereas those high in conscientiousness, extraversion, and agreeableness reported lower stress. Results further indicated that the association between personality and burden was mediated by caregivers' use of maladaptive coping strategies, i.e., passive avoidance coping. The findings have potential applicability for interventions to reduce caregiver burden.

258 **144.258** The Impact of the Environment on Primary Care for Individuals with Autism

L. I. Duker (Stein)[1] *and B. Pfeiffer*[2]*, (1)Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)Temple University, Hatfield, PA*

Background: Primary care provides health promotion, disease prevention, health maintenance, counseling, patient education, diagnosis and treatment of acute and chronic illnesses in a variety of health care settings. Providers of primary care play a large role in the health-related care of individuals with autism spectrum disorder (iASD). Although iASD are reported to engage in a greater number of health care encounters compared to their neurotypical peers, these encounters are often fraught with difficulties that impact the provision of effective healthcare. Strategies to support the provision of primary care for iASD often focus on person factors, with less consideration of environmental impact. As recognized by the International Classification of Functioning, Disability, and Health (ICF), the environment has the potential to facilitate or constrain function of individuals. As defined by the ICF, environmental factors include the physical, social, attitudinal, and political/system environments in which people live and conduct their lives.
Objectives: The purpose of this study was to describe the environmental barriers and facilitators impacting primary medical care for iASD across the lifespan.
Methods: A scoping review was conducted using systematic methodology. Eleven databases were searched using the keywords "primary/health/medical care," and "autism." Inclusion criteria included: (1) studies exploring primary medical care experiences/challenges, (2) participants were iASD, caregivers, or primary care providers, (3) published in a peer-reviewed journal, (4) written in English in the last 10 years. Reported factors were characterized into the following ICF environmental categories: (a) products and technology, (b) natural and human-made environment, (c) support, (d) attitudes, and (e) services, systems and policies.
Results: The search yielded 11 articles meeting all inclusion criteria; 4 focused on adults while 7 examined pediatric populations. Studies were surveys (n=5), qualitative interviews/focus groups (n=4), and interventions (n=2).
Articles indicate that challenges exist for iASD in regard to primary medical care in all five ICF environmental categories. For example, communication difficulties arose frequently during visits, but success with pictorial, graphic, and assistive and augmentative communication *products and technology* were reported. The design of the waiting and medical rooms were also named as challenges; however, individualized modifications to the built and sensory *environments* were reported to contribute to successful encounters. A lack of *support* was described with family support services and disability services reported to be difficult to obtain, but when accessed led to positive experiences. Provider acceptance of ASD stereotypes and a lack of respect for parents were common barriers to care; care was facilitated when providers treated parents as experts and partnered with them in decision-making (*attitudes*). *Health systems and policy*challenges were diverse, but included a necessity for longer duration visits, timely care, and negation of financial disincentives.
Conclusions: Individuals with ASD experience great challenges in the access to and provision of primary care. This information has the potential to improve patient-centered care for this population by helping professionals identify priorities for efforts to address the primary care-related needs of this population. Strategies to best serve iASD should aim to adapt all five aspects of the environment as delineated in the ICF.

259 **144.259** The Influence of Social Support on the Stress of Families of Children with Autism Spectrum Disorder

S. McKee[1]*, K. Bergez*[1]*, D. Truong*[1]*, A. Meinert*[1]*, A. Barton*[1] *and S. S. Mire*[2]*, (1)University of Houston, Houston, TX, (2)Psychological, Health, & Learning Sciences, University of Houston, Houston, TX*

Background: Families raising a child with ASD experience higher levels of stress compared to those with typically developing children or those whose children have other developmental disabilities (e.g., Hastings et al., 2005; Cuzzocrea et al., 2016). Social support is a protective factor against stress (Bailey, Wolfe, & Wolfe, 1994), and may lower stress in families of children with ASD (Pottie & Ingram, 2008). However, social support among parents of children with ASD is lower than among parents of typically developing children or of children with other disabilities (Glazzard & Overall, 2012; Weiss, 2002), and little is known about factors that may increase or decrease social support for families of children with ASD.
Objectives: To investigate types of social support and family factors that may predict lower parental stress among families of children with ASD.
Methods: Data from families of children with ASD (*N*=45) were collected from a subsample of families from the Simons Simplex Collection. Social support was measured via the Social Support Index (SSI; McCubbin et al., 1991) and further queried in questionnaire format. Parental stress was measured via the Parenting Stress Index – Short Form (PSI-SF; Abidin, 1995) or the Stress Index for Parents of Adolescents (SIPA; Sheras, Abidin, & Konold, 1998). Linear regression analyses were conducted to explore social support prediction of parental stress, and forthcoming analyses will allow further exploration of contributors to parental stress and differences among families depending on specific types of support.
Results: In this sample, all participants were mothers of children with ASD. Child age ranged from 6 to 17 years (*M*=11.17, *SD*=3.27). Family income ranged from $18,000 to $490,000 (*M*=$130,970, *SD*=94,198.19). Social support scores ranged from 42 to 78 (*M*=61.13, SD=6.75). Results of linear regression analysis indicated that overall social support significantly predicted parental stress, $F(1, 31) = 7.22$, $p<.05$, $R^2=.189$.
Conclusions: Current findings were consistent with previous research in that families' social support predicted parental stress. However, this sample of parents of children with ASD experienced *higher* levels of social support than samples of other families with typically developing children (McCubbin, Patterson, & Glynn, 1996), which is contrary to previous research (e.g., Weiss, 2002). One potential contributor to this surprising finding may be the higher-than-average mean socioeconomic status of this sample, which may increase access to community resources and supports. Notably, despite the sample's overall high level of social support, there was considerable variability in the levels of social support endorsed. Since higher social support predicts lower parental distress within a sample that is well-connected to community resources and supports, attending to families' connectedness may be key in improving overall family functioning. However, relationships between these factors may vary depending on characteristics of the family (i.e., culture, socioeconomic status, etc.), and this is an important area of future research.

260 **144.260** The Parent Motivation for Early Intervention Participation Scale for Children with Autism Spectrum Disorder

K. Marsh*, D. A. Prykanowski and A. C. Huggins-Manley, University of Florida, Gainesville, FL*

Background:
Family-based practices in early intervention (EI) facilitate the development of parental skills and provide families access to the resources necessary to support positive development of their young children with Autism Spectrum Disorders (ASD; American Psychological Association, 2013). Families are trained to use individualized strategies and acquire techniques in order to implement interventions with their children in the natural home setting (Hanson & Lynch, 2013). As family-implemented practices continue to be applied with parents of children with ASD, it is vital to evaluate how parental motivation to fully participate in implementation may affect the efficacy of these practices.
Objectives:
This poster will present findings from a pilot study on the development and implementation of the Parent's Motivation for Early Intervention Participation scale. The measure aims to assess parent's readiness to actively participate in interventions for their children with ASD.
Methods:
Using the Evidence-centered design framework, the researchers constructed forty-four items to represent a spectrum of motivation from readiness to resistant (Mislevy, Almond, & Lukas, 2003; See Figures 1-3). Readiness describes always being in a state of change and influenced by others, whereas ambivalent portrays clients who want their children's behaviors to change but realize this change may result in inconveniences in their lives. Resistance describes levels of denial and the act of defending the behaviors that are already in place (Rollick & Miller, 1993). Content validity was measured using seven experts who rated the items as "hard to agree with," "somewhat difficult to agree with," or "easy to agree with." Results were used to revise the items and finalize the rating scale, which was redistributed to a larger pool (n = 25) of experts in early childhood to further define theÂ targeted constructs. The final step in development includes distributing the scale to parents with children with ASD (n = 150) who are currently receiving EI services at home and conducting a factor analysis of the items.
Â Results:
The means of the items were calculated and ranked from highest to lowest. No item was rated as difficult to agree with by all seven experts. Experts were asked to rate how well the overall construct was being measured and the results ranged from 2 (adequately) to 4 (very much), with a mean rating on 3.14. Cronbach's alpha was .85 respectively, indicating high internal consistency. The average intra-class coefficient was .874 with a 95% confidence interval from .772 to .941. Results indicate that motivation may also be influenced by external barriers to participation (e.g., job responsibilities, finances) and the scale was revised to reflect these findings. Items applicable specifically to parents of children with ASD were also added to the finalized version of the rating scale.
Â Conclusions:
The construction of the parental motivation rating scale has helped further define reasons why families with children with ASD may or may not want to be actively involved in their children's intervention.Â Data from the final pilot study will be presented and discussed to further understand parents' readiness to actively participate in family-centered practices.

261 **144.261** The Quality, Not Quantity, of Play for Fathers of Children with Autism

***J. L. Bloom**, M. N. Gragg and J. B. Jones, University of Windsor, Windsor, ON, CANADA*

Background: Fathers continue to be involved with their children with Autism Spectrum Disorders (ASD), including engaging in physical play with them. Previous research suggests that fathers' quantity of physical play is associated with lower parenting stress. However, the quality and positive experiences during play have not been directly studied. The broaden-and-build theory suggests that the quality of play, including experiences of joy, can benefit individuals' well-being. This may be especially important for fathers of children with Autism, who report higher parenting stress, greater impact on parenting, and lower life satisfaction than fathers of typically developing children.
Objectives: Â The present study investigated the quality of fathers' physical play with their children with ASD and the outcomes of this for fathers, including: parenting stress, impact on parenting, and life satisfaction. Fathers' qualitative responses to questions regarding the quality of fathers' play were also examined. In addition, the established association between quantity of physical play and parenting stress was re-examined after accounting for the quality of fathers' play.
Methods: An online survey was completed by 60 fathers of sons with ASD aged 4 to 11 years. The survey included an ASD child screening measure, and questions regarding fathers' satisfaction with play, father-son relationship quality, frequency of play, and fathers' well-being (i.e. parenting stress, impact on parenting, and life satisfaction). Participants (M_{age} = 39.9) were primarily biological fathers, married, Caucasian, from Canada, and living in the same home as their sons with ASD (M_{age} = 6.9). An optional phone interview was conducted with a sub-sample of 20 fathers during which they answered two questions related to the quality of their play.
Results: Multiple regression analyses revealed that greater satisfaction with play and greater relationship quality both significantly predicted lower parenting stress, lower impact on parenting, and greater life satisfaction. Moreover, though frequency of play significantly predicted lower parenting stress for fathers, this was no longer significant after accounting for the quality of fathers' play. Responses to open-ended questions regarding the quality of fathers' play were analyzed qualitatively and four overarching themes were identified. Fathers reported that play is Positive and Fun, Negative and Challenging, Important to the Relationship, and part of a Father's Role.
Conclusions: Results suggested that the quality of play can have benefits for fathers of children with ASD, including aspects of parenting stress, impact on parenting, and life satisfaction. Moreover, results suggested that fathers' quality of play may be even more important to fathers' well-being than the quantity of play. These findings are consistent with the literature for fathers of typically developing children. Fathers' qualitative responses similarly highlighted their positive and negative experiences in play, and the importance of engaging in quality play for their father-son relationship and their role as a father. For instance, one father said, "my son and I have a very close relationship… we always try to find time for play and quality time together". Implications for conceptualizing father-child play and understanding the importance of engaging in quality play will be discussed.

262 **144.262** The Role of Parent Satisfaction with Parenting Efficacy in Links Between Depressive Symptoms and Observed Parenting in Families of Children with ASD

***M. Orr**[1], A. N. Bailey[1], J. M. Moffitt[1], S. M. Zeedyk[2], R. M. Fenning[2] and J. K. Baker[2], (1)Center for Autism, California State University, Fullerton, Fullerton, CA, (2)Child and Adolescent Studies, California State University, Fullerton, Fullerton, CA*

Background: Parents of children with autism spectrum disorder (ASD) are at risk for high levels of stress and mental health problems, including depression (see Ekas, Pruitt, & McKay, 2016, for a review). These factors tend to challenge parenting quality in the general population (Hoffman, Crnic, & Baker, 2006). Despite this risk, observational studies tend to find few to no differences in parenting quality based upon child ASD status (e.g., Baker et al., 2010; Siller & Sigman, 2002; Van Izjendoorn et al., 2007), suggesting potential compartmentalization whereby parents of children with ASD are able to shield their parenting from such deleterious effects.
Objectives: The present study examined an affective component more proximal to parenting, parents' satisfaction with their sense of parenting efficacy, to see if it could inform links between parent depression and the quality of parent-child interaction in families of children with ASD.
Methods: Participants included 31 ethnically and socioeconomically diverse primary caregivers (2 fathers) of children with ASD between the ages of 4 and 11 years (M = 6.35, SD = 1.96). Parents were asked to complete the Center for Epidemiological Studies-Depression scale (CESD-R; Eaton et al., 2004) and the Parenting Sense of Competence questionnaire (PSOC; Johnston & Mash, 1989), which includes a subscale focusing on parents' feelings of satisfaction with their ability to parent. Parental scaffolding behaviors were rated during a 5-minute parent-child problem solving activity using the Parental Scaffolding Rating System (Hoffman et al., 2006; Baker et al., 2007), which measures parents' ability to motivate, emotionally-support, and instrumentally guide their children through a frustrating task. These and similar parenting behaviors have been found to be powerful predictors of important outcomes in children with ASD and early developmental delays (e.g., Baker et al., 2007; Baker et al., 2010; Fenning & Baker, 2012).
Results: No demographic variable considered (e.g., ethnicity, child age, child gender, education, income) was related to the variables of interest in a way that would confound the findings (i.e., to two or more variables). Consistent with the potential compartmentalization suggested by the literature, the association between depression and scaffolding was in the expected direction but was relatively low and fell short of significance, r = -.18, *ns*. Parents' satisfaction with their parenting competence, however, was moderately related to both parent depressive symptoms, r = -.46, p < .05, and observed scaffolding, r = .39, p < .05.
Conclusions: Consistent with the compartmentalization hypothesis, parents of children with ASD demonstrated only weak and non-significant associations between ratings of their depressive symptoms and their observed parent-child interaction quality. Depression was, however, moderately related to less positive feelings about their parenting efficacy which, in turn, moderately predicted less optimal observed scaffolding. This cross-sectional study cannot determine causal direction, and transactions among the factors are likely; however, findings do suggest the importance of considering affective factors more proximal to the parenting experience when attempting to understand relations between parent mental health and parenting behavior in families of children with ASD.

263 **144.263** The Role of Parents in a Social Communication Intervention for Children Who Are Minimally Verbal

C. K. Toolan[1]*, A. Holbrook*[2]*, S. Y. Shire*[2] *and C. Kasari*[1]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)University of California Los Angeles, Los Angeles, CA*

Background: Â The success of an intervention hinges on its capacity for sustainability and generalizability. Consequently, parent training has become a crucial element of many early intervention programs, as parents' uptake of treatment strategies is ideal for implementation across contexts. Parents' level of buy-in (i.e., expectations about treatment) can affect strategy uptake, ultimately affecting treatment outcomes in children (Nock & Kazdin, 2001). This process may elucidate why some children acquire spoken language during the course of intervention while others do not.
Objectives: Â To examine: 1) the relationship between parent buy-in and parent uptake of intervention strategies, and 2) how changes in parent behavior are consequently related to changes in child language outcomes.
Methods: Â Preschoolers (n=23) who were low-rate communicators (approx. <30 words) received JASPER, a naturalistic developmental social communication intervention (Kasari et al., 2006, 2008), for 6 months. Parents received weekly 2-month individualized training in JASPER strategies, including matching child's language (# words, # utterances) and JA gesture use.
Parents completed a questionnaire that assessed the broad range of pre-treatment buy-in. Each parent-child dyad completed a videotaped 10-minute free play assessment (PCX) pre- and post-intervention.
Children's minimally verbal designation at both entry and exit was determined if they used <5 words on the ADOS, <5 words on the PCX, and <8 words on the MSEL. This formed three groups of children: 1) those who remained minimally verbal over the course of intervention (MV), 2) those who acquired language during the course of intervention, i.e., were speech-emergent (SE; met MV criteria at entry, but not at exit), and 3) those who were early communicators (EC; never met MV criteria).
PCX's were transcribed, coded, and analyzed for language and gesture use (pointing, showing, giving). Composites and change scores were calculated and analyzed using linear regression and ANOVA.
Results: Parents' level of buy-in, particularly their belief in child improvement, was associated with change in parents' total utterances during the PCX (b=-.64, p=.001, R^2=.41), but not with gesture use. Change in parent utterances was significantly related with MV status at the end of intervention (b=.58, p=0.023, R^2=.38).
There were significant differences in parent language change between the three groups of children (F(2,20)=7.12, p=.005, η^2=.42). Post-hoc tests indicated significant differences between MV and EC groups (p<.05, d=2.26) as well as between MV and SE groups (p<.10, d=1.41).
Conclusions: Â Results point to potential factors contributing to treatment effectiveness in a population that is not particularly well-researched. Parent buy-in is related to measurable change in parent behavior in the context of intervention. These changes are also related to measureable and significant gains in children's language outcomes, such that children who were potentially MV pre-intervention no longer met this criteria post-intervention.
Parents who bought into treatment decreased their utterance use, providing more opportunity for their children to verbally communicate. However, while this study highlights the relationship between parent buy-in, strategy uptake, and child outcomes, it does not propose a causal model. As such, future research should examine a cross-lagged model to determine directionality and causality of this relationship.

264 **144.264** This Is What Friendship Is to Me: A Grounded Theory

L. Hall *and E. A. Kelley, Queen's University, Kingston, ON, CANADA*

Background: Developing and maintaining social relationships is one of the greatest struggles faced by individuals with ASD. Individuals with ASD experience lifelong difficulties with social communication abilities, as well as many other behaviours that interfere with relationship building (Bauminger et al., 2008). Importantly, developing and maintaining friendships becomes increasingly difficult and complex through adolescence. While adolescents with ASD struggle in making friends, they consistently report a desire for friendship (Bauminger et al., 2000) and they do make friends (Petrina et al., 2014). More so, despite friendships that are unconventional and lower in quality, individuals with ASD are often satisfied with their friendships (Calder et al., 2012). Our understanding of friendship satisfaction among individuals with ASD is perhaps one of the greatest gaps in this field, and is largely the result of a lack of theoretical foundation for understanding how friendships are formed and experienced in this population from their own perspective.
Objectives: The present study addresses the question of how adolescents with ASD develop and maintain meaningful and satisfying friendships. This study explores the processes that are involved in establishing friendships in this population. Furthermore, this study examines the factors that contribute to and interfere with friendship building.
Methods: This study is being conducted in the methodology of constructivist grounded theory. The primary method of data collection is through interviews with 13- to 16-year-old adolescents with ASD. Prior to data collection the ADOS is administered to confirm ASD diagnosis. Interview data is currently being collected, and will continue to the point of saturation. Coding is being completed using the method of constant comparison (Charmaz, 2006; Glaser & Strauss, 1967), which involves continuously comparing the coding of interviews with each other to ensure that the eventual theory emerges from the data rather than from ideas imposed on the data by the researcher.
Results: Data collection and analysis is currently underway, and is projected to be completed in March 2017. The results of this study will establish a substantive theory of how adolescents with ASD establish and experiences friendship. This research will challenge traditional views that equate friendship quality with friendship satisfaction. Results will provide a better understanding of what a satisfying friendship can be for this unique population, how such a friendship is established, and the barriers that interfere with this process.
Conclusions: This research strives to develop a systematic understanding of the processes critical to the development and maintenance of meaningful friendships in adolescents with ASD in order to more effectively support them in meeting their needs. The development of theory from the ground up will provide a framework for developing new measures that will allow for a more accurate characterization of friendship among individuals with ASD. Most importantly, theory regarding the development of friendship specific to adolescents with ASD will provide a foundation for understanding how to appropriately and effectively support the development of these social relationships in a way that is meaningful and relevant to them.

265 **144.265** Toddler Social-Communication and Parenting Stress Are Mediating Factors in the Psychosocial Well-Being of Parents with ASD-Related Concerns

L. V. Ibanez[1] *and W. L. Stone*[2]*, (1)UW READi Lab, Seattle, WA, (2)Psychology, University of Washington, Seattle, WA*

Background:
The parents of toddlers with ASD-related concerns encounter significant delays to accessing diagnostic and intervention services for their child. While parents have reported feeling stressed, isolated, and fatigued during this time period, the psychosocial well-being of parents with ASD-related concerns about their toddlers has not been well-characterized empirically. The current study examined psychosocial well-being, as well as potential contributing factors that may affect parents' interactions with their toddlers (i.e., toddler social-communicative functioning and parenting stress), in 3 parent groups: those with ASD-related concerns, developmental delay (DD) concerns, and no developmental concerns.
Objectives:
To examine the extent to which the effect of parent group on psychosocial well-being is mediated sequentially by toddler social-communication and parenting stress.
Methods:
Parents completed surveys on the outcomes of interest at Time 1 as part of a longitudinal community-based research study; data collection is ongoing. The ASD-related concerns group *(n*= 22,males=16,$M_{age=}$ 26.41 mos) comprised toddlers whose parents indicated that they and/or a healthcare provider had concerns about ASD and/or social interactions.Â The DD concerns group *(n*= *15*,males=6,$M_{age=}$ 20.47 mos) comprised toddlers whose parents indicated that they and/or a healthcare provider had concerns about language and/or motor development. The no concerns group *(n*= *56*,males=21,$M_{age=}$ 19.95 mos) comprised toddlers whose parents indicated that they had no concerns about development.
Toddlers' social-communication was assessed as a mean score of the four domains on the Parent Interview for Autism-Clinical Version: Social Relating, Imitation, Nonverbal Communication, and Language Understanding. Parenting stress was assessed as a total score of the three subscales from the Parenting Stress Index: Difficult Child, Parental Distress, and Parent-Child Dysfunction. Parent psychosocial well-being was assessed as a mean score of the Psychological and Social Relationship scales on the WHO Quality of Life Survey.
Results:
A three-path, serial mediation analysis was conducted using PROCESS Model 6 (Hayes, 2013;**see Figure 1**). Parent group was analyzed as two dummy vectors and child age, sex, and parental education were included as covariates.
Parent group had a significant total effect on psychosocial well-being (path c); the ASD-related concerns group had lower levels than the other two groups. Parent group also had a significant effect on each of the two proposed mediators (path a_1 and a_2); the ASD-related concerns group had lower levels of toddler social-communication and higher levels of parenting stress than the other two groups. While the direct effect was not significant (path c'), indirect effect #3 was significant, indicating that the effect of parent group on psychosocial well-being is mediated sequentially by toddler social-communication and parenting stress.
Conclusions:
Toddler social-communication and parenting stress represent mechanisms that help explain why parents of toddlers with ASD-related concerns exhibit lower levels of psychosocial well-being than other parent groups. Lower levels of toddler social-communication and higher levels of parenting stress functioned sequentially to predict lower levels of psychosocial well-being. These findings suggest that providing the parents of toddlers with ASD-related concerns with strategies for improving their toddlers' social communication and their parent-child relationship may also have a positive and protective impact on their own well-being.

266 **144.266** Transition to Adulthood for Young People on the Autism Spectrum

C. Thompson[1,2]*, T. Falkmer*[1,2]*, S. Bolte*[1,3,4] *and S. J. Girdler*[1,5]*, (1)School of Occupational Therapy and Social Work, Curtin University, Perth, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Institutionen för kvinnors och barns hälsa (KBH), Karolinska Institutet, Stockholm, Sweden, (4)Stockholm County Council, Center for Psychiatry Research, Stockholm, Sweden, (5)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Brisbane, Australia*

Background:
Transitioning to adulthood can be an exciting albeit challenging time for all, but particularly for those on the Autism spectrum. While many young people with Autism have average to above average intellectual capacities they are underrepresented in employment, further education and independent living, commonly experiencing poor outcomes common across the lifespan. The paucity of services for young people on the Autism spectrum and their families contributes to high levels of unmet need, with many struggling to navigate the transition process.
Objectives:
This study aimed to explore the views of parents of young people on the Autism spectrum on the enablers of transition to adulthood for this group.
Methods:
Four structured focus groups with 19 parents (14 mothers, 4 fathers and 1 step-father) regarding 23 young adults revealed 132 condensed meaning units. All but two parents held tertiary qualifications and 14 parents were in paid employment. Five of the parents were not in employment, citing their child's diagnosis as the reason for their lack of workforce participation. In-vivo analysis identified the themes of *to be understood*, *to understand the world* and *to succeed*. Secondary analysis linked condensed meaning units to the International Classification of Functioning, Disability and Health (ICF).
Results:
The theme *to be understood* recognized the social marginalization of young people on the Autism spectrum due to their core symptoms. *To understand the world* pointed to the parents' recognition that young adults on the Autism spectrum often experienced difficulties with social communication. These young adults needed opportunities *to succeed* in adult life, to demonstrate their strengths and build their self-efficacy. Secondary analysis revealed the theme *to be understood* mapped chiefly against the ICF domain of the e*nvironment* (63%), and constructs within *activity and participation domain* (37%). The theme *to understand the world* mapped predominantly to the domain of the activity and participation domain (62%) with links to the domain of *environment* (38%). *To succeed* linked to the ICF domain of the e*nvironment* (50%) and to constructs within the domains of *activity and participation* (42%) and *personal factors* (8%).
Conclusions:
This study highlighted parents belief that young people on the Autism spectrum are marginalised in part as a result of the social deficits associated with their diagnosis. Strengths-based individualised approaches, maximising the person-environment fit of these young people, are likely to facilitate successful outcomes in adulthood. Peer mentoring is one such approach, potentially reducing the need for parent's to advocate on behalf of their young person on the Autism spectrum, positively impacting on this relationship. This study demonstrates the utility of the ICF in research in providing a framework facilitating data analysis, which in this study pointed to the environment as an important intervention target in supporting young people with Autism in their transition to adulthood.

267 **144.267** Understanding Concerns Relating to Uncertainty about the Future in Adults on the Autism Spectrum and Their Families.

R. Herrema[1], *D. Garland*[2], *M. R. Osborne*[3], *E. Honey*[4], *M. Freeston*[5] *and J. Rodgers*[6], *(1)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, UNITED KINGDOM, (2)National Autistic Society, Newcastle upon Tyne, United Kingdom, (3)Kids and Young Adults Klub Special Needs Support Group, The Kayaks Support Group, Newcastle Upon Tyne, United Kingdom, (4)Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle Upon Tyne, UNITED KINGDOM, (5)Psychology, Newcastle University, Newcastle, United Kingdom, (6)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom*

Background: Little is known about the everyday lives of adults on the autism spectrum. Small scale projects indicate that anxiety related to uncertainty is a significant problem for many individuals on the autism spectrum and their families, though no systematic large-scale research has explored the specific nature and impact of these concerns.
Objectives: The aim of this project was to consult with adults on the autism spectrum and their carers/relatives about concerns regarding uncertainty about the future.
Methods:

- Four focus groups were conducted with adults on the autism spectrum (n=23), exploring concerns and hopes for the future. Participants also discussed strategies that were helpful and unhelpful in managing these concerns.
- An online survey investigating concerns relatives/carers had regarding the future for the adults with autism they were supporting, was completed by 120 family members. Seven main topics were explored; *residence*, *day-to-day living*, *future happiness*, *finances*, *relationships with others*, *support* and *vulnerability from others*. Respondents also completed questionnaires relating to their own wellbeing; Depression, Anxiety and Stress Scale (DASS-21) and Penn State Worry Questionnaire (PSWQ), as well as a Quality of Life Scale relating to the autistic adults they were supporting.

Results:

- Focus groups: Thematic analysis revealed an overarching theme relating to pervasive feelings of '*uncertainty'*. Subordinate themes included *uncertainty related to the impact of autism diagnosis,* regarding specific barriers and understanding from others and *uncertainty related to provision of support*.
- Online survey: 64% of respondents stated their autistic relative was "not at all prepared" for the future and 70% worried about this *at least weekly*. The most endorsed concerns were "whether they will be happy" (72% worried weekly) and "who will look after/care for them" (58% worried weekly). Relatives self-reported moderate levels of worry and anxiety, mild levels of depression and stress and high levels of intolerance of uncertainty. Respondents indicated that 83% of the adults with autism they were supporting experienced anxiety, 47% experienced depression. Respondents who stated their autistic relative was "not at all prepared" for the future had significantly higher levels of worry, anxiety, stress and lower quality of life than those who reported some degree of preparation.

Conclusions: This is the first study to explore concerns regarding the future directly with autistic adults and their families. The results indicate that uncertainty about the future is a significant issue in the lives of autistic adults and those supporting them. Both groups of participants viewed the future as very uncertain, reported feeling unprepared and unsure about how to prepare for the future. Furthermore, high anxiety, worry and stress and lower quality of life in relatives of autistic adults were associated with lack of preparation for the future. Adults on the spectrum and family members identified that support in preparing for the future was inadequate or insufficient for their needs. Further research exploring the impact that uncertainty about the future has on the mental health and wellbeing of adults on the autistic spectrum and those supporting them should be a priority for the future.

268 **144.268** Understanding Stress in Mothers of Children with ASD

L. Hewitson[1], *C. Schutte*[1], *W. Richardson*[1], *C. Marti*[2] *and K. Barnhill*[1], *(1)The Johnson Center for Child Health and Development, Austin, TX, (2)Abacist Analytics, LLC, Austin, TX*

Background: Parents of children with autism spectrum disorder (ASD) are often faced with numerous potential challenges and daily stressors associated with parenting a child with special needs. These can be categorized as either parent- or child-specific. Parent-specific stress may be derived from the lack of social supports, the absence of effective coping strategies, and lower psychological well-being or depression in one or both parents. Child-specific stress is most commonly associated with the symptomology of ASD including communication impairments, decreased cognitive abilities, and impairments in social interactions.
Objectives: The objective of this study was to examine both the frequency and the level of stress in mothers of children with ASD who were initiating clinical services at our center, and to ascertain whether this was correlated with selected demographic data.
Methods: In this study, we examined maternal stress in the mothers' of 32 children with ASD (ages 2 to 11 years of age). Demographic data was compiled for each family, and mothers completed the Parental Stress Index-Long Form. ASD diagnoses in the children were confirmed by implementation of the ADOS and ADI-R assessments by a research-trained psychologist. Pairwise correlation analyses were conducted between maternal stress and selected demographic variables.
Results: Clinically relevant (>85th percentile) *Total Stress* PSI scores were reported in 72% (23/32) of mothers but this was not related to a number of demographic variables including maternal age, job status and education, marital status and family income.Â When broken down by *Child* and *Parent Domain* scores,Â 87.5% (28/32) and 18.75% (6/32) mothers had scores >85th percentile, respectively. Furthermore, out of mothers with clinically relevant *Total Stress Scores*, 30% (7/23) had *Total Stress* Scores of ≥99th percentile. A significant Defensive Responding raw score was reported for almost 10% (3/32) mothers, indicting that these respondents may have attempted to minimize their stress or the issues between themselves and their child in order to try to create a more favorable impression.
Conclusions: High maternal stress appeared to be driven by *Child Domain* scores, suggesting that many of the children in this study displayed qualities that make it more challenging for their mothers to fulfill their parenting roles, leading to dysfunctional mother-child interactions. What was more concerning, however, was the very high level of stress reported by some mothers. This has implications regarding the mother's immediate mental health status and that of the mother-child relationship. While developing and implementing a wide-range of supports for parents raising a child with ASD may be critical for family stability, more immediate interventions may be required for some parents to ensure the short-term health of their family unit.

269 **144.269** Using Mindfulness Based Stress Reduction to Reduce Caregiver Distress As Part of Behavioral Intervention for Young Children with ASD

A. S. Weitlauf[1]*, N. A. Broderick*[2]*, A. Stainbrook*[3]*, K. Herrington*[4]*, A. Nicholson*[5]*, P. Juárez*[6] *and Z. Warren*[7]*, (1)TRIAD, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt University Medical Center/Vanderbilt Kennedy Center, Nashville, TN, (3)Vanderbilt Kennedy Center, Nashville, TN, (4)Vanderbilt University Medical Center, nashville, TN, (5)Vanderbilt University Medical Center, Pleasant View, TN, (6)Vanderbilt University Medical Center, Nashville, TN, (7)Vanderbilt University, Nashville, TN*

Background: Caregivers of children with ASD report elevated levels of distress (Carter et al., 2009; Davis et al., 2008) that can negatively impact parental health as well as the potential effectiveness of early interventions (Gallagher et al., 2009; Osborne et al., 2008). Therefore, it may be critical for early intervention services to ameliorate clinically significant caregiver distress as part of early intervention itself.
Objectives: This preliminary data is drawn from the initial phase a longitudinal randomized control trial comparing the effectiveness of an empirically supported parent-coaching intervention program, the Parent-implemented Early Start Denver Model (P-ESDM; n = 14), to a P-ESDM intervention enhanced with Mindfulness Based Stress Reduction for caregivers (MBSR; n = 10). Our objective was to evaluate differences in caregiver mental health and parenting stress across groups.
Methods: Participants included the caregivers of young children (m_{age} = 1.57 years, sd = .39) recently diagnosed with autism spectrum disorder. Children's ADOS-2 scores indicated moderate-to-high levels of autism symptoms (m_{ADOS-2} = 21.67, sd = 4.44) and significant developmental delays on the Mullen Scales of Early Learning (m_{MSEL}= 53.43, sd = 5.70). Participating mothers (n = 20) and fathers (n = 4) were randomly assigned to receive 12 weekly sessions of P-ESDM with and without 6 concurrent sessions of MBSR. Data was gathered at treatment initiation and conclusion.
Results: Â At baseline, both groups reported statistically similar levels of depression (m_{PESDM} = 10.54, sd = 6.97; m_{MBSR} = 10.30, sd = 9.35), anxiety (m_{PESDM} = 7.92, sd = 6.61; m_{MBSR} = 9.50, sd = 6.64), and overall parenting stress (m_{PESDM} = 94.70, sd = 15.00; m_{MBSR} = 87.91, sd = 10.85) as measured by the Centers for Epidemiologic Studies – Depression scale, Beck Anxiety Inventory, and the Parenting Stress Inventory. Although within group changes were not significant, the entire sample of caregivers showed trends toward decreased depression symptoms (m_{T1CESD} = 10.44, sd = 7.89; m_{T2CESD} = 7.96, sd = 3.15; t = 2.061, p = .051). Group differences emerged in self-reported anxiety at post-treatment, with caregivers who received MBSR reporting significantly lower anxiety levels than caregivers who did not (m_{PESDM} = 8.46, sd = 8.03; m_{MBSR} = 2.10, sd = 1.96; t = 2.44, p < .05). Caregivers who received MBSR also reported significantly lower levels of parenting stress (m_{PESDM} = 87.91, sd = 10.85; m_{MBSR}= 73.63, sd = 16.12; t = 2.32, p < .05).
Conclusions: Promising preliminary evidence suggests that MBSR reduced anxiety and parenting stress across the course of treatment. This provides initial support for directly addressing caregiver distress as part of treatment for young children with ASD.

270 **144.270** Willingness of Mothers of Individuals with ASD to Engage in Mobile Health Research

J. S. Toroney[1]*, J. K. Law*[1]*, A. R. Marvin*[2]*, S. S. Dhingra*[3]*, E. J. Simoes*[4] *and P. H. Lipkin*[5,6]*, (1)Interactive Autism Network, Baltimore, MD, (2)Painter Bldg 1st Fl, Kennedy Krieger Institute, Baltimore, MD, (3)Public Good Ventures, Ltd., Atlanta, GA, (4)Health Management and Informatics, University of Missouri-Columbia School of Medicine, Columbia, MO, (5)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (6)Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD*

Background:
A new direction for healthcare research involves the collection of personal health information through mobile technology, such as apps and wearable devices (e.g. Fitbit). Information that is already collected from these mobile technologies can be utilized in a way that allows researchers to capture new and informative data that has not yet been studied.
Objectives:

- Engaging mothers of individuals with ASD in mobile health (mHealth) research.
- Comparing the willingness and attitudes of mothers of children and adolescents with ASD to participate in mHealth research.

Methods:
Maternal participants/caregivers in the Interactive Autism Network (IAN)—a community-powered research network that focuses on improving the lives of individuals with ASD and their families—were invited to complete an online questionnaire designed to determine caregiver willingness and attitudes toward engaging in mHealth research. Invited maternal caregivers had previously participated in a related IAN study. Mothers were divided into two groups based on the age of their child: Group A consisted of mothers of adolescents/young adults (ages 15-29) and Group B consisted of mothers of preschool/elementary-aged children (ages 3 -12). A few mothers fell into both categories and their responses were included in both groups. The overall response rate for the questionnaire was 52% (Group A=43.2%; Group B=59.5%), demonstrating successful re-engagement of IAN mothers, particularly among the younger group.
The questionnaire focused on maternal caregivers because of the correlation between maternal health and the health of their child with ASD. Individuals with ASD have been found to be less healthy overall than their counterparts in the general population; therefore, focusing on maternal health is an effective way to improve the health and well-being of individuals with ASD.
Analyses included crosstabs and t-tests for comparisons between the responses of the mothers of the children and teens/young adults with ASD.
Results:
622 mothers (Group A: n=231; Group B: n=391) completed the questionnaire. Regardless of age, mothers reported willingness to share mHealth data for research purposes.

- Mothers indicated willingness to share their health-data, especially if it allowed researchers to learn about the quality of healthcare, disease and prevention, and related issues (Group A=91.3%, Group B=94.6%; p=0.080).
- Mothers in each age group reported a preference for control over what and with whom their mHealth information was shared (Group A=96.5%, Group B=96.3%; p=0.882). Similarly, they wanted to know who accessed their data. <1% in each group reported that they did not care who accessed it (p=0.559).
- Younger mothers more willingly embraced newer technologies to share their health data, including sharing GPS location (Group A=57.4%, Group B=62.7%; p =0.019).

See Tables 1 and 2 for more details.
Conclusions:
Mothers of individuals with ASD were willing to share their mHealth data with researchers with the promise of anonymity and a level of control over their information. Younger mothers were more willing to use newer technologies to do so. With this knowledge in mind, it is possible to begin implementing mHealth studies that collect such information in a way that cultivates the highest potential for completion.

271 **144.271** 'You Are Labelled By Your Children's Disability' – a Community-Based, Participatory Study of Stigma Among Somali Parents of Children with Autism Living in the UK

L. Selman[1], *F. Fox*[2], *N. Aabe*[3], *K. Turner*[1], *D. Rai*[1,4] *and S. Redwood*[2], *(1)School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom, (2)NIHR CLAHRC West, Bristol, United Kingdom, (3)Autism Independence, Bristol, United Kingdom, (4)BASS Autism Services for Adults, Avon & Wiltshire Partnership NHS Trust, Bristol, United Kingdom*

Background: Â Children of migrant parents living in western countries are more likely to have an autism diagnosis than the general population, particularly autism with intellectual disability. Somali migrant populations carry a particularly high burden. Social stigma is commonly experienced by parents of children with autism, and can be more challenging for some parents than their child's impairments. There has been no previous in-depth exploration of autism-related stigma within a Somali community.
Objectives: Â To explore the nature of stigma experienced by Somali parents of children with autism in the United Kingdom (UK), and to consider how they coped with or resisted such stigma.
Methods: Â We used a community-based participatory research approach, collaborating with a community organisation of Somali parents. In-depth interviews with simultaneous translation were conducted with 15 Somali parents of children with autism living in Bristol, UK, in 2015. Parents were sampled purposively to capture diversity in children's age, severity of autism and time since diagnosis. Directed thematic analysis used Link and Phelan's model of stigma.
Results: Â Of the 15 participants, 12 were mothers (mean age 36). The 17 children with autism they cared for were 4-13 years' old, and five were girls. Two main themes with sub-themes were identified: the nature of stigma (labelling and stereotyping; separation; emotional reactions, discrimination and power), and coping and resistance (the power of language; faith as a resource; learning, peer support and community relationships). Children with autism were labelled and stereotyped (e.g. as 'sick', 'naughty', 'different') and parents blamed for not controlling them, leading to social rejection and isolation. Some parents isolated themselves and withdrew emotionally to protect themselves and their children, while others felt they were avoided and excluded. Stigma was associated with a poor understanding of autism, a lack of vocabulary related to autism in the Somali community, and prejudice against mental illness and disability. The disruptive behaviour associated with autism and the invisibility of the condition were identified as particularly difficult for others to understand. There was evidence of enacted and felt stigma and examples of discrimination. To resist stigma, parents countered negative labelling by finding their own language to describe their child's condition, learnt about autism, and drew on their religion and peer support from other parents.
Conclusions: Â Somali parents of children with autism experienced considerable stigma, in the form of labelling and stereotyping, as well as more overt forms of discrimination, leading to social exclusion and isolation. Supporting Somali parents to deal with stigma requires raising awareness of autism within the community, facilitating peer support, building on parents' existing coping resources and ensuring appropriate professional services and interventions are available.

272 **144.272** "I Thought the Regional Center Was a Deportation Trap" Documenting the Life Experiences of Undocumented Mexican Mothers of Children with Autism

P. Luelmo[1]*, Y. Sandoval*[2]*, A. Ochoa*[3] *and C. Kasari*[2]*, (1)Education, University of California, Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Fiesta Educativa, Inc., Los Angeles, CA*

Background: As we attempt to include more under-represented, low-resourced families in research studies, one group that is difficult to engage is undocumented families. We know little about whether these families are obtaining a timely diagnosis or services for their children with autism.
Objectives: Â This study attempts to examine how undocumented low-resourced Mexican mothers of children with autism navigate the special education process, the helpers and challenges they face in doing so.
Methods: In partnership with a community-based organization, six undocumented Mexican mothers of children with autism spectrum disorder (ASD) were recruited to participate in one interview using snowball sampling. Mothers were interviewed in a semi-structured format in settings ranging from a community center for immigrants, public library, and participant's home in a large city in Southern California. Various procedures were put in place to safeguard confidentiality. All participants were asked to provide a pseudonym due to their undocumented status. None of their personal information was collected. The interviews, transcription, coding, and final analysis were conducted in Spanish using Dedoose software. Two raters, a doctoral student and a research assistant used open-coding techniques applying conceptual labels looking for common themes across interviews. Inter-rater reliability was established using Pooled Cohen's kappa at .78.
Results: We examined three broad themes during the open-coding process (1) Immigration experience and cultural differences (2) Financial challenges and helpers (3) Autism diagnosis and services. In terms of immigration and cultural experiences results suggest that undocumented Mexican mothers experienced grim circumstances in their countries of origin *(e.g. "Here, we are poor, too, but at least we have a plate of food on our table"),* which forced them to immigrate to the United States. Three of the mothers experienced significant challenges en route to the United States (e.g. *"I crossed the border with my daughter in the trunk of a car with four other people- we were very scared").* The other 3 mothers stated that they originally entered the United States on a tourist visa but then overstayed. All of the children with ASD were U.S. citizens by birth. In terms of financial challenges and helpers, most of the mothers had very low household incomes (i.e. $10,000-15,000/year) ("e.g. *I used to get paid by the piece (of sewing) and worked 16-hour days, not even making minimum wage*"). Most mothers had difficulty accessing healthcare or financial benefits because of a lack of social security number despite having income tax regularly deducted from their paychecks. Finally, in terms of ASD diagnosis and services, most of the mothers received a late diagnosis of ASD for their children (e.g. over 6 years of age) delaying critical early intervention services (e.g. *"I had no idea what autism was")* and had difficulty navigating the special education process at the regional center and public schools (e.g. *"I thought the regional center was a deportation trap")*.
Conclusions: School staff and service providers need to be aware of the challenges of serving these families in order to avoid late diagnosis and services gaps for their children with ASD.

273 **144.273** "We Have to Fight More:" Experiences of Black and African American Families Raising Children with Autism

S. Dababnah*, W. E. Shaia and K. Campion, University of Maryland, Baltimore, Baltimore, MD*

Background: Previous research has described significant barriers to appropriate Autism Spectrum Disorder (ASD) screening, diagnostic and early intervention efforts in the African American community. African American children visit providers on average three times more than White children to receive an ASD diagnosis, with a longer period of time between initial provider contact and diagnosis. Furthermore, African American children with ASD are 2.6 times more likely than White children to receive an inappropriate diagnosis such as Conduct Disorder or Attention Deficit Hyperactivity Disorder on their first specialty care visit. Once African American children are diagnosed with ASD, studies have found these children and their families are underrepresented in early intervention and genetics research, and face additional barriers to care. Apart from these concerning statistics, the current literature focusing on African American children with ASD is limited.
Objectives: We explored caregiver stress, coping responses, and experiences accessing the continuum of ASD services, from screening and diagnosis through intervention, in a sample of urban Black and African American families raising children with ASD.
Methods: Â Our community-based research team recruited parents and other primary caregivers of Black and African American children ages 18 and under with ASD in an urban Mid-Atlantic city (N=18). Participants completed the Parenting Stress Index, Ways of Coping Questionnaire, and a semi-structured interview. Qualitative data were coded and analyzed using NVivo 10, using grounded theory methods. We analyzed the quantitative data using descriptive statistics in SPSS.
Results: Â Child-related caregiver stress was elevated in our sample (mean percentile = 85, SD = 18.2). Participants' most commonly-reported coping mechanisms were problem solving and emotion regulation. On average, caregivers described a nearly 30-month delay between their initial concern and ASD diagnosis, which was attributed in part during the qualitative interviews to poor provider-family communication. Many participants spoke in depth regarding the impact of race on their experiences raising a child with ASD, including low provider expectations of child's abilities, lack of adequate resources in local schools, perception of the need to "fight more" to receive services, incorrect provider assumptions regarding family structure, and stigma surrounding ASD within the Black and African American community. Caregivers' recommendations for improving service access for Black and African American children with ASD will be summarized.
Conclusions: Our exploratory study identified numerous obstacles Black and African American children with ASD and their families confront to access appropriate services and support. In addition to barriers often reported by families of children with ASD in general, our research uncovered additional challenges, such a neighborhood violence and racial discrimination, which exacerbated delays to care. Despite reports of high levels of parent stress, the caregivers in our sample used primarily adaptive coping mechanisms to address stress. Future research should identify culturally-responsive interventions to support families under stress and build on existing strengths.

274 **144.274** "You Have a Lot of Work on Your Hands": Unsupportive Social Interactions for Parents of Children with Autism

J. B. Jones*, M. N. Gragg and J. L. Bloom, University of Windsor, Windsor, ON, CANADA*

Background: Parents raising children with Autism Spectrum Disorders (Autism) report high stress that greatly affects their daily lives. Family Quality of Life (FQOL) refers to the ways in which a family member with a disability affects parents and siblings. Positive social supports can help to buffer against the strain associated with raising children with Autism. However, negative reactions that parents of children with Autism may receive from others have been less studied. Unsupportive Social Interactions (USI) refer to actions that are perceived as unhelpful or unwanted in the face of a stressful event. Very little research on USIs has been done in the context of parenting children with Autism. This concept is important to understand because negative or unsupportive responses may be more salient than positive social supports to parents' well-being.
Objectives: The purpose of the present study is to examine how USIs affect parents of children with Autism. This study investigates the extent to which positive social support and USIs are associated with FQOL for parents of children with Autism.
Methods: A sample of 97 mothers and 82 fathers of children with Autism aged four to 11 years completed an online survey (data collection is ongoing). Participants were primarily biological parents, Caucasian, married, had a family income of over $75,000 per year, had completed post-secondary education, and had one child with Autism. The questionnaires pertained to demographic information, family quality of life, social support, unsupportive social interactions, and other variables as part of a larger study. A subset of participants (n =12 mothers and 11 fathers) gave qualitative responses during a phone interview.
Results: Preliminary results suggested that the adequacy and availability of social support from professionals, family, and friends were significantly positively correlated with FQOL in this sample. In addition, a significant negative correlation was found between USI and FQOL, where more experiences of USI were associated with lower FQOL. Themes related to parents' experiences with USIs are described based on parents' interview responses.
Conclusions: Although researchers and clinicians have focused on the relevance of positive social supports for parents of children with Autism, it is also important to consider the harmful effects of USIs. The findings of this study support the extant literature that social support is closely related to FQOL. A novel contribution is the finding that USIs negatively affect FQOL for parents of children with Autism. Parents' qualitative responses illustrated similar findings. For example, one participant in this study described how a stranger in the grocery store said "you have a lot of work on your hands." The concept of USIs has received little attention in Autism research and should be studied in more detail. In order to promote optimal FQOL for parents of children with Autism, clinicians should also attend to the negative experiences that parents may face and explore ways to reduce their impact. Practical implications of this research are described, including how fostering Autism awareness in the community may help reduce the frequency of USIs.

275 **144.275** "the Dots Just Don't Join up": Understanding the Support Needs of Families of Children on the Autism Spectrum

J. Galpin[1], *P. Barratt*[1], *E. Ashcroft*[1], *S. Greathead*[1], *L. Kenny*[2] *and E. Pellicano*[2], *(1)The Bridge School, London, United Kingdom, (2)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom*

Background: Parenting a child on the autism spectrum can be a hugely rewarding experience. It can also be stressful for a variety of reasons, with parents often reporting stress levels that exceed those among parents of typically developing children, or those with other developmental conditions. Despite this knowledge, remarkably little research has examined the types of support that these families perceive to be beneficial to their and their children's lives.
Objectives: Â This study, co-produced with school-based professionals, sought to establish the support needs of autism families, living in inner-city London, from their own perspectives.
Methods: Â In Study 1, a sample of ethnically- and socioeconomically-diverse parents of autistic children with additional intellectual disabilities and limited spoken communication (*n*=139) took part in a brief initial survey examining parental wellbeing, self-efficacy and the extent to which they felt supported. In Study 2, in-depth semi-structured interviews were conducted with a sub-group of these parents (*n*=17), some of whom reported feeling supported in Study 1 and some of whom did not.
Results: Â The results from Study 1 suggested that, overall, parents' reports of their own mental and emotional health was encouraging: the majority of parents rated their health as 'good', 'very good' or 'excellent'. There was a substantial minority (23%), who reported they did not have someone to turn to for day-to-day help and support. Parents participating in Study 2 reported a distinct lack of services and supports designed to address their and their child's specific needs (particularly with regards to children's sleep, dietary, language and self-care needs), which ultimately made them feel isolated and alienated. When support was available, it was often perceived to be extremely difficult or even impossible to access and failed to fit with the realities of their everyday lives. Parents pointed to a combination of formal and informal supports that they felt would best meet their needs, generally corroborating the findings from the Study 1 survey data. The interviews, however, went further to identify the exact nature of the services they desired – that is, services that were proactive and family-centred in their approach, ultimately making them feel more connected and cared for.
Conclusions: Supporting parents around the specific areas of expressive language, diet, sleep and self-care skills should be seen as priorities for service providers. Critically, providing this support should be done within the context of a relational, family-centered approach – one that takes the time to understand the specific needs of the whole family (including siblings), building a close working relationship with them, and ensuring that they are supported at times when the parents and families feel they need it most.

276 **144.276** Engaging Latino Families in ASD Treatment Research

A. B. Ratto[1], *B. J. Anthony*[2], *R. Mendez*[2], *J. Safer-Lichtenstein*[2], *M. Biel*[3], *S. Seese*[4], *L. Kenworthy*[4] *and L. G. Anthony*[4], *(1)Children's National Medical Center, Washington, DC, (2)Center for Child and Human Development, Georgetown University, Washington, DC, (3)Georgetown University, Washington, DC, (4)Children's National Health System, Washington, DC*

Background: Â Low-income and ethnic minority families continue to face critical disparities in access to diagnostic and treatment services for autism spectrum disorder (Begeer et al., 2009). Despite the growing cultural diversity of the United States, ethnic minority children and families continue to be substantially under-represented in ASD research (Norbury and Sparks, 2013), and particularly in treatment research (West et al., 2016). There are currently no published studies on adapting ASD treatment for children and families from Latino immigrant communities, with the exception of a parent advocacy intervention (Magaña et al., 2016).
Objectives: Â To present an approach for adapting ASD treatment for Latino immigrant families, based on Rogers' Diffusion of Innovation (DOI) framework and evaluate its efficacy in engaging these families in treatment research.
Methods: Â The DOI framework identifies *knowledge* and *persuasion* as the first two stages in adoption of innovation. We targeted these two stages through steps taken to build awareness (*knowledge*), minimize complexity of the intervention (*persuasion*), increase the intervention's cultural compatibility with families (*persuasion*), and address issues of relative advantage and observability (*persuasion*). Research staff worked collaboratively with a stakeholder advisory board to adapt treatment manuals and strategies. Participants included 174 children and their parents drawn from 3rd through 5th grade in Title I schools in the DC metropolitan area. All participants met research criteria for either ASD or ADHD, though many had no prior clinical diagnosis. Treatment acceptability was assessed via parent attendance at trainings and a feedback questionnaire.
Results: Â Group differences were assessed using one-way ANOVA, using the FDR procedure to control for multiple comparisons. Latino families had significantly lower income (F=11.30, p=.001) and years of parent education (F=11.72, p=.001), which have been shown to predict lower engagement in research and treatment. Despite these barriers, Latino families attended the same number of trainings on average as other families (F=2.42, *ns*). Moreover, Latino families reported higher satisfaction with the program (F=17.56, p<.0001) and greater comfort with the skills (F=18.20, p<.0001) than other ethnic groups. Latino families also reported finding the manual more helpful, although this did not survive corrections for multiple testing.
Conclusions:
The strategies utilized in this study and pragmatic adaptations made over the course of the trial highlight the need for a thoughtful and flexible approach to working with low-income and ethnic minority families in community-based clinical research. Using these strategies, our team enabled high levels of engagement from Latino families who faced significant barriers to participation, outpacing all other ethnic groups in the study. Researchers need to take additional steps to build community trust and relationships in order to successfully recruit and retain participants in their studies. Researchers must be willing and able to invest more time at the beginning of their studies to involve community stakeholders in the process, establish trust within communities, and make changes to usual procedures in order to meet the needs of underserved families.

277 **144.277** Using Community Partnerships to Address the Fit of an Evidence-Based, Parent Mediated Intervention for ASD in a Medicaid System

K. Pickard *and B. Ingersoll, Michigan State University, East Lansing, MI*

Background: Â Within the autism spectrum disorder (ASD) field, service access barriers and rates of attrition in ASD services are particularly relevant for parent-mediated interventions and may suggest a lack of fit when these services are implemented in underserved community settings. One strategy to improve the fit of parent-mediated interventions in these settings is to engage stakeholders around improving the delivery of these services.
Objectives: In a prior study, Roger's Diffusion of Innovations theory was used to guide collaboration with parents from low SES backgrounds (i.e. below the federal poverty line) and providers working with these families in the Medicaid system around improving the delivery of an evidence-based, parent-mediated intervention, Project ImPACT. The goal of the present study was to determine the impact of these adaptations on parents' and providers' perception of program attributes specific to Roger's theory (i.e compatibility, complexity, and relative advantage), as well as their intent to use the program.
Methods: The target number of participants for this study is 100 parents of a child with ASD and 100 providers working with young children with ASD. Preliminary results are presented from 83 parents and 79 providers from a variety of socioeconomic backgrounds. Participants were randomized so that they either watched a 13-minute, video-based presentation of the original Project ImPACT program, or the same 13-minute, video-based presentation of the adapted Project ImPACT program. All presentations were standardized in format, length, and visual appeal. After watching the presentation, participants rated the following: 1) demographic information; 2) Project ImPACT attributes (i.e. compatibility, complexity, and relative advantage); 3) intent to use the program; and 4) either parent mental health or provider implementation climate.
Results: Two-way, between-subjects ANOVAs were run to examine the impact of program type (original vs. adapted), participant SES (i.e. above vs. below federal poverty line), and their interaction on perceptions of program attributes (i.e. compatibility, complexity, and relative advantage) and intent to use either program. Preliminary results are displayed in the supplemental table. Results show no main effect of program type or SES on parents' ratings of program attributes or intent to use. However, there was a significant interaction between SES and program type such that low SES parents rated the adapted program more favorably and reported greater intent to use than the original program. These findings were somewhat similar for providers, with providers working with low SES families rating the adapted program as less complex and reporting greater intent to use the adapted program, however, these results were only marginally significant.
Conclusions: Results from the present study suggest that community partnerships may be beneficial in increasing the perceived fit of parent-mediated interventions within low SES settings, although these benefits may be setting-specific. Importantly, Roger's Diffusion of Innovations theory may be a framework that can be used by researchers to guide adaptations aimed at improving the delivery of evidence-based, parent-mediated interventions without changing the core components of the intervention. Future directions include assessing the actual impact of these adaptations when implemented within the Medicaid system.

278 **144.278** Partnering to Adapt Evidence-Based Intervention for Delivery with Ethnic Minority Families

S. R. Rieth[1,2]*, L. Brookman-Frazee*[2,3]*, K. S. Dickson*[2,3]*, K. L. Searcy*[4] *and A. C. Stahmer*[2,5]*, (1)San Diego State University, San Diego, CA, (2)Child and Adolescent Services Research Center, San Diego, CA, (3)University of California, San Diego, La Jolla, CA, (4)Crimson Center for Speech and Language Pathology, San Diego, CA, (5)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA*

Background: Although difficulties implementing evidence-based practices (EBPs) exist across cultural environments, disadvantaged groups experience particularly limited access to EBPs in their communities. For individuals who access care, research suggests that ethnic minority families are likely to receive lower quality care than ethnic majority families across multiple quality indicators (Magaña et al., 2013; Magaña, Parish, Rose, Timberlake, & Swaine, 2012). Parents of Hispanic children, for example, reported that providers were not sensitive to family values and were more likely to report that providers did not offer enough information or create an environment that promoted partnership with parents. This research speaks to the need to specifically improve the dissemination of culturally sensitive interventions to improve early intervention for underserved, minority populations. The BRIDGE Collaborative is an academic-community partnership that has adapted a parent-mediated naturalistic developmental behavioral intervention with specific focus on cultural appropriateness for Spanish-speaking families. A community trial of the adapted intervention is currently underway.
Objectives: The objective of this presentation is to share the process of adaptation and implementation of a naturalistic developmental behavioral intervention that was designed for maximum community fit and cultural sensitivity. Additionally, fidelity of implementation of the intervention when delivered in English versus Spanish is examined.
Methods: The BRIDGE Collaborative is an academic-community partnership with the goal of improving access to care for young children with risk for ASD. This group identified an EBP that met stakeholder needs based on input from community sources at multiple levels, including Spanish-speaking providers and families. A systematic, iterative process of adaptation was conducted in collaboration with community stakeholders. The adapted intervention is now being tested in a large urban county, including delivery in English and Spanish. Fifteen agencies participated in a train-the-trainer model of intervention training; agency leaders received training from researchers and returned to their agencies to provide training to therapists. Five of the participating agencies have bilingual leaders and/or therapists who deliver the intervention in both English and Spanish. Video observations of participants were collected both before and after training, and were coded for fidelity of implementation. Additional measures (e.g., satisfaction with services, implementation surveys) were collected from interventionists, as well as families who received intervention.
Results: Feedback from Latino/a providers and parents resulted in the reduction of text in the parent manual, the development of culturally appropriate examples, the creation of summary handouts for intervention strategies and translation of materials into Spanish. Fidelity data from bilingual interventionists indicates substantial differences in strategy use depending on language of delivery (English or Spanish), including decreased prompting of specific skills and less modeling of communication and play when delivered in Spanish.
Conclusions: Differences in how intervention is delivered to English versus Spanish speaking families can inform efforts to improve the quality and fit of treatment for underserved populations. These data support the need for attention to the cultural appropriateness of individual strategies within an intervention. Further, it suggests the need to adapt intervention materials to meet the specific cultural and communication needs of multiple ethnic minority populations.

279 **144.279** A Community-Partnered Intervention in South Los Angeles for Young Children at-Risk for ASD

A. Gulsrud[1]*, T. Carr*[2]*, J. Panganiban*[3]*, C. Kasari*[4]*, N. Tu*[5]*, G. Hellemann*[5]*, F. Jones*[6] *and J. Kimbrough*[7]*, (1)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (2)UCLA Center for Autism Research and Treatment, Los Angeles, CA, (3)University of California Los Angeles, Los Angeles, CA, (4)University of California, Los Angeles, Los Angeles, CA, (5)UCLA Semel Institute, Los Angeles, CA, (6)Healthy African American Families, Los Angeles, CA, (7)The Children's Collective, Inc., Los Angeles, CA*

Background: As more effective interventions are developed for children with Autism Spectrum Disorders (ASD), there is an increasing demand for early detection and dissemination of empirically supported treatments, especially in under-resourced communities where African American and Latino families face disproportionate access barriers. There is a critical need to identify these children at younger ages and partner with community providers to promote positive outcomes.
Objectives: The goal of this study was to use Community Partnered Participatory Research (CPPR) practices to collaborate with childcare centers to increase access to ASD-related services in South Los Angeles by 1) identifying children at-risk for ASD, and 2) adapting and implementing an intervention teaching social communication and play.
Methods: Children between the ages of 16-60 months of age were recruited from the Children's Collective, Inc (TCCI), a childcare consortium serving children and families living in South Los Angeles.
Screening. Two parent questionnaires, the Parent's Evaluation of Developmental Status (PEDS) and the Modified Checklist for Autism in Toddlers were used to assess for early indicators of ASD. Children who screened positive were invited to participate in the classroom intervention.
Intervention. The experimental intervention is based on JASPER, an evidence based model for teaching social communication and play to young children with ASD. Childcare sites were randomized to either an immediate 4-week treatment or a waitlist. Intervention was comprised of teacher-mediated 30-minute sessions three days per week in the classroom. Children were assessed at the beginning and end of treatment.
Teacher-child play interactions were coded in one-minute intervals for engagement states, play level, affect, and teacher directiveness. In addition, the frequency of child joint attention gestures and language were continuously coded. This coding system has been reliably used in other classroom-based studies of preschoolers with ASD (Chang et al., 2016).
Results: 124 children across four child care centers participated in developmental screening. Of those 124, twenty children screened positive on either the PEDS or the MCHAT and were invited to participate in the intervention phase of the study. A mixed model analysis showed a significant treatment by time interaction such that children in the immediate treatment group showed greater improvement in play level across the intervention period compared to the waitlist control children ($F(1,31)=40.97$, $p<0.001$). There was also a trend showing that children in the treatment showed greater improvement in joint attention language compared to the waitlist ($F(1,15)=3.49$, $p=0.08$). Teachers in the treatment also showed less directive and more responsive interaction styles across the treatment period compared to the control ($F(1,18)=6.93$, $p<0.05$).
Conclusions: This study showed the effectiveness of JASPER when adapted and implemented in community with childcare providers and children who screened at elevated risk for ASD. Both universal screening and intervention were successfully employed using community-partnered practices, including shared decision making, and co-development of the intervention for the community setting. By partnering with the community in which the child resides to develop appropriate intervention models, one may begin to breakdown barriers to accessing early intervention.

280 **144.280** The Broad Autism Phenotype and Parenting Sense of Competence in Mothers of Children with Autism Spectrum Disorder

N. Ekas*, Psychology, Texas Christian University, Fort Worth, TX*

Background:
Mothers of children with autism spectrum disorder (ASD) face unique challenges associated with parenting their child. These challenges may lead to increased parenting stress and depression in mothers (Davis & Carter, 2008). Mothers of children with ASD also report negative perceptions of their own parenting abilities compared to parents of typically developing children (Giallo et al., 2013). Mothers of a child with ASD may experience milder symptoms characteristic of ASD, which are referred to as the broad autism phenotype (BAP). Higher levels of BAP symptoms are associated with increased depressive symptoms (Ingersoll & Hambrick, 2011); however, Lau and colleagues (2016) found no associations between BAP and parenting sense of competence (PSOC).
Objectives: To examine the association between the BAP and PSOCe in mothers of children with ASD. This study also sought to examine whether aspects of maternal well-being mediate this association.
Methods: Eighty-two mothers of a child with ASD ($M_{childage}$ = 8.70 years) participated in this study. Mothers completed surveys online via Qualtrics. Surveys included the Broad Autism Phenotype Questionnaire, the Parenting Sense of Competence scale (subscales consist of parenting satisfaction and parenting efficacy), the Center for Epidemiological Studies-Depression scale, and a measure of benefit finding. All scales have been used with this population in previous research.
Results: Maternal BAP was negatively associated with PSOC (r = -.36, p = .001). The PROCESS macro in SPSS was used to examine the hypothesized mediation model depicted in Figure 1a. As shown in Figure 1b, the direct effect of the BAP on PSOC was not significant (b = -2.96, SE = 1.54, p = .06). Instead, the association between the BAP and PSOC was mediated by maternal depressive symptoms (indirect effect = -1.07, SE = .54; 95% CI: -2.49, -.26), such that increased BAP symptoms were associated with elevated depressive symptoms which, in turn, were associated with lower PSOC. Although benefit finding was associated with both BAP symptoms and PSOC, the indirect effect fell short of significance (indirect effect = -1.06, SE = .71; 95% CI: -2.74, .13). Follow-up analyses with the individual subscales of the PSOC found that depressive symptoms mediated the association between BAP and parenting satisfaction (indirect effect = -.86, SE = .40; 95% CI: -1.87, -.26); however, only benefit finding mediated the association between BAP and parenting efficacy (indirect effect = -.78, SE = .38; 95% CI: -1.74, -.18).
Conclusions: Â Mothers of children with ASD who report elevated BAP symptoms also report feeling less competent as a parent. This relationship was explained by maternal depressive symptoms and the ability to find benefits as a result of their child's diagnosis. The BAP consists of difficulties making and maintaining relationships and difficulty adapting to change. Therefore, it is possible that these difficulties exacerbate the already existing challenges of parenting a child with ASD. Given that mothers of children with ASD with elevated BAP symptoms have difficulty implementing parent-mediated interventions (Parr et al., 2015), the results of this study highlight an important area for clinical consideration.

281 **144.281** Parenting Practices, Temperament, and Depressive Symptoms in School-Aged Children with Autism Spectrum Disorder

J. McCauley[1]*, E. J. Adler*[2]*, K. Argente*[2]*, P. C. Mundy*[3] *and M. Solomon*[2]*, (1)UC Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA, (3)University of California at Davis, Sacramento, CA*

Background: Positive parenting practices are essential for successful child development, yet there are few studies of parenting children with autism spectrum disorder (ASD). The available evidence suggests that while there may be minimal differences in how parents of children with ASD and parents of children with typical development (TD) parent (Maljaars et al., 2014), harsh parenting practices used by parents of children with ASD relate to increased behavioral problems (Brenner & Fox, 1997). In TD youth, positive parenting practices can buffer a child at risk for developing depression because they moderate the association between temperaments characterized by negative emotionality and depression (Belsky & Pluess, 2009). Because children with ASD are at high risk for depression and negative affect (Simonoff et al., 2008; De Pauw et al., 2011), we tested whether parenting practices similarly interact with child temperament to buffer against child depressive symptoms in those with ASD.
Objectives: We aim to (1) describe how parents of children with ASD rate their parenting practices compared to parents of TD children, and (2) examine whether parenting practices moderate the association between child temperament and depressive symptoms.
Methods: The current sample includes 37 children—19 with ASD, and 18 with TD—matched on verbal IQ and age (8-12). Parents reported their own parenting practices using the Child Rearing Practices questionnaire (CRPQ; Neppl et al., 2003), their child's temperament using the Temperament in Middle Childhood Questionnaire (Simonds & Rothbart, 2005), and their child's depressive symptoms using the Child Behavior Checklist (Achenbach & Rescorla, 2001). Using a composite variable comprised of positive reinforcement, inductive reasoning, and confidence scales from the CPRQ, we used multiple regressions to test the interaction effect of positive parenting and negative affect on depressive symptoms in the whole group and only within the ASD group. All analyses were performed using SPSS 23.
Results: There were minimal group differences on parenting practices as assessed by the CRPQ (Table 1), although parents of children with ASD reported higher frequency of managing behavioral problems and lower confidence when managing them. There also were few group differences in the moderator analysis. Negative affect was positively associated (b =.58, p<.001), and positive parenting was negatively associated (b = -.28, p<.05) with depressive symptoms in the combined groups. The interaction between negative affect and parenting practices was significant (b =.46, p<.001)—indicating that for children with low negative affect, positive parenting practices were associated with lower depressive symptoms. For children with high negative affect, positive parenting practices did not show the same protective association (Figure 1).
Conclusions: Parenting practices and their protective effect on child depression appear to be similar across bothÂ the ASD and TD groups. Positive practices related to lower ratings of child depressive symptoms—yet children with low negative affect appeared to benefit more. Given that positive parenting may be most useful for children after issues related to underlying negative affect have been addressed, clinicians should ensure that parents have the skills to successfully manage these issues while promoting positive parenting.

282 **144.282** What Contributes to Parenting Stress and Challenges in the Parent-Adolescent Dyad?: Consideration of Both Parent and Adolescent Factors.

H. K. Schiltz[1]*, A. McVey*[1]*, A. D. Haendel*[2]*, B. Dolan*[1]*, K. A. Willar*[3]*, S. Stevens*[4]*, J. S. Karst*[5]*, A. M. Carson*[6]*, F. Mata-Greve*[1]*, E. Vogt*[1]*, N. Fritz*[1]*, J. Hilger*[7]*, E. Habisohn*[1]*, K. M. Rivera*[1] *and A. V. Van Hecke*[1]*, (1)Marquette University, Milwaukee, WI, (2)Interdisciplinary PhD program (Psychology and Biomed Science), Marquette University, Milwaukee, WI, (3)Children's Hospital Colorado, Aurora, CO, (4)University of Minnesota Medical School, Blaine, MN, (5)Medical College of WI, Wauwatosa, WI, (6)Baylor College of Medicine/Texas Children's Hospital, Houston, TX, (7)Illinois State University, Normal, IL*

Background: Parents of adolescents with ASD face unique challenges. Unsurprisingly, there is ample evidence suggesting that these parents experience increased stress and challenges in parent-adolescent dynamics, especially for those with more severe ASD symptoms. Moreover, many parents also have an increased proclivity to be affected by intra-individual challenges, including psychopathologies such as anxiety and depression. Such predispositions may exacerbate and be exacerbated by parenting struggles. However, research has yet to examine the relative impact of adolescent and parent factors on parenting stress and parent-adolescent relationships in families of adolescents with ASD, nor the potential malleability of parental depression through a social skills intervention for adolescents with ASD.
Objectives: This study examined the relative importance of parent depression, adolescent ASD symptomology, and adolescent physiological regulation on parenting stress and the parent-adolescent relationship, as well as the effect of the PEERS®social skills intervention on parent depression.
Methods: Sixty-four adolescents (Age: M=13.67, SD=1.5; IQ: M=99.64, SD=17.72) with ASD participated in this study. ASD was confirmed using the ADOS. Participants were randomly assigned to an experimental (n=32) or waitlist group (n=32) for participation in the PEERS®(Laugeson & Frankel, 2010) social skills intervention. All parents completed questionnaires assessing their own depressive symptoms (Beck Depression Inventory), parenting stress (Stress Index for Parents of Adolescents), parent-adolescent relationship quality (Parenting Relationship Questionnaire and Parent-Child Relationship Inventory), and their adolescent's social abilities (Social Responsiveness Scale) during the intake appointment. Parents also reported on their depressive symptoms 15 weeks after the initial intake (post intervention for the experimental group). Respiratory Sinus Arrhythmia (RSA) was measured using Porges and Bohrer's (1990) technique via the Cardioedit and Cardiobatch programs (Porges: Chicago, IL) at intake.
Results: Parent Depression and Adolescent ASD Symptoms were related to, and each explained unique variance in, multiple dimensions of parenting stress and parent-adolescent relationship dynamics in families of youth with ASD (Table 1 and 2). Of note, when considered together, Parent Depression but not Child ASD Symptoms explained unique variance in the parent-domain of the parenting stress measure (Table 2). Adolescent RSA was related to specific components of parenting stress and parent-adolescent relationship factors (Table 1) such that higher RSA (less dysregulation) was related to less stress in the parent-adolescent relationship domain and better communication. Importantly, Parent Depression decreased from pre- to post-intervention for the experimental group ($t(29)=2.07$, $p=0.05$), while no such decrease was evident in the waitlist group ($t(32)=-0.32$, $p=0.75$).
Conclusions: Parents suffering from depressive symptoms and those parenting an adolescent with more severe ASD symptomology or greater physiological dysregulation were likely to experience heightened parenting stress and greater struggles in the parent-adolescent relationship. An alternate interpretation of these findings may be that depressed parents were more likely to perceive the challenges of parenting as more stressful and the parent-adolescent relationship as less optimal. Furthermore, receiving a social skills intervention for their adolescent may ameliorate depressive symptoms in parents of adolescents with ASD. Regardless, this study demonstrates the importance of considering individual differences among parents of adolescents with ASD in future research.

283 **144.283** Correlates of Barriers to Service Access for Individuals with ASD Across the Lifespan: Findings from a Canadian National Survey

J. Lai[1] *and J. A. Weiss*[2]*, (1)Psychology, York University, Montreal, QC, CANADA, (2)York University, Toronto, ON, CANADA*

Background: Across the lifespan, individuals with Autism Spectrum Disorder (ASD) have many health, community, and social service needs. Service needs are often left unmet and place a high level of burden on individuals and their families. Identifying the barriers of access to each service and the sociodemographic, clinical and systemic correlates of various barriers will improve the quality of life for individuals through targeted changes in policy.
Objectives: The objective of this study was to identify the barriers to service access for different services and the sociodemographic, systemic, and clinical correlates of barriers across the lifespan.
Methods: An online survey was administered across Canada through the Canadian Autism Spectrum Disorders Alliance, completed by 3251 caregivers reporting on 3317 family members with ASD. Analysis was done in an age-stratified manner. Current service use was operationalized as any service used in the last 6 months, from a list of 23 community and health services and an "other" category that was recoded as needed. From the same list, participants indicated which services were difficult to obtain and selected barriers to accessing services from a list of 10 and an "other" category.
Results: Â The number of systemic barriers endorsed was 3.4 (SD=1.9) and increased across age groups (4 years and under: 2.8, SD=1.6; 5-11 year olds: 3.2, SD=1.7; 12-17 year olds: 3.6, SD=2; 18-24 year olds: 3.6, SD=2; 25 and older: 3.5, SD=2; $F[3316,4]=14.12$, $p<.001$). Across the sample, the most common barrier to accessing services was being on a waitlist (75%), followed by a lack of trained professionals (48.5%) and affordability (31.6%). Older individuals were more likely to report not obtaining services because of a lack of trained professionals ($\chi^2=30.07$, $p<.001$; e.g. 52.7% of 25 years and older vs 35.6% of 4 and under) and that diagnosis did not qualify for needed services ($\chi^2=28.17$, $p<.001$; e.g. 42.4% of 25 years and older vs 12% of 4 and under). More than half of the respondents in both adult groups reported that a barrier to access was being too old for the needed service. Predictors of the total number of barriers included financial trouble, receiving caregiver services, and multiple clinical factors (i.e., more mental health concerns, behavioural concerns, worse health score; all p's <.001).
Conclusions: The results show the specific barriers to accessing services in a large sample of individuals with ASD. Future analyses will identify how sociodemographic, clinical need, and systemic factors predict barriers to different services in each age group. Discussion of the implications of these findings will follow.

284 **144.284** Family Quality of Life While Waiting for Government Funded Applied Behaviour Analysis Services for Children with ASD

M. Lloyd[1] *and S. Jones*[2]*, (1)University of Ontario Institute of Technology, Oshawa, ON, CANADA, (2)University of Ontario Institute of Technology, Oshawa, ON, Canada*

Background: Families of children with autism spectrum disorder (ASD) often experience high levels of stress related to demands on their time, the health and behavioural needs of their child with ASD, and the health of other members of the family. It is important to investigate their family quality of life (FQOL) in order to understand how best to serve the entire family, not just the child.
Objectives: The purpose of this study was to examine the FQOL of families with a child with ASD who were waiting for government funded Applied Behaviour Analysis Services in Ontario, Canada.
Methods: An adapted version of the FQOL Survey for main caregivers of people with intellectual or developmental disabilities (Brown et al., 2006) was sent out to families with a child or adolescent on the Durham Applied Behaviour Analysis (ABA)-Based services for Children and Youth with ASD waitlist. The adapted FQOL Survey consisted of six sections from the original instrument, including About Your Family, Health of the Family, Support from Disability Related Services, Leisure and Recreation, Community Interaction, and Overall Family Quality of Life. Parents were also asked a series of open-ended questions related to their community interactions, recreation and leisure, and overall FQOL. Of the 484 surveys sent out, 147 were returned (31% response rate); 123 (84%) of the returned surveys were for families with a child less than 12 years of age.
Results: The average age of the children in this sample was 7.3 years (19% female) and the average age at diagnosis was 5 years. Parents reported that they had been on the ABA waitlist for an average of 8.6 months. The most influential factors for FQOL were whether the child with ASD had a major health concern, whether the family's needs were met by disability-related services, and whether there were opportunities to engage in leisure and recreation activities. Parents reported that there were several disability-related services that their children were in need of, but that they were unable to access. Results also indicated that parents of children with ASD were living with a variety of chronic physical and mental health conditions (e.g. depression, Fibromyalgia). Parents expressed a desire to be able to take their child out in the community without a "meltdown," and particularly mentioned the social isolation they experienced.
Conclusions: Â These results indicate that parents feel that access to disability-related services for their child with ASD is very important for FQOL; however, many families are not accessing these essential services due to long wait-times, financial concerns, and their child being expelled from various programs due to behavior challenges. These results also demonstrate that family members of children with ASD may experience high levels of physical and/or mental health concerns, which negatively impacts overall FQOL. Future research and programming should target program accessibility and overall family health in order to better serve families of children with ASD.

285 **144.285** Family Quality of Life within the Context of a Participant-Directed ASD Funding Program

E. C. Gardiner[1] *and G. Iarocci*[2]*, (1)Pediatrics, University of British Columbia, West Vancouver, BC, CANADA, (2)Simon Fraser University, Burnaby, BC, CANADA*

Background: The province of British Columbia (BC) has adopted a participant-directed model of autism spectrum disorder (ASD) service delivery, in which families are able to allocate funds toward the services they deem appropriate.Â Although placing decision-making directly in the hands of families aligns with best practices of family-centred care, research indicates that families may struggle with the lack of structure, and perceive service coordination as burdensome and overwhelming. The way in which the service system is designed in terms of funding allocation, service accessibility, and availability of guidance likely plays a critical role in how well families feel they are supporting their child with a disability, as well as in overall family wellbeing.Â We are currently in the dark as to how BC families perceive funding and service access, and this research shed light on their experiences.
Objectives: Â The goal of this mixed-methods research was to ascertain families' perceptions of the provincial participant-directed funding program, as well as the perceived impact on family quality of life (FQOL).
Methods: Caregivers (*N*=118) of individuals with ASD (aged 6-18 years; *M*=11.7) completed an online survey, in which they rated their satisfaction with available support, and completed the FQOL Scale (Hoffman et al., 2006).Â One hundred and fifteen respondents also provided qualitative comments elaborating on their satisfaction ratings.Â Fifteen caregivers participated in follow-up interviews, in which they elaborated on their perceptions of service delivery, highlighting the associated strengths and challenges.Â Qualitative data was analyzed using a modified grounded theory approach (Weston et al., 2001).
Results: Overall, online survey results indicated that only 26% of participants were 'satisfied' or 'very satisfied' with the resources and funds available to their family.Â Participants' open-ended comments indicated that although they were grateful for the funding, they were frustrated by the many perceived limitations. These included long waitlists, lacking services for specific groups (e.g., adolescents), and a desire for supports geared toward parents and families (e.g., family counseling). Finally, caregivers communicated their wish that the funding system be more flexible.
Similar themes emerged within follow-up interviews. Although caregivers acknowledged their appreciation of the funding, they indicated that the provided amount was insufficient to access their desired level of support. Moreover, they described the funding system as inefficient, inflexible, and inconsistent. In particular, caregivers noted a prevailing lack of guidance, and highlighted their feelings of isolation in service navigation.
Conclusions: This research revealed important insights into the strengths and challenges associated with the BC participant-directed funding model, as perceived by service users. We suggest that it is not enough to simply make families responsible for service coordination if they are not also armed with the necessary knowledge and guidance to make informed decisions. Without such guidance, family-directed service is not viewed as empowering, as is suggested within the family-centred philosophy, but is instead perceived as overwhelming, burdensome, and time consuming. It appears that funding services for children with ASD is necessary, though not sufficient to address the complex needs of these families. We conclude with recommendations for practice and policy.

286 **144.286** Examining the Impact of an Hcbs Autism Waiver on Families of Children with Autism in Maryland: A Mixed-Design Study

K. Eskow[1] *and J. A. Summers*[2]*, (1)Towson University, Towson, MD, (2)University of Kansas, Lawrence, KS*

Background: Families of children with autism are under stress that exceeds that of families of typical children and even those of children with less challenging disabilities. States have begun to recognize the need for family support and many have tapped Medicaid funding through HCBS Waiver services. However, little is known about the impacts of these services. Maryland, which administers the largest autism Waiver program in the country, offers a unique opportunity to study family impacts due to the presence of both a large number of Waiver families as well as a registry of families waiting to access the Waiver. In conjunction with the Maryland State Department of Education (MSDE) research has been conducted since 2008 comparing families of individuals receiving waiver services to a control group of families who expressed interest in receiving services, but who were not yet determined eligible for services. The authors assessed families on a variety of quantitative measures including demographic questions, Family Quality of Life (FQoL), satisfaction with services, reported child progress, reported need for services, and employment information (Eskow et al., 2011; Eskow et al., 2015). Results indicated higher FQoL for individuals on the waiver compared to those on the registry (Eskow et al., 2011), as well as greater perceived *improvement* in child with autism's independent living skills (Eskow et al., 2015).
Objectives:

1. To examine the impact of Waiver services on family quality of life (FQOL), employment, and family perspectives of their children's progress, in comparison to families on the registry;
2. To explore family perspectives of the components of Waivers that contribute to family outcomes.

Methods: Â This was a mixed-design study. For the quantitative study, we used propensity matching to develop equivalent samples of 552 families, including 282 waiver recipients and 270 on the registry. We conducted a statewide mail survey of these families to measure their utilization of and satisfaction with services, their FQOL, impact of their child's autism on parents' employment, and perceptions of their child's academic, independent living, social, and communication progress. For the qualitative study, we purposively sampled families giving permission to be re-contacted to identify a diverse sample of 48 respondents. We analyzed the transcripts using Atlas+.
Results: We found that families on the Waiver scored significantly higher in their FQOL and in independent living skills for their children. Qualitative results suggested that in-home services and flexible partnership with the Waiver service coordinator were critical factors contributing to these results. Employment was more nuanced, with Waiver services enabling families to access a wider range of choices for employment.
Conclusions: Â Recent findings are consistent with prior research (2011, 2015) thus providing quantitative evidence of the relationship between support received through Waiver Services and satisfaction with family quality of life. Ongoing research through longitudinal study is needed to advance our understanding of appropriate services and service delivery methods as they impact progress and function when working with families and their children with ASD.

287 **144.287** Multi-Disciplinary Team Work in Israeli ASD-Preschools: What Does It Take for a Whole to be Greater Than the Sum of Its Parts?

Y. Sinai-Gavrilov[1], *T. Gev*[1,2], *I. Mor Snir*[2] *and O. Golan*[1], *(1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Association for Children at Risk, Givat-Shmuel, Israel*

Background: Best-practice guidelines for early-intervention in Autism Spectrum Disorder (ASD) call for intensive and comprehensive interventions. The Israeli special education system for preschoolers with ASD promotes an integrative-developmental model of treatment for ASD. Children attending these settings receive a 14-hour-per-week treatment package from multiple professionals, including occupational therapists, speech and language pathologists, psychologists, art and music therapists, physiotherapists and behavior analysts. These treatments are embedded in the preschool routine, which includes one-on-one and group educational interventions. This integrative model is based on the premise that no single early intervention approach was found to be the most effective in promoting development, and therefore, young children with ASD should benefit from an individualized treatment-plan that builds on elements from various disciplines.
Objectives: This study aims to examine the perspectives of professionals from different disciplines working in ASD preschools, with regards to the preschool staff's integrative work and cooperation in their settings. Using a qualitative approach, we have explored the various factors that influence the experience of collaboration and cohesion among staff members, and its relation to their perceived professional efficacy.
Methods: Twenty-four professionals working in preschools for children with ASD were given semi-structured interviews, focusing on their experience as part of a specialized multidisciplinary team in ASD preschools. The interviewees (21 females, 3 males) varied in their professional background (7 psychologists, 5 speech and language pathologists, 4 occupational therapists, 3 physiotherapists, 3 behavior analysts, 3 art and music therapists), age (M=30.1, range - 29-36), and years of experience in the field of ASD (M=2.7 years, range 1-7). Interviews were transcribed and content analysis was performed.
Results: Primary analysis revealed that the staff's collaborative dialogue plays a significant role in the professionals' satisfaction and their perceived ability to bring to favorable outcomes among treated children. Several themes emerged as influential on the perceived cohesion of the professional staff: the importance of a shared terminology and conceptual framework with regards to children with ASD and their families, with a psychodynamic terminology vs. an adaptive functioning terminology as the main competing frameworks; the staff's ability to maintain equal member participation in discussion and decision making; the staff's ability to bridge between the therapeutic and educational demands and their individual perspectives on intervention; the professionals' attitude towards learning and applying practices which pertain to different disciplines; and the robustness of the staff-member's own professional identity.
Conclusions: Our findings offer a wider understanding of the factors that support an inter-disciplinary dialogue, decision making, and collaboration in ASD preschool staff. These elements are of particular importance in settings promoting integrative intervention approaches when no single comprehensive treatment model is preferred. An association between the nature of the staff's dialogue, and the individual practitioner's self and professional efficacy is suggested.

Poster Session
145 - Miscellaneous
12:00 PM - 1:40 PM - Golden Gate Ballroom

288 **145.288** Evaluating Long-Term Effects of an Early Detection Program for Autism Spectrum Disorder in the Netherlands

M. K. J. Pijl[1,2], *J. K. Buitelaar*[1,2], *M. W. P. de Korte*[1,2], *N. N. J. Rommelse*[2,3] *and I. J. Oosterling*[1,2], *(1)Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (2)Karakter Child and Adolescent Psychiatry University Centre, Nijmegen, Netherlands, (3)Department of Psychiatry, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands*

Background: The importance of early detection of autism spectrum disorder (ASD) followed by early intervention has been increasingly emphasized for children's adaptive, social and cognitive functioning. Early detection programs have demonstrated to lower the age at diagnosis directly after implementation. However, long-term effects are largely unknown. This study aimed to evaluate the long-term effects of an early detection program, training primary care providers and using a systematic screening procedure, applied by Oosterling et al. (2010), after a freeze of active investment.
Objectives: To investigate the long-term effects of an early detection program for ASD on the age at referral compared to non-ASD diagnoses.
Methods: The early detection program encompassed (a) training of primary care providers to recognize early signs of autism, (b) use of a systematic screening protocol including the Early Screening of Autistic Traits questionnaire, and (c) formation of a multidisciplinary diagnostic team. The effectiveness of the program was evaluated by a controlled study involving ASD (N=513) and non-ASD (N=722) referrals (aged 0-6 years) across three periods: pre-implementation (PRE; status quo), implementation (IMPL; actual implementation), and post-implementation (POST). During POST the multidisciplinary team continued to provide highly specialized mental health care service for infants and toddlers, but there was no specific effort put into training of primary care providers and use of the screening protocol. The proportion of children referred < 36 months of age versus the proportion of children 3-6 years was used as the outcome measure in binary logistic regression modeling. Predictors included diagnosis (ASD vs. non-ASD) and time point (PRE, IMPL, POST).
Results: There was a significant diagnosis by time point interaction effect (Wald chi-square (2) = 7.898, *p*= .019). The odds of being referred before 36 months for ASD versus non-ASD was stronger during implementation, but not before or after implementation (IMPL vs. PRE: 3.1, 95% CI 1.2-7.6; IMPL vs. POST: 1.7, 95% CI 1.0-3.0; PRE vs. POST: non-significant), with 33.3% (vs. 66.7%), 58.7% (vs. 41.3%) and 42.9% (vs. 57.1%) of the cases being referred for ASD during PRE, IMPL and POST, respectively. Post-hoc analyses revealed that the ASD referrals were 3.8 times (95% CI 1.8-7.9) and 4.0 times (95% CI 2.7-6.0) more likely to be referred before 36 months during IMPL as compared to PRE and POST, respectively. No significant differences were found between PRE and POST. In contrast, non-ASD referrals were only 2.3 times (95% CI 1.6-3.3) and 1.9 times (95% CI 1.1-3.3) more likely to be referred before 36 months during IMPL and PRE, respectively, as compared to POST. No significant differences were found between PRE and IMPL.
Conclusions: The early detection program led to earlier referral of children with ASD when corrected for other referrals during that time period, but this effect was not sustained when active investment was ended. This study highlights the importance of ongoing investment and encourages policy makers and health care managers to overcome barriers after implementation.

289 **145.289** Dysregulated Microbiome in People and Mice with Autism-Associated Genetic Mutations

*L. Tabouy[1], O. Ziv[1], O. Koren[1] and **E. Elliott**[2], (1)Bar Ilan University, Safed, Israel, (2)Bar-Ilan University, Safed, ISRAEL*

Background: The gut microbiome may influence brain development and behavior, mainly through the modulation of physiological metabolism and the immune system. Recent studies have highlighted a possible role for microbiome dysregulation in the development of autism spectrum disorders. However, according to current data, over half of the risk of autism is due to genetics. Therefore, knowledge of the interaction between the genetic disposition to autism and the microbiome is necessary to understand the exact role of microbiome in autism development.
Objectives: Our main objectives are to determine the dysregulation of the microbiome in people with the autism associated chromosome 16p11.2 deletion, as well as microbiome dysregulation in the chromosome 16 deletion mouse model. A second objective was to determine the dysregulation of microbiome in the Shank3 mouse model and to correlate microbiome dysregulation to immune dysregulation.
Methods: Using 16S high-throughput sequencing of stool samples, we have determined the gut microbiome community of 26 individuals with the chromosome 16p11.2 deletion, and their non-affected siblings. Real Time PCR is used to verify dysregulation of specific bacterial species in the people, and to study their dysregulation in the mouse model. 16S high-througput sequencing was also performed on stool samples from Shank3 knockout mice. The immune system profile of the mice was performed to determine the correlation between microbiome dysregulation and immune dysregulation.
Results: We have identified specific bacteria which are increased in individuals with the chromosome 16p11.2 deletion. In addition, we have found that some of these species are also dysregulated in the chromosome 16p11.2 deletion mouse model, further suggesting that genetic changes directly lead to microbiome dysregulation. In the case of the shank3 mice model, we verified the dysregulation of several bacterial genus and species by real-time PCR. Some of these species overlapped with those found in the individuals with chromosome 16p11.2 deletion. Of particular interest, we found that a few specific species within the bacterial genus lactobacillus, which has previously been implicated in social behavior, is dysregulated in all of our experimental groups (people with chromosome 16p11.2 deletion and both mouse models included in this study) In addition, we identified a correlation between levels of specific bacterial species and dysregulation of blood cytokine levels, as well as neurotransmitter receptor levels in the brain.
Conclusions: These studies determine that genetic differences associated with autism can induce changes in the microbiota profile. While most work has focused on the role of the microbiome in environmental factor-induced susceptibility to autism, this study highlights the role of genetics in establishing the microbiome. These studies will further help us understand the role of the microbiome in autism and if probiotics may helpful in a subset of affected individuals.

290 **145.290** Performance-Based Social Skills Training Improves Treatment Outcomes for Youth with Comorbid ADHD or Anxiety

***A. H. Gerber**[1], E. Kang[2], A. Mulhall[1], T. Clarkson[1] and M. D. Lerner[2], (1)Psychology, Stony Brook University, Stony Brook, NY, (2)Stony Brook University, Stony Brook, NY*

Background: Group-based social skills interventions (GSSIs) are a widely-used efficacious treatment modality for children with autism spectrum disorder (ASD; Gates et al., 2016) that typically provide training rules for interaction (social knowledge), enriched social contexts (social performance), or both (Lerner & Mikami, 2012). There is a need to investigate comorbidity as a potential moderator of treatment outcomes, as it is common in youth with ASD (Simonoff et al., 2008; Lerner & White, 2015). Specifically, attention-deficit/hyperactivity disorder (ADHD) and anxiety have been linked to deficits in social skills (Barkley, 1997; Motoca et al., 2012). Research utilizing a social knowledge approach to GSSIs has found little differential benefit for youth with any comorbidity (Deckers, et al., 2016), and limited gains for youth with comorbid ADHD compared to comorbid anxiety and ASD alone (Antshel et al., 2011). As they may already exhibit intact social knowledge (e.g., Maedgen & Carlson, 2000), youth with comorbid ADHD and anxiety might particularly benefit from a social-performance training that allows them to practice skills in vivo, as compared to a social-knowledge training; however, this has never been examined.
Objectives: We examined the impact of psychiatric comorbidity on treatment response to a community-based GSSI that provides an enriched, in vivo social learning and practice opportunities for ASD youth (Lerner et al., 2011).
Methods: Seventy-five children and adolescents, ages 9 to 17 years (M=12.86 years, SD=2.19; 59 male) participated in a 6-week community-based summer GSSI. The majority of parents reported a diagnosis of ASD for their child (86.7%). Parents completed measures of broad psychopathology (BASC-2; Reynolds & Kamphaus, 2004) and ASD symptomatology (SRS; Constantino & Gruber, 2007) at baseline and endpoint.
Results: Using ANCOVA-of-change, presence of any comorbid psychiatric diagnosis was associated with improvements on the BASC-2 behavioral symptom index and externalizing problems, specifically in aggression and conduct problems (all $\beta<=-.21$, $p<=.05$). In addition, the presence of a comorbid ADHD diagnosis was associated with reduced BASC-2 behavioral symptoms and externalizing problems (all $\beta<-.28$, $p<.049$), and improved adaptive skills, notably in social skills and daily living activities (all $\beta>.29$, $p<.01$). Finally, presence of a comorbid anxiety diagnosis was associated with greater improvements on the SRS, driven by improvements in social awareness and cognition (all $\beta<-.23$, $p<.04$).
Conclusions: As hypothesized, the presence of a comorbid psychiatric disorder moderated the treatment outcomes for youths participating in a GSSI. Consistent with previous research, participants with anxiety made larger gains on the SRS compared to other participants (Antshel et al., 2011). Unlike previous studies, youth with comorbid ADHD showed augmented improvements in externalizing problems and improved their adaptive skills. This suggests that GSSIs employing social-performance approaches can be particularly beneficial for youth with ADHD. This is supported by recent research indicating that impaired social decision-making mediated the relationship between ADHD symptoms and social skills deficits for youth with ADHD (Humphreys, Galan, Tottenham, & Lee, 2016). Future research should examine the mechanisms of change for performance training GSSIs, which may further elucidate unique benefits for those with comorbid ADHD.

Oral Session - 6A

146 - Maternal Factors that Impact the In Utero Environment and Autism-related Outcomes

1:45 PM - 2:35 PM - Yerba Buena 3-6

Session Moderator: Jeremy Veenstra-Vander Weele, *Psychiatry, New York State Psychiatric Institute / Columbia University, New York, NY*

1:45 **146.001** Maternal SSRI Exposure Results in Developmental and Long-Term Social Behavior Disruptions in Offspring.

S. E. Maloney, *S. Akula, K. B. McCullough, K. Chandler, C. Jakes, S. Avdagic, M. A. Rieger and J. Dougherty, Genetics, Washington University School of Medicine, St. Louis, MO*

Background: Six recent epidemiologyÂ studies found a significant association between maternal antidepressant (AD) use, particularly Selective Serotonin Reuptake Inhibitors (SSRIs), and increased risk of autism spectrum disorder (ASD) in the offspring. The heightened risk of ASD diagnosis was independent of mothers' depressive symptoms, indicating the risk is mediated by exposure to the drug. Two more studies reported a significant association with ASD and maternal AD use prior to but not during pregnancy, while another two reported no significant increase in ASD risk following maternal AD use. Thus, while on the balance more of these retrospective human studies implicated SSRI exposure as a risk factor, the debate would be strongly informed by explanatory studies in a model organism to identify whether mechanisms exist for long-term behavioral disruptions due to maternal SSRI use. Animal studies in particular allow for precise experimental control of exposures, and can provide clear indication as to whether transient SSRI exposure can alter long-term social behavior in placental animals.
Objectives: The objective of this study was to model in the rodent the recent human patient population findings to directly examine the risk of presenting ASD-relevant behaviors following maternal SSRI exposure during pregnancy and lactation and to elucidate molecular and cellular mechanisms in the brain.
Methods: Pregnant C57BL/6J female mice were exposed to the SSRI fluoxetine (FLX) via drinking water at a dose approximately equivalent to the maximum recommended human dose. The developmental and behavioral consequences in the offspring were examined, as well as cellular morphology and cell-specific transcriptional changes. Maternal FLX exposure began prior to breeding and continued through pregnancy and lactation until the pups were P14. To examine critical exposure periods, dams were also exposed only until birth (P0) or until E16 (equivalent to first trimester of human brain development). We examined possible interactive effects on behavior of FLX exposure and genetic susceptibility by exposing mothers of *Celf6* mutants, which exhibit a partial ASD-like phenotype (Dougherty, Maloney et al. 2013).
Results: Compared with vehicle-exposed controls, maternal FLX exposure resulted in robust long-term social behavior disruptions. During early postnatal ages, FLX exposure robustly attenuated USV calls and decreased weight. Altered social behaviors were observed in FLX-exposed pairs during juvenile play. In adulthood, impaired sociability and robustly altered social dominance were observed in FLX-exposed mice. Only when FLX exposure extended to P14 were behaviors altered in the T-maze and marble burying task. In the genetically vulnerable line, FLX exposure and *Celf6* mutation acted separately but in the same manner on developmental and long-term behaviors. Dendritic morphology and cell-specific gene expression were examined at ages coinciding with early social communicative deficits (P9) and later sociability and dominance changes (P60).
Conclusions: Maternal SSRI exposure in the C57BL/6J mouse leads to social communicative deficits in pups and long-term social behavior deficits. The influence of drug exposure on repetitive patterns of behavior may be dependent on age at exposure, specifically postnatal exposure through lactation. This study may have implications for the safety of antidepressant use in pregnant women and further research is needed.

1:57 **146.002** Maternal Antibodies in Autism Spectrum Disorder: Isolation and Specificity

L. Brimberg[1], *S. Mader*[1], *V. Jeganathan*[2], *T. R. Coleman*[2], *P. Gregersen*[2], *P. T. Huerta*[2], *B. Volpe*[2] *and B. Diamond*[3], *(1)Center for Autoimmune and Musculoskeletal Diseases, The Feinstein Institute for medical Research, Manhasset, NY, (2)The Feinstein Institute for medical Research, Manhasset, NY, (3)The Feinstein Institute for Medical Research, Manahasset, NY*

Background:
The concept thatÂ in utero environment, specifically maternal antibodies can contribute to the development of Autism spectrum disorders (ASD) has been entertained for over a decade, but only recently specific antibodies have been identified. Studies, including our own, have shown that significantly more mothers of children with ASD have brain-reactive antibodies than unselected women of child bearing age or mothers of a typically develop child. The hypothesis is that these anti-brain antibodies exploit the natural mechanism of immune protection of the fetus, cross the placenta, and, at a time when the fetal brain is not protected by a competent blood brain barrier, they can perturb fetal brain development. Indeed, several studies showed that mice or monkeys exposed in utero to such antibodies demonstrate 'ASD'-like phenotype.
Objectives:
We opted to generate brain-reactive monoclonal antibodies from mothers with an ASD child, to study their antigenic specificities, contribution to ASD pathogenesis and to device a protection strategy.
Methods:
We generated anti-brain monoclonal antibodies by first separating memory (CD27+) B cells from the blood of women with a child with ASD previously shown to have brain-reactive antibodies. We then incubated CD27+ B cells with fetal human brain homogenate labeled with biotin, followed by fluorochrome tagged stretavidin. B cells bound to fetal human brain antigens were isolated. Single CD27+ B cells were then isolated and immunoglobulin heavy and light chain variable region genes were amplified by PCR and expressed in vitro. We determined antigenic specificity of brain reactive monoclonal antibodies using a human protein array and a cell based assay. We determined pathogenicity by analyzing brain and behavior of the offspring following in uterine exposure to a monoclonal antibody cloned from a mother of an ASD child.
Results: We have generated a panel of brain-reactive monoclonal antibodies. Three monoclonal antibodies from 3 different mothers were found to bind the extracellular domain of contactin-associated protein-like 2 (Caspr2). We assessed the pathogenic potential of one of those monoclonal antibodies, C6. We intravenously administered either non-brain reactive control antibody B1 or C6 to pregnant mice on Embryonic day (E)13.5. We demonstrate that male but not female mice exposed in utero to the C6 monoclonal antibody display abnormal cortical development at E15.5 with a thinner cortical plate and a reduced number of proliferating cells. At adulthood, the brain exhibits decreased dendritic complexity of excitatory neurons and reduced numbers of inhibitory neurons in the hippocampus, and the live offspring exhibit impairments in sociability, flexible learning, and repetitive behavior. We suggest that this effect might cause by antibody mediated early internalization of AMPA receptors. We further demonstrated that anti-Caspr2 antibodies are more frequent in women with brain-reactive serology and a child with ASD
Conclusions:
We show in a mouse model that exposure in-utero to a monoclonal anti-brain reactive antibody isolated from a mother of an ASD child induces neurodevelopmental effects in the offspring that can be observed already during the embryonic stage. Currently we are designing a strategy to protect the developing fetus from the harmful effect of anti-Caspr2 antibodies.

2:09 **146.003** Maternal and Fetal Genetic Control of Mid-Gestational and Neonatal Levels of Markers of Immune Function

L. Weiss[1], *L. S. Heuer*[2], *M. Traglia*[1], *C. Yoshida*[3], *R. Hansen*[4], *R. Yolken*[5], *O. Zerbo*[6], *J. Van de Water*[7], *G. C. Windham*[8], *M. Kharrazi*[8], *G. N. Delorenze*[3], *P. Ashwood*[9], *L. A. Croen*[3] *and K. L. Jones*[7], *(1)Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, San Francisco, CA, (2)University of California, Daivs, CA, (3)Kaiser Permanente Division of Research, Oakland, CA, (4)UCD MIND Institute, Sacramento, CA, (5)Johns Hopkins University School of Medicine, Baltimore, MD, (6)Kaiser Permanente, Oakland, CA, (7)University of California at Davis MIND Institute, Davis, CA, (8)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (9)UC Davis, Sacramento, CA*

Background:
The immune system plays an important role in neurodevelopment, and increasing evidence suggests a link between immune system dysregulation and autism spectrum disorder (ASD). Animal models show that maternal immune activation during gestation impacts fetal brain development and subsequent behavior, potentially driven by alterations in levels of cytokines and chemokines which serve as Soluble Immune Mediators (SIMs). We therefore aimed to assess whether levels of SIMs during pregnancy or at birth might be determined by maternal and/or fetal genetics, and thus influence ASD risk beyond the presence of infection.
Objectives:
To determine whether maternal and neonatal immune markers are regulated by genetics in addition to environmental immune stimulation.
Methods:
We utilized a multi-ethnic genotyped population-based nested case-control study of 790 women and 764 of their newborns (390 ASD cases, 400 controls) in the EMA (Early Markers of Autism) study (Croen, Autism Res 2008; Tsang, PLoS ONE 2013). Mid-gestational levels of 22 SIMs were measured in maternal serum, and 42 in neonatal bloodspots. We first estimated the maternal and neonatal genome-wide SNP-based heritability (h^2_g) for each SIM and then performed GWAS using linear regression to identify specific loci contributing to individual SIMs. Finally, we assessed the relationship between genetic SIM determinants and ASD outcome.
Results:
Levels of two maternal SIMs showed > 80% maternal heritability (P<0.05, each) and the levels of 4 separate neonatal SIMs showed > 50% neonatal heritability in a SNP-based model (Yang, Nat Genet 2010) adjusted for genetic ancestry, maternal sociodemographic confounding factors as well as offspring affection status. Genome-wide association revealed 19 independent loci associated with 27 SIMs (P<5x10^{-8}): 3 maternal alleles were associated with maternal SIMs, 3 maternal alleles were associated with neonatal SIMs, 1 neonatal allele was associated with maternal sIL2Ra, and 12 neonatal alleles were associated with neonatal SIMs. Thus, not only can maternal genetics influence immune markers during pregnancy and in her infant, but fetal genetics can influence maternal immune markers mid-gestation as well as neonatal immune markers immediately after birth. The specific genetic loci highlight the pleiotropic contribution of a neonatal locus mapping to *PLCL2*, (P_{min}=8x10^{-21}), previously associated with autoimmune diseases. Maternal CCL2 and maternal and neonatal IL-8 were nominally associated with offspring affection status (P<0.05, each). Of these, neonatal IL-8 showed a suggestively associated locus that interacts with ASD status and maps to chromosome 2 (with no nearby genes) (rs55823040; P=4x10^{-7}). Thus, association between neonatal IL-8 levels and ASD outcome appears only within one genotype class at this IL-8 associated SNP.
Conclusions:
Our results demonstrate strong mutual contribution of both maternal and neonatal genetics to maternal and neonatal SIMs, however further research is required to elucidate roles in the development of ASD.

2:21 **146.004** Maternal Whole Blood Serotonin Levels Are Inversely Correlated with Social Difficulty, Language Impairment, and Repetitive Behavior in Offspring with Autism Spectrum Disorder.

A. K. Montgomery[1,2,3], *L. C. Shuffrey*[1,4,5,6], *S. J. Guter*[7], *G. M. Anderson*[8], *S. Jacob*[9], *E. H. Cook*[10] *and J. Veenstra-Vander Weele*[1,4,5,11], *(1)Department of Psychiatry, Columbia University Medical Center, New York, NY, (2)New York Presbyterian Hospital - Westchester Division, Center for Autism and the Developing Brain, White Plains, NY, (3)Department of Child & Adolescent Psychiatry, New York State Psychiatric Institute, New York, NY, (4)Department of Child and Adolescent Psychiatry, New York State Psychiatric Institute, New York, NY, (5)Center for Autism and the Developing Brain, New York-Presbyterian Hospital, White Plains, NY, (6)Teachers College, Columbia University, New York, NY, (7)University of Illinois at Chicago, Chicago, IL, (8)Yale University School of Medicine, New Haven, CT, (9)University of Minnesota, Minneapolis, MN, (10)Psychiatry, University of Illinos at Chicago, Chicago, IL, (11)Weill Medical College of Cornell University, Sackler Institute for Developmental Psychobiology, New York, NY*

Background: Â
Biomarker, neuroimaging and genetic findings implicate the serotonin (5-HT) system in autism spectrum disorder (ASD). Several groups have investigated clinical correlates of 5-HT levels in ASD, with minimal and inconsistent findings across studies. Recently, we identified an impact of the maternal 5-HT system on embryonic forebrain 5-HT levels and neurodevelopment in mice (Muller et al., in press).
Objectives:
As an initial step in evaluating the contribution of the maternal 5-HT system to ASD risk, we hypothesized that mothers' serotonin levels would correlate with the clinical presentation of ASD in their offspring.
Methods: Â
Whole blood serotonin (WB5-HT) levels were obtained from 184 children diagnosed with Autistic Disorder, Asperger's Disorder, or Pervasive Developmental Disorder Not Otherwise Specified based on DSM-IV-TR criteria, as well as from 90 of their fathers and 105 of their mothers. The child social and repetitive behavior phenotypes were evaluated using the Autism Diagnostic Observation Schedule (ADOS-2, Lord et al., 2012). Language function was examined using the Peabody Picture Vocabulary Test (PPVT-4, Dunn & Dunn, 2006) and the Expressive One-Word Picture Vocabulary Test (EOWPVT-4, Martin & Brownell, 2000). Finally, adaptive function was assessed using the Vineland Adaptive Behavior Scale (VABS-2, Sparrow, Cicchetti & Balla, 2005). Participants or parents receiving medications influencing the 5-HT system, such as serotonin reuptake inhibitors, were excluded from analysis. Whole blood samples obtained by venipuncture were stored in Vacutainer tubes containing EDTA at -70° C, prior to WB5-HT assay by high-performance liquid chromatography.
Results:
Proband WB5-HT levels correlated with both maternal WB5-HT levels (r_s(99)=0.291, p=0.003) and paternal WB5-HT levels (r_s(88)=0.385, p=0.0002). Despite these within family correlations, maternal WB5-HT levels were significantly correlated with child social, language, and repetitive behavior phenotypes; whereas paternal WB5-HT levels and proband levels were not. Maternal WB5-HT levels were negatively correlated with ADOS-2 total scores of social affect (r_s(103)=-0.258, p=0.008), total scores of restricted and repetitive behavior (r_s(103)=-0.254, p=0.009) and overall ADOS-2 scores of social affect and restricted, repetitive behavior (r_s(103)=-0.300, p=0.002). Maternal WB5-HT levels correlated with language raw scores on the PPVT-4 and EOWPVT-4 (r_s(71)=0.386, p=0.001 and r_s(62)=0.421, p=0.001, respectively). Finally, maternal WB5-HT levels correlated with overall adaptive functioning on the VABS-2 (composite standard score, r_s(99)=0.268, p=0.007), and with standard scores in the communication and living skills domains (r_s(99)=0.291, p=0.003 and r_s(99)=0.328, p=0.001, respectively).
Conclusions:
We found that higher levels of maternal WB5-HT levels were associated with lower impairment in social and repetitive behavior, as well as higher language scores, reflecting less communication impairment in children with ASD. Work is ongoing to replicate these findings and assess whether maternal 5-HT levels define a specific subgroup of children with ASD. Future studies using animal models and longitudinal neuroimaging are needed to understand the mechanisms underlying these associations.

Oral Session - 6B
147 - Epidemiology: Risks and Prevalence
2:40 PM - 3:30 PM - Yerba Buena 3-6

Session Moderator: Craig Newschaffer, *Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

2:40 **147.001** Maternal Insecticide Exposure during Pregnancy and Risk of Autism in Offspring from a National Birth Cohort

A. S. Brown[1], *K. Cheslack-Postava*[1], *P. Rantakokko*[2], *H. M. Surcel*[3], *S. Hinkka-Yli-Salomäki*[4], *I. W. McKeague*[5], *H. A. Kiviranta*[6] *and A. Sourander*[7], *(1)Columbia University Medical Center, New York, NY, (2)National Institute for Health and Welfare, Helsinki, Finland, (3)National Institute for Health and Welfare, Turku, Finland, (4)Research Centre of Child Psychiatry, University of Turku, Turku, FINLAND, (5)Columbia University Mailman School of Public Health, New York, NY, (6)Health Protection, National Institute for Health and Welfare, Helsinki, Finland, (7)University of Turku, 20014 Turku, FINLAND*

Background: Dichlorodiphenyl dichloroethene (DDE) is a metabolite of the insecticide DDT and is a persistent organic pollutant. Despite declining levels with time, ongoing prenatal exposure potential exists for nearly all children. DDE is transferred across the placenta, demonstrated by high correlations between levels of this pollutant in maternal serum and placenta and maternal and cord serum. Maternal prenatal serum DDE levels have been correlated with lower scores on standardized early childhood neurocognitive tests and low birthweight.
Objectives: We sought to examine whether elevated maternal DDE levels during pregnancy were related to an increased risk of childhood autism in a large sample of offspring from a national birth cohort.
Methods: The study is based on a nested case-control design. Cases with autism were identified from the national Finnish Hospital Discharge Registry and linked to the Finnish Maternity Cohort, which includes archived maternal serum specimens from virtually all pregnancies in Finland (over 1.5 million). Cases were born from 1987-2005 and followed up until 2007. Cases were matched 1:1 to controls drawn from the birth cohort who were without ASD (N=750 matched pairs) on date of birth, sex, birthplace, and residence in Finland. The samples were assayed for DDE using gas chromatography tandem mass spectrometry (GC-MS/MS). In each batch of samples a control serum sample from the National Institute of Standards and Technology was included. In previous work the detection rate for DDE was >96%. DDE was classified as a dichotomous variable, with the cut-point at the 75th percentile of the control distribution. Data were analyzed using conditional logistic regression for matched pairs.
Results: In a preliminary analysis we demonstrated that maternal exposure to DDE levels in the highest quartile are associated with a 41% increased risk of childhood autism (OR=1.41, 95% CI=1.11-1.80, p=0.005). We will also present results from assays of polychlorinated biphenyls (PCBs) in maternal serum samples of autism cases and controls, and from multivariate analyses adjusting for covariates. In addition, we shall report findings on whether the association between maternal DDE and autism is mediated by perinatal complications and increased growth velocity of head circumference.
Conclusions: We found an increased risk of autism among subjects who were exposed during pregnancy to elevated levels of DDE, a metabolite of DDT. These preliminary data suggest that prenatal exposure to this insecticide is related to the risk of autism in offspring. Strengths of the study include a large, population-based, national sample and prospective measures of exposure. Since this persistent organic pollutant has been related to neurocognitive and other early life abnormalities, this work may ultimately lead to an improved understanding of the neurodevelopmental mechanisms that underlie autism and suggest preventive strategies.

2:52 **147.002** Prevalence of Autism Spectrum Disorders Among Young Adults in Union County, New Jersey

W. W. Zahorodny[1], *A. Fusco*[2], *J. Shenouda*[3], *M. Waale*[2] *and A. E. Mars*[4], *(1)New Jersey Medical School, Westfield, NJ, (2)Rutgers - NJ Medical School, Newark, NJ, (3)Rutgers University, Newark, NJ, (4)Hunterdon Regional Autism Center, Yardley, PA*

Background:
Minimal data currently exist regarding the prevalence of Autism Spectrum Disorders (ASD) in young adults, rendering planning for, access to, and implementation of medical and daily living services for adults with ASD both inefficient and ineffective, at best. A study of ASD prevalence in a community sample of adults in the United Kingdom (UK) identified an ASD rate of 1% across all ages of adults, consistent with the rate in children (Brugha et al., 2011). Additional epidemiologic studies of ASD in adults are needed, especially in the United States, where ASD rates have increased significantly among children.
Objectives:
To estimate ASD prevalence and to describe the expression of ASD in a cohort of young adults born in 1988 and residing in Union County, New Jersey (NJ) in 2006, using the Centers for Disease Control and Prevention (CDC) Autism and Developmental Disabilities Monitoring (ADDM) Network population-based method of prevalence determination.
Methods:
This study used the ASD ascertainment strategy of the CDC ADDM Network, described previously in the *Morbidity and Mortality Weekly Report (MMWR) Series* (Rice, 2007) and replicated repeatedly in biannual surveillance cycles. The ADDM Network methodology uses an active, multi-phase method, consisting of independent review, abstraction and analysis of medical and educational records. The study used consistent DSM-IV-TR definitions of ASD.
Results:
In a population of 6,865 young adults born in 1988 and residing in Union County NJ, in 2006, 40 individuals with ASD were identified, indicating ASD prevalence of 5.8 per 1,000 (95% confidence interval [CI] = 4.27-7.94). Significant differences were found in prevalence between males, 9.23 per 1,000 (CI=6.56-12.98) and females, 2.13 per 1,000 (CI=1.01-4.47). ASD prevalence was lower in Hispanic individuals than in Whites or Blacks: White, non-Hispanic 6.7 per 1,000 (CI=4.37-10.27); Black, non-Hispanic 5.6 per 1,000 (CI=3.01-10.4); Hispanic 1.8 per 1,000 (CI= 0.58-5.59). Nineteen of 40 (47.5%) cases had a documented ASD diagnosis by a community provider. Six of 40 (15%) cases received special education services under the Autism Classification. Among the young adults identified with ASD at age 18, 45% (n=18) had a co-morbid psychiatric or neurological disorder.
Conclusions:
ASD prevalence among 18-year olds was consistent with the two epidemiologic estimates for the cohort and period, but lower than expected, when compared to ASD estimates from later NJ cohorts, for example: 9.9 per 1,000 and 10.6 per 1,000 for cohorts born in 1992 and 1994. The findings suggest increasing ASD prevalence over time. Study findings also indicate the possibility of sex and race-based disparities and a significant proportion of undiagnosed/unrecognized young adults with ASD.

3:04 **147.003** Determinants of Autism Prevalence in Hispanics

D. H. Hoang[1], *G. Xing*[2] *and C. K. Walker*[3,4], *(1)Division of Epidemiology, Department of Public Health Sciences, School of Medicine,, University of California, Davis, Davis, CA, (2)Center for Healthcare Policy and Research, University of California, Davis, Sacramento, CA, (3)Obstetrics and Gynecology, University of California, Davis, Sacramento, CA, (4)MIND Institute, University of California, Davis, Sacramento, CA*

Background: Hispanic children have a lower rate of autism spectrum disorder (ASD) diagnosis compared to non-Hispanic counterparts according to U.S. surveillance data. Underlying explanations for this significant disparity in ASD prevalence are poorly understood.
Objectives: This investigation aims to determine whether the lower prevalence of autism among California Hispanics can be explained by specific demographic and / or clinical factors.
Methods: This retrospective cohort study includes births drawn from the Office of Statewide Health Planning and Development PDD-Birth files from 01/01/1991-12/31/2008 that survived their first year of life. Children diagnosed with autism between 1991 and 2012 by the California Department of Developmental Services (DDS) were identified (n=33,359). The remainder of the birth cohort served as controls (n= 6,897,246). Demographic variables and ICD-9-CM codes for medical diagnoses and procedures during pregnancy were assessed for confounding. Logistic regression models evaluated the relationship between ethnicity and autism, controlling for parental age and education, maternal diabetes and preeclampsia, child sex, gestational age, delivery payer, delivery mode, and multiple gestations.
Results: While crude analyses found that Hispanic children were 27% less likely to have autism compared with their Non-Hispanic counterparts, autism odds were actually 14% higher for Hispanic children in models adjusted for clinical and demographic factors (OR 1.14, 95% CI 1.11, 1.18). Similarly, crude odds of autism were 35% lower in Hispanic children with foreign-born parents, and again the association reversed with proper adjustment to parallel the primary analysis (OR 1.15, 95% CI 1.11, 1.20).
Conclusions: Our investigation reinforces the importance of careful adjustment for confounders in assessing epidemiologic risk. Social determinants greatly influence health disparities. The influence of pregnancy complications known to enhance autism susceptibility played a substantial role in this analysis, but more striking still was the impact of low parental educational attainment – a proxy for socioeconomic status – on autism risk in Hispanics. Parents with more restricted education may not fully understand the implications of neurobehavioral differences in their children. Those who seek help may face major obstacles advocating for their child and accessing much-needed health and educational resources. These hurdles may be more daunting for foreign-born Hispanic parents who may also face language barriers and hold accentuated cultural views.

3:16 **147.004** Parent-Report Delays in Diagnosis and Service Initiation for African-American Children in a Multi-Site National Study

A. Abbacchi[1], *Y. Zhang*[2], *R. Fitzgerald*[1], *A. Roux*[3], *P. Shattuck*[3], *C. A. Saulnier*[4], *J. C. Bates*[5], *S. Molholm*[5], *J. K. Lowe*[6], *D. H. Geschwind*[7] *and J. N. Constantino*[8], *(1)Washington University School of Medicine, St. Louis, MO, (2)Washington University School of Medicine, Saint Louis, MO, (3)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (4)Children's Healthcare of Atlanta, Emory University, Marcus Autism Center, Atlanta, GA, (5)Albert Einstein College of Medicine, Bronx, NY, (6)Geschwind Lab, University of California, Los Angeles, Los Angeles, CA, (7)UCLA, Los Angeles, CA, (8)Department of Psychiatry, Washington University School of Medicine, St. Louis, MO*

Background: To the best of our knowledge, the true prevalence of ASD does not vary by race, yet detection rates of ASD are 20% higher in White non-Hispanic children (1 in 65) versus African-Americans (1 in 76) (CDC, 2016). U.S. surveillance research found that African-American and Hispanic children were more likely than White children to have a documented developmental concern before the age of 3 years, yet they were less likely to receive an evaluation before 36 months, (CDC, 2016).
Objectives: This study explored the variability in autism identification pathways for families with African-American children focusing on three key events: a) first concerns and help seeking, b) first autism diagnosis, and c) start of special services. We developed an interview tool using EHCI methods to enhance accuracy of parent/caregiver recall regarding their experiences seeking an ASD diagnosis and services for their child. This *Diagnostic Odyssey*instrument (Shattuck et al. 2013) seeks to capture and quantify barriers to quality treatment, medical care, diagnosis of autism spectrum disorders, and service seeking experiences for African-American and minority families.
Methods: Â The sample was comprised of 312 African-American and bi-racial African-American children (251 male, 61 female) enrolled in the *Autism Genetics Network, Phase II, Increasing the Representation of Human Diversity*at four sites: Washington University in St. Louis (N=147), Emory University in Atlanta, Georgia (N=54), Albert Einstein University in Bronx, New York (N=41), and University of California, Los Angeles (N=70). Participants were diagnosed with or strongly suspected of having an autism spectrum disorder (275 diagnosed ASD; 37 suspected-ASD). Median household income was $36,500 for the ASD-diagnosed group, and $28,000 for the suspected-ASD group.
Results: Â In the diagnosed group (N=275), the mean age parents reported first concerns with their child's language, behavior or development was 21.4 months (SD=17.8), and they reported sharing concerns with a professional by a mean age of 27.1 months (SD=22.6). However, the mean age of receiving an official autism spectrum diagnosis in this group was not until 54.4 months (SD=36.3). In comparison, mean age of first concerns in the suspected ASD group (N=37) was 35.1 months (SD=26.2); mean age at the time of the research evaluation was 148.3 months (SD=75.9), with an average delay of 114.1 months (SD=75.2) between age of initial concern and identification of an ASD by research diagnosis. All parents of children suspected of having an ASD reported sharing concerns with a professional, mean age =42.0 months (SD=28.4), however only 46.0% of these children had been assessed for an ASD prior to study enrollment (mean age 91.0 months, SD=51.4). Seventy-six percent of children suspected of having an ASD diagnosis met DSM criteria based on a clinical best estimate research evaluation at the time of the study.
Conclusions: The findings of this study reveal continued concerns with delays in autism evaluations for African American children despite parents expressed concerns to professionals. This research can help us to guide interventions that may decrease the delay in diagnosis and adequate treatments for African-American children with autism spectrum disorders.

Oral Session - 7A
148 - Developmental Processes of Distinct Repetitive and Sensorimotor Behaviors
1:45 PM - 2:35 PM - Yerba Buena 7

Session Moderator: Matthew W. Mosconi, *University of Kansas, Lawrence, KS*

1:45 **148.001** Examining Cognitive Inflexibility and Anxiety in Relation to Restricted, Repetitive Behaviours in Autism Spectrum Disorders in a Large Multi-Site Study

D. V. Crawley[1], *J. Ahmad*[2], *H. den Ouden*[3], *G. Dumas*[4], *J. E. Tillmann*[5], *A. San Jose Caceres*[6], *T. Charman*[7], *J. K. Buitelaar*[3], *D. G. Murphy*[8] *and E. Loth*[9], *(1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom, (3)Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (4)Institut Pasteur, Paris, France, (5)King's College London, London, England, United Kingdom, (6)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (8)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (9)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:
Restricted and repetitive behaviours (RRBs) are core features of autism spectrum disorder (ASD). Previous studies have suggested distinct subtypes of RRBs, such as 'lower-order' (e.g. motor stereotypies) and 'higher-order' RRBs (e.g. restricted interests and insistence on sameness; Turner, 1999; Rutter et al., 2003). Despite various descriptions of RRBs, their origins are less well understood. This may be because: (1) different facets of RRBs have different underpinnings; or (2) the same facet has different underpinnings in different individuals. As an example: for some, cognitive inflexibility may underlie insistence on sameness (D'Cruz et al., 2013), whereas for others, anxiety in uncertain situations may be a factor (Lidstone et al., 2014).
Objectives:
(1) To examine the profile and severity of RRBs in children, adolescents and adults who participated in the EU-AIMS Longitudinal European Autism Project (LEAP); and (2) to investigate cognitive inflexibility and anxiety as possible underpinnings of RRBs.
Methods:
Participants were 431 individuals with ASD aged 6-30 years and 298 age-matched controls. RRBs were measured using the Repetitive Behaviour Scale-Revised (RBS-R). The RBS-R restricted interests and rituals/sameness subscales formed the 'higher-order' RRBs composite and the stereotyped and self-injurious behaviour subscales formed the 'lower-order' composite. IQ was measured using the Wechsler Scales and adaptive behaviour using the Vineland Scales. Cognitive inflexibility was assessed as the number of perseverative errors made on a computer-based probabilistic reversal learning (PRL) task (den Ouden et al., 2013). We classified perseverative errors made by ASD individuals using a normative modelling approach, which assessed each ASD participant's performance as the deviation from the age-estimated control group mean. Anxiety was measured using the Beck's Anxiety Inventory.
Results:
As expected, ASD participants scored significantly higher than controls on the RBS-R (p<.001,Â *d*=2.06). Within the ASD group: (1) participants had significantly greater 'higher-order' RRBs than 'lower-order' RRBs (p<.001,Â *d*=0.86; Figure 1); (2) RBS-R total scores significantly decreased with age (r=-.25, p<.001); and (3) RBS-R total scores were significantly negatively related to adaptive behaviour, independent of IQ (r=-.31, p<.001). On the PRL task, the ASD group made significantly more perseverative errors than the control group (p<.001,Â *d*=0.35). However, when stratifying ASD individuals (Figure 2), 62% performed within +/-1SD of the control group mean, and 91% within +/-2SDs. Only 9% performed below 2SDs. No significant relationship was found between perseverative errors and RRBs in the ASD group, nor did the 9% with extremely high perseveration differ in their RRBs profiles. Across age groups, RRBs – and in children notably rituals/sameness behaviours – were significantly related to levels of anxiety in ASD individuals without intellectual disability (all r's>.41,p's<.001).
Conclusions:
We found no evidence for a role of perseveration in RRBs in ASD. Despite significant case-control differences, only a small 'subgroup' of ASD participants demonstrated clinically meaningful (<2SDs) impairments in cognitive inflexibility; and they were unrelated to RRBs. Instead our findings provide proof of concept that anxiety may be a main driver of RRBs, and particularly insistence on sameness. If correct, this suggests an alternative treatment approach in ASD – targeting anxiety to reduce RBBs.

1:57 **148.002** Examining Convergent and Divergent Validity of the Repetitive Behavior Scale for Early Childhood (RBS-EC)

C. Lasch[1], *J. J. Wolff*[2] *and J. T. Elison*[2], *(1)Institute of Child Development, University of Minnesota, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN*

Background: Recent evidence suggests that aspects of restricted and repetitive behavior (RRB) manifest as early as 12 months of age in high-risk infant siblings subsequently diagnosed with autism, as measured with both direct observation and parent-report (Elison et al., 2014; Wolff et al., 2014). Improved measurement of RRBs could augment early identification.
Objectives: Following the initial psychometric validation of the Repetitive Behavior Scale – Early Childhood (RBS-EC; Wolff, Boyd, & Elison, 2016), we sought to explore the longitudinal continuity and convergent/discriminant validity between the RBS-EC and previously established behavioral measures. We predicted that RBS-EC scores from an initial time point would be positively correlated with the same participants' RBS-EC scores an average of 7.8 month later (range 0.45-13.8 months, *SD*=2.28 months). We predicted that a composite score of all behaviors addressed on the RBS-EC would be associated with dysregulating behaviors (including aspects of sensory sensitivity) as measured by the Infant and Toddler Social Emotional Assessment (ITSEA; Carter et. al., 2003). For discriminant validity, we tested the association of the composite RBS-EC score with the internalizing sub-scale of the ITSEA.
Methods: A community sample of parents of 53 participants (27 male, 26 female) completed the RBS-EC online at a mean age of 22.81 months (range 15.4-26.9 months, *SD*=2.79 months) as part of a larger study. Participants then participated in a follow-up behavioral visit and additional questionnaires again at a mean age of 30.8 months (range 24.6-38.8 months, *SD*=3.22 months). The Mullen Scales of Early Learning was administered to participants, and the Vineland Adaptive Behavior Scales-II was completed with parents. Key metrics from these assessments were used as control variables in the analytic models.
Results: RBS-EC sub-scale scores of repetitive motor, restricted behavior, composite behavior frequency, and interference ratings at the first time point were significantly correlated with scores on the same sub-scales at time of behavioral assessment, (all *r's* > 0.5, and *p's* < 0.001, see Figure 1). This indicates that most RBS-EC sub-scales show continuity across an average of 8 months.
Â After observing a zero order correlation between RBS-EC composite mean frequency at time point 1 and ITSEA Dysregulation at time point 2 (see Figure 2), a hierarchical regression analysis revealed a significant association between these variables when controlling for sex, VABS ABC, Mullen fine motor, and age at time point 2, $F(5, 47)=4.177$, $p=.003$, $\Delta R^2 = 0.149$. This demonstrates that the composite of all items on the RBS-EC has moderate convergent validity with established measures of dysregulation behaviors, and other items capturing ASD traits.
Finally, a hierarchical regression indicated that ITSEA Internalizing scores were not significantly associated with RBS-EC composite scores, ($F(5, 47)=1.287$, $p=.286$, $R^2 change=.007$), controlling for the same variables as above. The lack of association between these scores and RBS-EC's composite score provides preliminary evidence of divergent validity for the RBS-EC.
Conclusions: This study provides preliminary evidence for predictive, convergent, and discriminant validity for the RBS-EC. More work is needed to extend these findings to samples with higher risk individuals and those with current ASD diagnoses.

2:09 **148.003** Characterizing Restricted and Repetitive Behaviors: Exploring the Influence of Age on Rrb Phenotype Clusters

K. Berry[1] *and A. Sturm*[2]*, (1)Psychology, Michigan State University, Lansing, MI, (2)UCLA, Los Angeles, CA*

Background: Restricted and repetitive behaviors (RRBs) are a complex and heterogeneous phenotype of autism spectrum disorders (ASD). Despite being half of the diagnostic criteria dyad, the relationship between specific RRB subdomains and other individual characteristics such as age remains unclear.
Objectives: The purpose of this study was to explore 1) the factor structure of RRB symptoms 2) identify RRB phenotype clusters in a large sample of youth with autism spectrum disorder and 3) determine if phenotypic clusters differ for children as compared to adolescents.
Methods: Participants included 2,757 individuals from Simons Simplex Collection, Simons Ancillary and Simons VIP datasets between the ages of 4 and 18 years old (*M*= 9.2 years*)* diagnosed with ASD. An exploratory factor analysis (EFA) was conducted to determine the factor structure of the Repetitive Behavior Scale-Revised (RBS-R). After visual inspection of RRB subtypes identified by EFA, participants were dichotomized into two groups - participants 4 to 14 years old and participants 14 to 18 years old. A K-means cluster analysis was run on both age groups to determine RRB phenotype clusters and descriptive statistics were calculated for each group.
Results: The EFA resulted in five RRB subdomains, which included hand/body mannerisms (H/B), self-injurious behaviors (SI), compulsivity (C), rigidity (R), and perseverative interests (PI). Results from the cluster analysis indicated that for both age groups there was a cluster of individuals that had elevated scores in *all* RRB domains as well as a group who exhibit reduced frequency across *all* RRB domains. The younger group produced a cluster with elevated compulsivity, rigidity and perseverative behaviors and low levels of self-injury and hand/body mannerisms. Additionally, the remaining cluster endorsed H/B mannerisms the most, with moderate scores of self-injury and perseverative interests, with compulsivity and rigidity having the lowest endorsement. Older participants' mixed clusters exhibited a pattern of more complex RRBs (perseverative interests, rigidity and compulsivity) manifested comparably across clusters, with the lower RRBs (hand/body mannerisms and self-injury) exhibiting a similar pattern.
Conclusions: The present study shows that a simplified representation of RRB presentation would not account for the incredible variability that exists among individuals with ASD. The cluster differences between age groups implies that RRBs do not manifest in the same way across individuals with ASD; which poses complications when the measurement of RRBs is inconsistent across studies. Further, results suggest that the more complex RRB phenotypes (e.g. perseverative interests) may not be as strongly linked in younger children, as they are in 14-18 year olds. These findings have important implications for future research exploring intervention targets for RRBs. It is possible that interventions for RRBs must be domain-specific given the varied RRB subdomain combinations manifested across individuals. Further, researchers should continue exploring the various ways RRBs are manifested across individuals with ASD and across ages to inform appropriate and useful intervention approaches.

2:21 **148.004** Intrainsular Connectivity and Somatosensory Responsiveness in Young Children with ASD

M. D. Failla[1]*, B. R. Peters*[1]*, H. Karbasforoushan*[2]*, J. H. Foss-Feig*[3]*, K. Schauder*[4] *and* ***C. J. Cascio***[5]*, (1)Psychiatry, Vanderbilt University, Nashville, TN,*

(2)Neuroscience, Northwestern University, Chicago, IL, (3)Psychiatry, Seaver Autism Center, Icahn School of Medicine at Mount Sinai Hospital, New York, NY,

(4)University of Rochester, Rochester, NY, (5)Vanderbilt University School of Medicine, Nashville, TN

Background: The human somatosensory system comprises dissociable paths for discriminative and affective touch, reflected in separate peripheral afferent populations and distinct cortical targets. Developmental differences in behavioral and neural responses to affective touch may play an important role in early social experiences, which may be relevant for autism spectrum disorder (ASD). Integrity of two sensory-related white matter pathways may provide insight into developmental differences in affective touch. The thalamocortical tract (sensory thalamus to primary somatosensory cortex) carries discriminative tactile information, while the intrainsular tract (posterior to anterior insula) represents the cortical projection target of unmyelinated tactile afferents mediating affective touch (posterior insula) and integration of sensory and visceral inputs to interpret emotional salience of sensory stimuli (anterior insula). We hypothesized structural integrity in these pathways might mediate variability in behavioral responses to affective touch in young children with ASD.
Objectives: Â To determine structural correlates of behavioral responses to affective sensory stimulation in children with ASD.
Methods: Â Using diffusion tensor imaging and probabilistic tractography, we investigated the structural integrity of the thalamocortical and intrainsular tract by comparing fractional anisotropy, mean diffusivity, and tract volume in a group of young children with ASD (n=29, ages 5-8) and a group of typically developing (TD, n=26) peers. We assessed tactile discrimination and affective response to social touch using the Tactile Defensiveness and Discrimination Test-Revised (TDDT-R). We examined group differences in tract integrity and behavioral assessments (Student's t or Mann-Whitney), as well as relationships between white matter integrity and behavioral responses (Spearman's and linear regression).
Results: Â There were significant group differences in white matter integrity in both tracts investigated, such that individuals with ASD had higher mean diffusivity (MD, lower tract integrity) than individuals in the TD group in both tracts (intrainsular, p=.039; thalamocortical, p=.026). Consistent with previous findings, the ASD group exhibited impairment in tactile discriminative ability and aberrant affective responses (both positive and negative in valence) to touch. Associations between tactile seeking behavior, characterized by positive affective behavioral response and unusually intense interest in tactile stimuli, and intrainsular integrity significantly differed by group (significant group by intrainulsar MD interaction, p=.0032). In the ASD group, increased intrainsular tract integrity was associated with more seeking behaviors while the opposite was true in the TD group. Reduced integrity in thalamocortical tracts was associated with increased tactile defensiveness across both groups.
Conclusions: Individuals with ASD had reduced integrity in both sensory-related tracts, correlating with responses to affective touch, suggesting altered sensory responses may propagate across both discriminative and affective touch pathways in ASD. These results are in line with previous findings that positive affective response to touch is mediated by somatosensory input to the posterior insular cortex (Olausson 2002). Relationships between intrainsular tract integrity and sensory seeking also differed by group, suggesting unique mechanisms may contribute to altered sensory seeking behaviors in ASD.

Oral Session - 7B
149 - Physiological Markers of Sensory Processes Differentiating ASD and Related NDDs
2:40 PM - 3:30 PM - Yerba Buena 7

Session Moderator: Matthew W. Mosconi, *University of Kansas, Lawrence, KS*

2:40 **149.001** Evidence for Domain Specificity of Cortical Auditory and Somatosensory Response Delays in ASD

C. Demopoulos[1], *N. Yu*[2], *J. Tripp*[1], *A. Brandes-aitken*[3], *S. Desai*[2], *S. S. Hill*[2], *A. D. Antovich*[4], *J. Harris*[2], *S. Honma*[1], *D. Mizuiri*[1], *N. G. Mota Miranda*[1], *S. Nagarajan*[1] *and E. Marco*[5], *(1)Radiology & Biomedical Imaging, UCSF, San Francisco, CA, (2)Neurology, UCSF, San Francisco, CA, (3)University of California, San Francsico, San Francisco, CA, (4)N, UCSF, San Francisco, CA, (5)University of California, San Francisco, Larkspur, CA*

Background: Cortical auditory response delays are a well-replicated finding in individuals with Autism Spectrum Disorder (ASD) and have been associated with language deficits. It is unclear, however, whether these delays are specific to auditory processing, are present in other sensory domains, or are associated with generalized cortical latency delays. It is also unclear whether these delays are present in other groups who experience sensory dysfunction but do not meet other symptom criteria for ASD.
Objectives: to determine whether cortical sensory response delays are specific to ASD and whether the latency delays previously reported in ASD are specific to auditory processing.
Methods: Auditory and somatosensory cortical response latencies were compared in 8-12 year-old male participants with ASD (N=18), those with sensory processing dysfunction (SPD) who do not meet criteria for ASD (N=13), and in typically developing control (TDC) participants (N=19). Auditory and somatosensory latencies were measured via MEG evoked responses to standard stimuli presented in two passive mismatch negativity tasks (i.e., response to a 1000Hz tone for the auditory evoked response and application of a tap to the left middle fingertip for the somatosensory evoked task). Measures of communication (i.e., phonemic processing, language pragmatics, and verbal intellectual abilities) were administered to examine associations between auditory processing delays and language deficits associated with ASD.
Results: ANCOVAs were performed (age as covariate) to determine if groups differed in M100 or M200 auditory response latency in each hemisphere, or contralateral somatosensory response. Significant group differences were identified for the left auditory M200 latency, $F(2,45)=3.61$, $p=.035$, and right somatosensory latency $F(2,46)=3.63$, $p=.035$. Specifically, the ASD left M200 latency was significantly delayed relative to both the TDC and SPD groups, whereas the somatosensory response in the ASD group was only delayed relative to the TDC group and did not significantly differ from the SPD group, who presented with an intermediate somatosensory latency. Likewise, response latencies for the M100 response followed a similar pattern to the M200, with the clinical groups showing longer mean latencies bilaterally, although group differences were not statistically significant. A hierarchical regression analysis performed with nonverbal intelligence entered in Step 1, language variables entered in Step 2, and left M200 latency as the dependent variable demonstrated that language abilities accounted for 60.3% of the variance in left M200 latency after controlling for the effects of nonverbal intelligence (which accounted for 5.7% of the variance) in the ASD group, with $F(3,10)=5.91$, $p=.014$. These associations were not significant in the SPD or TDC groups. Finally, the cortical auditory M200 response latency delays detected in the ASD group were not significantly associated with delayed somatosensory latencies ($r=.172$, $p=.494$).
Conclusions: These results provide evidence of auditory and somatosensory response delays in ASD, and support prior findings demonstrating associations between delayed auditory latencies and language abilities. Further, while these cortical sensory responses were delayed in ASD compared to SPD and TDC groups, the weak association between these delays across sensory domains suggests that these deficits are domain specific rather than reflective of generalized cortical processing delays in ASD.

2:52 **149.002** Neuromagnetic Responses to Tactile Stimulation of the Fingers: Evidence for Reduced Cortical Inhibition for Children with Autism and Children with Epilepsy

W. Gaetz[1], *M. Jurkiewicz*[2], *S. Kilaru Kessler*[3], *L. Blaskey*[4], *E. S. Schwartz*[1] *and T. P. Roberts*[4], *(1)Radiology, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Division of Neuroradiology, The University of Pennsylvania Health System, Philadelphia, PA, (3)Neurology and Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Â Magnetoencephalographic (MEG) measurements of somatosensory evoked responses to tactile stimulation of the digits result in an early cortical response labelled the '$_T$P30m' and a '$_T$P50m' which occurs at approximately 50ms following the presentation of a transient mechanical stimulus (e.g., a finger tap). Several lines of evidence support the position that the $_T$P50m response is associated with GABA dependent post-excitatory inhibition. Moreover, GABA signaling is thought to be downregulated in both children with autism (ASD) and children with epilepsy (EPI).
Objectives: Â Our objective was to compare $_T$P50m responses from a group of 15 children with ASD (mean age 9.95 ±1.23 SD years; 3 female), and a separate group of 17 children with EPI (mean age 10.57 ±1.72 SD years; 4 female) with $_T$P50m responses recorded from a group of 15 age matched typically developing (TD) controls (mean age 10.21±1.61 SD years; 2 female). We hypothesized that separately, for children with EPI and children with ASD, we would observe decreased SEF$_T$P50m response amplitudes to tactile stimulation of the digits.
Methods: Â MEG recordings were performed at the Lurie Family Foundations' MEG Imaging Center of the Department of Radiology at the Children's Hospital of Philadelphia in a magnetically shielded room using a whole-cortex 275-channel MEG system. Somatosensory stimuli were presented to the left and right index fingers sequentially using pneumatic pulses of compressed air (30 p.s.i.) delivered via clip-on balloon diaphragms. Stimulation duration was 40ms and jittered between 0.5 and 0.7s random ISI. Data were collected in epochs of -0.1 to 0.3s for a total of 500 trials. Source localization of the $_T$P50m response yielded a $_T$P50m response strength parameter (i.e. equivalent current dipole (ECD) moment) as well as a peak latency which we considered in our linear mixed model using subject as a random effect, group and hemisphere as fixed effects, and age as a covariate.
Results: We observed a significant overall group effect of reduced $_T$P50m dipole moment $F(2,41)=3.99$, $P<0.05$. Independent post-hoc pair wise comparisons for dipole moment showed marginal means were significantly different comparing TD (21.3±1.8nAm) vs. ASD (15.4±1.9nAm), P=0.027 as well as TD vs. EPI (14.9±1.7nAm), P=0.014. In addition, we observed a significant overall group effect for $_T$P50m peak latency $F(2,41)=4.66$, $P<0.05$. Post-hoc pair wise comparisons for dipole latency showed this to be driven by a latency delay of ~8ms in the EPI group: marginal means were significantly different comparing TD (50±2ms) and EPI (58ms±2ms), P=0.014, and not significant for TD vs. ASD (50±2ms), P=0.9.
Conclusions: We observed significant decreases in $_T$P50m dipole moment values from the ECD source localized $_T$P50m response, for children with EPI and children with ASD. In addition, the latency of the $_T$P50m peak was observed to be equivalent between TD and ASD groups but was significantly delayed in children with EPI by approximately 8 ms. The failure to observe a latency difference in TD vs ASD is interesting in relation to the well-established finding of delayed auditory responses known to occur in children with ASD and will be the subject of future investigation.

3:04 **149.003** Can Parent Report and Direct Assessment Measures Enhance Sensory over-Responsivity Phenotyping and Inform the Neural Underpinnings of Sensory Processing Symptoms?

E. Marco[1], *A. Brandes-aitken*[2], *T. Tavassoli*[3], *L. J. Miller*[4], *S. A. Schoen*[5], *J. Owen*[6] *and P. Mukherjee*[7], *(1)University of California, San Francisco, Larkspur, CA, (2)University of California, San Francsico, San Francisco, CA, (3)Seaver Autism Center, New York, NY, (4)STAR Institute for SPD, Greenwood Village, CO, (5)Sensory Processing Disorder Foundation, Greenwood, CO, (6)Neurology, UCSF, San Francisco, CA, (7)University of California, San Francisco, San Francisco, CA*

Background: There is mounting evidence to suggest that sensory over-responsivity is common across children with neurodevelopmental disorders, including children with autism spectrum disorders (ASD) and sensory processing dysfunction (SPD). However, the standard methodology of determining these differences is with parent report questionnaires. There is no consensus on how to reliably measure sensory over-responsivity with a direct assessment tool by sensory domain. Reliable tools, both parent report and direct assessment, for determining the presence and nature of specific sensory dysfunction, such as over-responsivity, is a critical step for researchers and clinicians alike as we seek to understand the biologic underpinnings of sensory processing.
Objectives: This study has two main objectives, first to define a scoring methodology specific to tactile and auditory over-responsivity based on the Short Sensory Profile (SSP), a parent report questionnaire, and the Sensory Processing Scale Assessment (SPS-A), direct observation session, and then to analyze the inter-test agreement between these assessments. Second, using MRI Diffusion Tensor Imaging (DTI), we seek to determine whether children with auditory or tactile over-responsivity show uniquely decreased regions of white matter integrity.
Methods: Using a Research Domain Criteria (RDoC) approach this study included children with auditory and tactile over-responsivity from a mixed neurodevelopmental cohort (NDC), including children with ASD and SPD and children with no known neuro-sensory challenges. For our first aim, a large sample of typically developing children (TDC) children (n=128) was collected to establish cut-off scores for over-responsivity. Then all children (TDC, n=128 and NDC, n=21) were categorized as over-responsive in either the auditory or tactile domain if they deviated significantly from the expected mean. For the neuroimaging analysis, 39 children with both brain imaging and direct sensory assessment were included and grouped by sensory over-responsivity (yes/no) in either the auditory or tactile domain. Sensory-based group comparisons were then conducted comparing the white matter fractional anisotropy (FA) in 23 regions of interest (ROIs).
Results: Cut-off scores for auditory and tactile over-responsivity were established. Using the direct observation, 57% of the NDC children had auditory over-responsivity and 33% had tactile over-responsivity. The Inter-test-agreement between SSP and SPS-A for auditory over-responsivity was 65% and tactile over-responsivity was 50%. Using neuroimaging DTI analysis, we found that children with auditory and tactile over-responsivity by direct assessment had 19 total tracts showing decreased white matter integrity relative to children without either auditory or tactile over-responsivity. Of these atypical tracts, 15 were uniquely associated with auditory over-responsivity and 2 were uniquely associated with tactile over-responsivity.
Conclusions: This study identified cut scores for auditory and tactile over-responsivity using the SSP parent report measure and SPS-A direct observation. This direct observation measure can be used in clinical and research settings. The SSP parent report and SPS-A direct observation ratings overlapped moderately for sensory related behaviors. Furthermore, based on our preliminary DTI results, we suggest that non-overlapping white matter tracts may contribute to the disruption of auditory or tactile processing leading to a domain specific over-responsive phenotype.

3:16 **149.004** Visuomotor Integration: A Potential Biomarker of Autism Spectrum Disorder in Lab and Community-Based Settings

H. L. Miller[1], *P. Caçola*[2], *G. Sherrod*[1] *and N. Bugnariu*[1], *(1)University of North Texas Health Science Center, Fort Worth, TX, (2)University of Texas at Arlington, Arlington, TX*

Background:
In recent years, sensorimotor features of Autism Spectrum Disorder (ASD) have garnered increased attention. However, few studies have investigated how sensory and motor systems work in coordination, or how they differ between typical and atypical development and within various developmental disorders. To that end, we quantitatively assessed *visuomotor integration*–the use of visual information to guide motor behavior–and its influence on postural stability in two studies of individuals with ASD, typical development (TD), and Developmental Coordination Disorder (DCD). The first study took place in our virtual reality lab, and the second study took place at community, school, and clinical sites.
Objectives:
To define the relationship between postural control, eye movement, and visual context in ASD, and to determine whether this relationship varies between ASD, TD, and DCD.
Methods:
Study 1: 30 participants (10 ASD, 10 DCD, 10 TD) completed a variety of visuomotor integration tasks while wearing mobile eye-tracking glasses and standing on force plates in a full-body motion capture and immersive virtual reality system (Figure 1). These tasks required a range of behavioral responding, from "watch-only" conditions to "watch-and-move" conditions where participants engaged with the virtual environment via user-controlled objects.
Study 2: 50 participants (20 ASD, 10 DCD, 20 TD) completed a brief set of two visuomotor integration tasks while wearing mobile eye-tracking glasses and standing on a portable force platform. The first task tested postural control during quiet standing with vision unoccluded, occluded, and partially occluded. The second task tested postural control during a limits-of-stability task that required leaning to move a user-controlled object to static targets displayed on a screen. This community-based study used portable, low-cost equipment and rapid data collection (< 15 min per participant).
Results:
Across both studies, the ASD group had appreciable differences in quantitative measures of postural stability compared to the TD and DCD groups (Figure 2). These differences were particularly evident in tasks when visual context was unavailable or when the task required the use of information about visual motion (i.e., targets moving rather than static) to produce accurate responses. Eye movement differences were also evident, with the ASD group demonstrating difficulty maintaining visual pursuit of moving targets and a reduced ability to fixate static targets relative to DCD and TD groups.
Conclusions:
These data suggest that quantitative assessments of visuomotor integration may be a promising avenue of investigation as a biomarker to differentiate ASD from TD and other developmental disorders with shared motor features, like DCD. They also highlight the important role of visual information processing in the ability of individuals with ASD to maintain balance and to control intentional movements. While results from Study 1 provide a more detailed assessment of visuomotor integration in ASD, Study 2 demonstrates the feasibility of transferring these types of tasks and outcome measures to community settings including schools and clinics. A brief visuomotor screening of this nature may aid in identifying sensorimotor issues in individuals with ASD who have not received comprehensive evaluation, and may also facilitate individualized interventions tailored to meet specific sensorimotor needs.

Oral Session - 8A
150 - Perception, Memory, Language, and Decision Making
1:45 PM - 2:35 PM - Yerba Buena 8

Session Moderator: Natalie Russo, *Syracuse University, Syracuse, NY*

1:45 **150.001** The Influence of Prior Knowledge on Immediate Memory for Objects in ASD

***S. Pisani**, M. Poirier, D. M. Bowler and S. B. Gaigg, Psychology, City, University of London, London, United Kingdom*

Background: Recent evidence suggests that the perceptual experiences of individuals with ASD are modulated atypically by stored representations (*priors*), leading to a more accurate perception of incoming sensory information and less distortion by prior experience (e.g., Pellicano & Burr, 2012). It remains unclear, however, to what extent this difference in perception is a result of abnormalities in how experiences initially shape and update representations or in how representations are activated by sensory information. In the mainstream literature, Hemmer & Steyvers (2009) have developed an experimental paradigm that can shed some light on this issue. They showed that memory for the size of recently presented familiar stimuli (fruit, vegetables) is not only biased by the statistical properties of the stimuli presented during the experiment but also by the prior knowledge about the size of items that participants bring to the experiment.
Objectives: To shed further light on the interaction between prior knowledge and recent perceptual experience in ASD through the application of an adapted version of Hemmer & Steyvers' (2009) paradigm.
Methods: 17 ASD and 19 age and IQ matched typically developing (TD) adults participated in two experiments. Experiment 1 probed participant's long-term representations of the sizes of fruits by presenting photographs of these on a PC monitor and asking participants to resize them to what they considered to be the smallest possible, largest possible and average size of each item. Abnormalities in how prior knowledge is represented in long-term memory in ASD should lead to differences in the range and/or means of these sizes relative to controls. In experiment 2, 3 items were sequentially presented that could either be vegetables or control abstract shapes yoked in size to the vegetables. Participants were asked to remember the size of each item. Following each set, one item was re-presented in a new random size that participants needed to resize to the studied size. Importantly, the vegetable images included items that were either relatively small or large relative to their respective category mean (e.g., a small vs large radish). This design allows inferences to be drawn on how super-ordinate category and item-level representations of objects influence performance and comparison with the resizing of abstract shapes sheds light on how biases due to prior knowledge deviate from biases that develop during the course of the experiment.
Results: Experiment 1 revealed a tendency for ASD participants to report a greater range of sizes than TD participants, supporting the notion that prior knowledge may be represented atypically in ASD. In Experiment 2, participants with ASD were less accurate overall in re-constructing the sizes of to-be-remembered vegetables and shapes but both groups demonstrated similar levels of regression to the mean and biases that were induced by prior knowledge.
Conclusions: The results suggest that in ASD, the representations of recently viewed objects is slightly noisier or imprecise (Exp 2) and that this may lead to atypical representations of object properties in longer-term memory (Exp 1). The processes by which prior knowledge bias behaviour, however seem to operate typically.

1:57 **150.002** Decision-Making Under Ambiguity and Risk in Adolescents and Young Adults with Autism Spectrum Disorder

***M. K. Krug**, C. C. Coleman, G. C. Gower and M. Solomon, Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA*

Background:
Little is known about decision-making in autism spectrum disorder (ASD), despite its potential impact on functioning. Decision-making under ambiguity can be investigated using the Iowa Gambling Task (IGT), where learning is implicit. Studies have shown impaired performance on the IGT in ASD (Mussey et al., 2015; Zhang et al., 2015), although South et al. (2014) observed enhanced performance. A modified version of the IGT (mIGT), which eliminates the potential confound of differences in exploratory behavior, and allows for separation of approach (choosing to "play" a good deck) and avoidance (choosing to "pass" on a bad deck) behavior, has been developed but has not yet been used in ASD (Cauffman et al., 2010). Decision-making under risk can be assessed using the Game of Dice Task (GDT), where outcomes are unambiguous and explicit. Zhang et al. (2015) found impaired performance and suboptimal use of trial feedback in ASD.
Â Objectives:
1. Continue to investigate decision-making under risk using the GDT. 2. Examine decision-making under ambiguity using the new mIGT. 3. Explore how performance on decision-making tasks is related to cognitive functioning and psychopathology.
Methods:
22 ASD (Age = 16.45(2.67); FSIQ = 101.27(15.11)) and 29 TYP participants (Age = 16.07(2.91); FSIQ = 110.03(12.79)) performed the GDT and mIGT. In the GDT a bet is placed on 1, 2, 3 or 4 sides of the die. A selection of 1 or 2 sides is considered "risky," while selection of 3 or 4 sides is considered "safe." For each mIGT trial one of four decks is pre-selected and can be "played" or "passed." Cognition was assessed using the NIH Toolbox Cognition Battery (www.nihtoolbox.org). Psychopathology was assessed with the Achenbach System of Empirically Based Assessment (ASEBA) (Achenbach & Rescorla, 2001; 2003).
Results:
GDT: Mean net score (#safe choices – #risky choices) was significantly higher for TYP (12.59(6.67)) versus ASD (7.27(8.56)), F (1,48) = 4.820, p = .033. TYP was more likely to place a safe bet following a "safe" win trial (F (1,48) = 5.275, p = .026) and after a "risky" loss trial (F (1,36) = 3.688, p = .063, trend) compared to ASD (Figure 1a), indicating better use of feedback.
Â mIGT: For TYP, the difference in %played between good decks and bad decks was significant for Blocks 3, 5, and 6 (all ps <.05). A comparison of Block 1 and Block 6 indicated that TYP, but not ASD, participants learned to avoid bad decks (t(28) = 2.709, p = .011) (Figure 1b).
TYP performance on IGT was positively correlated with NIH Toolbox Cognitive Function Composite Score (Figure 2a). In ASD, there was an association between anxiety and obsessive compulsive symptoms and poorer IGT performance (Figure 2b, c).
Conclusions:
Participants with ASD show impairments in decision making under risk (GDT) and ambiguity (mIGT). Decision making is related to cognitive functioning in TYP and anxiety and compulsive symptoms in ASD.Â Data collection is ongoing, and age groups effects analyses will assess development of decision-making processes throughout adolescence and young adulthood and their relationship to adaptive functioning.

2:09 **150.003** Imitation, Joint Attention and Language Development in Autism Spectrum Disorder

L. E. MacKenzie[1]*, I. M. Smith*[2]*, J. Volden*[3]*, E. Duku*[4]*, S. Georgiades*[4]*, T. Bennett*[5]*, P. Szatmari*[6]*, P. Mirenda*[7]*, T. Vaillancourt*[8]*, L. Zwaigenbaum*[9] *and M. Elsabbagh*[10]*, (1)Psychology and Neuroscience, Dalhousie University, Halifax, NS, Canada, (2)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (3)University of Alberta, University of Alberta, AB, CANADA, (4)McMaster University, Hamilton, ON, CANADA, (5)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (6)Centre for Addiction and Mental Health, Toronto, ON, CANADA, (7)University of British Columbia, Vancouver, BC, CANADA, (8)University of Ottawa, Ottawa, ON, CANADA, (9)University of Alberta, Edmonton, AB, CANADA, (10)McGill University, Montreal, CANADA*

Background: Previous research indicates that early joint attention and imitation skills predict structural language development in children with ASD. Pragmatic impairments are universal in ASD; however, little research has examined contributions of joint attention and imitation to pragmatic communication versus structural language. In one study, imitation skills (assessed by parent-reported McArthur Communicative Development Inventory, M-CDI) predicted pragmatic growth in 34 children with ASD from aged 41 months to 54 months, whereas core language (also M-CDI) did not significantly predict pragmatics (Miniscalco et al., 2014). Research over a wider developmental range with specific, direct measures of imitation, joint attention, pragmatics, and structural language is required to test these associations.
Objectives: To investigate predictive contributions of early imitation and joint attention skills to structural language and pragmatic communication skills in a large longitudinal sample of children with ASD.
Methods: Data were analyzed from 421 children in the *Pathways in ASD* study at 3 points; Time 1 (within 4 months of diagnosis, mean age 39.8 mo), Time 2 (mean age 69.3 mo) and Time 3 (mean age 98.4 mo). At T1, children participated in tests of elicited imitation (Multidimensional Imitation Assessment, MIA), and joint attention (Early Social Communication Scales, response to joint attention; ESCS RJA). At T2, cognitive ability (Wechsler Preschool and Primary Scale of Intelligence, Fourth Edition, WPPSI-IV), structural language (Preschool Language Scale – 4, PLS-4) and pragmatic communication (Children's Communication Checklist – 2 Social Interaction Deviance Composite, CCC-2 SIDC) were assessed. At T3, children completed the T2 measures and an additional test of pragmatic communication via narratives, the Expression, Reception and Recall of Narrative Instrument (ERRNI).
The ERRNI Initial Ideas score variable revealed a zero-inflated distribution, so zero-inflated negative binomial regression was implemented. In the present study, the assessment of narrative skills requires a level of language ability that some children with ASD will not acquire (resulting in scores of 0 on narrative). Dependent variables with distributions approximating normality (CCC-2 SIDC, PLS-4 Total Language) were analyzed using multiple regression. All analyses were adjusted to control for non-verbal intelligence quotient (NVIQ).
Results: Decreased imitation at T1 was associated with pragmatic skill deficits at T2 (p=0.008), independent of structural language. T1 RJA was specifically associated with pragmatic discourse skills at T3 (p=0.041). T1 imitation and RJA were not significantly predictive of T2 structural language after controlling for NVIQ.
Conclusions: Although these results are inconsistent with evidence that both elicited imitation and joint attention strongly predict structural language (e.g., Stone & Yoder, 2001), many previous studies examined briefer developmental periods and did not consistently control for nonverbal intelligence. In this study, preschoolers' imitation and RJA skills were associated with later development of distinct pragmatic skills. These results from a large, well characterized sample of children with ASD add to the literature on predictive roles of early social communicative behavior to later language and pragmatic communication. Additional clarification is needed of the mechanisms underlying the development of structural versus pragmatic language.

2:21 **150.004** Enhanced Perceptual Capacity in the Classroom: Harnessing Cognitive Strengths to Promote Learning

S. O'Brien[1]*, M. Hanley*[2]*, D. M. Riby*[2]*, J. Swettenham*[3] *and* ***A. Remington***[1]*, (1)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom, (2)Department of Psychology, Durham University, Durham, United Kingdom, (3)University College London, London, UNITED KINGDOM*

Background:
Research has demonstrated evidence for increased perceptual capacity in autism: autistic children and adults can process more information at any given time than neurotypical individuals. In tasks with high perceptual load (large amount of task-relevant information), this additional capacity is beneficial, leading to superior performance. When perceptual load is low, however, spare capacity processes task-irrelevant information, leading to increased distractibility. In this way, increased perceptual capacity can account for both superiorities and deficits seen in the condition. Reframing autistic attentional behaviour in terms of increased capacity rather than a filtering deficit has implications for autism interventions, yet these have not been investigated.
Objectives:
This study aimed to explore the implications of increased capacity in educational settings. Currently, classrooms for autistic children tend to have minimal stimuli on the walls and tasks are often simplified. Our somewhat counterintuitive prediction is that increasing the amount of relevant information in an educational task would *improve* learning outcomes: the extra perceptual capacity could be used by the child for task-relevant processing rather than irrelevant distractions. The proposed project aimed to test this, investigating whether the higher perceptual capacity of autistic children can be indeed be capitalised on to improve learning in the classroom.
Methods:
73 children (6-14 years, 23 autistic, 50 neurotypical, matched on age and non-verbal IQ) performed a 'real-world' attention task. Participants watched a five-minute video of a teacher talking about an Irish myth or legend and were asked to remember as much as they could. The background behind the teacher which was either a) blank b) filled with relevant pictures (related to story being told) or c) filled with irrelevant pictures (e.g. solar system poster, number charts). At the end of the video, children were asked questions about aspects of the story, but also – unexpectedly - about items in the background. Each child watched three videos: one from each condition.
Results:
For *both* groups, learning outcomes (e.g. amount recalled from verbal story) were better in the high load, task-relevant background condition than when there was no background information ($p < .001$). Like their typical peers, autistic children benefitted from the additional information; in this case, simplifying the task hindered learning rather than facilitated it.
In accordance with increased perceptual capacity, we also found that autistic children processed more irrelevant background information than neurotypical children: scoring significantly higher when asked about the background images ($p = .039$). Given that the level of story learning was equivalent between the two groups, we conclude that irrelevant background items were processed as well as central task items, not instead of them.
Conclusions:
Our findings suggest that, at least in some situations, increasing the amount of task-relevant information of an educational task improves learning outcomes for autistic children. We hope this is the starting point of a line of applied research based on the idea of increased perceptual capacity in autism, which may inform the creation of new learning interventions for children on the spectrum, and have a significant impact on their educational success.

The IBIS Network*[13], *(1)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Carrboro, NC, (2)Children's Hospital of Philadelphia, Philadelphia, PA, (3)Department of Psychiatry, Washington University School of Medicine, St. Louis, MO, (4)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)UNC Chapel Hill, Durham, NC, (6)University of Minnesota, Minneapolis, MN, (7)Washington University School of Medicine, St Louis, MO, (8)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (9)University of North Carolina at Chapel Hill, Chapel Hill, NC, (10)University of Alberta, Edmonton, AB, CANADA, (11)University of Washington Autism Center, Seattle, WA, (12)Carolina Institute for Developmental Disabilities, Carrboro, NC, (13)University of NC, Chapel Hill, NC*

Background: Infant-sibling studies have indicated that infants who develop ASD exhibit emerging delays in language skills around 12 months that become more pronounced by 24 months. Toddlers with ASD tend to show balanced receptive/expressive profiles, whereas typically developing toddlers show a receptive language advantage (i.e., higher receptive than expressive scores; Hudry et al, 2014). However, language outcomes for unaffected siblings have been inconsistent (Landa et al., 2006; Charman et al., 2016). It is not clear if unaffected siblings show language delay and a receptive language advantage.
Objectives: This study included two main objectives: (1) to compare the language development of two groups of high-risk infants, those who go on to have ASD and those without ASD who demonstrate language delay, and (2) to determine if infants with ASD or language delay display normative patterns of receptive advantage.
Methods: Infants at high and low familial risk for ASD were assessed longitudinally at ages 6, 12, and 24 months. Inclusion criteria included the completion of least two assessments and diagnostic outcome at 24-months (N=525).
At each visit, infants were assessed using the Mullen Scales of Early Learning (MSEL). Verbal developmental quotients (VDQ) were calculated from receptive and expressive subscales. Receptive advantage scores were generated by computing receptive-expressive difference scores (Hudry et al., 2014). Positive values indicate higher receptive than expressive language scores.
Eighty-six infants met clinical best-estimate criteria for ASD (HR-ASD, 77% male) at age 24 months. The remaining high-risk infants without ASD were then classified by language delay. Criteria for LD was a t-score <35 on either the MSEL receptive or expressive language subscale (>1.5 SD below population mean), in accordance with standard measures (Northrup & Iverson, 2015). Of these high-risk infants, 41 met criteria for language delay (HR-LD, 65% male) and 255 did not meet criteria for either ASD or LD (HR-neg, 54% male). An additional 143 low-risk control infants (LR-neg, 58% male) did not meet criteria for ASD or language delay. Dependent variables included VDQ, MSEL expressive and receptive t-scores, and receptive advantage score. All models included the effects of group, time, group*time, and were covaried for sex, NVDQ, and maternal education.
Results: Longitudinal mixed models indicated that trajectories of language development differed across groups for VDQ, t-scores, and receptive advantage ($p<.005$). Follow-up cross-sectional analyses indicated that groups did not differ in VDQ at 6-months, however at 12 and 24-months group differences were evident, with HR-ASD and HR-LD < HR-neg < LR-neg (Table 1). Receptive advantage scores did not differ by groups at 6- or 12-months; however, at 24-months the HR-ASD group displayed lower receptive advantage scores than all other groups.
Conclusions: Our results indicate that high-risk toddlers who have ASD and toddlers who display language delay both show lower language scores at 12-months when compared to peers. Interestingly, toddlers with language delay displayed the expected receptive advantage profile at 24-months, whereas toddlers with ASD displayed a more balanced profile. These receptive advantage results may reflect an aberrant process specific to ASD that becomes apparent in the second year of life.

2:52 **151.002** Minimally Verbal Two-Year-Olds with ASD Succeed in Using Linguistic Information to Generate Expectations about the Visual World

A. Fitch[1]*, A. Valadez*[1]*, P. A. Ganea*[2]*, A. S. Carter*[3] *and Z. Kaldy*[1]*, (1)Psychology, University of Massachusetts Boston, Boston, MA, (2)Applied Psychology & Human Development, University of Toronto, Toronto, ON, Canada, (3)University of Massachusetts Boston, Boston, MA*

Background: Much of what is learned about the world occurs outside of the visual field. A unique and important aspect of human cognition is the ability to gather knowledge through language. Previous work with typically-developing (TD) toddlers suggests that the ability to use verbal information to make and update expectations about the visual world emerges by 16 months (Ganea et al., 2016). It is unknown how the development of this skill might differ for very young children with autism spectrum disorder (ASD), who often display weak receptive & expressive communication skills.
Objectives: Â The goal of this study was to examine the abilities of toddlers with ASD to form expectations based on verbal versus visual information.
Methods: Â Participants were 19 toddlers with ASD (18-36 months, *M* = 28.2 months) and 26 TD toddlers (15-22 months, *M*= 18.6 months). ASD diagnoses were confirmed with the ADOS-2 and a licensed psychologist's clinical impression. Using an eyetracker, we presented toddlers with a scene of a cat and dog. The scene was then occluded, and one of the animals (e.g. the cat) changed location. Toddlers either saw the cat passing between occluded locations (visual condition), or heard a description of it (verbal condition). We next revealed either a congruent outcome (the cat in the new location), or an incongruent outcome (the dog instead). Toddlers participated in both visual and verbal conditions, as well as congruent and incongruent trials (order was counterbalanced for congruency and condition). Looking time and number of fixations to the outcome were compared across congruency, condition (visual vs. verbal), and diagnostic group. Toddlers were assessed on the Mullen Scales of Early Learning (MSEL); the groups were not significantly different on nonverbal scales (visual reception and fine motor).
Results: There was a main effect of congruency on looking time ($F(1, 43) = 4.25$, $p = .04$, $\eta_p^2 = .09$), and number of fixations ($F(1, 43) = 5.865$, $p = .02$, $\eta_p^2 = .12$). Both measures were significantly higher in the incongruent than the congruent outcome across both groups and conditions. There was no main effect of condition, and no interactions, suggesting no verbal deficit for the ASD group ($\eta_p^2 < .005$) There was a main effect of diagnosis on looking time ($F(1, 43) = 8.94$, $p < .001$, $\eta_p^2 = .17$); TD participants looked longer overall. This effect was not present in the fixation count analysis, that is, participants with ASD accomplished the same amount of scene exploration in less time. The success of toddlers with ASD in the verbal condition is even more impressive as they had significantly lower receptive language scores on the MSEL than TD controls, ($p<.001$).
Conclusions: Both groups of toddlers looked longer and performed more exploration of incongruent outcomes, suggesting that they could use both visual and verbal information gathered during occlusion to generate expectations about the outcome. In other words, despite their weaker receptive language skills, 2-year-old toddlers with ASD showed no impairments in forming expectations based on linguistic information in our paradigm.

3:04 **151.003** Weak Organization of Semantic Categories in Young Children with ASD

C. E. Venker[1]*, E. Premo*[2]*, T. Mahr*[1]*, J. Edwards*[3]*, J. R. Saffran*[4] *and S. Ellis-Weismer*[5]*, (1)Waisman Center, University of Wisconsin-Madison, Madison, WI, (2)University of Wisconsin - Madison, Madison, WI, (3)Hearing and Speech Sciences, University of Maryland, College Park, MD, (4)Psychology, University of Wisconsin-Madison, Madison, WI, (5)University of Wisconsin-Madison, Madison, WI*

Background:
Young children with ASD show striking delays in vocabulary development, but we are only beginning to understand why this is the case. One under-explored possibility is that these children have trouble organizing early-learned words into semantic categories (e.g., clothing items, food, animals). Failing to categorize words based on semantic similarities could disrupt lexical retrieval, thereby contributing to the language delays experienced by so many young children with ASD.
Objectives:
Our objective was to determine whether young children with ASD organize semantic categories differently than typically developing (TD) children. To accomplish this objective, we designed an eye-gaze task using the looking-while-listening paradigm to measure the extent to which children looked at objects that were semantically related to a spoken label, when the labeled object itself was not visible (i.e., whether children looked at a sock—instead of an apple—upon hearing, *Where's the hat?*). We predicted that children with ASD would look less at semantically-related objects than typically developing children, indicating weaker organization of semantic categories.
Methods:
Participants were 24 TD children and 25 children with ASD. All children in the ASD group received a DSM-5 diagnosis of ASD as part of the research visit, based on the ADI-R, ADOS-2, and expert clinical judgment. Groups were matched on Auditory Comprehension growth scale values from the Preschool Language Scale, 5th Edition (p = .13). On average, TD children were 20 months old (SD = 1) and children with ASD were 32 months old (SD = 3).
For the eye-gaze task, children sat on their parent's lap in front of a large television screen. In Target Present trials, children viewed two images (e.g., apple, hat) and heard one named (e.g., *Where's the hat?*). In Target Absent trials, children viewed two images (e.g., apple, sock) and heard a label that was semantically related to one image (e.g., *Where's the hat*?). Eye movements were coded offline.
Results:
Gaze from 300 to 1700 ms after noun onset was modeled using growth curve analysis. Time was the independent variable and log odds of looking to target was the dependent variable. The model of each group included linear, quadratic, and cubic orthogonal time terms and allowed for participant and participant x condition random effects.
Not surprisingly, children in both groups looked less at the 'target' (i.e., semantically-related object) in Target Absent trials (ps < .001). However, the discrepancy between the Target Present and Target Absent conditions was more pronounced in the ASD group than in the TD group (see Figure), as indicated by a shallower linear slope in the Target Absent conditionÂ the Target Present condition in the ASD group alone (p = .002).
Conclusions:
These findings suggest that children with ASD have weaker semantic organization for early-learned words than TD children, which could contribute to the difficulties they experience learning language. Importantly, this was the case even though children in both groups recognized the words when the objects were correctly labeled. Learning semantic categories may be an important intervention goal for young children with ASD.

3:16 **151.004** How Beginning to Speak Alters Early Parent-Child Interactions in Autism

L. B. Adamson[1]*, R. Bakeman*[1]*, K. Suma*[1] *and D. L. Robins*[2]*, (1)Georgia State University, Atlanta, GA, (2)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Â The language development of young children with autism spectrum disorder (ASD) is quite unpredictable. Although onset is almost always delayed, outcome is remarkably heterogeneous. This heterogeneity is likely rooted in infancy when ASD-related joint attention deficits affect the child's access to language during parent-child interactions. Studies indicate that early joint engagement predicts language outcome. However, the evidence base is still too narrow to document how joint attention deficits hamper word learning as well as how partners might compensate for a child's difficulties.
Objectives: Â Our aims were 1) to broaden the view of joint engagement during interactions to characterize the partner's supportive role and the overall dynamics of the dyadic exchange as well as the child's joint engagement, and 2) to discern if beginning to speak transforms interactions.
Methods: Â 144 toddlers participated: 58 with ASD, 46 with non-ASD developmental delay (DD), and 40 typically developing (TD). Two 30 min parent-child interactions were video recorded, first at an *initial visit* that occurred before diagnosis (mean age = 24.4 m) and, for 46 in the ASD and 32 in the DD groups, in a *follow-up visit* approximately a half-year later (M age = 31.6 m).Â Reliable ratings were made using the 8 items from the Joint Engagement Rating Inventory (JERI) for child's joint engagement, affective communication, parent's scaffolding and following in of child's interests, and the interaction's fluency and connectedness.Â Children were classified as not speaking or speaking during the interaction at each visit.
Results: Â During the *initial visit*, all rating-item means were significantly lower for the ASD than for the DD and TD groups and all diagnostic group effects were significant with a median effect size of .34 (range = .24–.42; see Table 1). Moreover, all rating-item means were significantly lower for the not-speaking than for the speaking group (median effect size =.26, range = .18–.57) across both the ASD and DD groups. To determine whether beginning to speak altered interactions, we categorized those children with ASD and DD who completed the *follow-up visit* as:Â (a) remained not speaking, (b) became speakers, and (c) remained speakers. Changes in the rating items from initial to follow-up visits were most marked for children who became speakers.Â Notably, compared to children who remained not speaking, significant changes occurred in parent's scaffolding and the interaction's fluency and connectedness as well as in child's joint engagement and affective communication (see Table 2).
Conclusions: Â Our findings indicate that early parent-child interactions are negatively impacted by ASD even before early diagnosis, especially when the child is not speaking. However, if the child begins to speak, several aspects of interactions change significantly. This finding complements the claim that joint attention plays a pivotal role in early word learning by demonstrating the impact of language use on parent-toddler interactions. This work highlights the importance of transactional processes between social interactions and language use both for theories of early developmental processes in ASD and for early interventions.

Oral Session - 9A

1:45 PM - 2:35 PM - Yerba Buena 9

Session Moderator: Lonnie Zwaigenbaum, *University of Alberta, Edmonton, AB, CANADA*

1:45 **152.001** Comparison of Social Motivation and Sticky Attention Models of Early Development in ASD

A. T. Meyer[1]*, L. G. Klinger*[2]*, L. Turner-Brown*[3]*, S. Nowell*[1]*, E. Crais*[4]*, G. T. Baranek*[4] *and L. R. Watson*[4]*, (1)University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)UNC TEACCH Autism Program, Chapel Hill, NC, (3)UNC TEACCH Autism Program, University of North Carolina at Chapel Hill, Carrboro, NC, (4)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: Two models propose alternative theories related to the early development of ASD. Social Motivation theory posits that infants later diagnosed with ASD are less motivated by social information which creates reduced opportunities for social learning (e.g., Chevallier et al., 2012). In contrast, Attention theory suggests that infants and children with ASD have an atypical development of attention (e.g., "sticky attention") that interferes with later social communication development (Landry & Bryson, 2004; Sacrey et al., 2014).
Objectives: This study compared these two developmental models, Social Motivation and Attention theories, in a community-based sample of infants who screened positive on an autism screening inventory and were followed into early childhood.
Methods: Participants included 43 children identified at high-risk for a later diagnosis of ASD based on the First Year Inventory (FYI) community screening at 12 months of age. Toddlers were evaluated at 13 (Time 1) and 22 months (Time 2). A third evaluation was conducted during early childhood (age 3-5 years) to determine diagnostic outcome using the Autism Diagnostic Observation Scale, parent interview, and clinical judgment. Thirteen children were diagnosed with ASD and 30 children did not meet criteria for ASD at Time 3.
Video coding for social motivation (looking at people) and "sticky" attention (shifting of attention and RRBs) was completed using the Communication and Symbolic Behavior Scales (CSBS) at 13 and 22 months. Social motivation was defined as the proportion of time the child spent clearly looking at a person. An attention shift was identified when children disengaged their attention from a stimulus, shifted their gaze, *and* immediately re-engaged their attention with another stimulus. RRBs were measured using the CSBS RSM scale (Wetherby & Morgan, 2007). Group means are displayed in Table 1.
Results: Path analyses were conducted to evaluate the direct and indirect effects of measures of looking at people, attention shifting, and RRBs at Time 1 and 2 on ASD symptom severity as measured by the ADOS-2 comparison score after controlling for cognitive abilities at Time 1. Direct effects are shown in Figure 1. Results indicated a significant indirect effect from decreased looking at people at Time 1 to decreased attention shifting at Time 2 to increased ASD symptom severity during early childhood (β=-.36, *p*=.02). Further analyses indicated that this indirect effect remained when only examining social-specific shifting (i.e., attention shifting including a person) but was not present when only including non-social shifting (i.e., shifting attention between objects).
Conclusions: Using this longitudinal sample provides an opportunity to disentangle the role of social motivation and attention shifting. Results from this study better support the Social Motivation theory of ASD. Looking at people at 13 months predicted ASD symptoms during early childhood as mediated by attention shifting at 22 months. While impairments in attention clearly play an integral role in later diagnosis of ASD, attention shifting that included social information appears to play a larger role than attention shifting to non-social information. Future studies can examine trajectories starting earlier in development to better evaluate the developmental processes in ASD.

1:57 **152.002** Early Developmental Trajectories of Social Contingency Predict Language Outcome in Toddlers with ASD

***R. M. Fleurissaint**, J. Bailey, S. Ghai and G. Ramsay, Marcus Autism Center, Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA*

Background: Although deficits in speech and language are no longer part of the definition of autism, most children with ASD are delayed in acquiring spoken language, and many of those children never learn to speak. A significant body of research has recently demonstrated the importance of contingent interaction between infant and caregiver in stimulating vocal development, and it is possible that early deficits in social interaction, which are a core feature of the syndrome, are responsible for later deficits in speech acquisition. If this is correct, early biomarkers quantifying the development and derailment of social engagement in infancy should be useful in predicting later language, and identifying developmental pathways that can be targeted by early intervention.
Objectives: The goal of this study was to test whether early developmental trajectories of social contingency between infant and caregiver over 0-24 months predict later language outcome at two years of age.
Methods: As part of an NIH Autism Center of Excellence, we tracked vocal development in 44 high-risk infant siblings and 30 low-risk controls. Using a recording device (LENA) worn by each child, we made audio recordings of each child's language environment at monthly intervals from 0-24 months. Using automatic speech recognition technology developed in our laboratory, we counted the number of vocalizations per hour for child and adult, as well as the rate of contingent interactions based on timing statistics. Using Functional Data Analysis, we calculated developmental trajectories for each child as well as mean trajectories for each group. We found significant differences in all three trajectories between risk groups, but these differences emerged at different time points. Starting at around 12 months, low-risk infants show a significant increase in the number of vocalizations they make, the number of times adults vocalize back to them, and the rate of conversational turns between adult and child. In contrast, high-risk infants show no increase in contingent interaction, which may be an early sign of autism. Three months later, adult vocalizations begin to decline. After a further three months, high-risk infants lag behind their low-risk peers. The disruption of the natural process of vocal interaction between infant and caregiver clearly demonstrates the developmental cascade of derailment that unfolds from early deficits in social engagement. To determine the impact of this process on later language outcome, we examined the correlation between receptive and expressive language scores from the Mullen Scales of Early Learning for children who completed clinical assessments at 24 months, and the slope and intercept of a two-parameter exponential growth curve fitted to every child's data.
Results: We found significant correlation (r=0.399, P<0.05) between the expressive language score and the slope of the trajectory for conversational turns; surprisingly, no other correlations were significant.
Conclusions: Infants at risk of ASD undergo a developmental cascade of derailments that begins with an early decline in contingent interaction that predicts lower expressive language, consistent with the hypothesis that core deficits in social engagement associated with ASD are responsible for comorbid deficits in spoken language.

2:09 **152.003** The Fluid Nature of the Very Early ASD Phenotype: Examination of Diagnostic Stability of ASD within a General Population Cohort

***K. Pierce**[1], E. C. Bacon[2], C. C. Barnes[3], D. Cha[4], L. Pence[5], B. Kellman[4] and E. Courchesne[3], (1)Neurosciences, University of California, San Diego, La Jolla, CA, (2)University of California San Diego, La Jolla, CA, (3)University of California, San Diego, San Diego, CA, (4)University of California, San Diego, La Jolla, CA, (5)University of Colorado, Boulder, CO*

Background:
Very early detection (between 12-24 months) and early treatment have been flagship goals of government regulatory bodies such as the IACC, parent, and advocacy groups alike. Determining how early autism can be accurately recognized, and the stability of ASD once it is suspected, is still unclear. Almost all that is known in this area comes from baby-sibling studies. One such study by Ozonoff and colleagues, noted strong diagnostic stability of toddlers identified as ASD at 18 months (92% stability), however approximately half of the children diagnosed with ASD at 3 years were not identified as ASD when previously tested at 18 or 24 months. The stability of diagnoses in such baby sibling studies are usually presented in dichotomous terms: ASD or Not ASD, making it challenging to understand how a toddler initially identified around 18 months as typical or with a non-ASD delay may end up with an ASD diagnosis at age 3 years or vice versa. Understanding not only the stability of ASD identification in toddlers, but how this designation may be blurred across diagnostic boundaries across the first 3 years of life in a general population cohort is essential.
Objectives:
(1) To examine diagnostic stability of ASD starting at 12 months in age in the general population. (2) To determine the proportion of changes across diagnostic boundaries.
Methods:
545 toddlers at-risk for ASD and other delays between 12-24 months identified in the general population using the 1-Year Well-Baby Check-Up Approach, which centered around using the CSBS IT Checklist at pediatric well-baby visits, participated (M= 15mo). Toddlers participated in a comprehensive developmental evaluation and were followed every 6-9 months until their 3rd birthday when a final diagnosis was given (M= 37 mo). Developmental evaluations at every age were conducted by Ph.D. level licensed psychologists and diagnostic judgments for a range of delays (ASD, ASD features, language delay, global developmental delay, motor delay, etc.) at each age were tracked.
Results:
Overall, diagnostic stability of ASD between 12-24 months (~80%) was lower in this general population cohort in comparison to reports from baby sibling studies that report levels as high as 92%. Eight percent of toddlers initially considered ASD at intake age were given a designation of ASD-features at final diagnosis age, 8% showed a non-ASD delay (e.g., language delay), and 4% were considered typical. Similar to baby sibling studies, a large percentage of cases were not designated as ASD initially. Common diagnostic transitions included language delay to ASD (16% of final ASD sample) and global developmental delay to ASD (30%).
Conclusions:
While diagnostic stability of ASD as identified in toddlers in the general population may not be as high as noted in baby sibling cohorts, all but 4% of cases retained some delay designation at final diagnostic age, suggesting that stability of having a delay in general is extremely high (>95%). The persistence of deficits in key skills such as language and social behavior of toddlers initially identified as ASD warrant early treatment regardless of final diagnostic designation.

2:21 **152.004** Developmental Profile of Low Risk Children with Autism Spectrum Disorder during the First Two Year of Life

M. Davidovitch[1,2]*, N. Stein*[3]*, G. Koren*[4,5] *and B. C. Friedman*[6]*, (1)Child Development, Maccabi Healthcare Services, Tel Aviv, Israel, (2)Faculty of Medicine in the Galilee, Bar-Ilan University, Safed, Israel, (3)Maccabi Heathcare Services, Tel Aviv, Israel, (4)Research, Maccabi Healthcare Services, Tel Aviv, Israel, (5)University of Toronto and University of Western Ontario, Toronto, Canada, (6)Child Development, Maccabi Heathcare Services, Haifa, Israel*

Background:
Early recognition of autism spectrum disorder (ASD) enables early interventions which had been shown to improve clinical outcome. Defining the patterns of developmental trajectory of children with ASD across different developmental domains can contribute to better understanding of the neurobiology of ASD and to improved screening tools and earlier referral for diagnosis. Data regarding the acquisition of developmental milestones in children with ASD is scares and mostly derived from retrospective recall of parents. In Israel a nationwide computerized well care baby system contains data on children's achievement of developmental milestones gathered prospectively by a trained nurse during routine checkups in the first years of life. This database enables a prospective outline of the developmental trajectory across several developmental domains using uniform scales in different population groups.
Objectives: To outline the acquisition of milestones in different developmental domains in low risk children later diagnosed with ASD compared to typically developing (TD) children and to identify early signs observed in routine well care baby checkups that could indicate referral for further evaluation.
Methods:
We compared early developmental data of 355 children with ASD to matched 416 typically developing children using the well care baby database. Data was prospectively collected at 6 weeks and 3, 6, 9, 12, 18 and 24 months during regular checkup visits. In each visit 5 to 6 items representing different developmental domains (gross motor, fine motor, social, receptive and expressive language) were evaluated and recorded. Children with major developmental disabilities (such as cerebral palsy, genetic syndromes) and risk factors (such as prematurity) were excluded.
Results: Difference in acquisition of milestones between ASD a TD groups emerged at 9 months. 31% of children in ASD group failed the receptive language item compared to 12% in the TD group (p=0.0001), 40% in ASD group failed the gross motor item compared to 22% in TD group (p=0.002), 19% of ASD group failed the fine motor item compared to 8% in TD group (p=0.003), 16% of ASD group failed the social item compared to 9% of TD group (p=0.05). Difference in the expressive pre-verbal item was non-significant. At 12, 18, 24 months, differences between groups were highly significant in all developmental domains.
Conclusions:
Deviation from typical developmental trajectory is observed early, at nine month of age, in low risk children later diagnosed with ASD. This difference is especially prominent in receptive language and gross motor domains. Children representing these developmental delays should be closely monitored for communication deficit, for early diagnosis and treatment.

Oral Session - 9B
153 - Behavior in High-risk Infants
2:40 PM - 3:30 PM - Yerba Buena 9

Session Moderator: Jessica Brian, *Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

2:40 **153.001** Neural Correlates of Early Language Processing in 9-Month-Old Infants at Risk for ASD

T. Tsang[1]*, J. Liu*[1]*, L. P. Jackson*[2]*, C. Ponting*[3]*, S. S. Jeste*[4]*, S. Y. Bookheimer*[1] *and M. Dapretto*[1]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)Semel Institute, UCLA, Los Angeles, CA, (3)Clinical Psychology, UCLA, Los Angeles, CA, (4)UCLA, Los Angeles, CA*

Background: Language delays are one of the earliest autism-related concerns that parents report. Infants who develop autism spectrum disorders (ASD) often exhibit atypicalities in their early language profiles (e.g., Hudry et al., 2014). Moreover, toddlers with ASD and significant verbal delays show hypoactivity in canonical temporal language-processing regions during speech processing (e.g., Lombardo et al., 2015). Since language learning appears to be gated by the social brain (Kuhl, 2007), early deviations in language processing may index altered social development prior to overt deficits in social or verbal skills. Examining language processing during foundational stages of language acquisition may thus inform risk for ASD and later language difficulties.
Objectives: We examined the neural circuitry subserving language processing in 9-month-old infants at high (HR) and low risk (LR) for ASD to identify patterns of brain activity that may predict altered trajectories in language development and ASD risk. This will further substantiate the role of language in the early manifestation of ASD.
Methods: 19 HR and 13 LR infants underwent fMRI during natural sleep and were presented with speech samples produced by different female native speakers of English and Japanese. Both English and Japanese stimuli were matched for duration, intensity, peak amplitude, pitch, and pitch range. English and Japanese speech segments (8 segments per language, each lasting18s) alternated between periods of silence (12s each) in a traditional fMRI block-design. Individual data were registered to an infant atlas; preprocessing (including motion censoring) and statistical analyses were conducted in FSL. Behavioral measures of language, cognitive, and social functioning were assessed at 12 months [i.e., Mullen Scales of Early Learning (MSEL), Vineland Adaptive Behavior Scale (VABS), and Autism Observation Scale for Infants (AOSI)].
Results: Relative to LR infants, HR infants showed hypoactivity for both English and Japanese in temporal and frontal language regions, the cerebellum, and regions associated with attention (precuneus) and reward (amygdala, and caudate nucleus). In particular, LR infants showed greater activity in left temporal pole and caudate nucleus than HR infants for English, the infants' native language. The relation between neural activity for English and 12-month Verbal T Scores from the MSEL were also examined. For LR infants, greater activity in temporal language areas at 9 months predicted better verbal scores at 12 months. In contrast, for HR infants, better verbal scores were inversely related to activity in the precuneus and medial prefrontal cortex, the hubs of the default mode network (DMN), a resting-state network that is most active during passive rest and deactivated during information processing. Mean activation in these DMN hubs during language exposure was negatively correlated with 12-monthVineland Socialization Scores (r =-0.61, p= 0.01).
Conclusions: HR infants already show attenuated neural responses to language at 9 months, prior to overt signs of atypical development. The distinct patterns of brain activity during native language processing and its association with later verbal skills suggest that HR infants may be less attuned to the language inputs of their immediate environments, with negative downstream effects for language and social development.

2:52 **153.002** Parent and Clinician Agreement in Early Behavioural Signs in 12-Month-Old Infants at-Risk of Autism Spectrum Disorder: A High-Risk Sibling Cohort

L. A. Sacrey[1], *L. Zwaigenbaum*[2], *S. E. Bryson*[3], *J. A. Brian*[4], *I. M. Smith*[5], *W. Roberts*[6], *P. Szatmari*[7], *T. Vaillancourt*[8], *C. Roncadin*[9] *and N. Garon*[10], *(1)Autism Research Centre, Edmonton, AB, CANADA, (2)University of Alberta, Edmonton, AB, CANADA, (3)Dalhousie University, Halifax, NS, CANADA, (4)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (6)University of Toronto, Toronto, ON, CANADA, (7)Centre for Addiction and Mental Health, Toronto, ON, CANADA, (8)University of Ottawa, Ottawa, ON, CANADA, (9)Autism Spectrum Disorder Service, McMaster Children's Hospital - Hamilton Health Sciences, Hamilton, ON, CANADA, (10)Mount Allison University, Sackville, NB, CANADA*

Background: Identifying early impairments in children who will subsequently be diagnosed with Autism Spectrum Disorder (ASD) is crucial to ensure that they gain timely access to interventions that will improve functional outcomes. Although prospective studies of high-risk infants have increasingly focused on direct observation of infants' behaviour during interactive assessments, prospective parent reports may provide valuable and complementary information.
Objectives: The purpose of this study was to examine parent and clinician agreement at 12 months of age for the clinician observational assessment, the Autism Observation Scale for Infants (AOSI; Bryson et al., 2008), and the parent-report questionnaire, the Autism Parent Screen for Infants (APSI; Sacrey et al., 2016), which was modeled in content from the AOSI.
Methods:
Participants: High-risk infants (HR; have an older sibling diagnosed with ASD) were divided into two groups based on an independent expert clinical assessment using the ADOS and ADI-R at 36 months of age: HR siblings who *did not* receive an ASD diagnosis (HR-N; n = 155) and HR siblings who *did*receive a diagnosis of ASD (HR-ASD; n = 68).
Assessments: The APSI (Sacrey et al., 2016) is a 26-item parent-report questionnaire that complements the AOSI observational assessment (Bryson et al., 2008). These assessment tools share 19 items that cover early symptomatology of ASD. Parents completed the APSI and clinicians completed the AOSI at 12 months of age.
Statistical Analyses: Performance on the APSI and AOSI was compared between the two HR groups using independent t-test analyses. Agreement between parents and clinicians for the shared 19 items was analyzed using intraclass correlations.
Results: Intraclass correlations of AOSI and APSI items indicated poor agreement between parents and clinicians, ranging from -.06 to .23 for the combined group, -.06 to .30 for the HR-ASD group, and -.05 to 19 for the HR-N group. Item-level comparisons using independent t-tests indicated: (1) six items were informative in predicting diagnostic outcomes on both the AOSI and APSI, including responding to name, eye contact, hand-eye coordination, unusual sensory behaviours, engagement of attention, and shared interest (ps< .05), (2) six items were informative on the APSI only, including visual fixation, anticipating a social interaction, back-and-forth vocalizations, social smiling, reactivity, and repetitive motor behaviour (ps< .05), and (3) seven of the items were not informative on either assessment, including visual tracking, reacting to change in facial expression, imitation, showing interest and pleasure, transitions, difficulty using hands, and insistence on same object.
Conclusions: Prospective parent report is informative for early signs of ASD by 12 months and complements what may be elicited / observed during an interactive assessment. Some clinically informative behaviour may be more likely detected by parents based on their day-to-day observations than during a brief clinical visit.

3:04 **153.003** Patterns of Face Gaze Among Infants at Risk for ASD

A. Milgramm[1], *S. Macari*[1], *F. E. Kane-Grade*[2], *P. Heymann*[1], *E. Hilton*[1] *and K. Chawarska*[1], *(1)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale child Study Center, New Haven, CT*

Background: The core deficits of Autism Spectrum Disorder (ASD) can reliably be observed and classified by two years (Lord et al., 2006; Chawarska et al., 2009). Recent research has aimed to understand whether atypical behaviors that characterize ASD in toddlerhood (e.g., limited eye contact, decreased interest in faces) emerge in the first year of life. Behavioral observations of high-risk (HR) siblings later diagnosed with ASD suggest that face gaze may be preserved early in infancy, at 6 months of age, but declines significantly by 12 months (as reviewed in Jones et al., 2014). However, as previous studies have either exclusively evaluated mother-infant interactions or have examined face gaze during a general evaluation (e.g., Mullen), this is the first study to evaluate gaze patterns in HR-infants using a standardized social interaction procedure between an examiner and infant.
Objectives: To investigate patterns of face gaze directed at an experimenter using a novel interactive procedure at 6, 9, and 12 months among HR siblings who later develop ASD (HR-ASD), HR siblings who do not receive an ASD diagnosis (HR-nASD), and typically developing low-risk children (LR-TD).
Methods: Participants included 184 infants (HR-ASD, *n*=21; HR-nASD, *n*=104; LR-TD, *n*=59) who completed Social Orienting Probes at 6, 9, and 12 months and were evaluated for ASD at 24 and 36 months. Trained examiners administered a series of 1-minute probes designed to elicit attention through several means: a) motherese, b) song, and c) peek-a-boo. Videotaped sessions were coded offline by blinded coders for the duration of time, in seconds, that the infant looked at the examiner's face. Face gaze was calculated as the proportion of time spent looking at the examiner's face during each probe (%Face). Generalized linear mixed model analyses were used to examine the fixed effects of diagnostic group, probe, infant age, and their interactions on %Face, followed by planned contrasts using the sequential Bonferroni correction.
Results: Analyses of %Face revealed a main effect of diagnosis ($F(2, 1395)=4.4$, $p<.05$; HR-ASD<HR-nASD=LR-TD), a main effect of probe ($F(2, 1395)=245.3$, $p<.01$; peek-a-boo>song>motherese), no main effect of infant age ($p=.58$), a significant group x age interaction ($F(4, 1395)=2.7$, $p<.05$), and no three-way interaction ($p=.11$). Planned comparisons indicated that groups differed significantly only at 6 months across all probes, such that HR-ASD<HR-nASD=LR-TD ($p=.001$; see Figure 1).
Conclusions: Results of these analyses diverge from previous literature by revealing differences in infants' face gaze at 6 months, but not at 9 or 12, between HR-infants who are later diagnosed with ASD, unaffected HR-siblings, and LR-TD children during a standardized behavioral paradigm. The finding that ASD infants spend less time orienting to the face of an interactive partner contributes to evidence from neuroimaging (Wolff et. al., 2012), neurobehavioral (Chawarska et al., 2013; Shic et al., 2014), and neurophysiological (Elsabbagh et al., 2012) data that subtle abnormalities related to later emerging ASD can be detected as early as 6 months. This suggests a potential sensitive period early in infancy for the development of social cognition that may be highly influenced by social orienting and attention.

3:16 **153.004** Now You See It, Now You Don't: Context-Dependent Dyadic Vulnerabilities in Infants with ASD in the First Year of Life.

***S. Macari**, A. Milgramm, P. Heymann, F. E. Kane-Grade, E. Hilton and K. Chawarska, Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background:
The majority of studies of high-risk (HR) infant siblings with ASD have found little evidence of social abnormalities at six months of age, including social smiling, response to name, and gaze to a social partner (Bryson et al, 2006; Landa et al., 2007; Ozonoff et al., 2010; Nadig et al., 2007; Rozga et al., 2011; Young et al., 2009). Context may be key to revealing vulnerabilities, however. For example, video segments in which a person addressed the viewer using child-directed speech elicited longer looks away from the screen by toddlers with ASD, while segments containing the person engaging in other activities attracted their attention comparable to controls (Chawarska et al., 2012). Little is known about the effects of context within live interactions on social behavior of infants at risk for ASD.
Objectives:
To examine differences between 6-12-month-old infants later diagnosed with ASD and controls in social attention and directed affect during a variety of dyadic interactions with an examiner.
Methods:
184 infants at HR and low risk (LR) for ASD participated in a standardized social interaction with an examiner at 6, 9, and 12 months of age, and were evaluated for ASD by blinded psychologists at 24/36 months: HR-ASD; *n*=21, HR without ASD (HR-nASD; *n*=104) or LR typically-developing (LR-TD, *n*=59).Â Examiners administered a series of one-minute probes: speaking in motherese, singing, playing peek-a-boo, engaging in a tickle game, and demonstrating a toy. Sessions were videotaped and coded offline by blinded coders for infants' visual attention (looking at examiner's face) and affect (directed positive/negative affect), standardized over the length of each probe (%Face and %DirAffect). Hypotheses were evaluated using linear mixed models followed by planned contrasts.
Results:
Anaylsis of %Face revealed main effects of group ($F(2,2360)=8.78$, $p=.001$; HR-ASD<HR-nASD=LR-TD) and probe ($F(4,2360=15025.02$, $p<.001$; toy<tickle=motherese<song<peek-a-boo), a significant probe by group interaction ($F(8,2360)=2.67$, $p=<01$), and a significant age bygroup interaction ($F(3,2360)=3.59$, $p<.01$). Planned contrasts indicated that the HR-ASD group looked less at the examiner than both the HR-nonASD and LR-TD groups during motherese and tickle (ps<.05) but at rates similar to controls during peeka-a-boo, song, and toy probes. All three groups differed from each other at 6 months but not at other ages (*p*s<.05). Analysis of %DirAffect revealed main effects of group ($F(2,2394)=7.12$, $p=.001$; HR-ASD<HR-nASD<LR-TD), probe ($F(4,2394)=154.26$, $p<.001$; toy<song=motherese<tickle<peek-a-boo), and age ($F(2,2394)=5.21$, $p<.01$; 6mo<12mo), and a significant probe by group interaction ($F(8,2394)=1.94$, $p=.05$). Planned contrasts indicated that the HR-ASD group directed less affect to the examiner than the LR-TD group during peek-a-boo and tickle (*p*s<.05) but at rates similar to controls during the motherese, song, and toy probe.
Conclusions:
Infants age 6-12 months later diagnosed with ASD expressed vulnerabilities in social attention and shared affect during certain interactions but not others. The tickle and motherese episodes elicited less modulated social attention, while the tickle and peek-a-boo episodes exposed diminished sharing of affect compared to controls. As in eye-tracking studies presenting complex social content, varied in-vivo context can elicit vulnerabilities or be an equalizer for infants in the first year who later develop ASD.

Oral Session - 10A
154 - International and Cultural Perspectives on Family Wellbeing
1:45 PM - 2:35 PM - Yerba Buena 10-14

Session Moderator: Mayada Elsabbagh, *McGill University, Montreal, CANADA*

1:45 **154.001** Profile and Impact of Participating in a Parent Support Group in Latin America

J. P. Berman[1,2], *S. H. Cukier*[2], *R. A. Garcia*[3], *G. Garrido*[4], *C. Montiel-Nava*[5], *C. S. Paula*[6], *A. Rattazzi*[2], *A. Rosoli*[7] *and D. Valdez*[8], *(1)The Fulbright Program, Buenos Aires, Argentina, (2)PANAACEA, Programa Argentino para Niños, Adolescentes y Adultos con Condiciones del Espectro Autista, Buenos Aires, Argentina, (3)Universidad de Chile, Santiago, CHILE, (4)Universidad de la República, Montevideo, URUGUAY, (5)La Universidad del Zulia, Gainesville, GA, (6)Developmental Disorder Program, Mackenzie Presbyterian Univesrsity, Sao Paulo, BRAZIL, (7)OEI, Santo Domingo, Dominican Republic, (8)FLACSO, Buenos Aires, Argentina*

Background: Parent support groups (PSGs) have been shown to be an effective coping mechanism for parents of children with disabilities, reducing stress and improving quality of life. PSGs related to ASD in Latin-America have been instrumental in the development of research, resources, and advocacy, playing major roles in policy and awareness campaigns. Only a few studies have investigated the profile and impact of participating in ASD-specific PSGs, and mostly in North America.
Objectives: The objective of this study is to describe the profile of Latin-American families affected by ASD participating in PSGs compared to those not in PSGs, and to analyze the possible impact of being in a PSG in the Latin-American region on quality of life, access to services and attitudes towards stigma.
Methods: A needs survey for caregivers of people with ASD was performed in the Latin-American Region between 2015-2016 by the Red Espectro Autista Latinoamerica (REAL). 2965 families were surveyed in six Latin-American countries using the Autism Speaks Caregiver Needs Survey. The profile and impact of participating in a parent/family association was analyzed in this sample, considering: demographic characteristics, subjective quality of life, access to resources, satisfaction with services, and perception of stigma.
Results: Twenty-seven percent of survey respondents across countries reported having a family member who currently participates in a PSG. Participating in a PSG showed a very significant association with having more access to services; 29% of people not in PSGs reported receiving no services or treatment for the person with autism, while only 14% of the PSG group reported the same. Meanwhile, more than half of the PSG group reported receiving 3 or more types of services or treatment (compared to only 37% in the non-PSG group).
PSG involvement was also associated with fewer feelings of impotence and less perception of stigma; however, caregivers in the PSG group reported more financial impact of having a child with autism.
More people participating in PSGs had children in the 6-11 age range, and with lower level of functioning. No significant differences were found in sex, language level, cognitive level, problem behaviors or educational level of caregivers.
Conclusions: PSG participation showed a strongly significant association with access to services. Other factors that could be affecting access to services, like educational level of caregivers or distance from site of diagnosis, did not show significant differences between groups. Participation in PSGs might increase awareness of community prejudices and the existence and efficacy of treatments.
People in PSGs report fewer feelings of impotence and less concern about people knowing about their child's diagnosis, but are more conscious of the possibility of discrimination. Participating in a PSG might be a way of actively coping with having a family member with ASD.
PSGs have an important role for families in Latin-America, shown not only by the amount of families reporting participation, but also by the concrete benefits regarding access to services, feelings of empowerment, and more optimistic perceptions towards having a child with ASD.

1:57 **154.002** Stress, Coping, Stigma and Acculturation in Arab American Caregivers of Children with Autism Spectrum Disorder

S. I. Habayeb[1], *B. Rich*[1], *S. Dababnah*[2] *and A. John*[3], *(1)Catholic University of America, Washington, DC, (2)University of Maryland, Baltimore, Baltimore, MD, (3)Texas Christian University, Fort Worth, TX*

Background: Few studies have examined stress and coping in caregivers from minority ethnic or cultural groups raising children with an Autism Spectrum Disorder (ASD), such as caregivers in the Arab American community. The Arab American community is one of the fastest growing, yet least studied ethnic communities in the U.S. (Al Khateeb, Al Hadidi, & Al Khatib, 2014). An estimated 23,000 Arab American children in the U.S. live with a disability, however no research has focused specifically on ASD in this population.
Objectives: The current study aims to examine acculturation, stigma, stress and coping among Arab American caregivers caring for a child with ASD.
Methods: Arab American caregivers of children with ASD participated in this study. Participants completed a set of online questionnaires about their experience caring for their child with ASD, including: Family Stress and Coping Interview (Nachshen, Woodford, & Minnes, 2003), Brief COPE (Carver, 1997), Sources of Social Support Scale (Carver, 2006), The Support Questionnaire (Tehee, Honan, & Hevey, 2009), Adapted Perceived Stigma Scale (Mickelson, Wroble, & Helgeson, 1999; Rosenblum-Fishman, 2013), and The Male Arab American Acculturation Scale (Barry, 2005). Some participants participated in a follow-up phone interview to elaborate upon the stressors and support systems that they indicated on their survey responses.
Results: Data collection is currently underway, and by May 2017, we expect to have approximately 30 participants. Preliminary descriptive data is presented based on the eight participants who have completed the study to date. All respondents were mothers and seven were first generation immigrants (years in home country *M*=17.14, *SD*=9.18). Six children were male, and their mean age was 8.25 years (*SD*=4.08). Autism Society/Disability Organizations were the highest rated formal support systems. Caregivers reported a moderate level of support from their spouses (*M*=32.67, *SD*=12.13, Range = 10-50) and moderate to low levels of perceived stigma (*M*=21.88, *SD* =2.64, Range = 8-40). In regard to acculturation, caregivers endorsed greater levels of Assimilation over Separation (*M*=12.38, *SD*=3.93, Range = 7-28) and greater levels of Integration over Marginalization (*M*=21.88, *SD*=5.22, Range = 7-28). With the complete dataset, correlation analyses will be utilized to examine the relationships among perceived stigma, support, stress and coping variables in the sample. We expect to find a negative relationship between stress and positive coping, between perceived stigma and positive coping, and between acculturation and perceived stigma, along with a positive relationship between perceived stigma and stress. Qualitative data from the interviews will be analyzed using a grounded theory approach (Strauss & Corbin, 2008). General themes emerging from the qualitative interviews, to date, are insurance related obstacles and issues navigating school-based services.
Conclusions: Â Findings from this study will be discussed in the context of their implications for practice and future research. As such, results of this study have the potential to increase clinicians' awareness and cultural responsiveness in order to support Arab American families of children with ASD. Furthermore, results from this study will contribute to the development of culturally-sensitive interventions and advocacy programs designed to directly target the specific needs of this community.

2:09 **154.003** Bcri: A Family-Based Early Behavioral Intervention Program for Children with Autism Spectrum Disorders in Chinese Population

B. Chen[1], *F. Wang*[2] *and X. Zou*[3], *(1)Children Developmental & Behavioral Center, SUN YET-SEN UNIVERSITY, Guangzhou, Guangdong, China, (2)Child Developmental & Behavioral Center, Third Affiliated Hospital of SUN YAT-SEN University, GUANGZHOU, CHINA, (3)The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China*

Background: Autism Spectrum Disorder (ASD) is considered to be an early onset neurodevelopmental disorders characterized by qualitative social interaction impairments and repetitive stereotyped behaviors/restricted interests. However, strong evidence shows that promoting a structural early-intervention model may positively influence outcomes of ASD as well as reduce the burdens of lifetime care demands for society.
Objectives: BCRI intervention program aims to empower the parents to master appropriated approaches and strategies of BCRI early behavioral intervention, and provide positive affects to the clinical outcome for children with ASD.
Methods: 130 children diagnosed with ASD between the ages of 18 and 30 months were randomly assigned to the early BCRI group and CI group (community intervention). Both BCRI group and CI group participate in a two-day ASD seminar to receive basic knowledge about behavioral intervention in Phase-one. In Phase-two, BCRI group participate in a 24-halfday workshop to gain hands-on experience and one-on-one training from master trainers, then these family take another 11 months to implement BCRI intervention to their children in home settings, and CI group receives community service. Psycho-educational Profile-3rd Edition (PEP-3) assessment indexes were collected, and single and multiple Wilcoxon signed rank test were performed for statistical analysis.
Results: 85 participants (53 in BCRI group, 32 in CI group) completed primary endpoint at one year after enrollment. Statistically significant post-intervention improvements were found in BCRI group, which included Cognitive Verbal/Proverbial (CVP), Expressive Language (EL), and Receptive Language (RL) subsets in the Communication domain ($p<0.05$). By Comparison of pre- and post-intervention between BCRI and CI group, significant improvements were reported in combined score of Communication domain (CVP, EL, RL) plus Fine motor (FM) subset ($p<0.05$), and in combined score of Visual Motor Imitation (VMI) subset and FM subset ($p<0.05$).
Conclusions: It's the initial large sample randomized controlled study for family-based early behavioral intervention for ASD. We suggest that BCRI Intervention model have positive effects for children with ASD, to develop early communication skills as well as visual motor Imitation and fine motor skills. BCRI model emphasize the initial appliance of behavior management and problem solving strategies, which following by structural teaching infrastructure with appropriate level of education. BCRI also emphasize to emerge 'relationship elements' as part of social interaction intervention throughout every step of BCRI model, to Improve social skills of children with ASD. The study indicated that BCRI model is an effective early behavioral intervention method for child with ASD, and the feasibility to implement in middle-income countries.

2:21 **154.004** Mediators Between Receiving Early Interventions and Unmet Services Needs in Children: Findings from a Canadian National Survey

J. Lai[1] *and J. A. Weiss*[2]*, (1)Psychology, York University, Montreal, QC, CANADA, (2)York University, Toronto, ON, CANADA*

Background: Navigating the service sectors for children with ASD is a challenge for many caregivers, leading to a high level of burden and distress. Having an ID changes the dynamics of how service access. The early developmental period is a sensitive window for clinical outcomes; however, it is not known how access to early intervention relates to outcomes such as receiving other services. Articulating the relationship between having accessed early intervention services and unmet service need through mediating factors will provide a better understanding of how families navigate services and ways to support them better.
Objectives: The objective of this study was to identify the relationship between receiving early interventions and unmet service needs, and the demographic and clinical correlates for children with ASD across Canada, with and without ID.
Methods: An online survey was administered across Canada through the Canadian Autism Spectrum Disorders Alliance, completed by 3251 caregivers reporting on 3317 family members with ASD. Analysis was done on reports of 1704 children up to the age of 12 years. Participants indicated if they had ever received early intervention services, our independent variable. An unmet need score, our dependent variable, was created by summing the number of services they never received but would have liked to receive. Demographic, clinical and systemic factors were collected. Two mediator analyses, one for those with ASD and ID, and one for those with ASD alone, examined the factors that explained the relationship between getting early intervention services and unmet need.
Results: Overall, the mean age of receiving an ASD diagnosis was 3.89 (SD=1.9) years, and 86% of the sample had received early intervention services. The number of unmet needs was 3.78 (SD=2.6). Between the ASD alone (n=705) and ASD+ID (n=999) groups, those with ASD alone were diagnosed later ($p<.001$), had less caregiver services ($p<.001$), endorsed less systemic barriers to accessing services ($p<.05$), had less service receipt ($p<.01$), less concerning behaviours ($p<.001$), and lower health function score ($p<.001$) as defined by body function categories in the International Classification of Functioning, Disability and Health framework. They were also less likely to be in financial trouble ($p<.05$). After controlling for age, ethnicity and number of years in Canada, for children with ASD+ID, accessing early intervention did not relate to the level of unmet need ($p=.10$). However, for those with ASD alone, accessing early intervention was related to lower unmet need ($t=4.87$, $p<.001$). Mediators of this relationship were having caregiver-directed services, less mental health concerns, less behavioural concerns, and a younger age of diagnosis.
Conclusions: These results indicate that ID status plays a large role in how services are accessed. For individuals with ASD and no ID, access to early interventions led to less unmet need receipts, as a result of greater access to caregiver services and lower clinical need. In children with both ASD+ID, this relationship was not present. Discussion of the implications of these findings will follow.

Oral Session - 10B
155 - International and Cross-cultural Perspectives on Early Identification
2:40 PM - 3:30 PM - Yerba Buena 10-14

Session Moderator: Mayada Elsabbagh*, McGill University, Montreal, CANADA*

2:40 **155.001** Change over Time in the Age and Number of Children Accessing Autism Specific Funding in Australia

C. A. Bent[1]*, J. Barbaro*[1] *and C. Dissanayake*[2]*, (1)Olga Tennison Autism Research Centre, School of Psychology & Public Health, La Trobe University, Melbourne, Australia, (2)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia*

Background: The early identification and diagnosis of individuals with Autism Spectrum Disorder (ASD) is a critical step in the pathway through to early intervention and support services. Access to autism specific intervention and funding services is largely dependent on a diagnosis of ASD. Factors found to influence the age that a child is first diagnosed include child and family characteristics (such as cultural background and the severity of symptoms) as well as characteristics specific to the health system and services. Examining trends over time allows us to investigate the influence of changes within the service environment, such as the introduction of the revised diagnostic criteria (DSM-5) in 2013.
Objectives: The aim of the current study was to examine change over time in the age and number of children diagnosed with ASD and accessing autism specific funding, both prior to and following the introduction of the DSM-5.
Methods: This study utilised a large administrative data set regarding 32,199 children aged under 7 years who had received a diagnosis of ASD in the community (confirmed by a Pediatrician or multidisciplinary team assessment) and registered to receive autism specific funding through the Helping Children with Autism Package (HCWA) in Australia from January 2010 to June 2015.
Results: The average age and number of children diagnosed with ASD and registered to receive autism specific funding were both observed to increase over time; with increases in the frequency of diagnoses generally corresponding with a parallel increase in the average age of diagnoses (see Figure 1). The estimated annual incidence of children diagnosed with ASD and registered with HCWA increased from 20 per 10,000 in 2010 to 34.2 per 10,000 in 2013. Following the introduction of the DSM-5 in 2013, the estimated annual incidence of ASD plateaued, with no further significant increase in incidence evident from 2013 to 2015.
Conclusions: Characteristics of the service environment influence the average age and number of children diagnosed with ASD in a community. The parallel trends of increasing age and frequency of diagnoses observed in this study suggest that an increase in the number of children diagnosed with ASD in Australia has contributed to an increase in demand for diagnostic services, and slightly longer waiting lists. These findings also suggest that the introduction of the comparatively more stringent diagnostic criteria (DSM-5) may have contributed to an attenuation of the trend of increasing diagnoses over time; whereby relatively fewer children have received a diagnosis of ASD and registered to receive autism-specific funding since its introduction.

2:52 **155.002** Where Are All the Children with Autism Spectrum Disorder (ASD) in South Africa? a Comprehensive Database Search for All School-Aged Children with ASD in the Western Cape Province

S. Pillay[1], *M. E. Duncan*[2] *and P. J. de Vries*[3], *(1)Health Sciences, University of Cape Town, Cape Town, South Africa, (2)University of Cape Town, Cape Town, South Africa, (3)University of Cape Town, Cape Town, SOUTH AFRICA*

Background:
Little is known about Autism Spectrum Disorder (ASD) in Africa where the prevalence remains unknown. However, even in Africa the increase in ASD combined with better awareness and knowledge has resulted in more children being diagnosed and referred to educational services.
South Africa is considered one of the best resourced African countries in terms of ASD services. However, no study to date has sought to identify children with ASD in a specific education system in order to evaluate needs, determine capacity, and generate comprehensive, evidence-based, sustainable and scaleable solutions to the increasing demand for appropriate education for children with ASD.
Objectives:
The study objective was to perform a comprehensive database search of all children with ASD in the formal education system in the Western Cape Province of South Africa. An understanding of the number, ages, gender, geographical distribution and other socio-economic and cultural variables would contribute to a larger-scale situational analysis of services and service needs for school-aged children with ASD.
Methods:
A quantitative non-experimental descriptive design was used to provide numeric descriptions of the population of children with ASD on the Western Cape Education Departments (WCED) database. The Centralised Education Management Information System (CEMIS) is a web-enabled information management system used for registration and tracking of all children in the WCED. All data relating to children with ASD were extracted on 27 June 2016 from the existing dataset. The main variables of interest included disability information, demographic information and educational information.
Results:
A total of 940 children with a primary or secondary diagnosis of ASD were reported from a population of 1 063 349 school-going children in the province. This accounts for 0.0884% of the school-aged population. The overall male: female ratio was 5.48:1. Self-reported race and language patterns show that the majority of children with ASD in the province were Coloured (42%) and English speaking (61%). 90% of children with ASD were in schools for children with Special Educational Needs and only 10% were in Ordinary/Mainstream schools. 83% of the ASD school-going population were in urban areas and 17% attend schools in rural areas. Intellectual disability was reported in only 19% of the population. Low rates of co-morbid mental health disorders such as attention deficit disorder (2%) and epilepsy (1%) were reported. Interestingly data shows a 76.03% increase in ASD in schools from 2012 to 2016, with an average increase of 15.18% per annum.
Conclusions:
The comprehensive database search in the Western Cape Province of South Africa, showed a concerningly low rate of children identified with ASD. Most of those were in special educational settings, with very low identification of comorbid neurodevelopmental and mental health diagnoses. Results suggests that, even in one of the best resourced provinces of South Africa, there is likely to be a very significant under-identification of ASD in school settings. We propose that large-scale and systematic evaluation of educational systems for children with ASD in the Province and in South Africa should be performed.

3:04 **155.003** Disparities in the Diagnosis of Autism Spectrum Disorder According to Aboriginality and Remoteness

J. Fairthorne[1,2], *H. Leonard*[3], *J. Bourke*[4], *A. J. Whitehouse*[5], *N. de Klerk*[6] *and C. Shepherd*[7], *(1)Disability, Telethon Kids Institute, Subiaco, Perth, AUSTRALIA, (2)British Columbia Children's Hospital Research Institute, Vancouver, Canada, (3)Disability, Telethon Kids Institute, West Perth, AUSTRALIA, (4)Disability, Telethon Kids Institute, Perth, Australia, (5)Telethon Kids Institute, University of Western Australia, Perth, Australia, (6)Biostatistics, Telethon kids Institute, Perth, Australia, (7)Aboriginal Health, Telethon Kids Institute, University of Western Australia, Perth, Australia*

Background:
While Aboriginal children suffer persistent disadvantages across most measurable aspects of health and wellbeing, research indicates that they have an 80% lower prevalence of autism spectrum disorder (ASD) with comorbid intellectual disability (ID).
Objectives:
We estimated the prevalence of ASD with ID in children born from 1983-2005 in Western Australia according to Aboriginality, geographic remoteness and over time. In this way, we aimed to clarify whether the lower rate amongst Aboriginal children is a function of access to diagnostic services and whether access is improving over time.
Methods:
We linked registry data to access information on Aboriginality, remoteness, birth year and the diagnosis of ASD with ID in all children born from 1983-2005 in Western Australia. Non-parametric trend tests were used to assess trends over time.
Results:
In Aboriginal children, the prevalence of ASD with ID (23.3/10,000) was about half that of non- Aboriginal children (45.8/10,000) The prevalence of ASD with ID decreased with increasing levels of remoteness for all children, though the trend was only significant in non-Aboriginal children (possibly due to larger numbers). Over time, there was no evidence of an increasing trend in the prevalence of ASD with ID in Aboriginal children (P-value = 0.75). In contrast, over time, there was a significantly increasing prevalence in non-Aboriginal children (P-value <0.0005).
Conclusions:
Improved diagnostic opportunities for ASD with ID are needed for Aboriginal children and all non-metropolitan children. In addition, a particular focus is needed in Aboriginal children to address the lack of increase over time in this population. With assistance from health-care workers to ensure access, this would enable more children to receive suitable early interventions, other services and funding which would improve children's life opportunities and the Quality of Life of their families.

3:16 **155.004** Feasibility of the Autism Navigator® Training in South Africa

N. J. Chambers[1]*, A. M. Wetherby*[2] *and P. J. de Vries*[3]*, (1)Child and Adolescent Psychiatry, UCT, Cape Town, SOUTH AFRICA, (2)Florida State University Autism Institute, Tallahassee, FL, (3)University of Cape Town, Cape Town, SOUTH AFRICA*

Background: Â Across the globe autism spectrum disorder (ASD) is generally diagnosed long after parents first express concern about their child's development, and long after the age at which red flags can now reliably be identified. To help address this knowledge-practice gap, researchers at Florida State University developed the Autism Navigator® for Primary Care**,** a web-based professional development course with extensive video illustrations of over 2-dozen toddlers 18-24 months of age with ASD and families participating in early screening, diagnosis, and intervention. There are immense training needs in South Africa with respect to all aspects of ASD, including early detection. Time and cost-effective evidence-based training is essential to lower the age of detection of ASD and improve access to services.
Objectives: Â This study examined the feasibility of using the Autism Navigator for Primary Care® course in the Western Cape of South Africa. Professionals who may be the first person a family consults with concerns about their child's development were recruited from a range of sectors including public and private health, public education, autism-specific NGOs, undergraduates, and postgraduate medical students.
Methods: Â Participants were asked to complete Units 1-3 of the course as these were considered to be the most universally applicable in content. Changes in knowledge as well as satisfaction with the content and technology of the training in the South African context were examined using a mixed methods approach. Quantitative data included a researcher-constructed 18-item knowledge scale completed before and after the training and a survey of training variables. The impact of demographic characteristics on these measures was also examined. Qualitative data were collected to determine participants' views on the relevance and feasibility of the training.
Results: Seventy-nine participants gave consent for the training and 61 (77%) completed Units 1-3. Of the completers, 50 (82%) returned the post-training forms. Second language English speakers spent significantly longer completing the built-in learner assessments for all three content units. Lower self-ratings of computer proficiency were also associated with longer time spent in Unit 3. Initial scores on the knowledge instrument were significantly related to level of experience with ASD. The group demonstrated significant improvements in knowledge on this instrument from before to after the training, with smaller changes associated with more experience. Thirty-eight participants took part in group or individual feedback interviews. Comments regarding relevance of the training in their local contexts were very positive. Suggestions for local translations and adaptations were also made. The most commonly mentioned benefit of the training was the extensive library of videos to illustrate red flags. Barriers to the feasibility included length of the training, and technology access barriers.
Conclusions: Results indicate the feasibility of this web-based training in a low-resource setting and suggest that the Autism Navigator for Primary Care® may have valuable potential to improve knowledge of the early flags of ASD in South Africa. Findings highlight the need to consider language and technology demands of the web-based training and knowledge measurement across professionals with differing experience.

Panel Session
156 - Parent/Caregiver Education Training for ASD – What Is the Best Model for Delivery, and How Do We Best Evaluate Outcomes?

3:30 PM - 5:00 PM - Yerba Buena 3-6

Panel Chair: Petrus de Vries*, University of Cape Town, Cape Town, South Africa*

There is consensus that parent education training, often referred to as 'psycho-education', is an essential part of post-diagnostic intervention. However, there is not consensus on the best models to provide these trainings (e.g. duration, frequency, location and providers), or what key 'active ingredients' of parent education training might be. Furthermore, evaluation of parent education training programmes have been limited, and have typically consisted of 'pre-post' satisfaction questionnaires. There is therefore no broad-based evaluation framework to compare programmes, or to determine whether a programme had a positive outcome. In this panel, we present 5 very different parent education programmes to address these issues. In the first presentation, we examine an ultra-brief (1 hour) parent education training performed in a community setting in Tanzania. In the second and third presentations, we explore two programmes from India – a two-week inpatient and a 12-15 week non-residential group programme. Finally, we present an implementation science approach to two programmes evaluated in South Africa, one a 12-week widely-used, highly manualized programme from the UK (Early Bird/Early Bird plus), the other a locally-developed, one-week, non-residential outpatient programme. We aim to have a critical discussion to guide the development, evaluation and sustainable implementation of parent education training across the globe.

3:30 **156.001** Examining a Brief Intervention for Parents of Children with Autism in Global Contexts with Limited Resources

A. J. Harrison[1], *K. Long*[2], *K. P. Manji*[3], *K. K. Blane*[4] *and M. S. Kaff*[5], *(1)University of Georgia, Athens, GA, (2)Boston University, Boston, MA, (3)Muhimbili University, Dar Es Salaam, Tanzania, United Republic of, (4)Alpert Medical School of Brown University, East Providence, RI, (5)Special education, Kansas State University, Manhattan, KS*

Background:
Despite the global presence of Autism Spectrum Disorders (ASD), a paucity of treatment services exists in Tanzania and many other low- and middle-income countries. Two primary barriers to accessing ASD treatments in Tanzania include a lack of non-English manualized interventions and treatment providers who can deliver interventions in Swahili. Thus, developing feasible, sustainable methods to offer empirically-based interventions to Tanzanian children with ASD is a public health priority.
Objectives:
The aim of this study was to address these two primary barriers through the development of a very brief parent-based behavioral intervention protocol that can be feasibly delivered via an interpreter. This talk will (1) describe the development this intervention designed to introduce parents to general behavior modification strategies, (2) reports on the initial feasibility and acceptability of a pilot trial in Tanzania, and (3) examines the generalization of this intervention to a different cultural context.
Methods: Study development and pilot testing occurred in Tanzania in two phases. Twelve caregivers of children with ASD and other developmental disabilities (DD) participated in the initial intervention development phase. The intervention was tailored to meet collaboratively set goals. In the second phase of the study, the intervention was piloted among 29 caregivers of children with ASD and DD. Parents received a subset of nine brief behavior modification lessons in areas of general parent training and teaching self-help skills. Parents were provided verbal didactics (via an interpreter), handouts in Swahili with visuals depicting strategies, and therapist-modeling. To examine the generalizability of this approach data collection is ongoing to examine the implementation of the intervention in Mongolia.
Results:
In support of the feasibility of use among Swahili-speaking Tanzanians, all 29 caregivers approached agreed to participate in the study. Despite cultural, language, and logistical barriers, 86% of parents reported that the intervention was helpful, with the remainder of parents requesting more comprehensive training. Families received training in one to six (M=4.16, SD=1.53) of the behavioral modules depending on the treatment goals determined collaboratively between the clinician and caregiver. Those delivered most frequently included “Using Reinforcement Strategies” (86%), “Teaching Requesting” (71%), “Increasing Eye Contact” (65%), “Following Directions” (48%), “Imitating” (48%), and “Toileting” (45%). We examined differences in the number of modules administered to children with ASD as compared to children with DD and found no group difference, $t(26)=.82$, $p=.42$, thus indicating that the intervention modules were relevant for both diagnostic groups.
Conclusions: Teaching parents to implement basic behavioral principles may ameliorate functional impairments among Tanzanian children with ASD. Results from the pilot intervention support the feasibility of future use among Swahili speaking Tanzanians. Implications of this pilot extend to non-English families in the U.S. who are also in need of brief interventions to teach basic behavioral techniques. This approach will help to improve functional outcomes among children with ASD and reduce ASD disparities both locally and globally. In the discussion, we also will examine how this intervention generalizes to another global context, Mongolia, where intervention implementation and data collection is underway.

3:50 **156.002** The Impact of a Two-Week in-Patient Parent Training for Autism Spectrum Disorder in India

P. K. Panchal*, Department of Child & Adolescent Psychiatry, National Institute of Mental Health and Neurosciences, Bangalore, India*

Background:
The benefits of parent training for Autism Spectrum Disorder (ASD) on the child and family outcome are well proven. Most parent training interventions are similar in content but differ in the service delivery model. The present study was conducted at a tertiary child psychiatry centre in India. Most families seeking treatment at the centre belong to middle socio-economic status, are non-local residents, have poor understanding about their child’s problems, and lack resources locally. Majority of the children receive diagnosis of ASD for the first time at the tertiary centre, and are also diagnosed with multiple co-morbid disorders. Present study was conducted to assess the effect of brief parent training for ASD during the hospital admission.
Objectives:
To assess the impact of a two-week in-patient parent training for home based interventions for ASD on the parents.
Methods:
The sample consisted of families of twenty children between the ages of 3- 10 years, diagnosed of ASD and admitted in the centre. Baseline measures included Childhood Autism Rating Scale 2nd edition (CARS-2), Vineland Social Maturity Scale (VSMS), FISC-ASD (Family Interview for Stress and Coping -ASD), Autism Parenting Stress Index (APSI) and Autism Treatment Evaluation Checklist (ATEC). Parents received daily individualised sessions focusing on psycho-education, skills training, management of problem behaviour and alleviation of family stress. Parents were re-evaluated post intervention using ATEC, APSI and FISC-ASD. The FISC-ASD is a locally-developed, semi-structured tool. It has two sections: perceived stress and mediators of stress. Higher scores in section 1 and 2 mean higher family stress and lower awareness respectively. Parents were also asked to rate their experience of the intervention at the end through a feedback form.
Results: A total of thirty five caregivers (nineteen mothers, fourteen fathers and two grandparents) received the intervention. All the families were residents of other Indian States. Mean duration of stay was 15.5 ± 4.3 days. Mean age of children was 59.4 months (SD-21.8). Mean baseline scores were CARS-2 – 34.9 (SD-4.2), VSMS- 55.3 (SD-1.6), ATEC- 93.2 (SD-20.0) and APSI- 21.8 (SD-10.4). There was statistically significant improvement in the ATEC, APSI and FISC-ASD section on mediators of stress post intervention. There was no statistically significant change in the FISC-ASD section on perceived stress. There was no statistically significant correlation between pre-post scores of ATEC, APSI and FISC-ASD (mediators of stress). Eighty percent families reported that the training was very helpful to them.
Conclusions: Â A two week hospital admission helped to reduce parental stress, improve knowledge and child rearing practices of families across the socio-economic background. Majority of the parents perceived the training as very helpful. The main limitation of study was lack of a blind independent rater and matched control group. We propose that this in-patient service model is useful in a multidisciplinary, specialist setting where it may allow sufficient time to address the multiple issues (co morbid conditions, problem behaviour, poor parental knowledge) faced by the families and children with ASD.

4:10 **156.003** Parent Acceptance and Empowerment Training MODEL: Evidence from a Parent Training Intervention for ASD in New Delhi, India

N. Singhal[1], ***M. Barua***[1], *T. C. Daley*[2], *R. S. Brezis*[3] *and T. Weisner*[4], *(1)Action For Autism, New Delhi, INDIA, (2)Westat, Durham, NC, (3)Interdisciplinary Center, Herzliya, ISRAEL, (4)UCLA, Los Angeles, CA*

Background: The Parent Child Training Program (PCTP) was developed at Action For India, New Delhi, India in 2000 with acceptance of the child and empowerment of the parents as explicit program goals. The program additionally provides practical and theoretical knowledge on autism and behavior management. Training takes place with a group of approximately 12-15 families, thrice every year, over a 3-month period, with the parent and child attending together for 4 hours a day, five days a week. The training includes daily group and one-on-one activities with the children, and group discussions for the parents. To date, the PCTP has trained over 500 families from more than 20 Indian states and eight different countries. The program has been replicated in at least 15 different cities in three different countries.
Objectives: The purpose of the current study was to examine the effectiveness of the programme by focusing on mothers' empowerment and acceptance towards the child; and the extent to which parenting skills acquired through the training transfer to the home setting and are maintained over time.
Methods: Three consecutive cohorts of families (*n*=48 total) participated in the evaluation. Participants joined from a wait-list and entered on a first-come, first-served basis. Diagnosis was confirmed using the ADOS and SCQ. Both parents were interviewed at the start and end of the 3-month program and mothers attended the program. Parents and children were followed eight and 15 months after the conclusion of the PCTP program. Measures consisted of a combination of standardized tools and those developed specifically for this evaluation under a broader project on research on families with autism in India.
Results: Cohorts did not differ in demographic characteristics or baseline outcome measures. Significant gains were seen across all outcome measures, including parents' acceptance, empowerment, knowledge of autism, sense of competence, and stress from before to after the program. These gains were further maintained 15 months later.
Conclusions: The PCTP was developed specifically to meet the needs of families in India, where disability remains highly stigmatizing and services are limited. Using both standardized measures and those developed for this study, the current evaluation provides an estimate of project impacts in key parent outcomes. The fact that parents maintained their gains in acceptance and empowerment 15 months after the end of the program provides compelling evidence for the program's success and generalizability. The acceptance and empowerment focus of this model offers a novel way to conceptualize parent training, and has high relevance for families in situations where cultural, economic and other contextual factors may be similar to those in India.

4:30 **156.004** An Implementation Science Approach to Parent Education Training – Generation of an Evaluation Framework and Comparison of Two Programmes in a South African Setting

***J. J. Dawson-Squibb**, Division of Child & Adolescent Psychiatry, University of Cape Town, Cape Town, South Africa*

Background:
Parent Education Training (PET) is increasingly considered an important component of early treatment for Autism Spectrum Disorders (ASD). It covers a range of modalities and different PET programmes employ different approaches and goals. Ensuring these are contextually appropriate to stakeholders, including parents, is critical for effectiveness, sustainability and future scale-up. While there is growing research in this area, little comparison of different PET programmes has been attempted. Particularly in Low- and Middle Income Countries (LMIC), where financial restrictions are pervasive, selecting programmes that meet the needs of relevant stakeholders is paramount.
Objectives:
We set out to generate an evaluation framework for parent education training using a stakeholder participatory strategy, and then ran two different programmes for comparison using the agreed evaluation framework.
Methods:
The study used a consecutive, mixed-methods design. Given the absence of any universally-agreed tools to compare PET programmes, an evaluation framework was generated by a panel of 13 stakeholders. Stakeholders were recruited via consensus sampling and had knowledge and experience in the area of ASD while working in LMIC. Consensus discussion in groups was used to generate a final evaluation framework.
Two PET programmes were selected for head-to-head feasibility evaluation. Autism Cares is a locally-developed 5-day outpatient programme; EarlyBird is a well-established, manualised 12-week programme developed by the U.K.'s National Autistic Society. With ethics approvals, families were recruited to participate in a pilot feasibility study via a local not-for-profit ASD organisation. Semi-structured pre and post-interviews with the parents participating in the programmes were conducted, focusing on feasibility. In addition, a quasi-experimental pre-post design was used to assess outcomes in multiple areas, including knowledge of ASD, confidence, parental stress, and functioning of the child using standardised questionnaires. A waiting list group were used as control for the two active groups.
Results:
The consensus evaluation framework set out three core areas deemed relevant and important to PET programmes - Outcomes, Process and Implementation. 'Outcomes' related to changes in parent including knowledge of ASD and emotional well-being. In addition, changes in child well-being and family functioning were determined to be important features of PET goals. 'Process' included the acceptability and accessibility of the programme. 'Implementation' priority evaluation areas included sustainability, scalability and integration between systems and organisations.
11 families participated in the EB/EB+ programmes and 10 in Autism Cares,all completed the programmes. Participant ages ranged from 26 to 57 years and monthly household income ranged from less than $360 to between $1800-$7200. Qualitative post programme feedback from participants was very positive for both EB/EB+ and Autism Cares.
Here we will present the head-to-head comparison of findings in context of the consensus evaluation framework.
Conclusions:
Depite the acknowledged value of parent education training, there hasn't been consensus on an evaluation framework for the range of PET that are delivered around the globe. Our implementation science study suggested that, whilst efficacy is an important pre-requisite for potential use, many other factors may have to be considered to determine the most suitable programmes for successful implementation and scale-up in local communities.

Panel Session
157 - Addressing Disparities through Interventions in Diverse Community Systems
3:30 PM - 5:00 PM - Yerba Buena 7

Panel Chair: Laura Anthony, *Children's National Health System, Washington, DC*

Discussant: Connie Kasari, *University of California, Los Angeles, Los Angeles, CA*

Despite increases in awareness of ASD, there remain vast disparities in community-based screening, diagnosis, acceptance, inclusion, and access to evidence-based care. This panel will present findings from four very different community-based intervention projects; online resources to increase acceptance and reduce bias, a stakeholder informed primary care program to increase the rate of screening and referral for young Latino children; a school-based comparative effectiveness trial addressing executive function in low-income schools; and a program to increase the use of evidence-based practices in publically-funded mental health centers. Though the studies presented take place in very different community contexts, they share common goals of addressing disparities, using intensive stakeholder input and community partnerships for successful adaptations, and sustainability through using existing community-based systems and the staff who already work there. These projects and researchers also share common lessons learned, such as the amount of time that must be dedicated to building trusting relationships before making changes in disenfranchised communities, the need for creative and adaptive

methodologies, that crucial stakeholder input must include individuals with ASD, their families and those in the community service systems, as well as the need for very specialized adaptations for each community and setting.

3:30 **157.001** Impact of a Supported Screening Program to Increase Identification and Assessment of Latino Children at Risk for ASD

B. J. Anthony[1], *K. Linas*[1], *M. Biel*[2], *R. Mendez*[1], *S. C. Dos Santos-Arquinio*[1] *and D. Jacobstein*[1], *(1)Center for Child and Human Development, Georgetown University, Washington, DC, (2)Georgetown University, Washington, DC*

Background:
Screening in primary care is an important step in identifying young children with ASDs, expediting early behavioral and educational interventions. However, despite evidence that formal screening improves accuracy of identification over informal clinical assessment, there is far from universal use of ASD-specific screening tools with use is lower still with Spanish-speaking patient populations. Moreover, there continues to be strong evidence of disparities in identification, age at the time of initial diagnosis, referral, and treatment for Latino children compared to non-Latino white. Here, we present evidence for the effectiveness of an 18-month trial of *Supported Screening (SS)*—developed and implemented through a community participatory process to enhance the uptake of universal screening for ASDs in a large primary care center serving a primarily Latino population and increase identification and further assessment of children with ASD.
Objectives:
The goals of *SS* are to enhance the identification of ASDs and other developmental delays in Latino children by increasing: (1) screenings conducted at 18- and 24-month well-child visits; (2) positive screens; and (3) successful referrals and timely evaluations.
Methods:
SS was implemented at a large Federally Qualified Health Center serving a primarily urban Latino population in Washington, D.C and involved formative research with families, primary care providers (PCPs) and staff to inform: (1) family outreach activities and resources*;* (2) practice-wide training for PCPs and staff, and (3) services of Family Navigators (FN) with lived experience who provided support to families with a child identified at risk for ASD as well as ongoing care coordination with early intervention and medical providers. Screens and referrals were tracked for the approximately 7000 0-36 month old children per year, 70% of whom were identified as Latino.
Results:
Formative research, including cognitive interviewing, resulted in adaptation of M-CHAT and its administration (verbal, combined screening and follow-up, implementation by FNs and PCPs) and comprehensive training emphasizing engaging families/addressing barriers, coupled with available consultation. Training resulted significant increases in staff knowledge of autism, screening and factors that increase caregiver disclosure of developmental concerns. The percentage of children screened rose from under 10% prior to the onset of SS to almost 90%. PCPs completed only a small number of screens at the onset of SS but almost 50% by the end. Records indicated that no children were identified at risk for ASD in the year prior to SS; however, by the end of the trail 4% of eligible children screened positively on the M-CHAT and were referred for services, a rate comparable to those found in other Spanish language populations.
Conclusions:
Universal screening for ASDs in a center serving predominantly Latino families and successful follow-up of positive screens was facilitated by assessment of community/provider needs, increased staff skills in culturally appropriate family engagement, screening, and referral, and FNs integrated into the health provider system. Attention to these issues increase disclosure of developmental concerns by Latino families, produced improved attitudes of providers and families toward early screening and referral for ASDs, helping to reduce disparities in rates of diagnosis and treatment.

3:50 **157.002** Addressing Disparities By Reducing Stigma and Increasing Acceptance?: Sesame Street's See Amazing in All Children Online Initiative

L. G. Anthony[1], *H. A. Robertson*[2], *S. Seese*[1], *A. D. Verbalis*[1], *C. Domitrovich*[2], *C. L. Dickter*[3], *J. Burk*[3] *and B. J. Anthony*[4], *(1)Children's National Health System, Washington, DC, (2)Georgetown University, Washington, DC, (3)College of William & Mary, Williamsburg, VA, (4)Center for Child and Human Development, Georgetown University, Washington, DC*

Background:
While the diagnosis of ASD is common (CDC, 2016), poor understanding of the condition contributes to diagnostic and treatment disparities, discrimination, verbal abuse, and even physical violence (Sterzing et al., 2012). To help address this lack of awareness and acceptance, Sesame Workshop created “See Amazing in All Children.” This on-line, nationwide initiative, developed with input from parents, people who serve the autism community, and autistic people, includes video stories, an electronic storybook and routine cards for parents to use to help their kids with daily routines and life skills. These free resources offer all families ways to overcome common challenges and simplify everyday activities while fostering an affirming narrative around autism for all families and kids.
Objectives:
To assess the impact of the See Amazing in All Children initiative on parents of young children with autism by measuring knowledge, attitudes and biases towards children with autism, parenting competence, empowerment, and engagement with the community prior to (PRE) and after (POST) reviewing the initiative materials. A parallel study will collect similar data from a community sample.
Methods:
Parents review the materials and complete the PRE and POST evaluations on line. We expect to recruit at least 150 parents of preschoolers with ASD, 100 of those with both PRE and POST data. Here we report preliminary results; analyses of PRE data from 72 parents and PRE and POST data from 20 parents. The evaluation survey included:

- Detailed demographics (including gender, race/ethnicity, income, education displayed in table 1)
- Previous contact with the materials
- The *Social Communication Questionnaire* (Rutter, Bailey & Lord, 2003) to confirm diagnosis
- An Implicit Association Test to assess implicit bias, or hidden thoughts and feelings outside of conscious awareness and control, towards young children with autism
- Explicit attitudes and beliefs about autism through questions related to a short video of a child with ASD
- Parent knowledge about ASD, strain, competence and community inclusion/stigma/advocacy.

After PRE, participants are asked to view the *See Amazing in All Children* videos and other web content. Follow-up data is collected at 1 week and 1 month intervals after the parent reviews the materials.
Results:
Preliminary findings indicate strong associations among parents’ explicit attitudes and beliefs, total knowledge about ASD, stigma, and community inclusion. Implicit bias did not relate to other measures. See table 2 for findings. Preliminary pre-post data suggests improvements in knowledge will be evident at the one week time point. We hypothesize that the increase in knowledge gained from interacting with the See Amazing materials, and the positive and empowering nature of the materials, will result in a decreased sense of stigma, increased feelings of competence and empowerment, and a more positive attitude resulting in fewer biases.
Conclusions: Sesame Street, with its broad reach and positive messaging, is uniquely positioned to directly target parental and community knowledge and attitudes around ASD. The results of this study will not only tell us whether the Muppets are successful in their endeavor, but will provide insight into the factors that contribute to biases and stigma.

4:10 **157.003** Provider and Caregiver Perspectives on Disparities in the Delivery of Evidence-Based Strategies in Publicly-Funded Mental Health Services: Implications for Intervention and Provider Training Models

C. Chlebowski[1], *B. Wright*[2], *S. Magana*[3] *and L. Brookman-Frazee*[4], *(1)University of California, San Diego, San Diego, CA, (2)UCLA, Los Angeles, CA, (3)Disability and Human Development, University of Illinois at Chicago, Chicago, IL, (4)University of California, San Diego, La Jolla, CA*

Background: There are well-documented ethnic/racial disparities in access to and quality of community services for children with ASD. It is not known, however, if disparities persist when providers are trained to deliver evidence-based (EB) interventions. Understanding the role of cultural factors associated with treatment process when providers are delivering EB interventions is critical to tailoring interventions to fit the needs of client receiving care in community services.
Objectives: Gather community provider and caregiver perspectives to characterize disparities in delivery of mental health intervention for ASD and identify key adaptations to treatment and provider training protocols.
Methods: Data were collected in the context of a community effectiveness trial of AIM HI, an intervention designed to reduce challenging behaviors in the context of mental health services. Qualitative data were collected to complement and expand findings from the parent study. Participants included a subset of individuals enrolled in the effectiveness trial, including 17 therapists who participated in AIM HI training and 29 Hispanic caregivers (66% who speak Spanish as their primary language) whose child received mental health care from therapists trained in AIM HI. Data were obtained from the following sources: 1) therapist focus groups and individual interviews and 2) caregiver interviews.
Results: Themes regarding provider and caregiver perspectives were consistent with quantitative findings from observational session data from the parent study indicating few differences in treatment process by caregiver ethnicity. Qualitative data expanded to indicate that differences in treatment process were primarily related to client and caregiver education and social economic status (SES). The following factors were identified as influencing treatment process by therapists: (1) level of caregiver mental health literacy, including expectation regarding caregiver involvement; (2) caregiver understanding of ASD and its impact on child behaviors; (3) Caregiver primary language, including the complexity of conducting treatment through a translator or application of behavioral terminology when sessions were conducted in Spanish; (4) The cultural factors including the value of *respeto* and caregiver deference to providers, the influence of extended family members expectations of treatment, stigma, and the alignment of parenting values and a behavioral approach. Themes from caregiver interviews highlighted pragmatic variables influencing treatment, including logistics and time required to complete session activities and between session practice. Therapists also identified adaptations to the clinical intervention and therapist training l to address differences in treatment process including (1) changing the pacing of intervention to leave time for psychoeducation regarding ASD, (2) modifying materials to reduce technical terminology and increase “parent friendly” language to support understanding and home practice, and (3) explicit attention to new areas during AIM HI training, including how to deliver AIM HI with translators, key areas of psychoeducation, and incorporating cultural values in collaborative process with parents and identification of behavioral strategies.
Conclusions: This study was conducted as part of a broader line of research using community partnered approaches to intervention development and refinement. Results illustrate key issues that may influences disparities in treatment process and feasible adaptations to ensure the fit of interventions to families served in publically–funded mental health settings.

4:30 **157.004** Differential Outcomes in an Addressing Disparities Comparative Effectiveness Trial of Community-Based Executive Function Treatments in ASD and ADHD

L. Kenworthy[1], *L. G. Anthony*[1], *K. Hardy*[1], *J. Safer-Lichtenstein*[2], *A. D. Verbalis*[1], *M. Biel*[3], *S. Seese*[1], *J. F. Strang*[1], *A. B. Ratto*[4], *C. E. Pugliese*[4], *C. K. Kraper*[1], *J. L. Martucci*[1], *M. C. Wills*[4], *C. Luong-Tran*[5], *L. Cannon*[6], *A. C. Sharber*[5] *and B. J. Anthony*[2], *(1)Children's National Health System, Washington, DC, (2)Center for Child and Human Development, Georgetown University, Washington, DC, (3)Georgetown University, Washington, DC, (4)Children's National Medical Center, Washington, DC, (5)Children's National Medical System, Washington, DC, (6)Ivymount School, Rockville, MD*

Background: Economic disparities in access to diagnosis and treatment are prominent in ASD and in ADHD. Both disorders are strongly associated with executive dysfunction, which is itself also an outcome of child poverty. Contingency behavioral management (CBM) is currently considered to be standard care for children with ADHD to treat EF related problems in schools. Unstuck and on Target (UOT) is a cognitive-behavioral executive function (flexibility, goal-setting and planning) intervention, which we found to be effective in middle-income children with ASD (Kenworthy & Anthony et al., 2014). Unlike other cognitive-behavioral treatments, UOT is implemented in school instead of a clinic, making it low cost, accessible and more likely to generalize to real world settings. We adapted UOT and CBM for use with low income and minority families (in either English or Spanish) and children with ASD or ADHD. We developed the CBM intervention, called Parents and Teachers Supporting Students (PATSS) to be accessible/empowering to the students, parents and teachers (e.g. terminology adjusted—"antecedent" changed to "trigger; students participated in the development of their behavior goals), and to specifically target flexibility and other EF problems.
Objectives: Compare the effectiveness of two EF treatments, UOT and PATSS, in typically underserved children with ASD or ADHD and flexibility problems.
Methods: The interventions were embedded in 22 mainstream Title 1 elementary schools in which at least half of the students qualify for free/reduced lunch fees. All children: had IQ>70; were in 3rd-5thgrade; were identified by school staff as being inflexible and having characteristics of ADHD or ASD; and met diagnostic criteria for either ASD (ADOS-2) or ADHD (MINIKid). 145 children (ASD n=48; ADHD n=97) completed the trial. Of those that completed the trial, only 29.7% were White/Non-Hispanic. The intervention groups were equivalent regarding age, sex, and IQ. Both interventions were delivered by school staff to small groups of students in approximately 20 sessions of 30-40 minutes each. The two interventions were matched for amount of parent, teacher and interventionist training (70% of parents attended a parent training). We compared change in both groups from pre- to post-intervention (PRE, POST) via treatment blinded classroom observations, classroom teacher ratings (SKAMP), WASI Block Design and BRIEF scores.
Results: Fidelity ratings were adequate overall. Performance on all measures improved for both ASD and ADHD children following UOT, but PATSS demonstrated more differentiated effects with more improvements in ADHD. See Table below for paired samples t-tests. Blinded classroom observations also showed some important differential effects in specific behavioral targets. See Figure below for percentages of children who improved on each of the classroom behaviors observed.
Conclusions: Children with ASD and ADHD in low-income schools benefit from community-based EF interventions adapted to engage teachers and families.

Panel Session
158 - Developing Clinically Practicable Biomarkers for Autism Spectrum Disorder
3:30 PM - 5:00 PM - Yerba Buena 8

Panel Chair: James McPartland, *Yale School of Medicine, New Haven, CT*

Discussant: James McPartland, *Child Study Center, Yale School of Medicine, New Haven, CT*

Despite significant advances in understanding the biological bases of autism spectrum disorder (ASD), the field remains primarily reliant on observational and parent-report measures of behavior to guide clinical practice, conduct research, and evaluate intervention outcomes. There is a critical need for objective measures to more sensitively and validly quantify risk for ASD, ASD symptomatology, and its change in clinical trials. To maximize public health impact, such biomarkers must be cost-effective and utilize accessible and scalable technologies. This panel brings together five autism research centers, with panelists spanning early career faculty to senior leaders in the field. The biomarkers presented for study all rely on accessible and economical technologies. Three studies will be presented to highlight promising biomarker modalities that can be implemented feasibly in large clinical trials: electroencephalography (EEG), eye-tracking, and wearable autonomic sensors. A fourth study presents data integrating these modalities to provide unique composite information in the context of an ASD clinical trial. Discussion will focus on unique concerns for the development of biomarkers that can facilitate prediction of outcome and diagnostic stratification and on approaches to optimize understanding of these biomarkers through development of large-scale consortia and clinical networks.

3:30 **158.001** Early Electrophysiological Biomarkers of Risk for ASD: Insights Gained from Studies of Infant Siblings and Tuberous Sclerosis Complex

S. S. Jeste[1], *K. J. Varcin*[2], *A. Dickinson*[3], *J. Frohlich*[3], *M. Dapretto*[3] *and C. A. Nelson*[4], *(1)UCLA, Los Angeles, CA, (2)Telethon Kids Institute, Perth, Australia, (3)University of California, Los Angeles, Los Angeles, CA, (4)Boston Children's Hospital, Boston, MA*

Â

Background: A variety of genetic and environmental factors contribute to the heterogeneity of autism spectrum disorders (ASD). However, across etiologies, the underlying neurobiology of ASD converges on the regulation of fundamental processes of brain development such as cortical organization, synapse structure and function, and intra-cortical connectivity. These processes can be measured through methods such as electroencephalography (EEG) before behavioral signs of atypical development emerge. The investigation of infants at heightened genetic risk for ASD affords us an opportunity to examine early biomarkers of risk. Such investigations can shed light on mechanisms underlying atypical development.
Objectives: We present data from two studies of biomarkers of risk for ASD: (1) a study of infants with an older sibling with ASD ("infant siblings") and (2) a multisite study of infants with Tuberous Sclerosis Complex (TSC). We asked whether there were common and distinct biomarkers of risk across and within groups.
Methods: Infants in each study were tested longitudinally, the infant siblings (n=35 LR, n=47 HR) beginning at age 3 months and the infants with TSC (n=18 LR, n=40 TSC) beginning at age 6 months. Each group was compared to a cohort of "low risk" infants without a known genetic susceptibility for ASD. High density spontaneous EEG was recorded while infants watched abstract, non-social images on a screen. Variables of interest included EEG oscillatory power as a marker of baseline neural synchrony, and frequency variance and whole brain coherence as measures of connectivity and network formation. Cognition and social communication were measured beginning at 6 months of age, with ASD diagnosis made at age 36 months using the Autism Diagnostic Observation Schedule (ADOS) and clinical best estimate.
Results: Distinct trajectories were identified based on risk grouping in spontaneous EEG power, frequency variance, and coherence. More specifically, in the first year of life infants at high risk demonstrated (1) reduced power in alpha (8-11 Hz) [LR: relative power 0.15-0.20 across first year of life, HR: 0.08-0.10, $p<0.01$ at each age] and gamma (35-50 Hz) bands [LR:relative power 0.05-0.06, HR: 0.03-0.04, $p<0.01$ at age 9 and 12 months], with the greatest reduction in alpha power found in infants with TSC who developed ASD [$p=0.003$ at 18 and 24 months] and (2) differences in frequency variance (specifically, greater rate of change in FV in LR infants, $p<0.01$), alpha band coherence (modularity at 3 months lower in HR infants, 0.035 vs 0.040, $p=0.03$) that reflected differences in connectivity and signal complexity. Biomarkers of risk were detectable as early as 3 months in the infant siblings and 6 months in infants with TSC in EEG power and coherence.
Conclusions: The putative neurobiological processes that underlie the development of ASD unfold early in life and precede behavioral signs of atypical development. EEG holds particular promise as a biomarker of risk for both scientific and practical reasons. We consider the methodological, clinical, and ethical implications of pre-behavioral biomarkers of risk and discuss the potential for studies to inform the initiation of early developmental interventions before behavioral signs of ASD emerge.

3:50 **158.002** Eye Tracking As a Spectrum of Biomarkers in Children with ASD

F. Shic[1]*, Q. Wang*[2]*, A. Naples*[2]*, S. Macari*[2] *and K. Chawarska*[2]*, (1)Seattle Children's Research Institute, Seattle, WA, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Eye tracking has become a core methodology in autism research and is quickly moving towards relevance as a biomarker for ASD. Yet, the power of eye tracking lies not in its quantitative, objective, technical nature, but in the design of appropriate measures and paradigms that can tap into constructs with clinical and mechanistic relevance.
Objectives:
To critically examine, through a series of example studies, a spectrum of eye tracking data metrics, paradigms, and analysis approaches, with the ultimate goal of charting the trajectory of eye tracking as a potential biomarker for ASD.
Methods:
We aim to categorize eye tracking biomarker development efforts in ASD in terms of their (1) intended use; (2) selection of measures; and (3) theoretical approach. Using illustrative data from infants and toddlers on paradigms such as Chawarska et al., 2012 (including subsets of children with ASD (n=206), developmental delay (DD; n=51), children at high risk for autism without autism (HRNA; n=115) and typical development (TD; n=184)) we describe tasks and approaches designed to capture features of autism, describe mechanisms, and fulfill a practical role in early diagnostics or monitoring. We then turn towards a discussion of measures and contrast high-level region-based approaches to data-, computational-, and statistically-driven approaches.
Results:
We show that standard region-of-interest (ROI) based eye-tracking techniques replicate high-level deficits observed in ASD, such as diminished orienting towards social information ($p<.001$). We show that a single paradigm can be flexibly used to explore genetic mechanisms associated with autism (sex-linked differences between girls at high risk for ASD and other groups at 6 months, $p<.06$), to identify early markers of later developing autism (>80% predictive accuracy), and quantify features associated with clinical phenotypes (correlations with autism severity, $p<.05$). We discuss the utility of missing data and the distributional properties of fixations, saccades, and looking time, highlighting the importance of understanding the fundamental nature of eye tracking metrics and the errors that can result from lack of clarity. We show that data-driven methods, computationally-based approaches, and statistical techniques designed to quantify "atypicality" complement high-level approaches and provide additional precision towards our goal of defining "biomarkers" ($p<.01$). Stepping back and examining the field critically, we highlight the disconnect between eye tracking as a research methodology and as a clinical tool. Similarly, we reframe our progress as a field in terms of our goals for a viable biomarker for autism. We point towards cumulative evidence of the field of eye tracking in ASD research as a positive and the power of large data sets and new approaches to provide illumination.
Conclusions:
Eye tracking is a powerful tool that has provided us with a way of quantifying atypical behavior and social preferences in children with ASD. Viewed as a tool with multiple axes of flexibility and a spectrum of forms, it empowers us to make great progress towards identifying viable biomarkers for ASD symptoms and dimensions impacting quality of life. Yet, in order to do so, our research questions must be framed and appropriate methodology brought to bear.

4:10 **158.003** Wearable Sensor-Based Physiological and Physical Activity Biomarkers for Use in Laboratory and Naturalistic Environments to Assess Arousal and Repetitive Motor Movements in Individuals with Autism Spectrum Disorder

M. S. Goodwin*, Northeastern University, Boston, MA*

Background: Despite autism spectrum disorder (ASD) being widely recognized as the fastest growing and most costly neurodevelopmental disorder worldwide, there is no specific biomarker, laboratory test, or behavioral assessment procedure to identify, characterize, or monitor its progression. ASD is defined exclusively by past and present behavior determined from developmental history interviews, parent reporting on current behavior, and structured and semi-structured tasks that involve social interaction between an examiner and a child.
Objectives: Describe wearable sensor-based physiological and physical activity technologies enabling multimodal assessments of autonomic arousal and repetitive motor movements in ASD in both laboratory and naturalistic environments, and review their utility for biobehavioral phenotyping and response to intervention in ASD.
Methods: Ubiquitous and wearable computing is making it possible to capture data in laboratory, clinical, school, and home settings on an unprecedented scale. Coupled with advances in pattern recognition algorithms and large-scale computing, semi-automated measures of physiology and behavior are emerging including wireless sensors for monitoring physiological arousal and wireless 3-axis accelerometers and pattern recognition algorithms that can automate the detection of stereotypical hand flapping and body rocking.
Results: Results from two lines of research will be reported. The first employs wireless measures of autonomic nervous system (ANS) activity and demonstrates that severely affected children with ASD have different cardiovascular response patterns to various psychological, social, and sensory demands, including substantially higher and less variable heart rate (HR) than a typically developing group of age-sex matched peers. Moreover, in a follow-up replication study repeating the same assessment protocol in 43 severely affected children with ASD, 6 distinguishable subgroups within the ASD sample were identified who display normal, high, and extremely high HR, along with unreactive ('stabile') and reactive ('labile') response patterns using time series-based cluster analysis. In the second line of research, wireless 3-axis accelerometers and pattern recognition algorithms are employed as automated measures of stereotypical motor movements (SMM) in six severely affected individuals with ASD. Using five time and frequency domain kinematic features and a C4.5 decision tree classifier, average automated hand flapping and body rocking recognition rates of 89.5% in the laboratory and 88.6% in the classroom were achieved. Moreover, a direct replication wherein the same six individuals with ASD were observed three years later in their classrooms while wearing 3, 3-axis accelerometers to determine whether previously trained sensor-based classifiers maintain accuracy over time will be reported. Comparing automated recognition results for two different classifiers – Support Vector Machine and Decision Tree – using our previously established feature set yielded average accuracy across all participants over time ranging from 81.2% to 99.1% for all combinations of classifiers and features.
Conclusions: Identifying more objective and automated physiological and physical activity measures has the potential to transform our ability to better understand the pathophysiology of autism, enhance gold-standard assessments of ASD, aid in subtype identification, individualize treatment protocols, monitor treatment efficacy, and track developmental outcomes.

4:30 **158.004** Use of Biomarkers to Assess Outcomes in a Phase 1 Open Label Trial of Autologous Cord Blood in Young Children with Autism Spectrum Disorder

G. Dawson[1], *J. M. Sun*[2], *K. S. Davlantis*[3], *M. Murias*[4], *L. Franz*[4], *J. Troy*[2], *R. Simmons*[5], *M. Sabatos-DeVito*[6], *R. Durham*[7,8], *A. Song*[9] *and J. Kurtzberg*[2], *(1)Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (2)Department of Pediatrics, Duke University School of Medicine, Durham, NC, (3)Duke Center for Autism and Brain Development, Durham, NC, (4)Duke University, Durham, NC, (5)Department of Biostatistics, Duke University School of Medicine, Durham, NC, (6)Duke University Medical Center, Durham, NC, (7)Department of Pediatrics, Duke University, Durham, NC, (8)CT2, Duke University, Durham, NC, (9)Department of Radiology, Duke University School of Medicine, Durham, NC*

Background:
Umbilical cord blood (UCB) may facilitate neural cell protection/repair and reduce inflammation, resulting in improved social communication in children with autism spectrum disorder (ASD). We performed a phase I, open-label study of a single intravenous infusion of autologous UCB in young children with ASD and explored whether behavioral measures and neurophysiologic/imaging biomarkers could be utilized in a future Phase II, randomized trial.
Objectives:
To evaluate the safety of autologous UCB infusion and assess the feasibility and sensitivity to change of several validated behavioral outcome measures and eye-tracking and brain-based biomarkers in a Phase I clinical trial.
Methods:
We treated 25 children with ASD, 24-72 months of age. Diagnosis was based on ADOS-2 and ADI-R, and eligibility required a qualified banked autologous UCB unit. Participants were assessed at baseline, 6, and 12 months post-infusion with the Vineland Adaptive Behavior Scales-II (VABS), Clinical Global Impression (CGI), Pervasive Developmental Disorder Behavior Inventory (PDDBI; also at 3 months), and Expressive One Word Picture Vocabulary Test (EOWPVT). The eye tracking task was a dynamic video that included an actress making joint attention bids (ET; Regions: actress, eyes, mouth and face). MRI with DTI and EEG while viewing dynamic social and nonsocial stimuli were conducted. Adverse events were monitored. Statistical significance of change on VABS, CGI, and EOWPVT was evaluated using the Wilcoxon signed-rank test. A linear spline was fit for the PDDBI, and ET was analyzed using logit-link generalized estimating equations.
Results:
We observed improvements on the VABS socialization (median=2 points; range: -8, 30; P=0.016) and communication (median=4.5; range: -8.0, 20; P=0.002) standard scores, and the CGI-I indicated improvement on 13 patients (52%) from baseline to 6-months (P = 0.001). The PDD-BI Autism Composite, reflecting ASD symptoms, declined in the first 3 months (mean=7.52, 95% CI: -12.38,-2.67; P=0.004). A median change of 4 was observed on the EOWPVT from baseline to 6 months (range: -1, 24) and 5.5 points from 6-12 months (range: -12, 16) (P < 0.01 for both). A 20% increase in odds of gazing at the eyes over time was observed (odds ratio=1.20, 95% CI: 1.00, 1.43, P=0.048). A 7 point change in socialization standard score was associated with a 14% increase in odds of gazing at the actress (OR=1.14, 95% CI: 1.07, 1.21; P < 0.001). Changes in MRI fractional anisotropy were observed but were not significantly associated with the VABS socialization standard score (P = .067). Preliminary analysis of EEG showed significant increases in occipital alpha spectral power over time but no change in other anatomical brain regions. UCB infusion was well tolerated with no serious adverse events reported. Changes in outcomes were unrelated to number of hours of behavioral therapy outside the trial.
Conclusions:
Validated behavioral outcome measures and eye-tracking and neurophysiologic biomarkers were sensitive to change over a six-month period in an open-label study of the safety and feasibility of UCB infusion for ASD. These measures will be used in a larger, double-blind randomized trial investigating efficacy of UCB for reducing core symptoms of autism.

Panel Session
159 - Abnormalities of Neuronal Migration in Autism Spectrum Disorder
3:30 PM - 5:00 PM - Yerba Buena 9

Panel Chair: Manuel Casanova, *Greenville Campus Greenville Health Systems, University of South Carolina School of Medicine, Greenville, SC*

This panel will present tombstones of migratory abnormalities in the brains of ASD individuals. First, neuroimaging techniques have found a blurring of the gray/white matter junction. The blurring is the result of a migratory defect where cells going to the cerebral cortex get stuck in the subplate region. Second, we will explore the neuropathology of corpus callosum abnormalities in order to indicate that axonal guidance defects are closely related to abnormalities of neuronal migration, e.g., heterotopias, an increase in subpial neurons, and cortical malformations. These neuropathological findings have been reported in a significant number of ASD individuals. Third, diffusion tensor imaging (DTI) of the cerebral cortex of ASD individuals have shown abnormalities in diffusivity that correspond to minicolumnar disorganization. Lastly, during corticogenesis radially migrating neuroblasts interact with tangentially migrating neuroblasts to form physiological dyads. In ASD an apparent heterochonic migration of radial cells results in anomalous cellular dyads and a relative reduction of interneurons. The findings presented in this panel indicate that ASD is a neurodevelopmental disorder. The large variety of mechanisms involved in cellular migration as well as large time span that this process occupies during brain development may help explain some of the clinical heterogeneity observed in ASD.

3:30 **159.001** In Vivo Evidence of Reduced Integrity of the Grey-White Matter Boundary in Autism Spectrum Disorder

D. Andrews[1], *T. A. Avino*[2], *M. Gudbrandsen*[1], *E. Daly*[1], *A. Marquand*[3,4], *C. M. Murphy*[1,5], *M. C. Lai*[6,7,8], *M. V. Lombardo*[6,9], *A. N. Ruigrok*[6], *S. C. Williams*[4], *E. Bullmore*[10], *J. Suckling*[10], *S. Baron-Cohen*[6], *M. C. Craig*[1,5], *D. G. Murphy*[1,5] *and C. Ecker*[1,11], *(1)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Psychiatry & Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (3)Donders Institute for Brain, Cognition and Behaviour, Radbound University, Nijmegen, Netherlands, (4)Centre for Neuroimaging Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)National Autism Unit, Bethlem Royal Hospital, South London and Maudsley NHS Foundation Trust, London, United Kingdom, (6)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (7)Child and Youth Mental Health Collaborative at the Centre for Addiction and Mental Health and The Hospital for Sick Children, Department of Psychiatry, University of Toronto, Toronto, Canada, (8)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (9)University of Cyprus, Nicosia, Cyprus, (10)Brain Mapping Unit, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (11)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychiatry, Goethe-University Frankfurt am Main, Frankfurt, Germany*

Background: Histology studies have revealed abnormal cell patterning along the boundary between cortical layer VI and underlying white matter in Autism Spectrum Disorder (ASD) (Avino & Hutsler, 2010). These findings may be indicative of potential neural migration deficits in the condition. However, there are no *in vivo* studies that examine these particular features of cortical organization in ASD.
Objectives: The current study sought to replicate previous histology findings using *in vivo* neuroimaging based measures of grey-white matter signal intensity ratios (GWR). As individuals with ASD are thought to have less distinct grey and white matter boundaries we expected to find significant decreases in mean GWR amongst our ASD patients, including brain regions previously indicated by Avino & Hutsler (2010) as having abnormal cell patterning at the grey-white matter interface, namely the superior temporal gyrus, dorsolateral frontal lobe, and dorsal parietal lobe.
Methods: 98 right-handed adults with ASD (49 males & 49 females) and 98 matched typically developing controls (51 males and 47 females) aged 18-42 years were recruited and assessed (ICD-10, ADI-R, & ADOS) at the IoPPN, London, and the ARC, Cambridge. A quantitative T1-mapping MRI protocol (Deoni et al., 2008) was used to derive T1-weighted images. Tessellated cortical surface reconstructions were produced using FreeSurfer software (http://surfer.nmr.mgh.harvard.edu/). Tissue intensities were measured from at intervals from 10 to 60% into the thickness of the cortical ribbon from the pial surface for grey matter (G) and 1 mm subjacent to the grey-white boundary along the surface normal for white matter (W). GWR at each sampling depth was calculated as a percentage of grey to white matter contrast at each vertex (*i*): $100*(W_i-G_i)/0.5*(W_i+G_i)$ (Salat et al. 2009). GWR measures were subsequently smoothed using a 10mm FWHM Gaussian kernel. Vertex-wise statistical analysis of GWR was estimated by regression of a general linear model at each vertex with diagnostic group, sex, and site as categorical fixed-effects factors, and age and full scale IQ as continuous covariates. Corrections for multiple comparisons across the whole brain were performed using 'random field theory' based cluster analysis for non-isotropic images ($p<0.05$) (Worsley et al. 1999).
Results: When co-varing for the effects of biological sex, scanning site, age, and IQ, we found significant decreases in GWR measures in individuals with ASD compared to TD controls (RFT-based cluster-corrected, $p<.05$) in clusters centered on the parahippocampal gyrus (BA 36), fusiform gyrus (BA 20), inferior parietal lobule (BA 40), superior and middle temporal gyri (BA 21), and in the anterior cingulate (BA 32). As expected, these reductions were greatest when tissue intensities were sampled close to grey-white matter interface, which indicates a less distinct grey-white matter boundary in ASD.
Conclusions: Individuals with ASD have reductions in GWR measures in several brain regions across the cortex, which have previously been implicated in ASD. Our findings indicate that the boundary between grey and white matter in these regions is less distinct in ASD, which supports previous histology studies suggesting that ASD is associated with potential neural migration deficits in the brain.

3:50 **159.002** A Deficit of Long-Range Connectivity Due to Corpus Callosum Hypoplasia Is Present in Idiopathic and Syndromic (dup15) Autism

J. Wegiel[1], *W. Kaczmarski*[2], *T. Wisniewski*[3], *W. T. Brown*[4], *K. K. Chadman*[5], *E. London*[6], *K. Nowicki*[3], *I. Kuchna*[6], *S. Y. Ma*[3] *and J. Wegiel*[7], *(1)New York State IBR, Staten Island, NY, (2)Morphometry Laboratory, Institute for Basic Research, Staten Island, NY, (3)New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY, (4)Institute for Basic Research, Staten Island, NY, (5)New York State Institute for Basic Research, Staten Island, NY, (6)NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY, (7)NYS IBR, Warren, NJ*

Background: A reduced size of the corpus callosum (CC) is a common feature reported in neuroimaging studies in individuals diagnosed with autism (Minshew 2007, Frazier 2009) suggesting a deficit of long distance connectivity. Postmortem studies of the CC in idiopathic autism confirmed a reduced midsaggital area and explained neuroimaging findings by demonstrating a deficit of the total number of CC axons by 48.4% and axonal numerical density by 37% (Wegiel et al, submitted). We hypothesize that CC hypoplasia is a common marker of congenital abnormalities in autism regardless of disorder etiology.
Objectives: The aim of this postmortem study was to establish the type and topography of structural CC anomalies in individuals with dup(15), to compare patterns of CC pathology in dup(15)/autism and idiopathic autism, and to determine the contribution of this pathology to the deficit of long-distance connectivity and behavioral anomalies in these two groups.
Methods: Based on the results of clinical, genetic and neuropathological evaluations, eight brains of individuals with dup(15) were included in this study. Our preliminary evaluation had confirmed the diagnosis of dup(15) and autism, and revealed a high prevalence of epilepsy, microcephaly, focal defects of neuronal migration and dysplasia (Wegiel et al 2012). The brain hemispheres of eight individuals 5 to 39 years of age diagnosed with dup(15)/autism and 8 age-matched control subjects were fixed with formalin, dehydrated, embedded in polyethylene glycol, and cut into equidistant serial 50-µm thick sections. They were used to estimate the midsaggital area of the corpus callosum and the total number and numerical density of axons in five CC segments determined using Hofer and Frahm (2006) CC segmentation, which reflects the cortical distribution of neurons involved in CC formation and function.
Results: There was microcephaly with 20% less brain weight in dup(15)/autism than in control group (1,094g and 1354 g, respectively). Although the length of the CC was almost identical in these two groups (58 mm and 60 mm, respectively), the midsaggital area was 40% less in dup/15/autism than in control individuals (253 mm^2 and 419 mm^2, respectively). The total number of CC axons was 73% less in dup15/autism than in the control group (22 and 83 million, respectively) whereas the numerical density of axons (N/mm^2) was 52% less in the affected subjects than in control individuals (89,000 and 188,000, respectively). The significant deficit of the number of axons in all five CC segments corresponds to a severe deficiency of long distance connectivity of the prefrontal (segment I), premotor (II), motor (III), primary sensory cortex (IV), and the parietal, temporal and occipital cortex (V) in subjects with dup(15)/autism.
Conclusions: Finding similar patterns of developmental anomalies in dup(15)/autism and idiopathic autism indicate that reduced sizes of the CC are consistent markers of congenital brain defects in both autism with genetic and idiopathic etiologies. The results suggest that dup(15) has a direct contribution to both CC hypoplasia and the autistic phenotype.

4:10 **159.003** Altered Cellular Organisation in the Cerebral Cortex: A New Imaging Measure of Cortical Microstructure to Meet the Challenge of Heterogeneity in Autism

S. Chance[1]*, M. Torso*[2]*, R. McKavanagh*[3]*, M. Ravishankar*[3]*, K. Miller*[2]*, S. Sunaert*[4] *and M. Jenkinson*[2]*, (1)John Radcliffe Hospital, Oxford, Oxfordshire, UNITED KINGDOM, (2)University of Oxford, Oxford, United Kingdom, (3)University of Oxford, Oxford, UNITED KINGDOM, (4)University of Leuven, Leuven, BELGIUM*

Background: The key neuropathological findings include altered cortical minicolumns, reductions in cortical interneurons, cerebellar Purkinje cells and various dysplasias. Several theories attempt to integrate these findings but are challenged by the underlying heterogeneity of this condition. Until now, brain microanatomy has only been assessed in post-mortem or in vitro samples whereas macrostructure and cognition has been assessed in living people. It is desirable to identify a marker of microscopic cortical organisation in the same living populations as studied by cognitive neuropsychology.
Objectives: 3 experiments were conducted to confirm the utility of a new MRI measurement of diffusivity applied to the grey matter of the cerebral cortex.
Methods: The newly developed 'CHIPS' (Cortical High-Intensity Profile Segmentation) software was used to calculate several unique measures by comparing diffusivity data with the minicolumn axis in the cortex, derived from DTI of cortical grey matter.
i) *Post-mortem* MRI was conducted to validate the DTI signal as an index of minicolumn alteration by comparison with histological measurements from the identical region. 6 ASD and 6 TD control brains were studied.The 3T MRI acquisition protocol on formalin-fixed tissue included: Modified spin-echo sequence with 3D segmented-EPI, and Structural 3D balanced steady state free precession (BSSFP) sequence. Semi-automated analysis of minicolumns on histological brain sections was conducted using light microscope digital photomicrographs for comparison with semi-automated CHIPS measurements. Five different cortical regions were examined including prefrontal cortex and primary visual cortex.
ii) *Discovery cohort - in vivo* 7T DTI acquisitions were conducted in Oxford, UK. Data was collected from a final sample of 10 TD individuals and 10 ASD (intellectually able and/or Asperger's). Automated whole brain CHIPS analysis was conducted and a VBM analysis was also performed on the accompanying structural scans.
iii**)** *Test Cohort – in vivo* 3T DTI data from 24 TD controls and 20 ASD participants acquired in Leuven, Belgium. Automated whole brain CHIPS analysis was conducted and a VBM analysis was also performed on the accompanying structural scans.
Results:
i) The post-mortem DTI confirmed the predictions of the model indicating a clear correlation between new minicolumn diffusion measures and histological minicolumn width across both diagnostic groups. Also a significant difference in the minicolumn diffusion angle between TD and ASD in brain regions with wider minicolumns. Both effects were evident in all cortical regions assessed.
ii) The high resolution in vivo DTI found a difference in the components of diffusion which indicated wider minicolumns in ASD yielding clear separation of diagnostic groups for 18/20 participants (90% classification accuracy).
iii) The 3T DTI results found CHIPS cortical diffusivity values yielding clear separation of diagnostic groups for 42/44 participants (95% classification accuracy).
Conclusions: Diffusivity parameters in the cerebral cortex correspond to variation in the minicolumnar organisation of neurons spanning the cortical layers. Minicolumns are more widely spaced in several cortical regions in ASD and this can be detected using novel diffusivity measures. The detection of cortical microstructural changes in ASD using MRI opens the door to possible early assessment in young infants whose symptoms are unclear.

4:30 **159.004** Chandellier Cells Modify the Balance of Excitation/Inhibition in Autism

V. Martinez Cerdeno*, UC Davis, Sacramento, CA*

Background: An interneuron alteration has been proposed as a source for the modified balance of excitation/inhibition in the cerebral cortex in autism. We previously demonstrated a decreased number of parvalbumin (PV)-expressing interneurons in prefrontal cortex in autism. Our most recent data indicates that a specific type of PV-expressing neuron is altered in autism, the Chandellier (Ch) cell. Chandellier cells are interneurons that generate fast-spiking action potentials and synchronize the activity of numerous pyramidal cells through rhythmic inhibition. Chandellier cells innervate the axon initial segment of pyramidal cells – in contrast to the rest of interneuron input that takes place on dendrites. As a consequence, the loss of small numbers of Ch cells could critically alter pyramidal neuron output and impair cerebral cortex function.
Objectives: As discussed in our previous publication investigating PV+ interneurons in the autistic neocortex (Hashemi et al., 2016), the decreased number of PV+ Ch cells we detected in in autism may represent an actual decrease in cell number, on the other hand it may represent an apparent decrease in cell number resulting from reduced PV protein levels in Ch cells. To determine if the number of Ch cells, rather that the expression of PV by Ch cells, is altered in autism, we quantified Ch cartridges in autism and control tissue. If the number of Ch cells is decreased we also expect to find a decrease in the number of Ch cartridges.
Methods: We collected prefrontal BA9, BA46, and BA47 in samples obtained from 10 autism, 10 autism with seizure, and 10 control age-matched cases. The tissue was obtained from the Autism Tissue Program (ATP), currently known as Autism BrainNet, and the UC Davis Medical Center. We cut the tissue and performed immunostaining for GAT1 that clearly labels cartridges. We quantified the number of cartridges in 3 mm wide sections of cortex, and statistically compared data between groups.
Results: Our preliminary data indicate that in area BA 46 there is a decrease in the number of GAT1-cartriges in the autism and the autism with seizure groups when compare to the control group.
Conclusions: Here we demonstrated that both Ch cells and also their terminal axons, the Ch cartridges, are numerically decreased in autism. A decrease in the number of Ch cells could result from different factors including 1) decreased production of Ch cells by precursor cells during prenatal development, 2) increased cell death among Ch cells during development, or 3) altered migration of Ch cells to their final destination in the cerebral cortex. This finding expand our understanding of GABAergic system functioning in the human cerebral cortex in autism, which will impact translational research directed towards providing better treatment paradigms for individuals with autism.

Poster Session
160 - Brain Function (fMRI, fcMRI, MRS, EEG, ERP, MEG) II
5:00 PM - 6:30 PM - Golden Gate Ballroom

1 **160.001** A Functional Connectivity-Based Evaluation of Competing Models of Sex Differentiation and Autism

D. L. Floris[1], *M. C. Lai*[2], *T. Nath*[1], *M. P. Milham*[3] *and A. Di Martino*[1], *(1)NYU Child Study Center, New York, NY, (2)Psychiatry, University of Toronto, Toronto, ON, CANADA, (3)Institute for Pediatric Neuroscience, NY, NY*

Background: Accumulating evidence suggests that mechanisms regulating normative sex differences may be related to etiological mechanisms of autism spectrum disorder (ASD) (Lai et al., 2015). Two models have emerged: 1) the Extreme Male Brain theory (EMB) (Baron-Cohen 2002) suggesting that autism is related to hyper-masculinization, regardless of sex, and 2) the Gender Incoherence theory (GI) suggesting that females with ASD are masculinized, whereas males with ASD are feminized (Bejerot et al., 2012). While these models have been supported by evidence from the cognitive, physiological and brain structural imaging domains, to date no resting-state fMRI (R-fMRI) studies have compared them formally.
Objectives: We aimed to systemically examine whether regions of atypical intrinsic functional properties in ASD overlapped with regions showing normative sex differences.
Methods: We used data from two large previous R-fMRI studies: one showing normative sex differences (males (M)=471; females (F)=357; age=8-85 years; Yan et al., 2013), the other revealing atypical connectivity in males with ASD (neurotypical controls (NT)=403; ASD=360; age range=6-58 years; Di Martino et al., 2014). We examined five R-fMRI measures that have been shown to be affected in ASD (Di Martino et al., 2014) and to have distinct patterns by sex (Yan et al., 2013). These included degree centrality, fractional amplitude of low frequency fluctuations, regional homogeneity, voxel-mirrored homotopic connectivity and posterior cingulate cortex seed-based correlation. Spatial overlap analyses were performed by conjunction analyses of the statistical maps from the above studies. Four pairs of contrasts were examined: ASD>NT & M>F (EMB 1); NT>ASD & F>M (EMB 2); ASD>NT & F>M (GI 1); NT>ASD & M>F (GI 2). To test for significance of overlaps, we computed the null distribution of random spatial overlap via Monte Carlo simulations (5000 iterations) for 500 voxel-level thresholds ranging from p=0.0001 to p=0.05 (Lai et al., 2013). To address confounds related to differing preprocessing pipelines and demographics, secondary analyses were conducted in three different samples by a) aligning the preprocessing pipelines using the Configurable Pipeline For The Analysis of Connectomes, b) adjusting for differences in age using sub-samples (17.5-37 years) and c) replicating results using an independent sex difference sample (M=320; F=422; age range=17-35 years) based on the Brain Genomics Superstruct Project database.
Results: Across all R-fMRI measures, there were consistent and non-random overlaps above the 99th percentile of the null distribution between regions showing normative sex differences and those showing ASD-NT differences. Regions consistent with the EMB model were mainly in the default network (DN) bilaterally. In contrast, regions consistent with the GI model mostly encompassed left somatomotor, ventral attention and posterior auditory systems. Results were confirmed with all secondary analyses.
Conclusions: Here, we provide evidence for both EMB and GI models, both of which vary as a function of the neural system involved. Notably, aspects previously reported in ASD such as hypoconnectivity in the DN and posterior language regions may be regulated by atypical sexual differentiation in males with ASD. Future work is warranted to extend current analyses to females with ASD.

2 **160.002** A Preliminary Magnetic Resonance Spectroscopy Investigation Sex Differences in Gamma-Aminobutyric Acid in Autism Spectrum Disorder

M. Kirkovski[1], *C. Suo*[2], *P. G. Enticott*[1], *M. Yucel*[2] *and P. Fitzgerald*[2], *(1)Deakin University, Geelong, AUSTRALIA, (2)Monash University, Melbourne, Australia*

Background: The right dorsolateral prefrontal cortex (rDLPFC) and the right superior temporal sulcus (rSTS) have been implicated in social processing in autism spectrum disorder (ASD). Moreover, there is growing interest in the role of biological sex in ASD, and evidence to suggest that this might contribute to the heterogeneous nature of ASD. While the etiology of ASD remains unknown, it has been suggested that an imbalance of cortical inhibition/excitation might be associated with some of the neurobiological underpinnings of ASD. Recent research has associated gamma-aminobutyric acid (GABA, a major inhibitory neurotransmitter) concentration with the severity of ASD characteristics.
Objectives: This study uses magnetic resonance spectroscopy (MRS) to investigate sex differences in GABA concentration (mM/L) between adults with ASD and typically developing controls. Further, this study investigates the relationship between GABA concentration at the rDLPFC and rSTS, and traits and characteristics associated with ASD.
Methods: Â GABA was measured as part of a large protocol using a 3T magnetic resonance imaging (MRI) scanner. Voxels were placed at the rDLPFC and rSTS based on the participant's structural MRI. rDLPFC GABA concentration was obtained for 25 participants (9 ASD, 16 NT), and rSTS GABA concentration was obtained for 26 (12 ASD, 14 NT) participants. Data were analyzed using LCModel software.
Results: Â There were no differences in GABA concentration at either of these sites between groups, nor when data were stratified by sex. Following correction for multiple comparisons, there was a significant positive relationship between GABA concentration at the rSTS and social impairment in females with ASD.
Conclusions: Â Although inconsistent with a GABAergic model of autism, these findings provide preliminary support for sex differences in neurochemical mechanisms underlying social cognition in ASD.Â

3 **160.003** Abnormal Functional Activation and Maturation of Ventromedial Prefrontal Cortex and Cerebellum during Temporal Discounting in Adolescents and Adults with Autism Spectrum Disorder: A Cross-Sectional Developmental fMRI Investigation

C. M. Murphy[1], *A. Christakou*[2], *E. Daly*[3], *C. Ecker*[4], *P. Johnston*[5], *V. Giampietro*[6], *M. Brammer*[7], *D. Robertson*[8], *D. Spain*[2], *M. Consortium*[9], *D. G. Murphy*[3] *and K. Rubia*[10], *(1)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)King's College London, Institute of Psychiatry,, London, UNITED KINGDOM, (3)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychiatry, Goethe-University Frankfurt am Main, Frankfurt, Germany, (5)Institute of Psychiatry, King's College London, London, UNITED KINGDOM, (6)Department of Neuroimaging, The Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (7)Institute of Psychiatry, Psychology and Neuroscience, London, UNITED KINGDOM, (8)Sackler Institute for Translational Neurodevelopment and Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (9)Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (10)Department of Child & Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:
People with autism spectrum disorder (ASD) report having problems with, and avoidance of, decision making and have poor temporal foresight. This may adversely impact on their everyday life, mental health and productivity. However, the neural substrates underlying poor choice behaviour in people with ASD, or its' neurofunctional development from childhood to adulthood, are unknown. Despite evidence of atypical structural brain development in ASD, investigation of functional brain maturation in people with ASD is lacking.
Objectives:
1. To investigate the neural substrates underlying performance on a temporal discounting task in 38 healthy (11 - 35 years old) male adolescents and adults with ASD and 40 age, sex and IQ-matched typically developing healthy controls using fMRI.
2. To assess group differences in the neurofunctional maturation of temporal discounting across childhood and adulthood using cross-sectional fMRI investigation.
Methods:
The fMRI temporal discounting task measures the choice between a small reward that is immediately available or a larger delayed reward and requires both inhibition of immediate reward and temporal foresight (forward thinking/future consideration of current choice).
Seventy eight right handed medication-naive healthy adolescent and adult males with IQ > 70 (N = 38 with non-comorbid ASD and N = 40 age and IQ matched typically developing controls) completed the event related fMRI temporal discounting task on a 3T MRI scanner (General Electric, Milwaukee, USA).
fMRI data analyses compared groups in brain activation and tested for group by age interaction effects using non-parametric fMRI data analyses (XBAM: www.brainmap.co.uk). Correlations were tested between performance measures and ASD severity measures and brain activation differences.
Results:
Males with ASD had significantly poorer task performance and significantly lower brain activation in typical right hemispheric regions that mediate temporal discounting for delayed choices, including right ventrolateral, dorsolateral and ventromedial prefrontal cortices, striato-limbic regions and cerebellum. Importantly, differential activation in ventromedial frontal cortex and cerebellum was associated with abnormal functional brain maturation; controls, in contrast to people with ASD, showed progressively increasing activation with increasing age in these regions; which furthermore was associated with task performance and clinical severity measures of ASD (stereotyped/restricted interests).
Conclusions:
This cross-sectional develomental fMRI investigation provides first evidence that reduced activation in people with ASD of ventromedial frontal and cerebellar brain regions that typically mediate temporal discounting is associated with, and may be caused by, abnormal functional brain development in these regions between childhood and adulthood. Furthermore, both abnormal activation and functional maturation appear to be related to poor task performance and clinical severity of ASD.

4 **160.004** Abnormal Functional Connectivity Underling Social-Communicative Impairments in Autism Spectrum Disorder

F. Zhang[1,2], *H. Roeyers*[2], *G. Feng*[1,3] *and S. Wang*[1], *(1)School of Psychology, South China Normal University, Guangzhou, China, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (3)University of Texas at Austin, Austin, TX*

Background: Researchers have gained interest on aberrant functional connectivity (FC) in Autism Spectrum Disorder (ASD) over the past decade. However, it is still unclear whether and how abnormal FC between different brain networks is associated with their behavioral impairments. Two key brain networks, default mode network (DMN) and fronto-parietal control network (FPC), are proposed to be associated with social-communicative functions in typical populations. Abnormal FC within these two networks was found recently.
Objectives: Here, we investigated whether the FC between these two networks relates to the social-communicative impairments in ASD by using both group comparison and correlation of individual differences.
Methods: We selected 112 subjects (56 with ASD and 56 typically developing (TD), mean age 19.16 years) from The Autism Brain Imaging Data Exchange (ABIDE) with strict criteria (e.g., matched age, gender and IQ) . We analyzed the resting-fMRI dataset and calculated three brain measures, including a) the amplitude of low frequency fluctuation (ALFF), which reflected the local neuronal activity; b) regional homogeneity (ReHo), which reflected the local FC, c) and FC, which reflect interregional FC strength, in both groups. We compared both groups on these brain measures, and estimated to what extent the degree of FC correlates with the individual differences of social-communicative scores, assessed by ADOS.
Results: The main findings are as follows: (1) we observed increased ReHo in the right middle frontal gyrus (RMFG) in the ASD group. Within the ASD group, individual differences of ReHo in the RMFG ($r = 0.43$, $p < .005$), right superior frontal gyrus (RSFG) ($r = 0.38$, $p < .005$) and right middle temporal gyrus (RMTG) ($r = 0.36$, $p < .005$) were positively correlated with the individual differences of social-communicative deficit. In contrast, the ReHo in the PC ($r = -.45$, $p < 0.001$) showed a negative correlation with the social deficit in the ASD group. (2) We further found that the FC between PC, RSFG (two key regions in the DMN) and the lateral RMFG (a key brain region in the control network) were associated with social impairment. Specifically, the FC between the RMFG and the PC was negatively related to the social symptoms in ASD ($r = -.35$, $p < .01$). (3) We did not find any ALFF group differences. However, individual differences of ALFF in the RMFG ($r = 0.44$, $p < 0.001$), RSFG ($r = 0.39$, $p < .005$), RMTG ($r = 0.4$, $p < 0.001$), and posterior cingulate (PC) ($r = -.42$, $p = .001$) showed significant correlations with the individual differences of social deficit for the ASD group.
Conclusions: Our findings support our hypothesis that abnormal inter-network FC was showed in the ASD group as compared to the TD group. Specifically, the abnormal social-communication functions in autism were highly related to the functional connectivity between the DMN and CN, two key brain networks supporting social and communicative behaviors in typical populations. In summary, our study provided further evidence for the neurophysiological basis of the social barriers in ASD.

5 **160.005** Alterations in Brain Entropy in Autism Spectrum Disorders

J. O. Maximo[1], *D. L. Murdaugh*[1,2] *and R. K. Kana*[1], *(1)University of Alabama at Birmingham, Birmingham, AL, (2)Children's Healthcare of Atlanta, Atlanta, GA*

Background: Biological systems typically exhibit complex behavior with nonlinear dynamic properties. Nonlinear signal processing techniques such as sample entropy is a novel approach to characterize the temporal dynamics of the brain. Estimating entropy, the state of uncertainty of a system, is especially important in clinical populations such as autism spectrum disorders (ASD) as higher entropy would entail brain disease. Considering the models of atypical brain network connectivity in ASD, sample entropy would provide a novel dimension to understand brain organization.
Objectives: The main objective of this study is to examine the alterations in brain entropy in resting state functional MRI data in children with ASD. We hypothesize increased brain entropy in children with ASD compared to typically developing (TD) children.
Methods: Resting state fMRI data collected from 22 high-functioning children with ASD and 18 age-and-IQ-matched TD children were preprocessed using the CONN toolbox. This consisted of motion correction, normalization to MNI template (3mm isotropic voxels), spatial blurring (6mm), low-pass filtering ($.008 < f < .08$ Hz), CompCor (a method for identifying principal components associated with white matter and cerebrospinal fluid, CSF), and scrubbing using the ART toolbox. White matter and CSF were entered as nuisance variables along with motion parameters and outliers of head motion detected by ART. Sample entropy was then calculated in a whole-brain voxelwise manner for all subjects with the following parameters based on a previous study (Sokunbi et al., 2013; $r = 0.46$ and $m = 2$). Group differences were assessed using a two-sample *t*-test, and brain-behavior correlations were calculated using sample entropy, Social Communication Questionnaire (SCQ), and Social Responsiveness Scale (SRS) scores from all subjects.
Results: The main results are: I) significantly increased sample entropy in ASD, relative to TD in bilateral insula and right calcarine sulcus; II) significantly reduced sample entropy in ASD, relative to TD in left middle temporal gyrus; and III) positive correlations of average sample entropy in clusters of significant group differences (insula, calcarine sulcus) with SCQ ($r = 0.71$, $p < 0.001$) and SRS ($r = 0.63$, $p < 0.001$) scores across all subjects respectively were found.
Conclusions: Higher sample entropy found in insula and calcarine sulcus in ASD children indicate increased randomness of a system, meaning the dynamic system activity is less predictable and less organized. This might also reflect abnormal brain response in ASD, particularly in visual and salience networks (Samson et al., 2012; Uddin et al., 2013). These findings are consistent with altered sample entropy previously reported in clinical populations such as schizophrenia (Sokunbi et al., 2014), and ADHD (Sokunbi et al., 2014). The correlation of increased sample entropy with ASD symptoms in our study underscores the clinical implications of this neurobiological index.

6 **160.006** Autistic Traits Modulate Gaze and Neural Activity in Constrained Versus Unconstrained Conditions

K. Stinson[1], *S. A. A. Chang*[2], *S. M. Malak*[3], *J. A. Trapani*[3], *J. McPartland*[3] *and A. Naples*[4], *(1)Yale University- Child Study Center, New Haven, CT, (2)Yale University, New Haven, CT, (3)Child Study Center, Yale School of Medicine, New Haven, CT, (4)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Individuals affected by autism spectrum disorder (ASD) often display differences in cognitive control and flexibility which are measured reliably via electroencephalography (EEG) from frontal brain areas. Despite the ostensible ease of resting EEG paradigms, the cognitive demand to maintain fixation on a computer screen elicits differential brain activity in individuals with varying levels of cognitive control and behavioral rigidity. Brain activity via EEG, and gaze patterns, acquired via eye-tracking (ET), can provide information about relationships between behavioral measures, cognitive rigidity and biological states of visual hyposensitivity.
Objectives: Using concurrent ET and EEG recordings, we compared gaze behavior and spectral power between resting experiments where participants were free to look anywhere on a screen (unconstrained) and were required to maintain gaze on a fixation point (constrained). We explored the differential impact of how maintaining fixation affects its relationship with gaze, neural response and autistic traits.
Methods: Resting EEG data was recorded from 10 TD adults (data collection is ongoing) using a 128-channel sensor net. ET was acquired with an EyeLink-1000 camera system. Participants completed: (1) a 2-minute non-constrained viewing task in which they viewed a blank, gray colored screen; (2) a 2-minute constrained viewing task in which they were prompted to maintain gaze for 2 minutes within a dark square in the center of a light background. Self-report measures of behavioral rigidity and other autistic traits included (Broad Autism Phenotype Questionnaire; BAPQ) and sensory behavior (Glasgow Sensory Questionnaire; GSQ).
Results: Constrained vs. unconstrained viewing conditions demonstrated an overall reduction of delta power by 20%. Lateralized posterior beta power positively correlated with rigidity as measured by the BAPQ (left: r=.658, p=.039; right: r=.642, p=.045). Fixation duration in unconstrained contexts correlated negatively with visual hyposensitivity (r=-.646, p<0.05). Central and midline gamma during unconstrained viewing correlated with elevated levels of visual hyposensitivity (central: r=.723, p=.018; midline: r=.719, p=.019). Pupil diameter in unconstrained viewing correlated positively with visual hyposensitivity (r=.655, p<0.05).
Conclusions: Our data shows that differing relationships between brain activity, attention and autistic traits are revealed and dependent upon task demands in a resting context. Additionally, observations of pupil diameter during constrained conditions suggested that increased arousal is reflective of higher behavioral rigidity when instructed to maintain gaze. Increased fixation duration in unconstrained contexts indicates higher levels of attention amongst individuals with self-reports of high behavioral rigidity. This study highlights the importance in understanding the relationship of some observable behaviors and brain activity. By exploring the connections between gaze behaviors, brain activity and the clinical phenotype of ASD under differing task demands, we elucidate the extent to which brain and behavior differences reflect stable individual differences (trait) versus task dependent effect (state). These findings will guide the development of novel and appropriate methods for measuring brain activity in individuals with ASD.

7 **160.007** Behavioral Response Error Monitoring and Correction Function Deficits in Autism

G. Sokhadze[1]*, E. M. Sokhadze*[1]*, D. P. Kelly*[2] *and M. F. Casanova*[3]*, (1)University of Louisville, Louisville, KY, (2)Pediatrics, Greenville Health System, Greenville, SC, (3)Greenville Campus Greenville Health Systems, University of South Carolina School of Medicine, Greenville, SC*

Background: Error monitoring and correction is one of the executive functions and is important for effective goal directed behavior. Deficient executive functioning, including reduced error monitoring ability, is one of the typical features of such neurodevelopmental disorders as autism resulting in perseverative responding, stereotyped repetitive behaviors, and an inability to accurately monitor ongoing behavior. Our prior studies of behavioral and event-related potential (ERP) measures during performance on three-stimuli visual oddball tasks in high-functioning autistic (HFA) children showed that despite only minor differences in reaction times HFA children committed significantly more errors.
Objectives: The main goal of the study was to compare behavioral responses and error-monitoring correcting functions in children with ASD and typically developing children.
Methods: This study investigated error monitoring in children with autism spectrum disorder (ASD) with response-locked event-related potentials - the error-related negativity (ERN) and error-related positivity (Pe) recorded at fronto-central sites using dense-array Electrical Geodesics EEG Net Sensor system . The ERN reflects early error detection processes, while Pe has been associated with more late conscious error evaluation and attention re-allocation. Reaction times (RT) in correct trials and post-error slowing in reaction times was measured. Fourteen subjects with ASD and 14 age- and IQ- matched controls were administered a three-category visual oddball task with novel distracters.
Results: The analysis of data showed that the ERN and the Pe component of the response-locked ERP were substantially decreased in children with autism as compared to typical controls. The ERN had lower amplitude and longer latency in ASD group but localized in the caudal part of anterior cingulate cortex (ACC) in both groups. The Pe component was significantly prolonged but did not reach significant amplitude differences in ASD group compared to controls. We found significant post-error slowing in RTs in controls, and post-error acceleration in RTs in ASD group.
Conclusions: The reduced ERN and altered Pe along with a lack of post-error RT slowing in autism might be interpreted as an insensitivity to detect and monitor response errors and reduced ability of execute corrective actions. This might result in reduced error awareness and a failure in adjustment when dealing with situations where erroneous responses may occur. This deficit might be manifested in the perseverative behaviors often seen in individuals with ASD. The results are discussed in terms of a general impairment in self-monitoring and other executive functions underlying behavioral and social disturbances in ASD.

8 **160.008** Bias Towards within-Network Functional Connectivity Among Toddlers with ASD during Resting State

M. C. Datko[1]*, M. V. Lombardo*[2,3]*, L. T. Eyler*[1]*, K. Pierce*[1] *and E. Courchesne*[1]*, (1)University of California, San Diego, San Diego, CA, (2)University of Cambridge, Cambridge, United Kingdom, (3)University of Cyprus, Nicosia, Cyprus*

Background: While a small number of studies in younger participants suggest that atypical network connectivity patterns observed in adults with ASD begin much earlier in development (Dinstein et al., 2011; Lombardo et al., 2015; Shen et al., 2016), no studies have specifically investigated how the complex changes in within- and between-network connectivity dynamics previously observed in typically developing (TD) infants and toddlers (Gao et al., 2016) may differ in ASD. Of particular importance are examinations of resting state networks that develop in early life, such as primary sensory networks, as well as the default mode network (DMN), which is thought to be the cornerstone of self-referential processing and has previously been shown to have atypical connectivity in adults with ASD.
Objectives: Using resting state fMRI, we compared brain network connectivity between a group of ASD toddlers (N=47, mean age=26.5, range=14.2-44.1) and matched group of TD toddlers (N=47, mean age=26.5, range=13.2-44.5). We first compared connectivity between nodes across several networks on a node-to-node basis. We then compared the balance of within-network to between-network connectivity. Finally, we tested whether the developmental trajectories of brain connectivity differ between ASD and TD groups over the age range of our participants.
Methods: With resting state fMRI time series extracted from the set of 264 spherical ROIs (Power et al., 2011), we conducted mass univariate testing using the Network Based Statistic method (Zalesky et al., 2010). Next, using resting state fMRI time series extracted from a set of 333 ROIs based on a functional cortical parcellation map (Gordon et al. 2014), we defined within-network connectivity (WNC) for each network as the average of correlations between each pair of seeds belonging to a network. We defined between-network connectivity (BNC) for each network as the average correlation between each seed of that network and each other seed in all other networks. The Within-Network Bias (WNB) for each network was then calculated as the percentage of the total strength of all of its connections (WNC+BNC) attributed to the strength of its WNC. Finally, we tested for interactions between age and WNB across networks and groups, using a GLM approach.
Results: Using NBS, we found a graph component consisting of 25 connections between 24 seed ROIs in which ASD showed significantly lower connectivity compared to TD (FWER-corrected p=0.0368). The 24 ROIs belonged to the following networks: 8 in DMN, 7 in salience, 4 in visual, 2 in cingulate-operculum, 2 in auditory, and 1 in subcortical (Figure 1). ASD showed significantly higher WNB across all networks compared to TD (p=0.006, Figure 2). In a series of follow-up GLMs examining the interaction of participant age and WNB for each individual network, there was a significant interaction between group and age for the auditory network (p=0.0428).
Conclusions: We found evidence for hypoconnectivity between DMN, visual, and salience networks, and a global bias towards within-network connectivity in ASD toddlers. Our results demonstrate developmental differences of large-scale brain network connectivity between typically developing toddlers and those in the pre- or early clinical stages of ASD.

9 **160.009** Characterizing the Heterogeneity in Autism Spectrum Disorder Using Brain Connectivity Underlying Social Cognition

M. Thye[1] *and R. K. Kana*[2]*, (1)Psychology, University of Alabama at Birmingham, Birmingham, AL, (2)University of Alabama at Birmingham, Birmingham, AL*

Background: Autism Spectrum Disorder (ASD) is characterized by deficits in theory-of-mind (ToM) which negatively impact social interaction. Previous neuroimaging studies have found alterations in ToM brain network in individuals with ASD. However, most of these studies rely on standard fMRI analyses which concatenate results to arrive at a group-level model that may not be reflective of many or most of the participants within a heterogeneous group. A novel approach to studying functional connectivity that accounts for the heterogeneity of ToM regions in an ASD population is the *Group Iterative Multiple Model Estimation* (GIMME) algorithm which reveals divergent subgroups based on patterns of functional connectivity among a priori regions of interest (ROI) using a structural equation modeling framework.
Objectives: To examine the nature and extent of neural heterogeneity across ASD and typically developing (TD) participants in an fMRI study of ToM processing.
Methods: A total of 63 participants (32 ASD and 31 age-and-IQ-matched TD) between the ages of 10 and 36 years took part in this fMRI study. In the scanner, participants watched animations of geometrical shapes depicting ToM. ROIs were derived from a *Neurosynth* mask based on previous studies of ToM and included: left and right inferior frontal gyrus (LIFG; RIFG), left precuneus (LPCUN), left and right posterior superior temporal sulcus (LpSTS; RpSTS), and medial prefrontal cortex (MPFC). Based on the fMRI time-series information extracted from each ROI during the ToM condition, GIMME identifies the presence and direction of connections among the ROIs to arrive at a group level model that is then tested at the individual level to determine if subgroups exist within the data that differ from the group model.
Results: A group connectivity map was found with connections from MPFC to LIFG, LpSTS to MPFC and to LPCUN, and RpSTS to LpSTS. Within the ToM condition, two functional connectivity-based subgroups were identified: Subgroup A comprising 28% of the ASD and 39% of the TD participants was characterized by increased connectivity from LPCUN to RpSTS as well as increased connectivity from MPFC to RIFG. Conversely, Subgroup B which contained 72% of the ASD and 61% of the TD participants showed comparatively weaker connectivity with no additional pathways emerging above the group level model. Statistical comparisons of the individuals comprising the two subgroups revealed stronger connectivity of the group level connection from LpSTS to MPFC in Subgroup A compared to Subgroup B (t_{61} = -3.118, p< .05). No group level paths were stronger for Subgroup B.
Conclusions: The pattern of results within the ToM condition suggests possible underconnectivity in the group containing the largest percentage of ASD participants. The GIMME algorithm, which is blind to diagnostic classification, was able to detect the presence and direction of connections within a heterogeneous sample during a task-based fMRI study of ToM. The findings of this study are preliminary, and there are several follow-up analyses planned. These results should be examined further in the context of the diagnostic and demographic makeup of the subgroups.

10 **160.010** Comparison of Functional Connectivity Abnormalities in Autism and Williams Syndrome

J. S. Anderson[1]*, L. Dai*[1]*, M. D. Prigge*[1]*, M. South*[2]*, J. B. King*[3] *and J. R. Korenberg*[4]*, (1)University of Utah, Salt Lake City, UT, (2)Psychology and Neuroscience, Brigham Young University, Provo, UT, (3)Program in Neuroscience, University of Utah, Salt Lake City, UT, (4)Pediatrics, University of Utah, Salt Lake City, UT*

Background: Williams Syndrome and autism both exhibit characteristic social impairments, but differ in the specific social phenotype, with autism exhibiting social avoidance and Williams Syndrome exhibiting enthusiasm for social engagement but impaired skills in social interaction and also associated cognitive impairment. Differences in relationships between social brain regions in each condition may offer clues to how these divergent social impairment phenotypes may arise.
Objectives: We compared brain functional connectivity within the social brain for a large subset of autism patients from the ABIDE dataset and a smaller group of individuals with Williams Syndrome as well as individuals with typical development obtained locally.
Methods: Functional connectivity MRI measurements were performed during viewing of Looney Tunes cartoon videos in 13 subjects with Williams Syndrome and 10 typically developing subjects, grouop matched for age and sex (age range 14-35). Each subject viewed up to 7 cartoons of 7 minutes each, for a total of 67 7-minute scans in controls and 71 7-minute scans in Williams Syndrome participants. Imaging was acquired using multiband BOLD protocol on a Siemens Trio 3T scanner (TR = 730 ms, 2 x 2 x 2 mm resolution, 32 channel head coil). Postprocessing included motion correction, coregistration to MP2RAGE anatomic image, normalization to MNI space, and voxelwise regression of degraded ROIs within white matter, CSF, facial soft tissues, and time series from heart rate and respiratory waveforms obtained during scanning. Time series were extracted for 333 cortical regions parcellating cortical gray matter, 14 subcortical regions obtained from FreeSurfer-derived subject-specific segmentation of deep gray nuceli, and 14 cerebellar ROIs. Functional connectivity was measured in each pair of ROIs. Independently, functional connectivity was measured from the ABIDE dataset consisting of 972 autism and control subjects acquired from multiple sites with conventional resting state acquisition. Postprocessing was analagous with exception of heart rate and respiratory waveform regression. Regions showing connectivity abnormalities in each dataset were compared to a map of the social brain obtained from a reverse inference from the NeuroSynth.org website for the term "social," identifying regions significantly associated with the term social in the functional neuroimaging literature. Significant differences in connectivity were established using false discovery rate correction for multiple comparisons across all region pairs.
Results: Individuals with Williams Syndrome, compared to typically developing controls, exhibited widespread, significant decreases in cortico-cortical and cortico-subcortical connectivity. Regions most frequently involved in atypically decreased connectivity in Williams Syndrome included hubs of the social brain: medial prefrontal, inferior parietal, superior temporal sulcus, and amygdalar regions. Individuals with autism showed similar regions of greatest cortical underconnectivity, but also exhibited additional atypical connections not seen in Williams Syndrome, including decreased left-right homotopic connectivity and increased connectivity between default mode and salience networks.
Conclusions: We observe similar underconnectivity of social brain regions in Williams Syndrome and autism, but with differences in the functional connectivity pattern: homotopic underconnectivity, corticostriatal overconnectivity, and increased connectivity between default mode and attentional networks in autism, but more widespread corticocortical underconnectivity in Williams Syndrome. Such differences may contribute to differences in social impairment phenotype between the two conditions.

11 **160.011** Comparison of Neural Response to Language in Infants at Elevated Risk for ASD and in Infants with Nonsyndromic Craniosynostosis

A. H. Sun[1,2], *M. J. Rolison*[3], *T. A. Halligan*[1], *C. Chuang*[1,2], *J. F. Yang*[2], *P. Hashim*[2], *K. Chawarska*[1], *D. M. Steinbacher*[2], *N. Landi*[4], *L. Mayes*[1], *J. A. Persing*[2] *and J. McPartland*[1], *(1)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Section of Plastic and Reconstructive Surgery, Yale School of Medicine, New Haven, CT, (3)Child Study Center, Yale School of Medicine, New Haven, CT, (4)Haskins Laboratories, Yale University, New Haven, CT*

Background: Autism spectrum disorder (ASD) is characterized by impaired social interaction and communication. While language skills vary widely among individuals with ASD, language delay in infants is an important prognostic feature of ASD severity. The study of auditory event-related potentials (ERPs) in infants at high-risk for ASD (HR-ASD) has demonstrated atypical responses in several ERP components compared to typically-developing (TD) controls. To better understand the specificity of atypical neural response to language in ASD, clinical comparisons are needed. Nonsyndromic craniosynostosis (NSC), a congenital disorder characterized by the premature fusion of cranial vault sutures, is associated with impairments in learning and language that may resemble the deficits found in ASD. Mismatch negativity (MMN), an ERP component found between 80-300ms, has been used to index language acquisition via the phenomenon of perceptual narrowing.
Objectives: To compare neural response to auditory stimuli in HR-ASD and NSC in order to characterize specificity of language acquisition deficits in ASD.
Methods: 12 HR-ASD infants were recruited from the Yale Autism Program. 15 infants with NSC were enrolled from the Yale Craniofacial Clinic. 35 TD infants were used as age-matched controls. Participants were presented with a non-native phoneme discrimination task involving five blocks of ten repetitions each of the Hindi retroflex phoneme /da/ and the dental phoneme /da/ in random order. Auditory stimuli were presented at 80 dB, and EEG was recorded at 250 Hz using a 128-channel HydroCel Geodesic Sensor Net. Analysis focused on selected electrode clusters from four regions of interest: the left frontal, right frontal, left central, and right central clusters. The MMN component was calculated as the largest negative amplitude in the difference wave between 80-300ms after the stimulus.
Results: In the left frontal region, HR-ASD demonstrated marginally attenuated MMN compared to TDs (p=.092), while NSC demonstrated significantly attenuated MMN compared to TDs (p=.011). There were no significant differences in any electrode cluster between HR-ASD and NSC (ps>.05). All other pairwise comparisons did not show significant differences in MMN amplitude between different groups or within groups in different brain regions.
Conclusions: Previous work has shown that while TD infants demonstrate lateralized response to language, neither HR-ASD nor NSC infants display significant hemispheric lateralization. This atypical lateralization has previously been suggested to be an endophenotype of ASD that can be detected early in life. Our current study revealed significantly decreased MMN amplitude in NSC but not HR-ASD infants. Thus, while HR-ASD and craniosynostosis may share certain similarities in auditory response, such as atypical lateralization, there may also be differing neural processes that distinguish these two. Results suggest that additional research is required to understand variably impacted MMN in HR-ASD populations.

12 **160.012** Decreased Slow-Wave Activity in Sleeping Children with Autism

A. Arazi[1,2], *A. Tarasiuk*[3,4], *L. Manelis*[5,6], *G. Meiri*[6] *and I. Dinstein*[1,2,5], *(1)Department of Cognitive and Brain Sciences, Ben Gurion University of the Negev, Beer-Sheva, Israel, (2)Zlotowski center for neuroscience, Ben Gurion University of the Negev, Beer-Sheva, Israel, (3)Sleep-Wake Disorders Unit, Soroka University Medical Center, Beer-Sheva, Israel, (4)Department of Physiology, Ben Gurion University of the Negev, Beer-Sheva, Israel, (5)Department of Psychology, Ben Gurion University of the Negev, Beer-Sheva, Israel, (6)Pre-School Psychiatry Unit, Soroka University Medical Center, Beer-Sheva, Israel*

Background:
Sleep abnormalities are prominent in children with autism as demonstrated by studies using parent questionnaires and/or assessments of sleep architecture (e.g., reports of reduced REM sleep durations in autism). Very few studies, however, have examined EEG spectral properties in overnight recordings from young children with autism. Slow-wave sleep refers to the deep sleep stages (S3 and S4 of non-REM sleep), which can be quantified using EEG by examining slow-wave activity (SWA, in the 0.75- to 4.5-Hz range). The amplitude of SWA is a marker of the pressure to sleep: it is large during sleep onset and decreases in magnitude throughout the night. Previous studies have reported that reduced SWA power is associated with diverse cognitive impairments. Here, we compared SWA in retrospective polysomnography (PSG) exams of children with and without autism.
Objectives: N/A
Methods:
We identified PSG recordings of 11 children with autism (5.1 ±2 years old), 11 control children with no sleep apnea (5.5 ±1.9), and 10 children with mild obstructive sleep apnea (5.5 ±2). All PSGs were performed at the Soroka Sleep-Wake Disorders Unit between 2008 and 2012. PSG's were re-scored blindly by one of the investigators (A.T). We then computed the relative and absolute SWA in addition to EEG power in the Delta (1-4Hz), Theta (4-8Hz), Alpha (8-13Hz) and Beta (13-20Hz) frequency bands for each sleep stage.
Results:
Children with autism had significantly lower Delta power and larger Beta power during N2, N3, and REM sleep compared to both control groups. SWA was significantly reduced in the autism group throughout the night. In addition, we found that children with autism spent relatively less time in REM sleep than the two control groups.
Conclusions:
Children with autism exhibit significantly smaller magnitudes of SWA, which have previously been associated with cognitive problems in, for example, children with apnea. Additional research is necessary for determining whether cognitive and social impairments in children with autism are associated with these sleep abnormalities.

13 **160.013** Delayed but Not Deviant Developmental Trajectories Related to Language Impairment in Children with Autism Spectrum Disorder: Neural and Behavioral Evidence

E. Kwok[1]*, G. Albakri*[2]*, M. K. Wang*[1] *and J. Oram Cardy*[1]*, (1)Western University, London, ON, Canada, (2)School of Health Studies, University of Western Ontario, London, ON, Canada*

Background: It has been estimated that half of all children with ASD have co-occurring *language impairment* (ASD+LI, Blumberg, Bramlett, Kogan, Schieve & Jones, 2007). Eigsti and Bennetto (2009) found that the language abilities of these children lag behind the typical developmental trajectory (i.e., showing delay in development rather than deviance). Neural studies have proposed that atypical brain responses to sound underlie the language impairments in children with ASD (e.g., Oram Cardy, Flagg, Roberts & Roberts, 2008). However, brain function studies to date have not determined whether atypical neural response patterns are reflective of a developmental delay or deviance trajectory.
Objectives: To explore whether patterns of developmental delay or deviance in brain responses to sounds are related to language delays in children with ASD+LI.
Methods: Twenty-two children with ASD (*N*=13 without LI: ASD-LI; *N*=9 with LI: ASD+LI) participated. To explore the neural responses to sound, a 128-channel EGI system recorded *auditory evoked potentials (AEPs)* elicited by 225 trials of a 50ms, 490Hz tone. The *Clinical Evaluation of Language Fundamentals – 4 (CELF-4)*was administered to measure language ability. The following statistical analyses were performed to identify patterns of delay or deviance:

- **For language abilities:** Scatter-value (*S-value,* VanMeter, Fein, Morris, Waterhouse & Allen, 1997) was calculated based on the individual test items that each participant answered incorrectly using the equation S = sqrt(P xÂ ∑W), where peak (P) = the last correctly answered item and weight (W) = percentage of children with *typical development (TD)* who answered correctly (calculated from our previously established normative database). Children with a developmentally deviant language ability will show more intra-test scatter than their peers and earn higher S-values.
- **For neural responses:** For each participant, an AEP segment from 0-500ms post-stimulus presentation was compared to normative AEPs we previously established from 74 children with TD. Using intraclass correlation coefficient (ICC) as an indicator of resemblance, the AEPs of children with ASD were assigned an age-equivalent based on the comparison that yielded the highest resemblance score. Low resemblance of a participant's waveform compared to all normative waveforms result in a low ICC value, indicating a pattern of deviance in neural responses.

Results: Â As expected, children with ASD+LI scored lower on the CELF-4 compared to children with ASD-LI. However, the ASD+LI group did not have higher S-values on the CELF-4 than the ASD-LI or language-matched TD groups (see Table).In other words, there was no evidence to suggest a pattern of developmental deviance in the language performance of children with ASD+LI. Despite being equivalent in chronological age, children with ASD+LI had significantly younger AEPs than children with ASD-LI. The ASD+LI group did not have lower ICC-values when compared to ASD+LI or language-matched TD groups. This finding suggests that brain responses to sounds in the ASD+LI group are delayed relative to, rather than deviant from, a typical developmental trajectory.
Conclusions: Our data suggest that developmental delay in the neural responses to sound underlies the language delay in children with ASD+LI. Both the neural and behavioral data point to trajectories characteristic of younger children with typical development.

14 **160.014** Developmental Differences in the N170 in Individuals with Autism Spectrum Disorder

C. M. Esposito[1]*, C. M. Keifer*[2]*, E. Kang*[2]*, L. A. Santore*[2]*, J. G. Genovese*[2] *and M. D. Lerner*[2]*, (1)Stony Brook University, Staten Island, NY, (2)Stony Brook University, Stony Brook, NY*

Background:
Individuals with autism spectrum disorder (ASD) demonstrate deficits in processing both high and low intensity emotions in faces (Garman et al., 2016). However, changes in efficiency of processing across development remain unclear. The N170 event-related potential (ERP) component, recorded via electroencephalogram (EEG), is an early neural index of face processing (Bentin et al., 1996; Eimer, 2000; Nelson & McCleery, 2008). Previous research has shown that as children increase in age (regardless of ASD status), their N170 latencies decrease until age ~11 (Batty & Taylor, 2006 Hileman et al., 2011; Batty et al., 2011). However, in typically developing (TD) children, this process seems to plateau around age 14 (Batty & Taylor, 2006). No known studies have examined the relationship between N170 latencies and facial processing from childhood into adulthood. Additionally, previous research using the Diagnostic Analysis for Nonverbal Accuracy-2 (DANVA-2; Nowicki, 2004), a standardized paradigm assessing facial emotion recognition, has demonstrated that N170 latencies to high and low intensity emotional face stimuli are slower in ASD compared to TD individuals (McPartland et al., 2011). Studies have not examined how deficits in facial emotion processing or symptom severity in individuals with ASD may affect the relationship between age and N170.
Objectives:
The current study 1) examined if age correlated with N170 latencies in response to high and low intensity emotional facial stimuli in a sample of individuals with ASD spanning childhood and adulthood. Additionally, 2) we examine whether ASD severity and performance on the emotion recognition task, moderated the relationship between age and N170.
Methods:
Thirty-seven individuals (29 male; M_{age} = 17.62 SD_{age} = 8.55) with ADOS-2-confirmed ASD, completed the DANVA-2 emotion recognition task while concurrent EEG was recorded. N170 latency to high and low intensity faces were extracted. Additionally, the Social Responsiveness Scale (SRS; Constantino & Gruber, 2005) was administered to adult participants as well as parents of youth participants to measure ASD symptom severity.
Results:
Age correlated negatively with N170 latency to overall faces (-0.415 p = 0.011) as well as to high intensity faces (r = -0.332 p = 0.045) and low intensity faces (r = -0.375 p = 0.022). Neither SRS-2 scores nor errors made on the DANVA-2 moderated the relationship between age and N170 latency to overall, high intensity, or low intensity faces.
Conclusions:
N170 latencies to overall emotional faces were negatively correlated with age from childhood into adulthood. Additionally, the relationship between age and N170 was not moderated by ASD severity nor DANVA-2 performance. These results suggest that individuals with ASD evince increased processing efficiency (shorter N170 latency) with age regardless of level of ASD symptomatology or performance on the emotion recognition task. These findings also indicate that neurodevelopment of basic face processing (across levels of emotional intensity) may continue in individuals with ASD beyond the period in which this is evident in TD individuals. As such, this intimates the possibility of either delayed development of social-emotional neural systems, opportunities for enduring neuroplasticity (and therefore intervention) into young adulthood in this population, or both.

15 **160.015** Differences in the Late Positive Potential ERP As a Function of Valence Versus Intensity in Adults with and without ASD

C. M. Keifer[1], *T. Clarkson*[2], *E. Kang*[1], *A. Stoerback*[1] *and M. D. Lerner*[1], *(1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY*

Background: Research suggests that individuals with Autism Spectrum Disorder (ASD) demonstrate aberrant neural processing of emotionally salient social stimuli (Lerner et al., 2013). Research has focused on *early stage* face processing as indexed by the N170 and VPP event-related potentials (ERP) recorded via electroencephalogram (EEG; Bentin et al. , 1996; Faja, et al. 2016) showing blunted processing of emotional faces in individuals with ASD (McPartland et al., 2011). While these findings have been well-replicated, ERP research focusing on the *later stages* of emotional face processing in ASD has been largely neglected. The late positive potential (LPP), a slow wave ERP beginning 300ms after stimulus onset, is associated with sustained attention and motivation and larger amplitudes are found in response to salient emotional stimuli in typically developing (TD) individuals (Hajcak et al., 2009). One study has examined the LPP in individuals with ASD, finding an enhanced LPP to nonsocial vs. positive social stimuli (Benning et al., 2016). However, this study did not (1) control for differences in amplitude of early facial processing, which may evince differences that prefigure the LPP, and (2) identify whether LPP differences in the ASD group were a function of stimulus valence or intensity. It is essential to parse apart the stimulus qualities that contribute to LPP differences to better understand social emotional processing deficits.
Objectives: This study examined differential LPP response to high vs. low intensity and positively vs. negatively valenced emotional in individuals with and without ASD while controlling for differences in amplitude of early stage processing.
Methods: Thirty-two TD adults (10 male; M_{age}=22, SD_{age}=6.0), and 13 IQ-matched adults with ADOS-2 confirmed ASD diagnosis (11 male; M_{age}=27, SD_{age}=6.8) completed an ERP measure of facial emotion recognition (DANVA-2; Nowicki, 2004). VPP and LPP to high and low intensity, and positively and negatively valenced, emotional faces were extracted from ERP data. We examined the interaction between stimulus type (high vs. low or positive vs. negative) and diagnosis for LPP via repeated measures ANOVAs while covarying VPP amplitude.
Results: There was a significant interaction between intensity level and diagnosis (F=5.35, p<.05) such that individuals with ASD had a smaller LPP amplitude to high intensity faces (B = .28, p<.05; Figure 1). This interaction was robust to controlling for VPP amplitude to high intensity faces (F=5.62, p<.05). There was no effect for LPP for valence by condition.
Conclusions: While their slow wave neural responses to emotional valence appear to be intact, individuals with ASD demonstrate attenuated motivated attention to high intensity social emotional stimuli compared to their TD peers even when controlling for amplitude differences in early processing (i.e. VPP). Although previous research has focused on *early* ERP differences in processing low intensity emotions which may reflect blunted initial sensory processing, the current findings highlight attenuated *later stage* processing of high intensity faces, suggesting diminished motivational response to highly salient social information in the ASD group relative to TD controls. This study suggests that deficits in processing social emotional information vary across stages of processing in individuals with ASD.

16 **160.016** Distinct Brain Regions Associated with Item and Relational Encoding Impairments in ASD

J. Hogeveen[1,2], *J. D. Ragland*[2,3], *T. A. Lesh*[2,3], *T. A. Niendam*[2,3], *C. S. Carter*[2,3], *M. K. Krug*[1,4] *and M. Solomon*[3,4], *(1)UC Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry & Behavioral Sciences, UC Davis, Sacramento, CA, (3)Imaging Research Center, UC Davis, Sacramento, CA, (4)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA*

Background: The human brain is adept at storing and retrieving information from experienced events, and this 'episodic memory' system is critical to adaptive functioning in everyday life. Individuals with autism spectrum disorders (ASD) demonstrate a marked impairment in episodic memory, but the neurocognitive bases of this impairment remain unclear. The Relational and Item-Specific Encoding (RiSE) task was developed to differentiate the abilities to remember specific stimuli (item-specific encoding) and associative memory for relationships between stimuli (relational encoding). In a recent study, individuals with ASD showed impaired performance on the RiSE, particularly in the item-specific encoding condition (Solomon, McCauley, Iosif, Carter, & Ragland, 2016).
Objectives: The present study was designed to further investigate item-specific and relational encoding in ASD, and to use functional magnetic resonance imaging (fMRI) to elucidate the neural bases of episodic memory impairments in this population.Â
Methods: Data collection is ongoing, but currently 17 young adults and adolescents with ASD and 19 typically-developing participants (TYP) have completed the RiSE in an fMRI environment. The RiSE consists of two phases: i) an encoding phase where items are presented in pairs while participants are instructed to attend to the items themselves ("is one of the items living?") or to the relationship between items ("can one item fit inside the other?"), and ii) an item recognition (IR) phase where studied items are intermixed with unstudied foils and participants judge whether each item is "old" or "new". IR accuracy was analyzed using a 2 (encoding condition) x 2 (diagnosis) ANOVA, and preliminary fMRI data were analyzed using a mixed-effects model (FSL's FLAME1, uncorrected p<.01) and a region-of-interest mask derived from 270 'episodic memory' studies in the *Neurosynth* data archive.
Results: Behaviorally, we observed significant improvements in accuracy following relational encoding relative to item encoding (p<.001, h^2=0.61), and a generalized impairment across encoding conditions in the ASD group (Item: p=.03, d=0.76; Relational: p=.04, d=0.72), with no evidence of an interaction (p=.67). Preliminary fMRI analyses revealed that item and relational encoding impairments were associated with distinct patterns of brain activity. In both the ASD and TYP groups, encoding recruited medial temporal lobe (MTL) and dorsolateral prefrontal cortex (dlPFC), with dlPFC demonstrating greater recruitment during relational vs. item encoding. Between groups, relational encoding was associated with greater recruitment of dlPFC in TYP relative to ASD, but similar levels of MTL recruitment. In contrast, the TYP group demonstrated greater MTL recruitment in the item-specific encoding condition than the ASD group.
Conclusions: The present study provides further evidence for an episodic memory impairment in ASD, which was observed regardless of whether information was encoded in an item-specific or relational fashion. Furthermore, the study provides novel fMRI evidence that distinct MTL and PFC subregions may be associated with item and relational encoding impairments in ASD, respectively, which could lead to a better understanding of the neural mechanisms underlying different types of memory failures in ASD. As data collection is ongoing, rigorous methodological standards for statistical power and multiple comparisons correction will be implemented prior to IMFAR 2017.

17 **160.017** ERN As a Predictor of Treatment Response to Social Skills Interventions in ASD

***T. Clarkson**, T. Rosen, C. M. Keifer and M. D. Lerner, Stony Brook University, Stony Brook, NY*

Background: Larger neural responses to error commission are a biomarker for increased anxiety symptoms (Meyer et al., 2015) and are measured by error-related negativity (ERN) amplitudes, an event-related potential (ERP) component measured via electroencephalogram (EEG). However, the extent to which this is true in youth with ASD is still unclear (Boulter et al., 2014; vs. Henderson et al., 2006; 2016). Moreover, while anxiety, when measured by informant-report, has been shown to moderate treatment outcomes in ASD (e.g., Pellecchia et al., 2015), physiological indices of anxiety, such as the ERN, have not been examined in this manner. Therefore, we aimed to examine the relation of the ERN to 1) anxiety symptoms in youth with ASD, and 2) anxiety and ASD-related treatment outcomes in youth with ASD following Social Skills Intervention (SSI).
Objectives: This study examined whether differences in neural responses of ERN amplitudes at baseline index anxiety in ASD and predict treatment response to SSI.
Methods: Thirty-seven youth (M_{age}=12.11, SD_{age}=2.91; 29 male) with IQ≥70 (M_{IQ}=104.68, SD_{IQ}=15.84) and ADOS-2-confirmed ASD diagnosis participated in a 10-week SSI. At pre- and post-treatment, parents completed ratings of psychopathology, anxiety and ASD symptomatology, respectively (CASI-5, Gadow & Sprafkin, 2016; SRS-2, Constantino & Gruber, 2005), and participants' rated general and social anxiety symptoms (MASC-2; March et al., 1997; SAS, La Greca & Lopez, 1998). At baseline, unstandardized residual scores of the mean ERN amplitudes were computed by saving the variance leftover in a regression equation wherein the Correct Response Negativity (CRN) was regressed on the ERN (Meyer et al., 2016).
Results: Residualized ERN amplitudes correlated with parent reported symptoms of general anxiety disorder at baseline on the CASI-5 (r= -0.322, p= 0.052). Residualized ERN amplitudes predicted change (via ANCOVA-of-change models) in self-reported treatment outcomes of total social anxiety symptoms, as measured by the SAS (B=0.400, p=0.001) and anxiety symptoms, as measured by the MASC-self (B= .887, p=0.008), wherein smaller ERN amplitudes predicted *greater* treatment-related improvements, but *larger* ERN predicted *attenuated* improvements. MASC-self effects were driven by general anxiety disorder, humiliation and rejection, performance fear, social anxiety, obsession and compulsions, panic, and physical symptoms (all B > .608, p < .041), but not separation anxiety, tension or restlessness, or harm avoidance (all p>.241). No effects of ERN on treatment outcomes of ASD related symptoms on the SRS were found.
Conclusions: Results suggest that the ERN relates to concurrent parent-reported anxiety symptoms in youth with ASD, replicating previous work in children with anxiety disorders (Meyer et al., 2015) and ASD (Boulter et al., 2013, but see Henderson et al., 2006, 2016). We found that the *direction of change* on multiple self-report anxiety measures was dependent on baseline ERNs, such that smaller ERNs predicted augmented – but larger ERN predicted attenuated – treatment effects.Â This pattern of results suggests that the ERN may be a marker for subjective anxiety treatment response, but not parent-observable anxiety symptom or ASD symptom treatment response after SSI. Thus, the ERN may be a useful predictor of individual differences regarding self-reported anxiety symptom reduction following an SSI.

18 **160.018** Early Childhood Longitudinal EEG Analysis to Investigate Neural Correlates of Language in Children at Risk for Autism

***C. L. Wilkinson**[1], A. R. Levin[2], H. M. O'Leary[2], H. Tager-Flusberg[3] and C. A. Nelson[4], (1)Developmental Medicine, Boston Children's Hospital, Boston, MA,*

(2)Neurology, Boston Children's Hospital, Boston, MA, (3)Psychological and Brain Sciences, Boston University, Boston, MA, (4)Boston Children's Hospital, Boston, MA

Background: Â The neural mechanisms of autism spectrum disorders (ASD) are still poorly understood. In part, this is due to the complexity and heterogeneity of the disorder and our limited understanding of typical neural processing in early childhood. Longitudinal studies of infants at increased familial risk for autism are needed to uncover early differences in neural circuitry in ASD and identify which abnormalities impact language and cognitive development.
Rhythmic synchronization of brain activity in the gamma frequency range (~30-50Hz) is thought to be crucial for higher order cognitive processing, including sensory integration and binding of information. Differences in gamma have been observed in older children and adults with ASD. In typical infants, recent EEG studies also support gamma's association with language processing, with increased gamma power at 2 years of age correlating with better language ability.
Objectives: Â To characterize spontaneous gamma power and its correlation with language ability in infants and toddlers at risk for ASD compared to low risk children.
Methods: This study analyzed EEG data collected as part of the Infant Sibling Project, a longitudinal study comparing infants at high risk of developing ASD with low risk controls. Infants with a sibling with ASD were designated high risk, while infants with least one typically developing sibling and no known first degree relatives with ASD were designated low risk. Each infant was developmentally evaluated at multiple intervals, including 24 and 36 months by the Mullen Scales of Early Learning. Infants were evaluated for ASD at 24 and 36 months. High-density spontaneous EEG recordings conducted at 12, 18 and 24 months of age were analyzed. Spontaneous frontal gamma power at these ages was correlated with language outcomes at 24 and 36 months.
Results: Spontaneous frontal mean gamma power was not significantly different at 12, 18, or 24 months between low risk (LR) and high risk (HR) groups, including the subgroup of high risk children with ASD (HR/ASD). However, *correlation* of spontaneous gamma power and language skills at 24 months was directionally opposite and significantly different between LR and HR groups (Fisher z-transform; -1.91, $p<0.05$; n=36 LR, 33 HR). At 24 months left frontal gamma power was *positively* correlated with language skills in the LR group (Pearson r = 0.351, $p<0.05$), but *negatively* correlated in the HR group (Pearson r = -0.354, $p<0.05$), and the HR/ASD subgroup (Pearson r = -0.51, $p>0.05$, n=8).
Conclusions: Preliminary EEG analyses support differences in the function of spontaneous frontal gamma power in LR and HR children. While LR and HR groups had similar mean frontal gamma power, the correlation between gamma power and language ability is strikingly different. Future analysis of evoked gamma in auditory language tasks will help to further elucidate these differences.

19 **160.019** Electrophysiological Markers of a Potential Excitatory:Inhibitory Imbalance in Children with Autism Spectrum Disorder

L. C. Shuffrey[1,2,3], *H. L. Green*[2], *J. Veenstra-Vander Weele*[3,4] *and K. Froud*[2], *(1)New York State Psychiatric Institute / Columbia University, New York, NY, (2)Biobehavioral Sciences, Teachers College, Columbia University, New York, NY, (3)Center for Autism and the Developing Brain, White Plains, NY, (4)Psychiatry, New York State Psychiatric Institute / Columbia University, New York, NY*

Background: Â Sensory processing abnormalities are a core feature of Autism Spectrum Disorder (ASD). Emergent evidence suggests that hyper- or hypo-reactivity to sensory input(s) in ASD may be due to a neurochemical imbalance between excitatory glutamate (Glu) and inhibitory γ-aminobutyric acid (GABA) neurotransmission, also known as the excitatory:inhibitory (E:I) theory of ASD.
Objectives: To explore possible consequences of imbalanced GABA:Glu neurotransmission on the visual system, we investigated surround suppression in ASD using a visual motion processing task during electroencephalography (EEG) recording to derive the N1 event related potential (ERP). Behavioral studies have demonstrated that healthy adults have a directional impairment of discrimination in conditions of large/high-contrast visual stimuli, which is thought to reflect surround suppression of motion selective neurons and to be driven by GABA (Tadin et al., 2003; Aaen-Stockdale et al., 2009). Behaviorally, individuals with ASD have demonstrated weakened surround suppression, i.e. a selective enhancement of motion perception in conditions of large, high-contrast stimuli (Foss-Feig et al., 2013; Horder et al., 2014). To our knowledge, there have been no prior studies to investigate an ERP marker of surround suppression. To validate this paradigm, we demonstrated that healthy adults have delayed processing in conditions of large/high-contrast thought to reflect surround suppression as indexed by N1 ERP latency ($p=0.013$).
Methods: Â In the pilot study, five high-functioning medication-free children with ASD based on DSM-5 criteria and four typically developing children from 7 – 12 years of age were recruited. ASD classification was confirmed using the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2) (Lord et al., 2012). All participants reported no history of neurological disorder and had normal or corrected-to-normal vision. Participants were screened for a contrast-sensitivity impairment using the Pelli-Robson Contrast Sensitivity Acuity Chart. During EEG recording participants completed a visual processing task. Stimuli were programmed using Psykinematix (Beaudot, 2009) and consisted of 1 cycle/degree drifting vertical sine wave gratings surrounded by two-dimensional Gaussian envelopes drifting either right or left at a consistent speed. Stimulus size (large vs. small) was either 5.0° or 0.7° and stimulus contrast (bright vs. faint) was either 92% or 2.8%. Recruitment is ongoing for the main study.
Results: In the high-contrast experiment, we demonstrated children with ASD have significantly enhanced processing of large stimuli compared to small stimuli thought to reflect weakened surround suppression ($t(4) = 5.023$, $p=0.007$) as indexed by N1 ERP latency. Typically developing children did not demonstrate N1 ERP latency differences in the high-contrast experiment ($t(3) = -2.296$, $p=.105$). Children with ASD had significantly shorter N1 ERP latencies to large/high contrast-stimuli than typically developing children ($t(7) = -3.953$, $p=0.006$). As expected, there were no processing differences between stimuli sizes in conditions of low contrast, since surround suppression is contrast-dependent.
Conclusions: Medication free children with ASD demonstrated weakened surround suppression. Shorter N1 latencies in conditions of large, high-contrast stimuli could lend support to the E:I imbalance theory of ASD. This paradigm may have potential for use as a clinical outcome measure in research trials to evaluate the effectiveness of investigational pharmaceuticals that act on GABAergic neurotransmission.

20 **160.020** Exclusion Bias in ASD fMRI Studies: The Effect of Participant Anxiety on Scan Motion Artifact

M. G. Pecukonis*, L. C. Anderson, E. Sadikova and E. Redcay, Department of Psychology, University of Maryland, College Park, MD*

Background: Functional MRI (fMRI) is used to understand the neurobiological basis of neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD). While data from an fMRI scan can be highly informative, it is susceptible to artifacts caused by participant motion. Previous literature suggests that 30% of data is lost from scans conducted with ASD participants due to scan motion artifacts (Yerys et al., 2009). Researchers can effectuate methods to reduce these motion artifacts with use of mock scanner training protocols (de Bie et al., 2010; Raschle et al., 2012; Nordahl et al., 2016). Nevertheless, there are some variables that may increase motion but are difficult to control, such as participant trait anxiety. Given the high co-morbidity of anxiety disorders in individuals with ASD, it is important to consider whether anxiety affects fMRI data quality and leads to exclusion biases. No previous study has examined the relation between anxiety-like symptoms and scan motion in a childhood ASD sample.
Objectives: We investigated the relation between child-reported and parent-reported anxiety and average scan motion (i.e., frame displacement) during a social interaction fMRI paradigm in children with ASD.
Methods: To date, participants include 16 children (15 males), 11.59 ± 2.26 years, FSIQ 110.94 ± 21.45, diagnosed with ASD. The Screen for Child Anxiety Related Emotional Disorders Scale (SCARED; Birmaher et al., 1999) was administered to participants and to one of their parents. The SCARED is a validated questionnaire used as a continuous measure of childhood anxiety symptoms and includes the following factors: somatic/panic, general anxiety, separation anxiety, social phobia, and school phobia. Before entering the fMRI scanner, children received practice in a mock scanner to decrease scan-related anxiety. During the scan, participants completed an innovative social interaction paradigm, in which they believed they were chatting with a peer in real time (functional results from this experiment are discussed in another submission). Average frame displacement (FD) was calculated for each run. We conducted partial correlations between average FD and SCARED factor scores, including age and FSIQ as covariates.
Results: Results demonstrated a significant positive correlation between average FD and the parent-reported generalized anxiety factor, $r(12) = .540$, $p = .046$. In addition, there was a significant positive correlation between average FD and the parent-reported somatic/panic factor, $r(12) = .743$, $p = .002$ (see Figure 1). There were no significant correlations between child-reported anxiety factors and average FD.
Conclusions: Preliminary results suggest that parent-reported anxiety on the generalized and somatic/panic factors relate to fMRI scan motion in children with ASD. Scan motion can cause artifacts and spatial misalignment and thus the data is often excluded from research analyses. Researchers should be aware of these moderate to strong correlations between participant anxiety and scan motion, as excluding these participants from their dataset may result in a sample that is not fully representative of the ASD population. These findings are particularly relevant for paradigms examining social interactions, which may exacerbate social anxiety in participants with ASD.

21 **160.021** Executive Function in the Autism and Schizophrenia Spectrums

***S. Hampton**, R. C. M. Philip, E. C. Johnstone, S. M. Lawrie and A. C. Stanfield, University of Edinburgh, Edinburgh, UNITED KINGDOM*

Background: Autism and schizophrenia are known to have overlapping phenotypic features, including difficulties with aspects of executive function such as working memory. Overlaps between autism and schizophrenia are particularly pronounced for higher functioning individuals with autism spectrum disorders (ASD) or schizotypal personality disorder (SPD). It is not known, however, whether these shared features result from common or distinct brain mechanisms. Knowledge of the neural mechanisms involved can help inform how best to address executive function difficulties in each particular condition.
Objectives: This study aimed to characterise the neural basis of working memory in those with ASD and SPD using functional magnetic resonance imaging (fMRI), in order to explore similarities and differences in the underlying mechanisms involved in both conditions.
Methods: 76 individuals participated in the study: 24 with ASD, 20 with SPD and 32 typically developing controls. While in an MRI scanner, participants completed the n-back task as a measure of working memory. During this task, participants were presented with a sequence of letters and instructed to report whether the letter on the screen matched the one presented *n* steps earlier in the sequence. Four conditions were employed: 0-back, 1-back, 2-back and 3-back, with each condition placing an increasing load on working memory.
Results: No significant differences in activation were seen between the ASD and SPD groups. However, significantly less of an increase in activation was seen in the ASD group compared to controls as working memory load increased in a cluster which stretched from the left superior parietal lobule into the cuneus and precuneus and extended into left posterior cingulate. Significantly less of an increase in activation was seen in the SPD group compared to the control group as working memory load increased in a bilateral cluster in posterior cingulate, extending into cuneus, precuneus and lingual gyrus.
Conclusions: While the ASD and SPD groups showed slightly different activation compared to controls, there were no significant differences between the ASD and SPD groups. Those with ASD and SPD, therefore, do not appear to differ with regard to the brain mechanisms underlying working memory. These findings have implications for therapeutic interventions that target the mechanisms behind difficulties in executive function in these conditions.

22 **160.022** Exploring the Potential of Oxytocin for Enhancing Interpersonal Motor Resonance upon Direct Eye Gaze: A Transcranial Magnetic Stimulation Study

***K. Alaerts**[1], S. Brams[1] and J. Prinsen[2], (1)University of Leuven - KU Leuven, Leuven, Belgium, (2)Rehabilitation Sciences, KU Leuven, Leuven, BELGIUM*

Background: Among different social cues from the environment, the eyes constitute a very salient source for initiating social interaction or communication. Interestingly, previous work from our and other labs demonstrated that direct eye contact between two individuals can readily evoke an increased propensity to 'mirror' other peoples' actions. Particularly, using transcranial magnetic stimulation (TMS), we showed that mirror-motor mapping at the level of the primary motor cortex (M1), also known as "interpersonal motor resonance" (IMR), is significantly increased upon the observation of actions accompanied by direct eye contact, compared to the observation of actions accompanied by averted eye gaze.
Objectives: Â With the present study, we investigated the role of eye contact on IMR further, and in particular, explored whether administration of the 'prosocial' neuropeptide oxytocin (OT) can influence eye-contact induced IMR. OT is known to play an important role in promoting prosocial behavior and the perception of socially-relevant stimuli, such as eye gaze. To date however, the link between OT and IMR is less clear.
Methods: Twenty-six neurotypical adult males (18-29y) participated in a double-blind placebo-controlled cross-over design including two sessions, separated by one week. Participants were randomly assigned to receive a single dose of OT (24 IU) or placebo nasal spray at the first and second session. In each session, TMS was used to measure changes in cortico-motor excitability at the level of M1 while participants observed video stimuli of an actress performing simple hand movements combined with either direct or averted gaze. Additionally, eye tracking was performed to evaluate potential changes in spontaneous viewing behavior of the participants.
Results: At the baseline session (after PL spray), a tentative effect of eye gaze on IMR was revealed, indicating that IMR during movement observation was higher when combined with direct eye gaze, compared to averted gaze ($p=0.09$). Exploration of inter-individual variance at baseline provided indications that the effect of eye gaze on IMR was related to inter-individual variance in state attachment avoidance (State Adult Attachment Measure (SAAM)), such that - at baseline - significant modulations of IMR by eye gaze were only observed in participants with low attachment avoidance ($p=0.003$), whereas in participants with high attachment avoidance, the facilitating effect of eye-contact on IMR was absent ($p=0.50$). Strikingly however, participants with high attachment avoidance that failed to display eye contact-induced IMR enhancements at baseline were shown to significantly increase eye contact-induced IMR after a single-dose of OT ($p=0.043$).
Conclusions: Â Our results provide indications that a single-dose of OT can promote motor-mirroring of others' movements upon direct eye contact. Particularly, in participants with high attachment avoidance, OT may increase the saliency of social cues originating from the eye regions of others, which in turn may promote the propensity of an individual to automatically 'mirror' the actions and behaviors of surrounding others. Overall, these findings stimulate future investigations on the potential of OT therapy for targeting eye contact avoidance in patient populations with particular implications in this domain, such as autism spectrum disorders.

23 **160.023** Frontal Asymmetry and Reward-Based Decision Making in Children with High Functioning Autism Spectrum Disorder

***R. Gilbert**, A. M. Zhou, J. Donehey, J. Buirkle and S. Faja, Boston Children's Hospital, Boston, MA*

Background:
Children with autism spectrum disorder (ASD) have impairments in motivation and reward-based decision making compared to typically developing (TD) children (Dawson et al. 2005; Kohls et al. 2012; Faja et al. 2013). In a study of decision-making and goal directed behavior, researchers suggested that anxiety and other influences such as personality and temperament may be moderators of risk-taking behavior (South et al. 2011). Among TD children, temperament has been related to frontal asymmetry, but studies of frontal asymmetry in ASD have been less conclusive. Most resting state EEG studies of ASD have shown greater frontal asymmetry across alpha frequency in comparison to a TD sample (Wang et al. 2013) and within a high functioning ASD sample, individuals with greater right frontal asymmetry exhibited greater social impairment and better visual analytic skills than individuals with greater left frontal asymmetry (Sutton et al. 2005). Studying resting EEG asymmetry may offer insight on the neural underpinnings of motivational approach or avoidance in goal-directed decision making.
Objectives:
To explore the relationship between reward-based decision-making, anxiety and internalizing/externalizing behaviors, and frontal asymmetry among children with ASD.
Methods:
Participants included 48 children diagnosed with ASD and 31 IQ and age-matched TD children. Participants completed the Hungry Donkey Gambling Task, which offers insight on long-term and short-term reward-based decision-making. Anxiety, internalizing, and externalizing behaviors were reported by parents using the Child Behavior Checklist (CBCL). EEG data was recorded from a subset of 28 subjects with ASD during eyes open and eyes closed resting conditions. Frontal asymmetry between F3 and F4 was calculated from the mean alpha power found during the eyes-closed condition, as this was found to be a better measure of baseline arousal (Barry et al. 2009).
Results:
In comparison to an age and IQ-matched sample of TD individuals, we found no differences in risk taking on the Hungry Donkey gambling task with our ASD sample. Looking at individual differences within the ASD sample, we also did not find significant correlations between anxiety or internalizing/externalizing behaviors reported in the CBCL and performance on the Hungry Donkey Task or with frontal asymmetry. However, we did find a significant correlation between reward-based decision making on the Hungry Donkey task in the final two blocks and frontal asymmetry, $r(27)= -0.42$, $p<.05$.
Conclusions:
While there were no significant group differences in performance on the Hungry Donkey gambling task between groups, the correlation between risk taking and frontal asymmetry within the ASD sample poses interesting questions about frontal asymmetry as a biomarker of approach/avoidance behavior in both a social and nonsocial context. Further exploration is needed to understand this relationship, the heterogeneity of ASD, as well as group differences between ASD and TD populations. We plan on recruiting and collecting resting state EEG data from approximately 30 TD participants to compare to compare to our ASD sample. We also anticipate recruiting an additional 20 ASD participants over the coming months, which will increase statistical power across our measures.

24 **160.024** Gaze Preference and Underlying Brain Responses to Dynamic Eye Movement in Individuals with ASD Across Development

***T. C. Day**[1], B. Lewis[1], A. Naples[2], K. A. McNaughton[1], S. A. A. Chang[1], M. J. Rolison[1], K. Ellison[1], J. Wolf[1], E. Jarzabek[1], S. M. Malak[1], J. A. Trapani[1], K. Stinson[1], J. H. Foss-Feig[3,4] and J. McPartland[1], (1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (4)Psychiatry, Seaver Autism Center, Icahn School of Medicine at Mount Sinai Hospital, New York, NY*

Background: Impairments in eye contact are a notable symptom of autism spectrum disorder (ASD). Past research has shown individuals with ASD demonstrate atypical gaze responses and brain activity to passive electroencephalography (EEG) paradigms. Brain-behavior responses during dynamic social paradigms are essential to understand individuals with ASD in more ecologically valid contexts. Understanding these relationships in the context of child development is critical for the creation of clinically practicable biomarkers.
Objectives: The primary aim of the study was to explore brain-behavior relationships in ASD during an interactive social neuroscience paradigm. Specifically, this study assessed the relationship between the N170 and gaze behavior during a gaze-contingent paradigm in children and adults with ASD.
Methods: Participants included individuals with ASD (n = 78) and typically developing (TD) individuals (n = 56) matched on age (range: 8–36 years) and IQ (range of standard scores: 71–158). EEG was recorded with a 128-channel Geodesic Sensor Net, and eye-tracking (ET) was recorded with an EyeLink-1000 remote camera system. ET and EEG were co-recorded while the participant underwent a gaze-contingent viewing paradigm. Participants viewed a cross hair followed by a face. Once the participant looked at the eyes, the face responded by looking at (direct-gaze) or away from (averted-gaze) the participant. Behavioral data, time spent looking at facial features, and neural responses, N170 amplitude and latency, were collected.
Results: TD individuals looked significantly more at the left eye than between the eyes [F(1, 108) = 11.19, p < .01], while individuals with ASD did not demonstrate a gaze preference. Across groups, increased time spent looking at the left eye was associated with faster N170 response in the averted-gaze condition (r = -.222, p = .03). Gaze-condition effects were present in both groups; specifically, the N170 amplitude to direct-gaze was more negative than to averted-gaze [F(1, 108) = 6.95, p = .01)], and N170 latencies were faster in response to direct-gaze [F(1, 108) = 8.55, p < .01]. A main effect of hemisphere revealed N170 amplitudes were more negative in the right hemisphere than the left for both ASD and TD groups across conditions [F(1, 108) = 6.72, p = .01]. In the averted condition, right and left N170 amplitudes were highly correlated in the TD group (r = .47, p < .01) but not in the ASD group (r = .11, p = .37). Across groups, increasing age was related to faster N170s in the right hemisphere in the direct condition (r = -.25, p < .01).
Conclusions: This study demonstrated differences in gaze preference and brain responses to direct and averted gaze. The robust relationship between gaze and diagnostic status revealed atypical viewing patterns in ASD. Differences may be attributable to variation in cross-hemisphere connectivity as demonstrated by synchronization of the N170 amplitude in TD individuals but not those with ASD. Both groups showed developmental effects, with efficiency of gaze perception increasing with chronological age. These results add to the body of evidence supporting N170 as a promising social-communicative biomarker.

25 **160.025** Impaired Categorical Perception of Lexical Tones in Chinese Children with Autism: An Event-Related Potential Study

X. Wang[1], *Y. Zhang*[2], *Y. Fan*[3], *D. Huang*[3], *H. C. Chen*[4] *and S. Wang*[1,5,6], *(1)School of Psychology, South China Normal University, Guangzhou, China, (2)Department of Speech-Language-Hearing Science, University of Minnesota, Minneapolis, MN, (3)Guangzhou Rehabilitation & Research Center for Children with ASD(Guangzhou Cana School), Guangzhou, CHINA, (4)Chinese University of Hong Kong, Hong Kong, Hong Kong, (5)Guangdong Provincial Key Laboratory of Mental Health and Cognitive Science, Guanghzou, China, (6)Center for Studies of Psychological Application, Guanghzou, China*

Background: Previous research has shown enhanced pitch discrimination in individuals with autism in comparison with controls. While the same phenomenon was found for nonspeech stimuli in tonal-language speakers with autism, it did not generalize to the discrimination of lexical tones, which are primarily cued by pitch differences.
Objectives: It was unknown whether the abnormal pitch discrimination could be examined by categorical perception, and whether the distinct pitch processing pattern for speech and nonspeech stimuli in autism was due to a speech-specific deficit in categorical perception of lexical tones. Further it was unknown whether the categorical perception of autism could predict their pitch discrimination ability. The present study was designed to answer the above questions.
Methods: The stimuli were chosen from a 10-step lexical tone continuum used in previous CP studies (Xi et al., 2010; Zhang et al., 2012), including speech and nonspeech context. Two groups of children participated in this study: 16 children with autism, and 15 typically developing controls matched on age and IQ scores. They all completed both behavioral part and ERP part. In the behavioral part, two classical paradigm of categorical perception—identification task and discrimination task—were used to test two groups of children's perception of lexical tone in natural condition. We analyzed the accuracies of two tasks in both conditions.Â A passive oddball paradigm was adopted to examine two groups of Chinese children's Mismatch Responses (MMRs) to equivalent pitch deviations representing within-category and between-category differences in speech and nonspeech contexts.We analyzed the ERP waveforms in each condition with a traditional approach, measuring the average MMR amplitude.To further examine group-level differences in the MMRs to categorical perception of speech/nonspeech stimuli or lack thereof, neural oscillatory activities at the single trial level were further calculated with the inter-trial phase coherence (ITPC) measure for the theta and beta frequency bands.
Results: Â The behavioral results illustrated the categorical perception with autism was impaired in speech context rather than that in nonspeech context.The MMR results showed evidence for the lack of categorical perception in the lexical tone condition with an opposite trend in the harmonic tone condition for children with autism.The frequency data showed that the increased theta was induced in the between-category offering a clear phonetic identify for typically developing children in speech condition while a similar phenomenon was not found for children with autism. In the mean time, the correlation of behavioral data and ERP data was analyzed and it showed that the brain electrical signal could predict individuals' behavior to some extent.
Conclusions: Â All the data from the Chinese children with autism showed evidence for lack of categorical perception in the lexical tone condition. In view of the important role of lexical tones in acquiring a tonal language, the results point to the necessity of early intervention for the individuals with autism who show such a speech-specific categorical perception deficit.

26 **160.026** Impaired Frontal Processing in 3- to 5-Year-Old Children with Autism and a Developmental Language Delay during a Mismatch Negativity Paradigm.

Y. Yoshimura, *M. Kikuchi, C. Hasegawa, H. Hiraishi, S. Kitagawa, H. Kumazaki, T. Ikeda and Y. Minabe, Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan*

Background: The inferior frontal and superior temporal areas in the left hemisphere are crucial for language processing. Language abilities are highly variable in individuals with ASD, with difficulties that range from mild to severe impairments in pragmatics and/or social communication. Currently, language level is considered to be a continuous, rather than categorical, variable. Intriguingly, accumulating electrophysiological evidence suggests that deficits in the discrimination of rapid sound changes are associated with impaired speech processing in children with ASD. However, no previous magnetoencephalography (MEG) studies have focused on analysis of the Mismatch Field (MMF) source in young children with ASD in 3- to 5-year-old.
Objectives: The aim of this study was to investigate regional activity in the brain during a speech perception task in order to explain the phenotypic heterogeneity in language development among children with ASD.
Methods: Forty-six young TD children and 47 children with ASD participated in this study. we investigated the mismatch field (MMF) evoked by voice stimuli in 3- to 5-year-old typically developing (TD) children and children with autism spectrum disorder (ASD) using child-customized magnetoencephalography (MEG). A human voice pronouncing the syllable “ne” with a high falling tone was randomly presented as a rare deviant among frequent utterances of “ne” pronounced with a flat tone.
Results: A longer MMF latency in the left pars orbitalis in the children with ASD was associated with a lower performance in expressive language. Based on the results for the MMF amplitude, the children with ASD exhibited significantly decreased activation in the left superior temporal gyrus compared with the TD children in the 100 – 200 ms time window. If we classified the children with ASD according to the presence of a speech onset delay (ASD - SOD and ASD - NoSOD, respectively) and compared them with the TD children, both ASD groups exhibited decreased activation in the left superior temporal gyrus compared with the TD children in the 100 - 200 ms time window. In contrast, in the 200 - 350 ms time window, the ASD - SOD group exhibited increased activity in the left frontal cortex (i.e., pars orbitalis) compared with the other groups (Figure 1). For all children with ASD, there was a significant negative correlation between the MMF amplitude in the left pars orbitalis and language performance.
Conclusions: This investigation is the first to show a significant difference in two distinct MMF regions in ASD – SOD children compared with TD children; one region was independent of a speech onset delay (SOD), and the other region was dependent on SOD. The results from the first region (left superior temporal gyrus) suggested that reduced MMF amplitude in response to a change in the tone of a human voice may represent a biomarker for ASD regardless of the presence of SOD. The results from the second region (left pars orbitalis) suggested that enhanced and delayed activation in response to a change in the tone of a human voice reflects the developmental delay in language acquisition in young children with ASD.

27 **160.027** Implicit Facial Emotion Processing Abilities in Children with ASD

S. Van der Donck[1,2], *S. Vettori*[1,2], *M. Dzhelyova*[3], *J. Steyaert*[1,2], *B. Rossion*[3] *and B. Boets*[1,2], *(1)Centre for Developmental Psychiatry, KU Leuven, Leuven, Belgium, (2)Leuven Autism Research Consortium (LAuRes), KU Leuven, Leuven, Belgium, (3)Psychological Sciences Research Institute and Institute of Neuroscience, UCL, Louvain-la-neuve, Belgium*

Background: Social non-verbal behaviour is largely determined by efficient face processing. Individuals with autism spectrum disorder (ASD) are characterized by deficits in social communication and interaction, including difficulties in processing faces. An extensive research tradition suggests that individuals with ASD are less sensitive for socio-communicative information, and pay less attention to the eye region and more to the mouth region.
Objectives: The present study aims to examine the nature of face processing impairment in 9-to-12 year old children with ASD vs matched typically developing (TD) control children. More specifically, we investigate the subtle and implicit socio-emotional face processing abilities (i.e. facial emotion discrimination and preferential processing of the eye or mouth region) and try to delineate biomarkers that are sensitive at the individual subject level.
Methods: We use a new innovative approach where we combine scalp electroencephalography (EEG) with fast periodic visual stimulation (FPVS). The general principle of FPVS EEG is that it elicits a steady-state visual evoked potential at exactly the same frequency of visual stimulation. We present images of faces periodically at a 6 Hz base rate and we assess the sensitivity for certain socio-communicative features by periodically entering oddball images displaying changes in expression and/or identity (i.e. every 5th image; 6 Hz/5 = 1.2 Hz oddball rate). Sensitivity for these features can be assessed by quantifying the neural response at the oddball frequency. Participants have to focus on small changes in the fixation cross that is either presented on the eye region or on the mouth region.
Results: Both TDs and children with ASD display a neural response at the oddball frequency and its harmonics, and responses in both groups are reduced when the faces are inverted. Between group analyses show reduced bilateral occipito-temporal responses in ASD compared to TD. Occipito-temporal responses for both groups are higher when focusing on the mouth as compared to the eyes region.
Conclusions: With this innovative FPVS EEG method, we studied the implicit emotion discrimination abilities of children with ASD. Preliminary analyses show clear peaks at the oddball frequency and its harmonics in both the ASD and control group. Reduced neural responses in ASD, compared to controls, indicate that TDs are overall better in detecting brief changes in expression when there is no change in identity. However, these results also reveal the ability of children with ASD to implicitly discriminate between facial expressions, suggesting a quantitative difference in emotion processing abilities. Reduced responses in both groups for the inverted images indicate the presence of the inversion effect in ASD and TDs. This highly versatile EEG approach offers an objective and quantifiable index of implicit face processing abilities, reliable at an individual level, within a few minutes of time and without any complex data analyses. These analyses reveal that the technique works robustly in children and clinical populations, and elicits clear peaks at the oddball frequency and its harmonics.

28 **160.028** Influence of Autistic Traits and Social Anxiety on Gaze Patterns to Faces and Associated Neural Response

S. M. Malak[1], *S. A. A. Chang*[2], *J. A. Trapani*[3], *K. Stinson*[4], *J. McPartland*[3] *and A. Naples*[5], *(1)Yale School of Medicine, New Haven, CT, (2)Yale University, New Haven, CT, (3)Child Study Center, Yale School of Medicine, New Haven, CT, (4)Yale University- Child Study Center, Milford, CT, (5)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Autism Spectrum Disorder (ASD) is characterized by decreased social motivation, as well as anxiety. Both attention, measured via eye-tracking, and brain response, as measured by event-related potentials (ERP) are reliable indices of social motivation and social anxiety. The N170, a face-sensitive ERP, is slowed and attenuated in ASD; in contrast, individuals with anxiety show faster, enhanced N170s. Furthermore, while individuals with ASD show decreased attention to faces and eyes, individuals displaying social anxiety show increased attention to eyes and faces. The interplay between anxiety and ASD and attention/neural response to faces remains unexplored.
Objectives: Using EEG and eye-tracking, we examined relationships among autistic and social anxiety traits and: (1) looking patterns to neutral and fearful face stimuli; (2) brain response to faces; and (3) the relationship between these parameters and self-reported ASD symptomatology and social anxiety. We predicted that individuals with higher ratings of social anxiety symptoms would look more to the eyes, especially in the fear condition. In addition, we hypothesized that individuals with higher ratings of autistic traits would show an attenuated N170 response to faces. Those with higher anxiety were hypothesized to show an exaggerated and faster N170 to faces.
Methods: ERPs were recorded from ten neurotypical adults using 128-channel Geodesic sensor nets while eye movements were recorded concurrently with an SR eye-tracking system. Participants viewed neutral and fear faces presented in random sequence for 5 seconds. ERPs were segmented to the onset of the face and to subsequent fixations. Eye-tracking variables included dwell time in specified ROIs (eyes, left/right eyes, between eyes, mouth, and nose) fixation duration, and dispersion. Social anxiety traits and autistic traits were quantified through self-report questionnaires (Social Avoidance and Distress Scale [SAD]; Autism Quotient [AQ]; Social Responsiveness Scale [SRS]). Data collection is ongoing.
Results: Preliminary results indicate that earlier N170 latency is significantly correlated with higher scores on the AQ (fear condition: r= -.824, p= .003; neutral: r= -.838, p=.002), SAD (neutral condition: r= -.690, p= .027), and SRS (fear condition: r=-.828, p= .003; neutral: r=-.843, p=.002). Ongoing analyses of visual gaze data and fixation-related ERPs during free-viewing of faces will reveal relationships among anxiety and social function, neural response, and gaze.
Conclusions: Initial results reveal relationships among measures of both autistic traits and social anxiety and N170 latency. The hypothesis that those with more social anxiety traits would have faster N170 responses was supported; contrary to our predictions, autistic traits were also associated with decreased N170 latency. These findings may reflect hypervigilance and associated increased efficiency of neural response in individuals with higher levels of anxiety. These results indicate mutual influence of subthreshold ASD and anxiety on ERP indices of social perception.

29 **160.029** Interactive Social Neuroscience to Assess Resting State Brain Activity in the Broad Autism Phenotype

M. J. Rolison[1], *A. Naples*[2], *H. Rutherford*[1] *and J. McPartland*[1], *(1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Autism Spectrum Disorder (ASD) is hallmarked by interpersonal difficulties, yet there is limited research examining brain activity during actual social interactions. To investigate this issue, this study utilized interactive social neuroscience methods to examine alpha oscillations (8-11 Hz) measured with electroencephalography (EEG) in social context and associations between brain activity and autistic traits in typically developing (TD) pairs of adults.
Objectives: Â Characterize neural markers of resting brain activity during an interpersonal interaction and their association with autistic traits in a social context.
Methods: Â 16 TD adults, grouped in same-sex dyads, sat quietly for two minutes with their eyes opened (EO) and eyes closed (EC) in three conditions: (1) “separate” rooms, (2) the same room with their “backs” to each other, and (3) the same room while “facing” each other. EEG was simultaneously recorded from each member of the dyad using wireless recording devices. The Autism Quotient (AQ) was administered to quantify social function and dysfunction.
Results: For alpha power at frontal sites, a significant interaction between condition (separate, back, facing) and eyes (EO/EC) was detected (p=.017). Post-hoc paired samples t-tests indicated: (1) EO elicited greater alpha power than EC in the separate condition but not in back or facing conditions (p=.040); and (2) in the EO condition, greater alpha power in the separate condition than in the back condition (p=.040). Analysis then examined alpha power in each individual frontal electrode; only significant findings are reported. There was a main effect of eyes at left frontal (FL; F(1,12)=5.864, p=.032), Fz (F(1,12)=6.810, p=.023), and right frontal (FR; F(1,12)=5.748, p=.034) sites. There was also a main effect of condition at FL (F(1.1, 13.4)=5.404, p=.033), Fz (F(1.2,15.2)=6.969, p=.014), and FR (F(1.3,15.3)=6.268, p=.018). Pairwise comparisons revealed greater alpha power in EC than EO in FL (p=.032), Fz (p=.023), and FR (p=.034), as well as attenuated alpha power in facing compared to back (FL, p=.013, Fz, p=.044) and separate (FL, p=.021; Fz, p=.010; FR, p=.014) conditions. Further, the difference in alpha power between separate and back with EO in FL (p=.015) and separate and facing with EO in FR (p=.048) was correlated with the attention switching subscale of the AQ. Additionally, scores on the attention to details subscale of the AQ were associated with the difference in alpha power between separate and back conditions with EC in FL (p=.011) and FR (p=.002) and separate and facing conditions with EC in FL (p=.023) and FR (p=.018).
Conclusions: This study applied interactive social neuroscience to investigate the relationship between autistic traits and resting EEG activity during varying levels of interpersonal interaction. Results reveal that the presence of another person modulates resting brain activity. Individuals with lower levels of autistic traits exhibited greater alpha power when resting separately compared to when resting with another person, suggesting greater sensitivity to the presence of another person. Our findings provide new insight into modulation of resting state brain activity through the presence of another person and emphasize the importance of utilizing more ecologically-valid approaches in neuroscientific studies of social brain function.

30 **160.030** Modulation of Brain Activation and Serotonin during Sustained Attention in Autism Using Tianeptine

R. H. Wichers[1,2], *J. L. Findon*[1,2], *A. Jelsma*[1,2], *V. Giampietro*[3], *D. Robertson*[4], *C. M. Murphy*[5,6], *G. M. McAlonan*[2,5], *K. Rubia*[7], *C. Ecker*[8], *E. Daly*[4,5] *and D. G. Murphy*[2,5], *(1)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)FANS, The Sackler Institute for Translational Neurodevelopmental Sciences, IoPPN, King's College London, London, United Kingdom, London, United Kingdom, (3)Department of Neuroimaging, The Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (4)Sackler Institute for Translational Neurodevelopment and Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King’s College London, London, United Kingdom, (5)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King’s College London, London, United Kingdom, (6)Behavioural Genetics Clinic, Adult Autism Service, Behavioural and Developmental Psychiatry Clinical Academic Group, South London and Maudsley Foundation NHS Trust, London, United Kingdom, (7)Department of Child & Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (8)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychiatry, Goethe-University Frankfurt am Main, Frankfurt, Germany*

Background: Prior research has demonstrated abnormal brain activation during sustained attention in individuals with autism spectrum disorder (ASD). The neurobiological basis for this is unknown but the serotonergic system may play a key role. For example, hyperserotonemia has been frequently reported in ASD; and we demonstrated that reducing serotonin by acute tryptophan depletion (ATD) modulates abnormalities in brain function. However, ATD cannot be easily used in clinical settings. Hence, investigating the modulating role of an existing drug that reduces serotonin may shed light on a novel treatment opportunity with the potential to be rapidly translated into the clinic.
Objectives: To test the effect of the selective serotonin reuptake enhancer (SSRE), tianeptine, on sustained attention networks in ASD.
Methods: We included 19 right-handed adult males with ASD (diagnosed using the ADI-R and ADOS) and 19 age- and IQ- matched control subjects. Pharmacological magnetic resonance imaging (phMRI) was used to compare brain activity during a parametrically modulated sustained attention task under an acute dosage of 12.5 mg tianeptine and placebo in a randomised, double blind procedure. The phMRI data were analysed using a nonparametric approach (c.f. http://brainmap.it) and significance was defined as p <.05 (corrected for multiple comparisons).
Results: Individuals with ASD had significantly decreased activation under placebo in regions involved in regulating sustained attention - including right caudate, right thalamus, left precentral gyrus and left middle frontal gyrus. In contrast they had increased activation in left insula and right middle temporal gyrus. After tianeptine administration brain activation in individuals with ASD was modulated towards control placebo levels in brain regions that mediate sustained attention - including right thalamus, right caudate, right middle temporal gyrus, left precentral gyrus, left middle frontal gyrus and left insula.
Conclusions: Our findings provide first evidence that serotonergic modulation with an SSRE can 'normalise' brain activation during sustained attention in adults with ASD. This is now being 'translated' to the clinic to establish whether tianeptine is an effective symptomatic treatment for some individuals with ASD.

31 **160.031** Motor Cortex Inhibition in Youth with ASD and Co-Morbid ADHD a Marker for Clinical Executive Functioning

*L. N. Mooney[1], D. L. Gilbert[2], M. P. Hong[1], J. L. Guilfoyle[1], S. W. Wu[3], C. A. Erickson[4], L. K. Wink[4] and **E. Pedapati**[5], (1)Psychiatry, Cincinnati Childrens Hospital, Cincinnati, OH, (2)Neurology, Cincinnati Childrens Hospital, Cincinnati, OH, (3)Cincinnati Childrens Hospital, Cincinnati, OH, (4)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)INSAR Cincinnati Children's Hospital Medical Center, Cincinnati, OH*

Background: Individuals with a co-diagnosis of ADHD and co-morbid ASD are reported to have higher rates of hospitalization, medication treatment, and behavioral therapy than ASD alone [1]. In addition, youth with dual diagnosis have therapeutic implications including distinct treatment and neural correlates [2, 3]. Currently, there lack of an objective methodology for the diagnosis and management of ASD+ADHD , especially in regards to pharmacotherapy response. Previously, we have demonstrated that a transcranial magnetic stimulation (TMS) evoked measure, short-interval cortical inhibition (SICI) has been associated with ADHD diagnosis and severity [4]. SICI is a TMS measure of the efficiency of inhibitory interneurons in the primary motor cortex (M1) [5].
Objectives: To measure resting paired pulse TMS evoked cortical inhibition (SICI) and determine the relationship between SICI and executive functioning deficits in youth with ASD and co-morbid ADHD.
Methods: Baseline TMS measures of youth with ASD and co-morbid ADHD currently enrolled in a double-blind placebo controlled randomized control trial examining physiological effects of a single dose methylphenidate was analyzed for association with clinical severity of the Connors-3 Parent Rating Scale rating scale. The modulus of TMS motor evoked potentials by surface electromyography of the dominant hand was used as the primary outcome.
Results: Â The dataset included 13 male subjects with ASD with a mean age of 15 (SD 2.8, range 11 to 20). As expected, significant inhibition of MEP modulus was demonstrated with a 3 ms subthreshold paired pulse (M=0.008; SD=0.010) compared to single pulse TMS (M=0.011; SD=0.009) t=3.916, p < 0.001). There was a correlation between SICI and Connor's total executive functioning score (Figure 1; r=-0.578, n=13, p=0.039). A trending relationship was identified between SICI and the total Connor's score (r=-0.518, n=13, 0.070).
Conclusions: We identified preliminary data suggesting that a TMS measure of motor cortex inhibition is significantly associated with a well-validated behavioral measure of executive function. As a quantitative physiological marker of motor function that can be obtained quickly, SICI is an ideal candidate which to clarify fundamental mechanisms of cerebral function that underlie impaired behavioral control.

32 **160.032** Movement during MR Scanning in Children with Autism Spectrum Disorder

***N. A. Puts**[1,2], M. Mikkelsen[1,2], S. H. Mostofsky[3] and R. A. Edden[1,2], (1)Radiology and Radiological Science, Johns Hopkins University, Baltimore, MD, (2)FM Kirby Research Center for Functional Brain Imaging, Kennedy Krieger Institute, Baltimore, MD, (3)Kennedy Krieger Institute, Baltimore, MD*

Background: GABA levels, measured with edited MRS, are reduced in children with Autism Spectrum Disorder (ASD). Long scan times are needed to obtain a sufficiently high signal-to-noise ratio (SNR) to quantify GABA reliably. SNR increases with scan duration but suffers from motion and frequency drift. Measurements in neurological pediatric cohorts can be difficult and understanding the pattern of movement, in particular *when* children move, might benefit the design of future imaging studies and optimize the trade-off between scan time and SNR.
Objectives: To assess the movement behavior of children with and without ASD during edited MRS of GABA.
Methods: Volunteer and parental consent was obtained under local IRB approval. *Eligibility*: Children with ASD met DSM-V diagnostic criteria, confirmed using the Autism Diagnostic Observation Schedule-Version 2 (ADOS-2). All typically developing children (TDC) were free of criteria for psychiatric disorders based on the Diagnostic Interview for Children and Adolescents. Data were acquired in 21 children with ASD and 20 TDC with normal IQ (8–12 yrs). *Imaging*: GABA-edited MR spectra were acquired from a 27 mL voxel over the right primary sensorimotor area using MEGA-PRESS on a 3T Philips Achieva scanner (Philips Medical Solutions) (320 transients; scan time = 10 min). Children watched a movie during scanning. *Analysis:Â* The frequency of the suppressed water signal in each transient (frame) was extracted for both groups using Gannet 2.0. The step size between each frame was calculated and a frequency step over 2 Hz (0.016 ppm) was defined as a motion event. Differences in movement behavior in the two groups were assessed in terms of (i) size and number of movements and (ii) correlation with time point of movement (i.e., are children more likely to move near the beginning or end of the scan?).
Results: Â Figure 1 shows a histogram of movement frequency among the cohort, as well as accumulative percentages. Movement frequency increased significantly throughout the scan (frames binned into groups of 10) across all children (Fig 2; R = 0.56), but more in ASD (R = 0.54) than in TDC (R = 0.3) although this was not significantly different (Fisher R-to-Z, p = 0.38). While no differences were shown in movement frequency, children with ASD had larger movements (4.8 ± 5.1 Hz) compared to TDC (3.4 ± 1.2 Hz), although not significantly (p = 0.3).
Conclusions: These data show that children with ASD do not show more movements than TDC during MRS scanning. These results are important in establishing that previously reported GABA differences are not driven by movement. More children with ASD show *no* movement behavior (ten without movement versus five for TDC, Fig 1). There were no significant differences in the size of movement. Importantly, children are more likely to move near the end of a 10-min scan so while shorter scans (e.g. 7 minutes instead of 10) may impact SNR, they may benefit from reduced movement related artefacts. Near-end-of-scan motion should be taken into account when planning MRS experiments, as well as prospective frequency and motion-correction.

33 **160.033** Neural Correlates of Hearing One's Own Name and Others' Names in Adults with Autism Spectrum Disorder

***A. Nijhof**, J. Goris, M. Brass and J. R. Wiersema, Ghent University, Ghent, Belgium*

Background:
Autism spectrum disorder (ASD) has been linked to a different 'sense of self' from its very first descriptions, and studies indeed suggest altered self-referential processing in ASD. Infants later diagnosed with ASD often fail to respond to their own name (Zwaigenbaum et al., 2005), which has been argued to be a trait of the broader autism phenotype (e.g., Nadig et al., 2007). Surprisingly, as of yet, no published study has looked at neural correlates of hearing one's own name in adults with ASD. In a recent ERP study (Cygan, Tacikowski, Ostaszewski, Chojnicka, Nowicka, 2014), neural responses to visual presentation of their own versus other people's names were investigated in adults with ASD and neurotypical controls. P3 amplification was observed for seeing one's own name (versus other names) in controls, while this effect was absent for adults with ASD, suggesting a self-referential processing deficit.
Objectives:
As we reasoned that investigating hearing one's own name in ASD may be more ecologically valid than seeing one's own name, we evaluated for the first time ERP responses to hearing one's own name versus others' names in adults with ASD and neurotypicals. We hypothesized a P3 enhancement for own name versus others' names in neurotypicals, and this effect to be absent or diminished in adults with ASD.
Methods:
Participants (ASD group: N = 24; neurotypical group: N = 23) performed an auditory oddball task, while their EEG was being recorded using 64 electrodes. Each participant was presented with 5 different sound conditions: standard sounds (66%, 198 trials), target sounds to which they had to respond (4%, 12 trials) and three task-irrelevant name conditions: own name, name of close other, unfamiliar name (each 10%, 30 trials).
Results:
A familiarity effect appeared at the frontocentral N1, with larger amplitudes for one's own name and the name of a close other than an unfamiliar name. Groups did not differ with respect to this effect. The amplitude of an early P3 subcomponent with a central topography (P3a) was found to be enhanced for hearing one's own name versus the name of a close other in the neurotypical group, indicating a self-referential effect. However, as hypothesized, this effect was lacking in adults with ASD.
Conclusions:
ERPs showed an early familiarity effect at the N1, and a self-referential effect at the P3. Processing of familiarity was found to be intact in adults with ASD. However, adults with ASD were specifically impaired in self-referential processing as the typical P3a amplification for one's own name as seen in neurotypicals was absent in adults with ASD. Hence, our findings indicate diminished self-referential processing of a highly familiar self-related stimulus, namely one's own name, in adults with ASD, which may have a serious negative impact on everyday social interaction.

34 **160.034** Neural Correlates of the Pupillary Light Reflex in the Broader Autism Phenotype

***S. A. A. Chang**[1], F. Shic[2], B. Li[3], S. M. Malak[1], K. Stinson[1], J. A. Trapani[1], J. McPartland[1] and A. Naples[4], (1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Seattle Children's Research Institute, Seattle, WA, (3)Center for Child Health, Behavior and Development, Seattle Children's, Seattle, WA, (4)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Autism spectrum disorder (ASD) is characterized by early emerging deficits in social communication and restricted/repetitive behavior. In addition to these core symptoms, individuals with ASD often exhibit atypical arousal regulation. As the locus coerulus (LC) has numerous projections throughout the central nervous system, with norepinephrine (NE) acting as the main neurotransmitter, the LC-NE system has been linked to arousal and attention. The LC-NE system is thought to be indexed by the pupillary light reflex (PLR) because the LC releases NE to control pupillary dilation. Adolescents with ASD exhibit a hyposensitive PLR (Fan et al., 2009); however, infants at high risk for ASD display a hypersensitive PLR (Nystrom et al., 2015); thus, the developmental trajectory of the PLR remains unclear. Finally, while the PLR itself is well characterized, associated neural response and relations to social function are poorly understood.
Objectives: To investigate relationships among PLR, electrophysiological brain correlates, and subthreshold autistic traits.
Methods: Pupil data were collected on an Eyelink-1000 system, and simultaneous EEG recording was collected with a 128-channel Hydrocel Geodesic Sensor net. Stimuli consisted of a white central fixation on a black background, which flashed white for approximately 75 ms. Participants viewed 50 consecutive trials of PLR. EEG data were decomposed and power was computed for the delta (2-4 Hz), theta (4-8 Hz), and alpha (8-13 Hz) frequency bands. Four regions of interest were created by averaging across channels: left frontal, right frontal, left posterior, and right posterior. Characteristics of the PLR were extracted from averaged trials. Autistic traits were measured with a self-report measure, the Broad Autism Phenotype Questionnaire (BAP-Q).
Results: Preliminary analyses of 10 subjects (data collection is ongoing) revealed that subjects with higher scores on the BAP-Q rigidity scale exhibited faster PLR (r -.653, p=0.041). Higher scores on the BAPQ Pragmatic score significantly correlated with slower constriction velocity (r=-.665, p=0.036). Greater pupil constriction was associated with increased power in the right frontal delta band (r=.909, p=.001). Decreased theta power in the right posterior was associated with increased impairment on the BAP-Q pragmatic language scale (r=-.747, p=.021), as well as decreased pupil constriction (r=.776, p=.014).
Conclusions: In the current study, autistic traits related to rigidity were associated with hypersensitive PLR; in contrast, autistic traits related to pragmatic language difficulties displayed a hyposensitive PLR. These distinctions suggest that previous discrepant results may be due to developmental effects, with rigidities being more active in infancy and pragmatic language becoming more focal in subsequent development. Moreover, variance in autistic traits and PLR were associated with oscillatory brain activity. These results shed light on the relationships between subcortical regions supporting arousal, cortical EEG, and social functioning, providing insight into mechanisms relevant to the development of targeted interventions and personalized medicine.

35 **160.035** Neural Fingerprints of Behavioural Rigidity in Autism

E. Poljac[1,2]*, V. Hoofs*[3]*, M. M. Princen*[3]*, R. Haartsen*[4]*, R. van der Cruijsen*[5] *and E. Poljac*[2]*, (1)University of Freiburg, Freiburg im Breisgau, Germany, (2)Radboud University, Nijmegen, Netherlands, (3)Ghent University, Ghent, Belgium, (4)Birkbeck, University of London, London, United Kingdom, (5)Leiden University, Leiden, Netherlands*

Background: Recent literature on behavioural rigidity in autistic individuals has suggested that this core symptom might be associated with difficulties in generating task intentions. Empirical evidence for this idea comes from experimental designs in which participants were not only required to switch between two simple cognitive tasks but were also instructed to deliberately choose which of the two tasks to perform next. These voluntary task-switching (VTS) studies revealed that compared to their neurotypical (NT) peers, autistic individuals have a generally stronger tendency to continue repeating tasks (i.e., increased *repetition bias*) and that once they decide to switch tasks, their performance declines more (i.e., increased *switch costs*). These observations are considered to reflect behavioural rigidity of autistic individuals within experimental settings.
Objectives: The current study was developed to follow on this line of research, and its main objective was to specify the neural fingerprints of behavioural rigidity in autistic individuals as reported in the VTS studies.
Methods: Participants were 31 autistic individuals and 32 NT controls, matched on their age and IQ. They were instructed to choose between two simple cognitive tasks at the beginning of each trial. The tasks included responding to the location or responding to the shape of the presented stimuli. The participants pressed a spacebar to indicate that the choice had been made, which triggered the stimulus presentation. They were then required to respond to either the stimulus location or the stimulus shape, dependent on their task choice for that trial. Using this VTS paradigm, we could investigate the intentional component (task choice) separately from its implementation at the level of task execution (responding to the presented stimulus). We recorded their task choices, as well as their subsequent responding to the stimuli in terms of reaction times (RTs) and error rates. Importantly, the corresponding brain activity was measured with electroencephalography (EEG). The EEG markers of interest were the preparatory contingent negative variation at frontal sites (CNV) as a marker of (the formation of) task intentions and the stimulus-locked P3 at centro-parietal sites as a marker of stimulus-related task execution.
Results: Our behavioural findings replicate previous observations of a significantly stronger repetition bias and significantly larger switch costs in terms of RTs in autistic participants. Crucially, they demonstrated a significant attenuation of the CNV, which is typically associated with a weaker intentional task preparation. However, no significant differences in the latency or peak amplitude of the P3 were observed between the groups. Specifically, the P3 component demonstrated a usually reported attenuation in switch trials compared to repeat trials, with this pattern being similar in both groups.
Conclusions: Our results imply that the way in which global task intentions are formed differs between autistic individuals and their NT peers. The way that tasks are actually being executed seem to differentiate only at the behavioural level. Altogether, the present study suggests that the tendency of autistic individuals to engage in repetitive behaviours is associated with the formation of task intentions when tasks are chosen voluntarily.

36 **160.036** Neural Signature of Dynamic Facial Processing in Children with ASD

R. Ma[1]*, C. M. Hudac*[2]*, A. Kresse*[3]*, A. Naples*[4]*, S. Faja*[5]*, J. McPartland*[6] *and R. Bernier*[7]*, (1)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, MA, (2)Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA, (3)Seattle Children's Research Institute, Seattle, WA, (4)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Boston Children's Hospital, Boston, MA, (6)Child Study Center, Yale School of Medicine, New Haven, CT, (7)University of Washington Autism Center, Seattle, WA*

Background:
Faces are highly complex visual stimuli and fundamentally dynamic; thus, interpretation of facial movement requires frequent updating of visual representations in tandem with higher-order integration of social knowledge (Jemel et al., 2006; Webb et al., 2010; Naples et al., 2015). Impaired interpretation of facial expression is a striking social deficit that has been commonly observed among children with autism spectrum disorder (ASD; Mottron et al., 2006; Webb et al., 2010; Webb et al., 2012). EEG mu rhythm attenuation has been associated with infants' response to emotional facial motion (Rayson et al., 2016), as well as understanding and interpretation of others' actions more generally (Muthukumaraswamy & Johnson, 2004). Prior research indicates that children with ASD demonstrate atypical mu rhythm attenuation when attending to dynamic social information (i.e., biological movement; Bernier et al., 2007; Hudac et al., 2015), although findings are inconsistent (Oberman et al., 2012; Bernier et al, 2013). However, little is known about this neural signature during the observation of dynamic facial expressions in ASD.
Objectives:
The focus of current work is twofold: 1) to examine spectral power in the mu rhythm during the observation of dynamic facial information perception in ASD and 2) to extend our understanding of this neural activity to social behavior.
Methods:
Children with ASD (*n*=37, *M*=11.6, *SD*=3.24) and typically developing (TD) children (*n*=42, *M*=11.5, *SD*=2.21) participated in an EEG study during which they were presented with photorealistic, computer-generated faces. As reported in Naples et al. (2015), the faces consisted of fearful movement and affect free movement (puffed cheeks). Power spectra relative to resting baseline across scalp electrode clusters surrounding C3 and C4 were averaged across trials for each condition. Following Bernier et al. (2013), mu attenuation was calculated as the log of the ratio of power in 8-13 Hz during observation over power in the same frequency range during resting baseline for each individual. Data collected from the Benton Facial Recognition Test (BFRT, Benton, 1983) and the Reading the Mind in the Eyes Task – Revised (RMET-R; Baron-Cohen et al., 2001) served as social behavior outcomes.
Results:
Univariate ANOVA indicated that both groups displayed mu attenuation in response to dynamic facial movement relative to a resting state baseline. However, there was no significant effect of group (p=.196) or condition (p=.654) on mu attenuation. Consistent with previous literature, one-way ANOVA indicated that children with ASD scored significantly lower (2.46 points) on the RMET-R [F(1,77)=11.57, p=.001]. Group differences were not observed on the BFRT (p=.09).
Conclusions:
Despite group differences in behavioral measures of social information processing based on observation of static images of emotionally expressive eyes in ASD, as indexed by the RMET-R, children with ASD and TD in this study exhibited similar patterns of mu attenuation in response to facial movement. These results concord with previous research failing to find differences in mu attenuation across diagnostic groups, extending these results to the perception of dynamic facial movement.

37 **160.037** Probing Visual Correlates of Excitatory/Inhibitory Imbalance Using EEG: A Transdiagnostic Study in ASD and Schizophrenia

Background: Excitatory/inhibitory imbalance is a mechanistic theory posited to explain dysfunction in both autism spectrum disorder (ASD) and schizophrenia (SCZ). In visual cortex, excitatory/inhibitory balance underlies surround suppression effects, in which neural response to a central stimulus is suppressed when it is surrounded by parallel stimuli but facilitated when it is surrounded by perpendicular stimuli. By assessing suppression of neural response in the context of parallel vs. perpendicular surround, this study provides a direct probe of the excitatory/inhibitory imbalance hypothesis across disorders.
Objectives: This study aimed to (i) evaluate an event related potentials (ERP) index of surround suppression in adults with ASD and schizophrenia and (ii) examine transdiagnostic associations between neural response and social and perceptual difficulties.
Methods: Participants included 14 adults with ASD and 12 with SCZ. EEG data was recorded using a 128-channel sensor net. Participants observed vertical sinusoidal gratings filling a central annulus, either alone, surrounded by gratings that were perpendicular, or surrounded by parallel gratings (Fig.1). With intact surround suppression, attenuated ERP amplitudes are expected to parallel vs. perpendicular surround. To maintain attention, participants pressed a button when a central fixation turned green; these trials were discarded from analysis. EEG data was preprocessed off-line, and the P50 and N1 components were extracted over occipital scalp (Oz). Participants completed the Social Responsiveness Scale (SRS), Schizotypal Personality Questionnaire (SPQ), and Sensory Gating Inventory (SGI). Between-group differences were examined with repeated measures ANOVAs (DVs: P50 and N1 mean amplitude, 40-60ms and 75-125ms after stimulus onset, respectively). Transdiagnostic associations between neural response to perpendicular versus parallel surround and self-report of social and perceptual difficulties were explored with bivariate correlations.
Results: For the P50, there was a significant main effect of Group (F=4.41, p=.046) such that P50 amplitude was attenuated in ASD vs. SCZ across conditions. There was no main effect of Condition and no Condition by Group interaction (ps>.26), indicating that neither group showed significant suppression of the P50 response with parallel surround (Fig.2). For the N1, there was a marginally significant main effect of Condition (F=4.04, p=.056), wherein N1 amplitude was attenuated to parallel vs. perpendicular surround across groups; however, there was no significant interaction or main effect of Group (ps>.26). Across ASD and SCZ, suppression of N1 response was not associated with self-report of ASD symptoms on the SRS. However, reduced N1 suppression was associated with greater levels of symptoms on the SPQ ideas of reference scale (r=-.688, p=.04). Stronger N1 suppression was associated with greater fatigue and stress vulnerability with sensory input on the SGI (r=.578, p=.039).
Conclusions: Here, we show evidence for surround suppression in both ASD and SCZ in the N1 response to parallel versus perpendicular surround that does not differ by diagnostic category. Instead, strength of suppression mechanisms related to perceptual delusional beliefs and behavioral experience with sensory stimuli, transdiagnostically. These findings support a dimensional (RDoC) approach to understanding the extent and impact of excitatory/inhibitory imbalance in ASD and related disorders.

38 **160.038** Reduced Frontal P1 Amplitude Differentiation As a Neural Signature of Speech Sound Disorder in ASD

A. B. Arnett[1], *C. M. Hudac*[1], *T. DesChamps*[2], *R. Ma*[3], *B. E. Cairney*[4], *A. S. Wallace*[4], *J. Gerdts*[4] *and R. Bernier*[4], *(1)Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, MA, (4)University of Washington Autism Center, Seattle, WA*

Background: Auditory statistical learning supports acquisition of language and social skills and is therefore of particular interest in autism spectrum disorder (ASD). The extant literature is inconclusive regarding the role of statistical learning in language deficits associated with ASD. Prior research on this topic has been limited by inclusion of only high functioning individuals and reliance on explicit measurement of this implicit process (e.g. Mayo & Egsti, 2012). Moreover, the heterogeneity of the ASD phenotype has potential to mask patterns of neurodevelopmental differences among clinical subgroups. The P1 event related potential (ERP) is an index of auditory cortical development (Sharma et al., 2005) that can be measured during passive statistical learning tasks, and thus has potential as a marker of disrupted, bottom-up processing of auditory information in ASD.
Objectives: The current study aims to characterize the P1 ERP component in youth with ASD in the context of auditory statistical learning. We hypothesize that the ASD group will have more difficulty encoding and recognizing auditory stimuli, as evidenced by reduced frontal P1 differentiation between learned and unlearned sequences of speech-like sounds. Additionally, we expect that within the ASD group, weaker frontal P1 differentiation will be associated with a profile of lower verbal IQ, verbal memory deficits, and impaired speech production.
Methods: 102 youth with ASD (n=58), comorbid ASD and speech sound disorder (ASD+SSD; n=12), or no neurodevelopmental diagnosis (n= 32) ages 7 to 17 years (mean = 12.74) participated in electroencephalogram (EEG) testing as part of two larger studies of ASD. ASD and comorbid diagnoses were established by trained clinical professionals following a clinical evaluation that included thorough clinical interview, cognitive and behavioral assessment. ERPs were measured during an eight minute, passive, auditory word segmentation task. During an initial exposure period, participants listened to streams of nonword syllabic phonemes. This was followed by a test phase wherein both novel and previously heard tri-syllabic combinations were randomly presented across 48 trials.
Results: Results of the two-level, repeated measures analysis are presented in Table 1. Auditory statistical learning in the test phase was evidenced across the entire sample by a significantly stronger mean frontal P1 amplitude response to the learned versus unlearned stimuli. Age attenuated this effect, with older youth demonstrating smaller differences between stimuli and weaker mean amplitudes overall. Contrary to expectations, ASD diagnosis, verbal IQ and verbal memory did not moderate the effect. However, ASD+SSD youth did show significantly weaker differentiation between learned and unlearned stimuli, indicating impaired auditory statistical learning within this clinical subgroup.
Conclusions: Increasingly, research on ASD is emphasizing the heterogeneity of the disorder, including variability in psychiatric comorbidity. In the current study, abnormal frontal P1 amplitude is identified as a neural signature of comorbid ASD + SSD. The results are consistent with a deficit in bottom-up processing of auditory input that affects encoding and reproduction of speech sounds, but may also be consistent with a bi-directional effect, wherein poor speech production impairs refinement of specialized neural circuits that support phonemic awareness.

39 **160.039** Residual Relationships Between Motion and Bold Activity Remain after Preprocessing

L. Byrge *and D. P. Kennedy, Psychological and Brain Sciences, Indiana University, Bloomington, IN*

Background: Head motion is known to influence the BOLD fMRI signal, but its effects are not yet fully understood. Certain techniques, such as functional connectivity MRI (fcMRI), are particularly sensitive to motion, which has been shown to spuriously affect conclusions in studies comparing groups that differ in movement characteristics (Power et al., 2012; Deen & Pelphrey, 2012; Tyszka et al., 2014), such as controls and individuals with ASD. Many data cleanup practices (e.g. censoring/"scrubbing") require considerable loss of data, and might not fully eliminate residual motion influences (Burgess et al., 2016). Thus a further characterization of the influences of motion on the BOLD signal is needed.
Objectives: To develop new methods to quantify relationships between head movement and BOLD activity, and assess whether current cleanup methods adequately account for movement-related effects on the BOLD signal.
Methods: We analyzed two datasets. (1) Two 16-minute resting state fMRI scans (TR=813ms) from 29 adolescent and adult controls and 24 matched individuals with ASD collected at Indiana University. (2) Two 14-minute resting state scans (TR=720ms) from 75 unrelated Human Connectome Project participants (Van Essen et al., 2013). Both datasets were preprocessed nearly identically using state-of-the-art cleanup methods (ICA-FIX; Salimi-Khorshidi et al., 2014; Smith et al., 2013). Dataset 1 was also alternatively preprocessed using conventional motion and nuisance regression (with and without global signal). We developed a new analytic method for assessing residual movement-linked BOLD artifact, both at the individual and group level, by quantifying the relationship between movement severity and subsequent BOLD activity.
Results: We found that movements are systematically linked with structured and prolonged changes in the BOLD signal that depend on the severity of the preceding motion. This relationship was not limited to high movement epochs; in fact, remarkably small movements were linked with structured BOLD changes occurring considerably later in time. Nearly all motion magnitudes (including those well below typical censoring thresholds) were associated with structured BOLD changes extending as far as 30s later; for some larger motions, over 50s later. Effect sizes of motion-linked BOLD changes were largest at approximately 6s and 20s following motion. These patterns were replicated in 4 independent sessions from two different scanners and persisted robustly across multiple preprocessing methods, but were not observed in four different null models. Note that scrubbing procedures cannot eliminate these temporally distant BOLD changes, as they persist much later than typical temporal masking (e.g. over 5-10 TRs post-motion).
Conclusions: We provide a novel description of systematic and temporally far-reaching influences of motion on the BOLD signal, supporting previous case reports (Power, 2016; 2014). These influences are not yet adequately handled by state-of-the-art preprocessing methods, and have the potential to artifactually influence results of fcMRI studies that compare groups differing in motion characteristics. Characterizing this pattern is a critical first step in developing new methods that can address it appropriately. Our results suggest caution in interpreting the meaning of different patterns of functional connectivity between ASD and controls until we better understand the interaction between motion and the BOLD signal.

40 **160.040** Resting State EEG and Sensory Responsivity in ASD and Schizophrenia

S. Hasselmo[1]*, S. M. Malak*[2]*, J. A. Trapani*[2]*, M. J. Rolison*[2]*, K. A. McNaughton*[3]*, T. C. Day*[2]*, S. A. A. Chang*[4]*, K. Ellison*[2]*, B. Lewis*[5]*, E. Jarzabek*[2]*, J. Wolf*[3]*, J. H. Foss-Feig*[6]*, V. Srihari*[7]*, A. Anticevic*[7]*, A. Naples*[8] *and J. McPartland*[2]*, (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale School of Medicine, New Haven, CT, (3)Yale Child Study Center, New Haven, CT, (4)Yale University, New Haven, CT, (5)Yale School of Medicine, Darien, CT, (6)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (7)Yale University School of Medicine, New Haven, CT, (8)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Many individuals with autism spectrum disorder (ASD) report and display atypical sensory experiences and responses. These manifest heterogeneously: individuals experience both hyper- and hyposensitivity to different sensory modalities and react with both sensory-avoidant and sensory-seeking behaviors. Similar experiences are frequently reported by individuals with schizophrenia spectrum disorders (SZ) and are endorsed by many typical adults, suggesting that sensory features associated with ASD vary continuously throughout the population. The mechanisms underlying the heterogeneity of sensory profiles in individuals with and without ASD are poorly understood; the study of these mechanisms will inform basic understanding of sensory responsivity and guide clinical response to sensory sensitivities and behaviors that impact quality of life in multiple clinical populations.
Objectives: This study examines (a) relationships between EEG power spectra and individual differences in sensory responsivity and (b) whether these relationships differ among individuals with ASD, SZ, and TD adults.
Methods: Resting EEG data were acquired from 33 adult participants (enrollment ongoing; ASD: n=18,13 male; SZ: n=10 9 male; TD: n=5,3 male) using a 128-channel net. Power spectra for delta, theta, alpha, beta, and gamma frequency bands were generated for frontal, temporal, parietal, posterior, and midline regions of the cortex from 2-second segments of EEG data. Sensory sensitivity and responsivity were evaluated using the Glasgow Sensory Questionnaire (GSQ), a 42-question self-report questionnaire that quantifies hypo- and hypersensitivity in 7 sensory modalities.
Results: Â Principal components analysis identified a single component accounting for the majority of variance in the GSQ's subscales, so preliminary analyses examined participants' total scores on the measure. Multiple regression results showed that diagnostic group (ASD/SZ) and GSQ score were significant independent predictors of higher left and right temporal delta power (*left*: ASD, β=140.46, p<0.001; SZ, β=165.58, p<0.001; GSQ, β=4.96, p<0.001; *right*: ASD, β=129.01, p=0.005; SZ, β=148.3, p=0.007; GSQ, β=4.338, p=0.0012). While higher GSQ scores were associated with higher temporal delta power in TD controls, they were associated with lower delta power in participants with ASD or SZ (*left*: ASD:GSQ, β=-5.13, p=<0.001; SZ:GSQ, β=-4.95, p=0.001). This pattern was also seen in the right parietal region: delta power increased with GSQ score in TD controls, and decreased with GSQ score in participants with a diagnosis of ASD or SZ (GSQ, β=3.47, p=0.017; ASD:GSQ, β=-4.05, p=0.009; SZ:GSQ, β=-3.878, p=0.017). Midline gamma (30-80 Hz) power showed significant effects of schizophrenia diagnosis and GSQ score independently, as well as interactions between GSQ and diagnosis of either ASD or SZ (SZ, β=-3.08, p=0.013; GSQ, β=-0.07, p=0.01; ASD:GSQ, β=0.07, p=0.015; SZ:GSQ, β=0.096, p=0.004), suggesting that midline gamma power decreased with higher score on the GSQ in TD controls and increased with GSQ score in participants with SZ, staying constant in participants with ASD.
Conclusions: Neural oscillations in specific regions and frequency bands varied with sensory sensitivity and responsivity; associations between the power in these spectra and sensory sensitivity were modulated by diagnosis of ASD or schizophrenia in a direction opposite of that observed in TD participants. These results suggest common neurological mechanisms underpinning atypical sensory processing and response in ASD and SZ.

41 **160.041** Resting-State Theta Oscillations Predict Executive Functioning Deficits in Children with Autism Spectrum Disorder

A. M. Zhou[1]*, T. Clarkson*[2]*, A. R. Levin*[3] *and S. Faja*[1]*, (1)Boston Children's Hospital, Boston, MA, (2)Psychology, Stony Brook University, Stony Brook, NY, (3)Neurology, Boston Children's Hospital, Boston, MA*

Background: Â Children with autism spectrum disorder (ASD) often show deficits in executive functioning (EF), the ability to manage complex or conflicting information to achieve a goal. EF deficits in ASD may be associated with impaired prefrontal activity and functional integration with the rest of the brain (O'Hearn et al., 2008). In particular, resting-state theta oscillations have been suggested to play a general integrative role in the organization in brain activity, and are particularly important for EF domains that require a variety of cognitive processes such as working memory and inhibitory control (Sauseng et al., 2010). There is significantly greater resting-state theta power in individuals with ASD in the frontal and parietal regions (Wang et al., 2013; Cornew et al., 2013). Taken together, prior research suggests that resting theta oscillations in children with ASD may be a possible neural system abnormality that underlies EF deficits. To our knowledge, associations between resting theta oscillations and EF deficits within children with ASD have not yet been explored.
Objectives: To examine whether frontal and parietal resting-state theta oscillations predict EF deficits in children with ASD.
Methods: 28 children with ASD (M = 114 months, SD= 13.53) provided adequate EEG data with data collection still underway. EEG was recorded during both eyes-closed and eyes-open resting conditions. To compute power spectra, 2 minutes of EEG were divided into intervals of 2-seconds. A Hanning window and a Fast Fourier Transformation were applied. Children also completed a Flanker task as a measure of inhibition, and EEG was recorded and analyzed for the N2 event-related potential. Parents completed the Behavioral Rating Inventory of Executive Function (BRIEF), which measures global EF skills as well as specific domains of EF.
Results: Linear regressions controlling for age, gender and IQ examined the relation between theta power and EF deficits. Lower frontal theta power during eyes-open condition predicted worse working memory (β = -0.54, t(16) = -2.20, p = 0.04) and planning/organization (β = -0.56, t(16) = -2.77, p = 0.02) on the BRIEF. With eyes open, reduced parietal theta power predicted increased N2 amplitude during incongruent trials (β = -0.38, t(15) = -3.00, p = 0.01) but faster reaction times during the flanker task (β = -0.55, t(15) = -2.68, p= 0.02).
Conclusions: These results suggest that resting theta oscillations predict EF deficits in children with ASD and provide some preliminary evidence that individual differences in the resting-state neural systems in children with ASD may be associated with task-dependent activation in the brain during EF tasks. However, increased theta in both frontal and parietal regions predict *better* EF performance. This is surprising given that decreased theta power during resting is correlated with better cognitive performance in a typically developing sample (Klimesch, 1999). The relation between parietal theta and increased N2 amplitude suggests there may be an association between decreased theta power during rest and increased anterior cingulate cortex activation during the flanker task. We plan to examine these associations in a typically developing sample, and compare resting-state theta power between groups.

42 **160.042** Sensory Characteristics and Autistic Traits Influence Neural Responsivity to Predictable Versus Unpredictable Visual Information

J. A. Trapani[1]*, S. A. A. Chang*[2]*, S. M. Malak*[1]*, K. Stinson*[3]*, K. Ellison*[1]*, J. McPartland*[1] *and A. Naples*[4]*, (1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale University, New Haven, CT, (3)Yale University- Child Study Center, Milford, CT, (4)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Hypo- and hyper-sensory response and preference for predictability are common features of autism spectrum disorder (ASD). Prior research investigating sensory sensitivities and using event-related potentials (ERPs) has demonstrated atypical early visual processing in individuals with ASD. However, most ERP paradigms are repetitive and temporally predictable. Because early visual brain response is influenced by expectancy, the temporal regularity of previous ERP experiments represents a potential confound, raising the possibility that differences attributed to abnormalities in low level visual processing might reflect atypical response to predictable stimuli rather than disruptions in the functional integrity of the visual pathway.
Objectives: This study investigates the (a) relationship between sensory processing, as indexed by visual evoked potentials (VEPs), and the predictability of visual stimulation and (b) the degree to which this relationship is modulated by autistic traits and sensory characteristics.
Methods: ERPs were recorded from 10 typically developing adults (data collection is ongoing) using 128-channel sensor nets. Eye movements were recorded concurrently with an SR eye-tracking system. In two experimental paradigms, black and white checkerboards appeared on screen and reversed phase. In the predictable condition, the phase reversal occurred every 500ms. In the unpredictable condition, reversal occurred randomly between 300 and 1000ms. ERPs were time-locked to each phase reversal; occipital P1 and N1 amplitude and latency were extracted for analyses. Self-report questionnaires captured sensory features (Glasgow Sensory Questionnaire; GSQ) and autism characteristics (Broad Autism Phenotype Questionnaire; BAP-Q; Social Responsiveness Scale; SRS).
Results: Preliminary data analyses indicated that predictability of visual change had a statistically significant effect on P1 amplitude, $F(1,9)=6.323$, $p=.03$, such that P1 amplitudes were larger for the unpredictable condition. Larger N1 peak amplitudes in the unpredictable condition correlated with greater subthreshold autistic symptomatology (SRS Restricted Interest and Repetitive Behavior subscale, $r=.707$, $p<.05$). Difference scores for P1 amplitude between the unpredictable and predictable conditions correlated with the Visual Modality of the GSQ, $r=.764$, $p<.05$, such that increased amplitudes in the unpredictable condition explained higher levels of visual sensitivity. Additionally, difference scores for P1 latency demonstrate that earlier P1 responses in the unpredictable compared to the predictable condition were associated with an increased level of autistic traits (BAP-Q Pragmatic Language Subscale, $r=-.773$, $p=.009$).
Conclusions: Distinct neural responses were elicited by visual stimuli presented at predictable versus unpredictable rates. Moreover, variability associated with expectancy explained variance in the autism phenotype. Individuals who displayed enhanced or more rapid response to unpredictable stimuli reported increased visual sensory sensitivities, higher level of social-communication difficulties, and more repetitive interests and behaviors. Ongoing analyses will explore oscillatory harmonics of the VEP and the relationship between pupil dilation, brain activity, and symptomatology. These data show that symptom variability is associated with both early visual processing and top down expectancies and that these relationships are dissociable. By exploring the intersection of top-down and bottom-up sensory driven brain activity we are better poised to determine how these factors influence sensory and social symptomology and uncover sources of heterogeneity in ASD.

43 **160.043** Sex Differences in Amygdala Resting State Connectivity in Young Children with Autism Spectrum Disorder

J. K. Lee[1], *B. Winder-Patel*[2], *M. Solomon*[3], *S. Ozonoff*[1], *D. G. Amaral*[3] *and C. W. Nordahl*[3], *(1)Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (2)MIND Institute, University of California, Davis, Sacramento, CA, (3)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA*

Background: Sex differences in neuropathology and neural phenotypes of autism spectrum disorder (ASD) are currently poorly understood. While prior research in pre-school aged males with ASD implicated atypical amygdala resting-state functional magnetic imaging (rfMRI) connectivity, these differences in functional connectivity have yet to be examined in a female cohort of young children.
Objectives: The current research examines sex-differences in resting state amygdala functional connectivity in preschool aged children with ASD.
Methods: The sample included 105 children with ASD (76 male, 29 female) and 51 age-matched typically developing (TD) controls (30 male, 21 female) (mean age 3.76 years). Diagnostic assessments for ASD were carried out by expert clinicians using the ADOS and ADI-R. Structural and resting state EPI BOLD images were acquired during natural nocturnal sleep. Resting state images were preprocessed using tools from AFNI, FSL, and ANTS in the Configurable Pipeline for the Analysis of Connectomes (C-PAC) using identical preprocessing parameters as reported in Shen et al., (2016). In brief, EPI images were time-shifted, motion corrected, and band-pass filtered ($.008 < f < .08$ Hz). Volumes with frame-wise displacement greater than 0.25mm were scrubbed. EPIs were then co-registered to the participant's structural T1-weighted image and then to MNI space, and smoothed at 6 mm FWHM. Seed-based connectivity analyses compared sex, diagnosis, and sex by diagnosis group differences in functional connectivity between amygdala and the rest of the brain. Cluster based correction for multiple comparisons was carried out using Gaussian Random Field theory using FSL ($Z > 2.3$, $p_{GRF} < .05$).
Results: Preliminary results revealed atypical amygdala functional connectivity in both boys and girls with ASD. Investigation of sex by diagnosis interactions revealed multiple clusters in frontal, temporal and cingulate cortices. In general, sex differences that were observed in typically developing males and females were attenuated in children with ASD. These results suggest that the neural phenotype of ASD in young children is differentially presented in males and females compared to their respective typically developing peers.
Conclusions: These preliminary data suggest that females and males with ASD have at least partially dissimilar patterns of functional connectivity with the amygdala.

44 **160.044** Sex Differences in the Neural Processing of Interactive Eye Contact in Individuals with Autism Spectrum Disorder

K. A. McNaughton[1], *B. Lewis*[1], *A. Naples*[2], *T. C. Day*[1], *S. A. A. Chang*[1], *M. J. Rolison*[1], *K. Ellison*[1], *E. Jarzabek*[1], *J. Wolf*[1], *S. M. Malak*[1], *J. A. Trapani*[1], *K. Stinson*[1], *J. H. Foss-Feig*[3] *and J. McPartland*[1], *(1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY*

Background: Sex differences in autism spectrum disorder (ASD) exist in the manifestation of social deficits (Lai, Lombardo, Auyeung, Chakrabarti, & Baron-Cohen, 2015), including differences in neural processing of static faces (Coffman, Anderson, Naples, & McPartland, 2015). However, sex differences in the neural correlates of social processing during dynamic social perception have not yet been examined, which may better reflect the interactive demands of social activity.
Objectives: To identify sex differences in neural processing of interactive eye contact in individuals with ASD and typical development.
Methods: Individuals with ASD (*n*=55; male=41) and typically developing (TD) individuals (*n*=44; male=26) participated in a gaze-contingent EEG experiment. Sex by diagnosis subgroups were matched for age and IQ. EEG data were collected using a 128 electrode Geodesic net, and eye-tracking data were collected using an SR-Research EyeLink 1000. Each trial began with a face displaying direct or averted gaze. When the participant looked at the face, the face responded by either looking at (direct gaze) or away from (averted gaze) the participant. P100 and N170 ERPs, components reflecting lower-level visual processing and face processing, respectively, were examined.
Results: A significant interaction was found between sex, diagnosis, and hemisphere for N170 peak amplitude ($F(1, 93)=9.10$, $p<.01$). Specifically, left hemisphere N170s were more negative than right hemisphere N170s for females with ASD, while males with ASD and TD females and males displayed the opposite lateralization pattern. There was also a significant interaction between sex, diagnosis, and condition (direct or averted gaze) for N170 peak amplitude ($F(1, 93)=5.26$, $p=0.02$). More negative N170s were evoked to direct gaze compared to averted gaze for females with ASD and males in both groups, while TD females displayed the reverse pattern. Eye-tracking results revealed a significant interaction between sex, diagnosis, and condition for amount of time looking at the eyes ($F(1, 93)=5.71$, $p=0.02$). Females with ASD spent a significantly longer time looking at the eyes in the averted compared to the direct condition ($t(15)=2.61$, $p=0.02$). There was no significant difference in looking patterns between conditions for other sex by diagnosis subgroups.
Conclusions: These findings suggest that there are important differences in how females with ASD respond to dynamic social interactions in both behavior and neural processing. Females with ASD look longer at eyes displaying averted compared to direct gaze, and, during these interactive tasks, this group displays atypical left-lateralization in neural response that differs from males with ASD and TD peers. Sex-specific brain activity and looking patterns in individuals with ASD highlight the importance of considering sex as a variable in understanding ASD and suggest distinct mechanisms underlying social perception in females with ASD.

45 **160.045** Striatal and Thalamic Metabolite Levels and Restricted and Repetitive Behaviors in Twins with Autism Spectrum Disorder

J. P. Hegarty II[1]*, M. Gu*[2]*, D. Spielman*[2]*, S. Cleveland*[1]*, J. Hallmayer*[1]*, L. Lazzeroni*[1]*, M. Raman*[1]*, T. W. Frazier*[3]*, J. M. Phillips*[1]*, A. L. Reiss*[1] *and A. Y. Hardan*[1]*,*

(1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Radiology, Stanford University, Stanford, CA, (3)Cleveland Clinic Center for Autism, Cleveland, OH

Background:
Cortico-striatal-thalamo-cortical (CSTC) circuits are involved with carrying out goal-directed behaviors and disruption of these pathways is associated with aberrant behaviors, such as atypical repetition. Although limited, investigations of individuals with ASD support a relationship between CSTC circuit abnormalities and restricted and repetitive behaviors (RRB). For example, volumetric abnormalities in the striatum and thalamus in individuals with ASD are significantly associated with the severity of RRB symptoms.
Objectives:
The goal of this investigation was to examine neurochemical profiles of CSTC regions to determine whether children with ASD exhibit abnormalities that are related to RRB symptom severity.
Methods:
Data were acquired as part of a neuroimaging study of same-sex twin pairs that included monozygotic (MZ) and dizygotic (DZ) twins with ASD and typically-developing (TD) control twins. Clinical diagnosis of ASD was confirmed with the Autism Diagnostic Interview-Revised (ADI-R) and Autism Diagnostic Observation Schedule (ADOS). Cognitive and behavioral assessment included measures of intelligence, the Stanford Binet Intelligence Scales-Fifth Edition (SB-5), and autism-related symptom severity, the Social Responsiveness Scale (SRS) and Repetitive Behaviors Scale-Revised (RBS-R). Magnetic resonance imaging was carried out on a 3T GE scanner and an axial MR spectroscopy chemical shift imaging slab was acquired. The corresponding grid was shifted during post-processing to center voxels on the left and right thalamic nuclei and striatum. Metabolites were assessed in relation to internal creatine levels and adjusted for tissue composition. A subset of participants (only a single twin from each pair) with valid spectra from the thalamus and striatum (CRLB < 20%) were included.
Results:
For this preliminary analysis, thalamic voxels were available from 47 individuals with ASD (21 MZ and 26 DZ) and 33 TD (19 MZ and 14 DZ) and striatal voxels were available from 15 individuals with ASD (6 MZ and 9 DZ) and 20 TD (11 MZ and 9 DZ). The ASD and TD samples included children and adolescents (age range: 6-15 years) and were adequately matched as there were no group differences in age or gender, $p>0.05$. However, individuals with ASD exhibited lower IQ compared to controls ($M_{ASD}=74.49$,$SD=26.76$; $M_{CTRL}=112.00$,$SD=11.86$), $p<0.001$. Examining metabolite levels, N-acetyl aspartate (NAA) was significantly lower in ASD in the left thalamus ($M_{ASD}=1.39$,$SD=0.17$; $M_{CTRL}=1.47$,$SD=0.12$; $F(1,77)=7.89$, $p=0.021$) and left striatum ($M_{ASD}=1.32$,$SD=0.21$; $M_{CTRL}=1.47$,$SD=0.26$; $F(1,32)=7.36$, $p=0.011$). Furthermore, NAA levels in the thalamus ($r_{RBS-R}=-0.34$,$p=0.004$) and striatum ($r_{RBS-R}=-0.43$,$p=0.021$) were significantly associated with RRB symptoms, such as the compulsive behavior subscale of the RBS-R.
Conclusions:
Preliminary data from this investigation indicate that children and adolescents with ASD may be more likely to exhibit lower NAA levels in regions comprising CSTC circuits. NAA is a marker of neuronal integrity and is decreased in numerous neurological conditions; thus decreased NAA is considered a marker of underlying neuropathology. Our findings suggest that perturbation of CSTC circuits is associated with the presentation of RRB. Larger samples, more regions, and additional analyses, such as the assessment of heritability, will be examined as additional data is processed and will allow further elucidation of the neurobiological basis of restricted and repetitive behaviors in individuals with ASD.

46 **160.046** The Neural Mechanisms of Gaze-Based Social Interaction in Adults with High-Functioning Autism: Investigating the Effects of Predictability

H. Parpart*, M. L. Brandi and L. Schilbach, Independent Max Planck Research Group for Social Neuroscience, Max Planck Institute of Psychiatry, Munich, Germany*

Background: Autism is characterized by impairments in communication and social interaction. Recent findings indicate that this might be due to disturbances in the automatic integration of social cues for decision-making. In addition, it has been proposed that low levels of predictability of the outcome of an interaction might be particularly problematic for individuals with autism.
Objectives: Hence, the main focus of this study is to examine whether the predictability of the outcome of an interaction has an influence on the neural basis of social encounters in adults with autism.
Methods: In a combined fMRI and eyetracking study individuals with high-functioning autism (HFA) and matched healthy controls were, therefore, asked to interact with a virtual character via gaze, who they believed was controlled by a real person outside the scanner. In contrast to this cover story, the agent's gaze behavior was systematically varied on a trial-by-trial basis to either follow or not follow the participant's gaze. Additionally, trials were either initiated with a cue predicting the outcome of the interaction or not. Accordingly, we analyzed how differences in the prior knowledge about the person's behavior would influence the neural activation patterns during gaze-based social interaction in individuals with HFA compared to the control participants.
Results: Results replicate previous findings that demonstrate the involvement of reward-related neurocircuitry during gaze-following in control subjects. By contrast, in HFA participants, differential effects were observed in primary sensory areas, while effects in reward-related regions were more strongly modulated by the predictability of the outcome of the interaction.
Conclusions: In sum, this study offers valuable insights into the neural mechanisms of gaze-based social interactions in individuals with HFA by demonstrating modulatory effects of predictability on the neural processing of social interactions.

47 **160.047** The Relationship Between Neural Correlates of Face Processing and Social Communication in Individuals with ASD and Schizophrenia

T. A. Halligan[1], *A. Naples*[2], *J. Wolf*[1], *S. A. A. Chang*[1], *S. M. Malak*[1], *J. A. Trapani*[1], *T. C. Day*[1], *K. A. McNaughton*[1], *M. J. Rolison*[1], *E. Jarzabek*[1], *K. Ellison*[1], *B. Lewis*[1], *J. H. Foss-Feig*[3], *V. Srihari*[4], *A. Anticevic*[1] *and J. McPartland*[1], *(1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (4)Yale University School of Medicine, New Haven, CT*

Background: Difficulty interpreting facial expressions is a common feature of both autism spectrum disorder (ASD) and schizophrenia (SCZ), a disorder with many genetic, neurobiological, and phenotypic similarities to ASD. Consistent with the NIMH's Research Domain Criteria (RDoC) initiative, we sought to understand the neural correlates of face processing across these disorders. This study applied interactive neuroscience methods to study electrophysiological (EEG) brain response during a gaze-contingent paradigm that simulated face-to-face interactions. We aimed to explore the relationship between clinician-rated social communication and neural components of face processing across diagnostic categories.
Objectives: To examine the relationship between face-processing event related brain potential (ERP) components and social communication in ASD and SCZ.
Methods: ERPs were recorded from 14 adults with ASD and 12 adults with SCZ using a 128 electrode Geodesic Net; data collection is ongoing. Participants were presented with 80 distinct photorealistic, animated faces matched for low-level visual features. Utilizing gaze-contingent eye tracking technology, stimuli responded to a participant's direct fixation to the face by exhibiting happy or fearful emotions. P1 and N250 amplitudes were extracted from selected electrodes. All participants were administered the Autism Diagnostic Observation Schedule, 2ndÂ Edition (ADOS-2), a gold-standard diagnostic measure of ASD. ANCOVAs were conducted to investigate the relationship between ADOS severity or item scores and amplitude of the P1 and N250 components.
Results: There were no significant main effects or interactions involving diagnostic group (ASD, SCZ); thus, the following results collapse across diagnostic group. Preliminary analyses revealed a significant interaction between hemisphere, emotion, and ADOS Social Affect (SA) severity score, the covariate, on the mean amplitude of the N250 component (p=.037). Post-hoc correlational analyses showed that as SA severity increases, the N250 component in the right hemisphere is significantly attenuated when viewing happy faces (r= -.479, p=.013). There were no significant correlations between the N250 mean amplitude and SA severity in the left hemisphere or for fearful faces. An additional ANCOVA revealed a significant interaction between hemisphere, emotion, and the ADOS Unusual Eye Contact item score (p=.026) on the peak amplitude of the P1 component. Within-group follow-up t-tests revealed a trend toward more right lateralized P1 when viewing fearful faces for those with normative eye contact (p=.071); in contrast, those with more atypical eye contact showed increased right lateralization when viewing happy faces (p=.012). Between group follow-up t-tests did not reveal significant differences between the P1 peak amplitude of those with atypical eye contact and those with typical eye contact (p>.10).
Conclusions: Our results indicate that clinician ratings of social function are associated with neural response to emotional faces. Distinct patterns of responsivity were observed for different facial expressions, and eye contact during in vivo social interactions was associated with lateralization of brain responses to emotional expressions. These findings reveal relationships between social communication and neural sensitivity to facial expressions that span diagnostic categories, suggesting the importance of examining social communicative biomarkers in transdiagnostic samples.

48 **160.048** Visual Evoked Potentials As a Candidate Endophentype for Autism Spectrum Disorder

J. L. George-Jones[1], *J. Zweifach*[2], *S. M. Lurie*[2], *J. Norry*[1], *A. Durkin*[1], *K. Meyering*[1], *A. Kolevzon*[3], *J. D. Buxbaum*[3] *and P. M. Siper*[1], *(1)Seaver Autism Center at Mount Sinai, New York, NY, (2)Ferkauf Graduate School of Psychology, Yeshiva University, Bronx, NY, (3)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: Sensory symptoms are common in individuals with autism spectrum disorder (ASD), particularly within the visual domain. Visual evoked potentials (VEPs) are an objective, reliable measure of early-stage visual processing that can be used to understand neural mechanisms in the brain while probing for disease pathology. The identification of endophenotypes, quantifiable, hereditary measures of risk that can help to identify links between phenotypic and genotypic variables, is critical for understanding disease susceptibility and protective factors. Previous literature has identified endophenotypes of schizophrenia using VEP paradigms. The current study seeks to examine endophenotypes of ASD using similar VEP methodology.
Objectives: To assess the integrity of visual pathways in unaffected siblings (SIBS) of children with idiopathic ASD (iASD) compared to typically developing (TD) children and children with iASD.
Methods: This study included children with iASD, SIBS, and TD controls between the ages of 2 and 12. ASD diagnoses were based on DSM-5 criteria, the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2), and the Autism Diagnostic Interview-Revised (ADI-R). Genetic testing (chromosomal microarray) was conducted on the ASD sample to rule out the presence of a genetic finding. Children in the SIBS and TD groups were screened with the Social Responsiveness Scale, Second Edition (SRS-2). VEPs were collected using single-channel EEG recording based on the International 10-20 system with an active electrode at Oz (occipital). A battery of both transient and steady-state VEPs was collected, which included a contrast-reversing checkerboard condition to elicit transient VEPs and two isolated-check conditions using bright or dark patterns of increasing contrast to elicit steady-state VEPs.
Results: Participants in the SIBS group displayed intermediate responses compared to the iASD and TD group for both transient and steady-state conditions. Results also replicated previous findings indicating significantly weaker VEP responses in children with iASD compared to TD controls. Specifically, significantly smaller amplitudes were found in response to the transient VEP condition and significantly smaller signal-to-noise ratios were found at low levels of contrast in the steady-state conditions, which reflects ON and OFF pathways in the brain.
Conclusions: Our results suggest that VEPs may reflect an endophenotype of ASD and are consistent with literature from neuroimaging and higher order electrophysiological studies demonstrating intermediate responses in unaffected siblings. The stimuli used in this study reflect mechanisms associated with excitatory/inhibitory imbalance (transient responses) and abnormalities in the magnocellular pathway (steady-state responses). Future studies should continue to examine these mechanisms and their potential as treatment targets. In addition, studies examining high-risk infant siblings are an important step to elucidate the relationship between VEP abnormalities and the presence of iASD.

Poster Session
161 - Cognition: Attention, Learning, Memory
5:00 PM - 6:30 PM - Golden Gate Ballroom

49 **161.049** A Gaze Contingent Exploration of Social Attention in Autism Spectrum Disorder

J. S. Black *and M. Bindemann, School of Psychology, University of Kent, Canterbury, United Kingdom*

Background:
Attending to faces is extremely important for understanding social cues and it is thought that atypical social attention may contribute to social difficulties in Autism Spectrum Disorder (ASD). However, research findings are mixed as to whether faces have the same special status in attention for people with ASD as in typical development. Methodological differences across studies make it hard to reach a consensus about social attention in ASD and why it may appear typical or atypical in different studies. Additionally, the Social Motivation Theory of autism predicts that individuals with ASD will attend to non-social objects of particular interest to them, rather than faces, and previous research has found that objects of Circumscribed Interest (CI) may disrupt social attention when co-occurring with people in a scene.
Objectives:
The present study employed visual scenes containing people and objects of CI to which adults with ASD have previously been found to attend atypically. A novel gaze contingent window technique explored the allocation of attention across these scenes among adults with and without ASD. This technique provides a measure of top down allocation of attention by removing opportunities for automatic attentional capture in peripheral vision.
Methods:
In Experiment 1, a gaze contingent window revealed part of a scene containing people and CI objects within 4˚ visual angle around the point of fixation, and moved with the participants' eye movements. In Experiment 2, participants saw an array of gift boxes, which, upon fixation, revealed a different image of either a face, an object of CI, or a neutral object. Frequency and duration of fixations within each area were recorded. Participants also later rated how much they liked each image and how interesting they found it to explore explicit interest in the stimuli.
Results:
Preliminary results (ASD: n=20 out of 30; Control: n=4 out of 30) found that all participants in Experiment 1 fixated for longer on faces within scenes compared to body or CI regions (ps < .04). In Experiment 2, participants with ASD had longer fixations to neutral objects compared to faces (p=.05). The frequency of fixations on each category of objects did not differ. In addition, participants with ASD rated faces as significantly less interesting and likeable than neutral or CI objects.
Conclusions:
Experiment 1 showed that when peripheral visual information is removed from a scene, social attention appears typical in adults with ASD, with faces holding attention longer than other objects once fixated. However, Experiment 2 found evidence for a reduction of social attention in participants with ASD, when objects were viewed without any meaningful context. This could be because social cues are more contextually relevant when trying to form an overview of a natural scene that is occluded (Experiment 1), compared to when there is no relation between hidden images (Experiment 2). This suggests that adults with ASD are able to preferentially allocate information to social cues when distracting information is removed, and it is beneficial to do so. Further time course analyses will help to elucidate these results.

50 **161.050** An Information Theory Approach to Assessing Perceptual Expectations in Autism

O. E. Parsons[1] *and S. Baron-Cohen*[2]*, (1)University of Cambridge, Cambridge, Cambridgeshire, England, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom*

Background: The capacity to implicitly process statistical regularities in one's environment is a core aspect of perception and cognition. Prior experiences of environmental regularities are used in conjunction with incoming sensory information to arrive at the perceived interpretation of the external environment.
There have been suggestions that there may be impairments in the ability to build these 'priors' in autism. Despite this, studies looking at implicit learning have failed to find significant differences between people with autism and the typical population. However, it is important to note that these studies predominantly focus on implicit learning under deterministic and stable conditions.
Objectives: We set out to assess i) whether differences in implicit learning occur in individuals with autism when underlying regularities are probabilistic rather than deterministic and ii) whether individuals with autism show differences in their ability to update these priors when the underlying regularities change.
Methods: We used a probabilistic serial reaction time task in which participants were asked to use key presses to respond to a visual target which appeared on the screen in one of four possible locations.
During the task, trial outcomes were determined by a probabilistic Markov chain. This was designed so that for each 2-back context, there was a probable and improbable target location for the subsequent trial. Acquiring implicit knowledge of the underlying structure of the trial sequence leads to reduced response times during probable trials when compared to improbable trials.
The participants (15 with a diagnosis of autism and 20 controls) were asked to complete a primary phase of 8 blocks (of 120 trials each) before moving on to a secondary phase of 8 blocks in which probable and improbable locations were reversed for all contexts.
Results: Individual differences in implicit acquisition of the underlying sequence in the task were assessed by comparing response times for probable and improbable trial types. To assess differences in the ability to adapt to changes in the underlying predictive structure, we calculated gain scores for performance in the second session relative to the first session.
We conducted a Bayesian Independent T-Test on the gain scores between the autism group (ASC) and the control group (CTR). The CTR group had higher gain scores on average than the ASC group (M = 0.67 and -1.21 respectively), with a Bayes factor of 19.90 in favor of the alternative hypothesis suggesting that there is strong evidence in support of a group difference.
We then used a computational model to assess how perceptual expectations are influenced by using different lengths of temporal window when calculating the level of uncertainty (Entropy) in the task environment.
Conclusions: Under stable probabilistic conditions, the ASC group showed increased rates of implicit learning relative to the CTR group. However, when the underlying probabilistic structure changed the ASC group were slower to update these expectations.
We discuss how data from computational models can be used to infer how attending to statistical regularities across different time scales might lead to the observed group differences in the behavioral data.

51 **161.051** Association Between Executive Functioning and Attention Deficit/Hyperactivity Disorder Symptoms in Younger Siblings of Children with Autism Spectrum Disorder.

M. P. Trelles[1], *C. R. Newsom*[2], *E. B. Lee*[3], *J. A. Crittendon*[4], *C. Burnette*[5], *E. Malesa*[4], *W. L. Stone*[6], *Z. Warren*[3] *and J. H. Foss-Feig*[7], *(1)Icahn School of Medicine at Mount Sinai, New York, NY, (2)Pediatrics, Vandetbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Vanderbilt, Nashville, TN, (5)University of New Mexico, Albuquerque, NM, (6)Psychology, University of Washington, Seattle, WA, (7)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY*

Background:
Relatives of individuals with autism spectrum disorder (ASD) often present with a variety of social and neurocognitive difficulties, despite not meeting formal criteria for ASD. This profile is termed "broader autism phenotype" (BAP) and often includes subclinical ASD symptoms. Difficulties in executive functioning (EF) characterize ASD and are associated with BAP. However, EF deficits are not unique to ASD, as it is also central to other disorders, including Attention Deficit/Hyperactivity Disorder (ADHD). ADHD and broader attentional problems are also present in relatives of individuals with ASD; therefore, whether EF difficulties in this population are more associated with ASD- or ADHD-like clinical profiles remains unclear.
Objectives:
To evaluate whether EF vulnerabilities are associated with symptoms of either BAP (sub-threshold ASD) or attention problems in a sample of younger siblings of children with ASD.
Methods:
22 younger siblings of children with ASDÂ (Mean age: 65.55 months; SD: 5.98, Range: 60-80 months) were administered a battery of EF tests from the NEPSY-II (Inhibition-Naming, Inhibition-Inhibition, Design Fluency, Auditory Attention, Statue) and evaluated for ASD and ADHD using the Social Responsiveness Scale (SRS), Autism Diagnostic Observation Schedule (ADOS), Child Behavior Checklist (CBCL) Attention Problems subscale, and clinician best estimate (CBE) of ASD and ADHD. Bivariate correlations were conducted to assess the association between EF and clinical symptomatology.
Results:
The EF Composite was not correlated significantly to indices of ASD-related symptomatology on the ADOS (r=-.074, p=.74), SRS (r=-.233, p=.32), or ASD CBE (r=.187, p=.42). Moreover, no EF subtest correlated significantly with any measure of ASD-related symptomatology (all ps>0.17). In contrast, EF abilities at five years-old were correlated significantly with the CBE of ADHD (r=-.663, p=.001) and correlations between the EF composite and parent reported symptoms on the CBCL Attention Problems subscale score approached statistical significance (r=-.398, p=.067). The Auditory Attention subtest scaled score correlated significantly with the CBCL Attention Problems score (r=-.515, p=.014), as well as marginally with the ADHD CBE score (r=-.350, p=.12). ADHD CBE correlated significantly with Inhibition-Naming (r=-.581, p=.006), Inhibition–Inhibition (r=-.550, p=.01), Statue (r=-.480, p=.028), and Design Fluency (r=-.468, p=.032).
Conclusions:
In younger siblings of children with ASD who do not meet criteria for ASD, EF difficulties are more associated with broad attention problems and ADHD than with subthreshold ASD features typically associated with BAP. Despite the high recurrence rate of ASD in siblings, these findings suggest that, when considering EF difficulties in relatives of individuals with ASD, clinicians should consider other clinical profiles, such as ADHD. In addition, further exploring the overlap and boundaries between ASD and ADHD may be an important area for future studies when considering EF in both clinical and non-clinical populations.

52 **161.052** Attention Engagement in ASD

J. M. Bebko[1], *C. A. McMorris*[2], *M. Ferland*[1] *and A. Porthukaran*[3], *(1)York University, Toronto, ON, CANADA, (2)York University, Calgary, AB, CANADA, (3)York University, Toronto, ON, Canada*

Background:
Deficits in attention related to disengaging from a stimulus and shifting to another is said to be impaired in autism spectrum disorders (ASD). This has been referred to as “sticky attention”, and tends to occur more in specific experimental paradigms versus being a central deficit in ASD (e.g., see McMorris & Bebko, this conference). Sticky attention has typically been measured by the latencies in participants’ responses to a new peripheral stimulus once presented. However, disengaging and shifting times may also be impacted by the degree to which participants are engaged in the *previous* stimulus *prior* to presentation of the new stimulus. That is, previously identified delays in disengaging or shifting may be secondary to events that preceded the onset of the new stimulus versus what occurs once the new stimulus is presented.Â In this study we look at variability of engagement that children and youth with ASD demonstrate with what has been termed the “central” stimulus in previous studies. Attention difficulties are often present in children with ASD (Keehn et al., 2010) and these differences are hypothesized to manifest in different degrees of engagement with stimuli, measured by time spent looking at a single stimulus prior to onset of a new stimulus.
Objectives:
Using an eye-tracking attention task, we examined the degree of attention engagement of children with ASD compared to typically developing (TD) peers as measured by duration of fixations to stimuli.
Methods:
Twenty TD children and 20 children with ASD matched on chronological age (range: 75-184 months) and cognitive abilities, watched a series of videos where stimuli would appear for 3 seconds sequentially in 4 quadrants of a TV screen. To examine potential differences in engagement by stimulus type, 2 types of stimuli were presented, social (a person telling a story) and non-social (e.g, hand playing a piano). Eye fixations were recorded using a Tobii eye-tracker.
Eye fixations were analyzed in two ways: 1) the sum total of all durations on each stimulus (SUMTOT); and 2) the duration of the last fixation before a new stimulus appeared (DLF). If sticky attention is related to the degree of *engagement* of attention *before* a new stimulus is shown, then longer durations should be seen in both methods for ASD.
Results:
Analysis of the DLF data yielded a main effect of group with TD being significantly more engaged than ASD, $F(1, 38) = 16.00$, $p < .001$. Similarly, SUMTOT was greater for TD, $F(1,36) = 9.78$, $p < .01$. Further analyses looking at the effect of stimulus type within groups are ongoing.
Conclusions:
These results suggest that differences in disengagement and shifting times in ASD found in previous research need to be re-evaluated in light of significant differences in degree of engagement with the central stimulus *prior* to the presentation of a second stimulus. Differences in engagement with one stimulus may facilitate/interfere with recognition of a changing display when a new peripheral stimulus is presented, altering the latency of response.

53 **161.053** Autistic Traits and Social Anxiety As Unique Predictors of Neural Attentional Responses during Facial Emotion Identification

C. L. Dickter[1], *J. Burk*[1] *and S. Taylor*[2], *(1)College of William & Mary, Williamsburg, VA, (2)College of William and Mary, Glen Allen, VA*

Background:
Individuals with autism spectrum disorder (ASD) exhibit impairments in the ability to perceive and respond to social cues, including facial emotion identification (e.g., Gross, 2004; Keehn et al., 2013). One reason for this deficit may be impairments in neural processing that occurs during emotion identification. Recent research using event-related potential (ERP) components of EEG has demonstrated both that autistic individuals show different neural processing when attending to emotional faces than that of non-ASD individuals (e.g., Sokhadze et al., 2015) and that neural processing is associated with differences in social skills (Hileman et al., 2011). Additionally, social anxiety is often co-morbid with ASD and, in individuals with ASD, social anxiety contributes to impaired facial emotion recognition (Corden et al., 2008). Research is needed to examine how traits related to autism and to social anxiety uniquely contribute to facial emotion identification.
Objectives:
The current study tested whether neural attention to faces depicting different emotions would be differentially affected by traits related to autism and social anxiety.
Methods:
Participants were 41 non-ASD undergraduate students (48.8% men; M_{age} = 19.7 years). Participants completed two self-report measures, the Autism Quotient (AQ, Baron-Cohen et al., 2001), and the Social Phobia and Anxiety Inventory (SPAI-23 Roberson-Nay et al., 2007), which assess autistic behaviors and social anxiety, respectively. While EEG was recorded from 65 electrodes, participants completed an oddball task in which deviant faces representing a change in emotion (i.e., happiness, anger, surprise, and fear) were presented within a series of faces displaying neutral emotions.
Results:
As is typical with an oddball task, visual inspection revealed a P3 ERP component which was quantified at electrode Pz between 300ms and 650ms. Separate analyses were conducted for each of the four oddball emotions: happiness, anger, surprise, and fear. Regression analyses were chosen to examine the unique contribution of autistic traits and social anxiety. These analyses revealed that, for happy stimuli, the AQ was a significant predictor of P3 amplitude, $B = -.95$, $t = -2.35$, $p = .043$, such that participants with more autistic traits showed lower amplitude P3s to happy faces. In addition, for fear faces, both AQ, $B = -.94$, $t = -3.04$, $p = .019$, and social anxiety, $B = 1.07$, $t = 2.48$, $p = .042$, significantly predicted P3 amplitudes. Interestingly, whereas higher autistic traits corresponded with smaller P3 amplitudes to the fear faces (see Figure 1), higher social anxiety was related to larger P3 amplitudes to the fear faces (see Figure 2).
Conclusions:
This study revealed that neural attention to faces depicting different emotions was uniquely predicted by traits related to autism and social anxiety. In fact, although measures of autistic traits and social anxiety are highly related, they were associated with different patterns of brain responses to fearful faces. This work sheds some light on differences in neural activation that impact the ability to perceive and respond to social cues. Future research should continue to examine how traits related to autism and to social anxiety uniquely contribute to facial emotion identification.

54 **161.054** Behavioral Flexibility and the Effect of Various Feedback Types: A Developmental Study

E. Oberwelland[1,2], *J. A. Kruppa*[3,4], *G. R. Fink*[2,5], *B. Herpertz-Dahlmann*[1], *K. Konrad*[1,2] *and M. Schulte-Rüther*[1,2], *(1)Child and Adolescent Psychiatry, University Hospital Aachen, Aachen, Germany, (2)Institute of Neuroscience and Medicine (INM-3), Research Center Jülich, Jülich, Germany, (3)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital RWTH Aachen, Aachen, Germany, (4)Cognitive Neuroscience, Institute of Neuroscience and Medicine (INM-3), Jülich Research Center, Jülich, Germany, (5)Neurology, University Hospital Cologne, Cologne, Germany*

Background:
In an ever-changing environment it is essential to shift strategies or adapt response patterns based on obtained feedback. Such behavioral flexibility is linked to executive functioning and cognitive control, but it has also been shown to have implications for social interactions. Accordingly it has also been linked to two core deficits of autism spectrum disorder (ASD): (1) deficits in social interactions and communication and (2) restricted, repetitive behaviors. Recent studies have used probabilistic reversal learning tasks to examine behavioral flexibility in adolescents and adults. By means of computational modeling (e.g., Hierarchical Bayesian learning models), the underlying processes could be examined more systematically and in depth[1,2]. However, developmental data is still scarce.
Objectives:
In our present study we aim to investigate behavioral flexibility in children and adolescents with and without ASD and systemically examine the effect of various feedback types (i.e. social, individualized and control feedback).
Methods:
The study is still ongoing. Until now 19 typically developing (TD) children (8 and 12 years of age), 14 TD adolescents (13 – 18 years of age) and 12 individuals with ASD (8 and 18 years of age) completed three runs of a probabilistic reversal learning task with either social, individualized or control feedback.
Results:
First, TD children needed more trials to reach the learning criteria (i.e., three consecutive correct trials) compared to TD adolescents. Second, TD adolescents profited more from control feedback than TD children. Third, TD adolescents made more preservative errors (i.e., an incorrect trial after reversal whereby participants have still chosen the previously reinforced response before they at least once chose the new/correct target) than TD children, whereas TD children made more regressive errors (i.e. an incorrect trial after reversal whereby participants choose the previously reinforced response after having already chosen the new/correct target at least once) than TD adolescents. Both type of errors are also highly negatively correlated. This might indicate that children are more susceptible to “false feedback” (which inevitably occurs due to the probabilistic task), and consequently may adapt their response choices more immediately and thus be less systematic than adolescents. The learning behavior of individuals with ASD was comparable to age- and gender-matched TD individuals, but children with ASD rated social feedback as less rewarding than their TD peers. In a next step, we aim to implement computational modeling of the behavioral data to pinpoint individual learning strategies. Additionally, the model parameters will be compared to various background variables (e.g., IQ, autistic traits, attention spam). This again would allow for a more systematic comparison of changes in behavioral flexibility during the course of development as well as its effects in ASD.
Conclusions: Â N/A

55 **161.055** Behavioral Response Inhibition Deficits in Individuals with Autism Spectrum Disorder and Their Parents

E. Bojanek[1], *L. M. Schmitt*[1], *S. P. White*[2], *J. A. Sweeney*[3] *and M. W. Mosconi*[1], *(1)University of Kansas, Lawrence, KS, (2)UT Southwestern Medical Center at Dallas, Dallas, TX, (3)University of Cincinnati, Cincinnati, OH*

Background: Individuals with autism spectrum disorder (ASD) show deficits in behavioral response inhibition, or the ability to suppress contextually inappropriate behaviors. We previously reported that response inhibition also is impaired in unaffected parents and siblings of children with ASD, suggesting that this deficit may be familial and serve as a useful intermediate phenotype for determining pathophysiological processes.
Objectives: To examine if deficits in response inhibition are evident in both individuals with ASD and their biological mothers and fathers.
Methods: Four participant groups completed a manual motor Stop Signal task (SST). Fifty-three probands with ASD ages 5-23 years were matched with 25 typically developing controls (ConPro) on age (5-23 years), gender, and nonverbal IQ. One hundred parents of the ASD (ASD parents) sample ages 29-54 years were matched with 43 typically developing adults (ConPts) on age (28-51 years), gender, and nonverbal IQ. For the SST, participants were seated with their thumbs resting on a button-box. Two types of trials were presented. During “GO” trials, a peripheral “GO” target appeared and participants were instructed to press the button corresponding to the side of the screen where the target appeared. During “STOP” trials, a central cue appeared at a variable delay after the “GO” cue indicating that they should inhibit their response. Prior to the SST, participants completed a block of GO trials to determine their baseline reaction times. We also examined participants’ reaction times for SST GO trials and their rate of successfully inhibiting responses on STOP trials.
Results: Individuals with ASD showed increased rates of stopping errors compared to ConPro ($t(76)=-2.225$, $p=0.029$). Participants increased their reaction times from baseline to SST GO trials, ($t(206)=34.400$, $p<0.001$). Individuals with ASD showed a smaller increase in reaction time from baseline to SST GO trials compared to controls ($t(62)=-2.108$, $p=0.039$). Greater increases in reaction time from baseline to SST GO trials were associated with increased rates of inhibition on STOP trials for probands ($r(39)=.459$, $p=0.003$) and ConPro individuals ($r(21)=.753$, $p<0.001$). This relationship was marginally stronger in ConPro than ASD individuals ($z=1.75$, $p=0.080$). ASD parents also showed increased rates of stopping errors compared to ConPts ($t(141)=-2.333$, $p=.021$). ASD parents showed lower reaction times at baseline ($t(141)=-2.766$, $p=0.006$) and during SST GO trials compared to ConPts ($t(141)=-2.786$, $p=0.006$). However, these groups did not differ on the degree to which they slowed their reaction times from baseline to SST GO trials ($p>.05$). Reduced rates of inhibiting STOP trials were associated with smaller increases in reaction time from baseline to SST GO trials for the ASD parents ($r(98)=.488$, $p<0.001$) and the ConPts ($r(41)=.305$, $p=.047$).
Conclusions: Our findings show that individuals with ASD have a reduced ability to inhibit inappropriate behaviors, and that these deficits reflect a failure to strategically delay the onset of these behaviors. Similar patterns of increased rates of stopping errors and reduced behavioral reaction times were seen in unaffected parents of individuals with ASD, suggesting that deficits in inhibitory control processes may be familial in ASD and useful for identifying pathogenic mechanisms.

56 **161.056** Characterizing the Heterogeneity of Academic Achievement in ASD

H. N. Wakeman[1], *L. Chen*[2], *T. Iuculano*[3], *M. Rosenberg-Lee*[4] *and V. Menon*[5], *(1)University of Colorado - Boulder, Boulder, CO, (2)Psychiatry, Stanford School of Medicine, Palo Alto, CA, (3)Stanford University School of Medicine, Palo Alto, CA, (4)Psychiatry, Stanford University School of Medicine, Palo Alto, CA, (5)Stanford University School of Medicine, Stanford, CA*

Background: Â While autism spectrum disorders (ASD) are known for heterogeneous symptom presentation (Hu, 2009) and cognitive ability (Lenroot, 2013), the heterogeneity of ASD in academically-relevant domains, like math and reading, is still poorly understood. Although previous studies (Jones, 2009; Wei, 2015) have provided initial evidence on individual differences in academic achievement in ASD, no studies to date have used unbiased, data-driven, and quantitatively-validated approaches, nor included a typically-developing (TD) comparison group.
Objectives: Â The current study aims to: (a) characterize heterogeneous patterns of academic performance, namely math and reading skills, in children with ASD, using an unbiased and data-driven approach; (b) determine whether heterogeneous patterns are unique to children with ASD compared to TD peers; and (c) identify cognitive factors contributing to these heterogeneous patterns in ASD.
Methods: Â 118 children with ASD (ages: 7 – 13 years old; *M*=9.68; *sd*=1.51) and 96 age- and IQ-matched TDs (ages: 7-13 years old; *M*=9.39; *sd*=1.09) completed two standardized math (Wechsler Individual Achievement Test-II Numerical Operations and Mathematical Reasoning) and reading (WIAT-II Word Reading and Reading Comprehension) assessments. We used hierarchical clustering with complete-linkage criterion based on Euclidean distance (*NbClust* package in *R*) to separately cluster the ASD and TD samples by achievement measures. Logistic regression analysis was conducted to investigate cognitive predictors (IQ, verbal, visuo-spatial and executive working memory) of cluster-membership in both groups.
Results: The *NbClust* package recommended a two-cluster solution, characterized by one cluster with low and the other with high achievement, in each group (see Figure 1). In the ASD sample, we found a larger difference in math measures (71.54 points), between the Low and High clusters, than that in reading measures (23.35 points, $F(1, 116)=104.58$, $p<.001$). Moreover, the difference in math achievement between Low and High clusters was more pronounced in children with ASD than TD children (71.54â€…vs.Â 45.84 points, $F(1, 210)=24.41$, $p< .001$).
Logistic regression analysis revealed that a) IQ was predictive of cluster-membership in both groups (both $p < .01$); but (b) distinct components of working memory predicted cluster-membership in ASD vs. TD: in the ASD group, cluster-membership was predicted by verbal ($Z = 2.36$, $p = .018$) and executive ($Z = 2.44$, $p = .015$) working memory; whereas visuo-spatial working memory was predictive in the TD group ($Z = 3.46$, $p< .001$).
Conclusions: Â Our study addressed three key questions related to heterogeneity of academic skills in a large group of 7-13 year-old children with ASD. We found that (a) there was a heterogeneous pattern of weakness in math in the low achievement group and relative strength in math in the high achievement group (b) the math weakness in the low achievement group is unique to ASD relative to their TD peers; and (c) cognitive factors such as working memory differentially contribute to heterogeneous patterns of skills in ASD relative to TD children. These findings advance our understanding of heterogeneity in academic achievement in ASD, which may ultimately help us develop appropriate interventions to target and remediate low academic performance in this population.

57 **161.057** Comparing fNIRS-Based Cortical Activation Patterns Between Children with and without Autism, during Transitive and Intransitive Gestures

M. Culotta[1], *S. Trost*[1], *M. Hoffman*[1] *and A. N. Bhat*[2], *(1)Physical Therapy, University of Delaware, Newark, DE, (2)University of Delaware, Newark, DE*

Background: Children with Autism Spectrum Disorder (ASD) have significant impairments during gestural performance including errors during tool use, pantomime, and meaningless actions. Children with ASD had more errors during meaningless gestures compared to tool use or pantomime tasks; perhaps due to lack of a clear context (Smith & Bryson, 2007). Atypical perception-action couplings during early development in the children with ASD may impair one of the following processes represented within the Mirror Neuron Systems (MNS) and the sensori-motor systems: a) gesture perception involving temporal cortices, b) storage or transcoding of learned gestural sequences in the inferior parietal or frontal cortices and/or d) execution of motor programs by the primary motor cortices (Dowell et al., 2009).
Objectives: In the current study, we compared MNS and sensori-motor activation during three gestural tasks - object use, pantomime, meaningless.
Methods: 12 children with and without ASD between 6 and 12 years of age and 12 healthy adults were seated at a table with a hammer and pegboard. The task involved holding a hammer and hitting eight pegs on a pegboard in 3 ways: a) *Holds hammer*: the child hit the pegs with an actual hammer, b) *Pantomimes*: *the* child pretends to do the same hammering action, and c) *Meaningless*: the child performs air tapping. 24 trials were collected, 8 per condition using a randomized block design. The oxy hemoglobin response of the fNIRS signal was further analyzed to study differences in activation patterns between tasks, between hemispheres, and between the regions of interest (temporal, inferior frontal and parietal).
Results: Our preliminary data suggest greater cortical activation during the meaningless condition compared to pantomime or tool use conditions within the inferior parietal and inferior frontal cortices. We did not notice clear patterns in terms of hemispheric or regional differences.
Conclusions: Differences in MNS and sensori-motor cortex activation across gestural tasks will help explain the differing cortical contributions. In terms of intervention implications, our findings may support the notion of providing a clear context to aid successful completion of transitive gestures in children with ASD.

58 **161.058** Comparison of Parent- and Teacher-Report of Executive Function Deficits on Adaptive Behavior Skills in Individuals with and without ASD

J. L. Mussey *and L. Guy, TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: The importance of the real-world everyday skills defined by adaptive behavior for successful social functioning and independent living of individuals with ASD has been documented in the literature. There is often a significant gap between IQ and adaptive behavior for individuals with ASD without co-occurring intellectual disability (HFASD). Deficits in executive function (EF) skills have been associated with impaired adaptive functioning. However, most studies have assessed EF skills via parent report on measures such as the Behavior Rating Scale of Executive Function (BRIEF) and have not also included a second source of information such as teacher observations of EF skills in the classroom. Inclusion of another informant could enhance the understanding of previous findings.
Objectives: The study aim is twofold: 1) Examine the role of teacher-reported EF deficits on adaptive behavior functioning in comparison to parent report among a group of individuals with HFASD and 2) Determine if the relationship between EF deficits and adaptive behavior is transdiagnostic by including a clinical comparison group of individuals referred for an ASD evaluation but not meeting diagnostic criteria.
Methods: This is an IRB-approved record review study of diagnostic evaluations of a clinically-referred population ages 6-18 years seen at an outpatient clinic. ASD diagnoses were based on ADOS-2 scores and experienced clinical judgment; SRS-2 was used as a measure of ASD symptom severity. Adaptive functioning was measured by parent report on the ABAS-2 and ABAS-3 Practical domain. The BRIEF and BRIEF-2 were used to measure EF skills.
Results: Data collection and analyses are ongoing with a total anticipated n=60-65. Currently, ASD group n=28 and non-ASD group n=19. The groups are evenly matched for age (ASD *M*=9.82; non-ASD *M*=9.63, $t(45)=-.25$, $p>.05$) and nonverbal IQ (ASD *M*=99.11; non-ASD *M*=94.21, $t(45)= -1.09$, $p>.05$). Both groups had significantly impaired functioning on the Practical domain (ASD *M*=67.54; non-ASD *M*=70.47). Parent and teacher report of overall EF deficits were not correlated in either group (ASD $r=.25$, $p=.17$; non-ASD $r=.28$, $p=.17$). Teacher report of EF subscales were not correlated with the Practical domain for the ASD group (r's<.16, p's>.27), yet Initiate and Organization of Materials was negatively correlated with Practical domain in the non-ASD group (r's>.47, p's<0.4). Per parent report, significant correlations between the Practical domain and Initiate, Working Memory, and Plan/Organize existed for the ASD group (r's>.32, p's<.04), while in the non-ASD group Practical skills were correlated with Shift ($r=-.42$, $p=.04$).
Conclusions: Â While EF and Practical skills deficits were noted across clinical groups, parents tended to report more difficulties. Different relations between EF and Practical skills were found between the ASD and non-ASD groups. A better understanding of the factors that contribute to a more successful outcome for high functioning individuals with ASD is necessary to develop effective interventions. Nearly half of individuals with ASD have average or above cognitive abilities yet do poorly with the practical everyday adaptive behavior skills. Interventions that improve EF skills may be particularly helpful in increasing functional independence for this fastest growing subgroup of individuals with ASD.

59 **161.059** Cultural Influence on Natural Scene Viewing in Autism: A Comparison Between Japan and the UK

N. Harada[1,2], *E. Pellicano*[2], *Y. Tojo*[3], *T. Hasegawa*[4], *H. Osanai*[5] *and A. Senju*[1], *(1)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (2)Centre for Research in Autism and Education (CRAE), UCL Institute of Education, University College London, London, United Kingdom, (3)Ibaraki University, Ibaraki, Japan, (4)The University of Tokyo, Tokyo, JAPAN, (5)Musashino Higashi Gakuen, Musashino-shi, JAPAN*

Background: It is well established that the broader social context in which we live, such as cultural background, plays a critical role in shaping perceptual and cognitive development. For example, previous cross-cultural research has found that East Asian and Western adults have different viewing styles while looking at non-social naturalistic pictures – Western adults tend to look longer at the focal objects whilst East Asian adults focus more on background information (Chua, Boland & Nisbett, 2005). There is very little research, however, on the extent and nature of these cultural differences in children, and especially in children on the autism spectrum.
Objectives: We therefore investigated (1) whether cultural differences in non-social perception can also be observed in typically developing children, and (2) whether autistic children also show similar perceptual patterns as their same-culture counterparts.
Methods: Four groups of children took part in the study; Typical Japanese (n=31), Typical British (n=27), Autistic Japanese (n=31) and Autistic British (n=26), all aged between 6 and 18 years, and matched in terms of intellectual ability and gender. All Japanese children were tested in Tokyo; all children in the UK were tested in London. We used static images from Chua et al., each of which contained one focal object (e.g., animal or vehicle) in naturalistic backgrounds (e.g., mountains). We excluded stimuli containing human images from our study to focus on non-social perception. Children were asked to look freely at a series of 14 images on the screen. Each picture was presented for 3 seconds.
Results: Participants' eye movements were recorded using a Tobii TX300 eye tracker and the proportions of time spent looking at the focal and background areas of interest (AOIs) were calculated for analyses. We found an interaction between cultural backgrounds and AOIs, $F(1,111)=8.95$, $p=.003$. Japanese children looked significantly longer on the background AOI than on the focal AOI, $t(113)=-3.06$, $p=.003$, opposite to British children who looked longer on the focal AOI, $t(113)=3.06$, $p=.003$. Critically, however, there was no significant effect of diagnostic status (autistic, typical) and no interactions involving diagnostic status, all $ps \leq .43$
Conclusions: This is the first studies to examine cultural differences in non-social perception in school-age typical and autistic children with eye-tracking technique. We found strong cultural influences on non-social perception between Japanese and British participants, and these influences were similar across autistic and typical children. These results suggest that children on the autism spectrum are as much influenced by their broader social environments, such as cultural background, as their typically developing counterparts when engaging in a non-social free-viewing task. Future research should examine the role of cultural background in the development of perception *and* cognition in autistic individuals in order to draw a fuller picture of the condition.

60 **161.060** Differences in Sleep Related Learning in Children with ASD and Williams Syndrome

J. Hayton[1], *M. M. Chadiarakos*[1] *and D. Dimitriou*[2], *(1)Lifespan Learning and Sleep Lab, Institute of Education UCL, London, United Kingdom, (2)UCL, Institute of Education, London, England, United Kingdom*

Background: Several factors have been outlined as having a negative impact on cognitive and behavioral functioning of individuals with Autism Spectrum Disorders (ASD) and Williams Syndrome (WS). Sleep is the main focus of the current study since a number of studies reported that children with ASD and WS experience severe sleep problems. Since sleep has been found to play an active role in children's memory consolidation, it is vital to assess the impact of sleep on children's functioning.
Objectives: The current study aimed to examine if there were any specific sleep related learning patterns in two developmental disorders, namely ASD and WS. Children in both disorders have been reported to have specific sleep problems: children with ASD often suffer from frequent night wakings, whereas children with WS suffer from sleep onset delay. In both groups, comparison of the sleep-dependent memory consolidation has not been examined.
Methods: Participants included school aged children: 12 typically developing (TD)and 12 children with ASD and 12 children with WS.
Sleep dependent memory consolidation was assessed using an Animal Names task, a child-friendly and engaging declarative memory task. Sleep was further assessed using the Childhood Sleep Habits Questionnaire and actigraphy to objectively measure sleep quality and quanitity.
Results: As expected, TD children had higher scores on the Animal Names task following intervals of sleep, rather than wake, indicating that during periods of night-time sleep children's memory traces of the animal's names were strengthened. Similary children with ASD showed similar pattern to the TD group albeit showing poorer performance scores. Children with WS showed a different pattern to both groups. Significant differences in Sleep Duration, Night Wakings were found between the groups. There were large group differences in all sleep variables, showing specific sleep problems in the clinical groups as well as learning patterns when correlated to sleep.
Conclusions: The current study suggests that sleep plays an active role in cognitive functioning in children. The study emphasizes the importance of sleep in children with developmental disorders and its role in the process of learning. It is concluded, that sleep has a strengthening effect on the memories of both TD and children with ASD but not WS.
Gaining a better understanding of the influence of sleep on learning in children is an important factor in order to implement better teaching interventions.

61 **161.061** Differing Perspectives: Examining Reports of Executive Function in Children with ASD & ADHD

S. Seese[1], *J. Safer-Lichtenstein*[2], *A. D. Verbalis*[1], *C. Luong-Tran*[3], *K. Hardy*[1], *M. Wolff*[4], *K. Tiplady*[5], *M. F. Skapek*[4], *B. J. Anthony*[2], *L. Kenworthy*[1] *and L. G. Anthony*[1], *(1)Children's National Health System, Washington, DC, (2)Center for Child and Human Development, Georgetown University, Washington, DC, (3)Children's National Medical System, Washington, DC, (4)Children's National Health System, Rockville, MD, (5)University of Florida, Ashburn, VA*

Background: Measuring Executive Function (EF) skills is imperative in assessing overall behavior and outcomes in children as they progress through school. EF deficits are prominent among children who have an Autism Spectrum Disorder (ASD) or Attention Deficit Hyperactivity Disorder (ADHD).
Objectives: This study aims to evaluate how parents, teachers and observers report EF behavior among the two diagnostic groups.
Methods: A sample of mainstream school children either with an ASD (N=46) or ADHD (N=103) (ages *M*=10.03; *SD*=.89) participated in a school-based EF intervention study. Student behavior was observed by treatment-blinded research staff twice within the school year, and teachers reported on behavior using a modified version of the SKAMP (Swanson, 1992). Parents completed the Behavior Rating Inventory of Executive Function (BRIEF) (Gioia et al., 2000). SKAMPS and classroom observations yield scores on several EF skills, including transitioning, attending to work, and following rules, while the BRIEF assesses EF in the school and home environments. Greater impairment of EF skills are indicated by lower scores on the classrooms observations and higher scores on the SKAMPS.
Results: Within the entire sample, parent scores on the BRIEF Global Executive Composite index (GEC) were correlated with teacher's reports of EF skills on the SKAMP (*r*=.222, *p*<.002). Total SKAMP and classroom observation scores were significantly correlated for both groups (*r*=-.340, *p*<.00). When divided by diagnosis, differences were found between the two groups, specifically in regards to parent report. Children with ASD had similar overall levels of EF skills, as reported on the SKAMP and classroom observations (*r*= -.486, *p* <.000). However, BRIEF GEC scores were not correlated with SKAMP scores. When parents reported difficulties within the Monitor scale on the BRIEF, correlations were found for SKAMP items, including: the total SKAMP score, sticking with tasks, and getting started on assignments. Within the ADHD sample, teacher and parent ratings were significantly correlated (*r*=.216, *p*<.010). Observation total scores and BRIEF GEC scores were not correlated (*r*=.005, *p*<.943).
Conclusions: Among teachers, parents, and blinded observers, agreement was significant within the entire sample for behaviors related to EF. However, differences were found within the two diagnostic groups, suggesting that multi-informant approaches are important when measuring outcomes. Varying the lenses for reporting EF skills in children is important in capturing different behaviors, as well as across diagnoses.

62 **161.062** Dimensional Autistic Traits Predict Susceptibility to False Memory: Sex Differences in Source Monitoring and Gist Construction

J. M. Valla[1] *and M. K. Belmonte*[2]*, (1)National Brain Research Centre, Manesar, India, (2)Com DEALL Trust, Bangalore, INDIA*

Background: Â Fuzzy trace theory (FTT) has been used to account for autistic individuals' often exceptional verbatim memory, and to suggest that the same autistic cognitive style may confer resistance to false memory.
Objectives: Â To assess the relationship between dimensional variations in autistic traits and false memory.
Methods: Â The Deese-Roediger-McDermott (DRM) word-list false-memory paradigm was used in combination with Autism Spectrum Quotient (AQ) subscales and two performance-based measures of autistic traits – the 'Reading the Mind in the Eyes' Test (RMET) and the Embedded Figures Test (EFT) – to assay effects of individual and sex differences in empathising and systemising traits on authentic and false memory in 89 (45 female) typically developing young adults.
Results: Â A Sex x AQ(Social) interaction predicted correct recalls, $F(1, 74) = 5.19$, $p = .026$, and the output positions thereof, $F(1, 74) = 4.13$, $p = .046$: in females high AQ(Social) predicted fewer ($r = -.288$) and earlier ($r = -.173$) correct recalls. Likewise, in females high RMET predicted more correct recalls, $F(1, 75) = 5.23$, $p = .025$, $r = 0.281$. No such effects were present in males. Sex x AQ(Social) x AQ(Detail) influenced number of critical lure false recalls, $F(1, 74) = 5.92$ $p = .017$: among males with high social skills (low AQ(Social)), attention to detail (high AQ(Detail)) increased the number of false recalls, but in males with low social skills, attention to detail decreased the number of falsely recalled critical lures. Females exhibited the opposite pattern, high social skills yielding a negative and low social skills a positive relationship between attention to detail and number of falsely recalled critical lures. Again in females, faster disembedding on the EFT (Sex x EFT $F(1, 75) = 6.98$, $p = .01$, $r = 0.429$) and lower RMET score (Sex x RMET $F(1, 75) = 8.97$, $p = .004$, $r = 0.308$) both were associated with fewer critical lure false recalls.
Conclusions: The restriction of semantic gist (reduction in critical lure recalls) associated with increased AQ(Detail) in those females with low AQ(Social) suggests that in females the main determinant of false recall is systemising. Whereas heightened RMET in males only reduced false memory, implying a source-monitoring effect, females' RMET increased both correct *and* false memory, associating heightened empathising skill with heightened gist construction. These relationships suggest that semantic and theory-of-mind aspects of females' empathising abilities are more closely related than males': Empathising deficits may impair semantic association in females, but source monitoring in males. Implications include the identification of traits predicting individual differences in false-memory susceptibility (a rarity in false-memory research), greater understanding of cognitive mechanisms underlying the uniquely autistic style of memory, and appreciation of the potential clinical importance of false-memory susceptibility in persons with autism spectrum conditions: This interpretation predicts that in males with Broader Autism Phenotype or in general high levels of autistic traits, confusion of endogenous beliefs with exogenous observations – particularly where impaired social perception creates a vacuum of true observations – might in part underlie deficits in the formation and maintenance of social relationships.

63 **161.063** Distinguishing Between Implicit and Explicit Measures of Metacognition in ASD

T. Nicholson[1]*, C. S. Grainger*[2]*, S. Lind*[3]*, P. Carruthers*[4] *and D. M. Williams*[5]*, (1)University of Kent, Canterbury, England, United Kingdom, (2)School of Psychology, University of Stirling, Stirling, UNITED KINGDOM, (3)Durham University, Durham City, County Durham, UNITED KINGDOM, (4)University of Maryland, Washington, MD, (5)School of Psychology, University of Kent, Canterbury, United Kingdom*

Background:
Metacognitive monitoring (awareness of one's own mental states/cognition) is a key component of self-awareness and plays an important role in learning. The few existing studies of metacognitive monitoring in ASD have employed tests that require participants to make explicit judgements about the state of their own knowledge. The closer the correspondence between *judgements* of one's knowledge and *actual* (objectively-measured) knowledge, the more accurate metacognitive monitoring is. Findings using such explicit tasks have been mixed. In the current investigation, we aimed to resolve a discrepancy in findings across previous studies by employing not only a standard test of explicit metacognitive monitoring, but also a paradigm adapted from one used in comparative psychology to assess metacognitive monitoring non-verbally/implicitly.
Objectives:
The aim of the present study was to investigate implicit *and* explicit metacognition in ASD.Â
Methods:
Data collection is ~80% complete. 22 participants with ASD and 18 age- and IQ-matched comparison participants completed a "gambling" paradigm based on that used among monkeys by Son & Kornell (2005). This involved a visual discrimination task (e.g., judging most pixelated of two squares). After a decision had been made on each trial, participants were required to choose from one of two shapes (circle/triangle). Correct visual discrimination resulted in a payment gain, while incorrect visual discrimination resulted in financial loss, with subsequent shape selection dictating whether gain/loss was of high (triangle) or low (circle) value. Accurate metacognitive monitoring was indicated by a greater tendency to choose the high-value "Triangle" on successful visual discrimination trials than on unsuccessful trials, and to choose the low-value "Circle" more on unsuccessful than successful trials. In a second session, participants completed the same gambling task (but different visual discrimination task). This time, after each visual discrimination trial, participants were explicitly asked "Are you confident?", with "Yes" (high-value gain/loss) or "No" (low-value gain/loss) chosen in response. Selecting "Yes" on successful visual discrimination trials more than on unsuccessful trials and, vice versa, by choosing "No" more on unsuccessful than successful trials indicated accurate metacognitive monitoring.
Results:
In both tasks, Gamma correlations were utilised to measure metacognitive performance. Across both tasks, between-group differences were apparent. Gamma correlations were lower among participants with ASD than comparison participants in both the implicit (ASD M = .32, SD = .59; Comparison M = .58, SD = .26; t = 1.78, p = .08, d = .58) and explicit tasks (ASD M = .56, SD = .39; Comparison M = .71, SD = .21; t = 1.49, p = .15, d = .49). Correlations between metacognitive monitoring performance and background cognitive measures of theory of mind and of ASD feature severity/traits will be analysed and discussed.
Conclusions:
These results complement the existing literature and provide evidence of an explicit metacognitive deficit in ASD. However, they extend the field significantly by providing the first evidence of a deficit in a non-verbal/implicit form of metacognitive monitoring. This suggests a pervasive difficulty with this ability at all levels among people with ASD, which may contribute to learning difficulties in this disorder.

64 **161.064** Early Learning Processes in Autism and Williams Syndrome: Commonalities and Differences in Relation to Cognitive and Adaptive Functioning

P. A. Fanning[1], *G. Vivanti*[2], *C. Dissanayake*[3] *and D. R. Hocking*[4], *(1)School of Psychology and Public Health, La Trobe University, Melbourne, Australia, (2)AJ Drexel Autism Institute, Philadelphia, PA, (3)School of Psychology & Public Health, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (4)Psychology & Counselling, Developmental Neuromotor & Cognition Lab, La Trobe University, Melbourne, AUSTRALIA*

Background: Autism spectrum disorder (ASD) and Williams syndrome (WS) are neurodevelopmental disorders with an opposing profile of cognitive and behavioral features. While opposing propensities for social engagement appear to be the key distinction between ASD and WS, there are striking commonalities in social and communicative difficulties across these disorders. Both convergences and divergences have been observed across domain-general and domain-specific early learning processes that might shape differential outcomes across ASD and WS.
Objectives: In the present study, we examined how preschoolers with ASD, WS and typical development (TD) performed in tasks tapping both domain-general (working memory, sustained attention, habituation) and domain-specific (social and joint attention, motor intention, imitation, spontaneous object use) early learning processes. Here we aimed to (1) document early emerging commonalities and differences across key early learning processes in children with ASD and WS, and in comparison to TD children, and (2) examine concurrent associations with intellectual and adaptive functioning in ASD, WS and TD children.
Methods: We recruited young children (aged 27 to 92 months) with ASD (n = 54, mean DQ = 66), and with WS (n = 24, mean DQ = 56) who were age-matched to a group of TD children (n = 20, mean DQ = 108). Measures of domain-general and domain-specific early learning processes were administered using a combination of eye tracking and behavioural observation. Multiple regression was used in preliminary analyses to assess the relative contribution of individual aspects of early learning to concurrent levels of intellectual and adaptive function.
Results: Preliminary results revealed that groups performed similarly in working memory, social attention, and motor intention, while in all other tasks group differences were evident. In the ASD group, sustained attention was the only significant factor associated with intellectual and adaptive function. In the WS group, spontaneous object use and joint attention were significantly associated with intellectual function, while imitation was associated with adaptive function. In TD children, sustained attention and joint attention were significantly associated with both intellectual and adaptive function, while habituation and spontaneous object use were associated with intellectual function.
Conclusions: Children with ASD and WS show different patterns of relationships between key early learning processes and intellectual and adaptive development. In young TD children both domain-general and domain-specific cognitive abilities emerged as significant factors in intellectual and adaptive functioning. This contrasted with ASD where only sustained attention was associated with intellectual and adaptive functioning, and WS where domain-specific cognitive abilities appeared to be more significant. These findings have the potential to inform our understanding of syndrome-specific early learning processes that might shape intellectual and adaptive outcomes, and inform the development of early interventions that focus on relative cognitive strengths to build on domains of weakness, an approach that may have cascading effects on later outcomes in ASD and WS.

65 **161.065** Emotional False Memories in Children with Autism Spectrum Disorder

E. J. Adler[1], *C. Mirandola*[2], *M. K. Krug*[1], *K. Argente*[1], *J. Farren*[1], *C. W. Nordahl*[1], *D. G. Amaral*[1], *S. Ghetti*[3] *and M. Solomon*[1], *(1)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA, (2)Department of General Psychology, University of Padova, Italy, Padova, Italy, (3)Department of Psychology, University of California-Davis, Davis, CA*

Background: Memory functioning in children with ASD is a relatively neglected area of research. However, there is evidence that adults with ASD, compared to adults with typical development (TD), may be less prone to experience associative illusions of memory as a result of impaired ability to engage in semantic processing (Beversdorf et al., 2000). However, it is unclear whether this pattern of results is present in children tested for memories of pictures of sequences of life events and memories that include emotional content. Work in other neurodevelopmental disorders has shown that children with non-verbal learning disorder (NLD) show a tendency to falsely recognize unseen causes of negative emotional events more than neutral events, suggesting that emotion facilitates this type of inferential error for children with NLD (Mirandola et al., 2014). In contrast, our work has shown that adolescents and young adults with ASD struggle to process positive emotion as demonstrated by their failure to process positive feedback (Solomon et al., 2011).
Objectives: To test if emotion facilitates the rate and type of false recognition of events in a sample of children with ASD and TD.
Methods: The present study examined children with ASD (N=27; Age M=10.8, SD=1.4) and an IQ-matched sample of children with TD (N=37; Age M=11.3, SD=1.5). Participants viewed a series of photographs for scripted events (e.g., making dinner, waking up in the morning). Embedded in each scripted episode were positive, negative, and neutral consequences (i.e., effects) of unseen actions (i.e., causes). Memory was then tested on a yes/no recognition task that included old and new photographs (i.e., distractors). Three classes of distractors were used: *Causal*: These photographs depicted unseen causes of seen effects (positive, negative and neutral); *Gap-Filling*: These photographs included unseen events that were consistent with viewed scripts (positive, negative and neutral); and *Inconsistent*: These photographs included unseen events that were inconsistent with viewed scripts.
Results: Both groups provided strong evidence of memory for photographs as indicated by high recognition hit rates for viewed photographs and low false alarm rates of unseen and script inconsistent pictures (See Table 1). Children with ASD falsely recognized more unseen photographs than did children with TD (t=4.259, p<.001), but the type of distractor mattered. Interestingly, children with ASD were equally likely to falsely recognize both unseen causes of seen photographs and photographs consistent with the script when they were positive (t= -0.592, p=.559), while both groups were more likely to falsely recognize unseen causes (i.e. causal errors) of negative and neutral events compared to gap-filling negative and neutral events. See Figure 1. Neither group showed an association between age and rate of error type.
Conclusions: These results support past research by showing that generally children have higher overall rates of causal errors than gap-filling errors though we found that children with ASD did not show this pattern for positive events. This atypical process of positive emotion is consistent with our group's prior findings of impairment in use of positive feedback and could have important implications for self-esteem, learning, and psychopathology.

66 **161.066** Endogenous Visual Orienting with and without Saccades in Autism Spectrum Disorder: An Eye-Tracking Study

*S. J. Fleming[1], **O. Landry**[1], K. A. Johnson[2], S. G. Crewther[3] and P. A. Chouinard[1], (1)La Trobe University, Bendigo, Australia, (2)Psychological Sciences, University of Melbourne, Victoria, Australia, (3)School of Psychology and Public Health, La Trobe University, Melbourne, Australia*

Background:
Endogenous visual orienting is the allocation of visual attention resources to a spatial location driven by symbolic cues or internal goals. Previous research suggests that people with ASD display differences in their use of symbolic cues in endogenous orienting compared with people who do not have ASD, and that temporal aspects of task performance may play a significant role in group differences (Landry et al., 2009; Landry & Parker, 2013).Â
Objectives:
The study examined the temporal properties of endogenous orienting in the context of traditional endogenous orienting with a button press response, and with eye-tracking.
Methods:
Participants with ASD (n = 16, Males = 13, mean age = 10.79 years, age range = 6 to 21 years) and typically developing participants (TD) (n= 16, Males = 12, mean age = 10.92 years, age range = 6 to 22 years) completed the tasks. Both groups were matched on raw scores for the Raven's Progressive Matrices, age and gender. Two experimental tasks were completed: a traditional Posner (1980) arrow cuing task with forced-choice button press responses, and an overt orienting task in which participants were instructed to saccade to the target. Both tasks included valid (75%) and invalid (25%) cues at different cue-target SOAs (150ms, 300ms, 450ms, 600ms, 750ms, 900ms). To maintain task engagement, the saccade task also included the instructions that participants should press a button if the target was an animal (and not press for an object). Eye-tracking was performed during both tasks. This was to ensure participants maintained central fixation during the traditional button press task, and to measure saccades during the saccadic overt orienting task.
Results:
A 2x2x6 Mixed ANOVA examined orienting effects (calculated as: (invalid-valid) / average RT across all trials). No differences were found between ASD and TD participants in the magnitude of orienting overall (ME Group p=.46), nor as a function of SOA (Group x SOA p=.33), nor did they differ in orienting as a function of whether the task was the traditional button press Posner task or a saccadic overt orienting task (Task x Group x SOA p=.24); Figure 1 shows the patterns of orienting for both groups. A 2x2x6 Mixed ANOVA was used to examine saccadic velocity during the saccadic overt orienting task. A significant Group by SOA interaction was found, F (3, 31) = 8.45, p<.001; Figure 2 shows the different SOA patterns shown by the two groups.
Conclusions:
In this sample, we did not replicate previous findings of differential orienting performance for ASD. We found very similar patterns of orienting across 6 SOAs in both a traditional button-press arrow-cued endogenous orienting task and when saccadic RT was measured in overt shifts following endogenous cues. We found different patterns of saccadic velocity across SOA between ASD and TD participants. This finding is intriguing, as orienting performance did not differ between groups on the saccadic task, despite different patterns of saccadic velocity across SOA between groups.

67 **161.067** Error Types in Synchrony Judgements of Audiovisual Stimuli in Children with Autism Spectrum Disorders

***M. Ferland**[1], J. M. Bebko[2], M. Segers[2], B. L. Ncube[3] and R. A. Stevenson[4], (1)343 St Clair Ave. W apt. B, York University, Toronto, ON, Canada, (2)York University, Toronto, ON, CANADA, (3)York University, York, ON, CANADA, (4)Psychology, University of Western Ontario, London, ON, CANADA*

Background:
Intermodal perception (IMP), the ability of integrating multiple sensory information (e.g., visual and auditory) into a single, coherent perception, is crucial to different aspects of development (e.g., Bahrick, 2010). Atypical IMP has been found in individuals with autism spectrum disorders (ASD) (e.g., Bebko et al., 2013; Iarocci & McDonald, 2006; Stevenson et al., 2014), and there has been a growing appreciation of potential links between the sensory experiences of those with ASD and social-communicative deficits. For example, Bebko et al., 2006 found a linguistic-specific deficit in children with ASD when discriminating the synchrony of audiovisual stimuli using a preferential looking paradigm.
Objectives:
The current study attempts to expand on the results of Bebko et al., 2006, by using a task requiring an explicit response about whether auditory and visual stimuli are synchronous (synchrony judgement). Patterns of correct responses and error types were analyzed to gain a better understanding of what is contributing to atypical IMP in ASD.
Methods:
Twenty children with ASD (M= 12.7 years, SD=2.96) and thirty non-clinical children (TD) (M=11.9 years, SD= 3.05) were asked to determine whether audio and visual components of a stimulus were synchronous or not. Five stimulus types were presented: social-linguistic (SL: someone reading a story), social-non-linguistic (SNL: a person making popping sounds), non-social-non-linguistic (NSNL: e.g., a hand playing the piano), and emotion (EH: someone laughing or crying).
Results:
The ASD group (*M*= 77.36%) had a significantly lower percentage of correct synchrony judgements versus the TD group (*M* = 85.66%), *F*(1,49)=6.575, *p*=.013. The proportions of errors made were examined by stimulus type in a 2-way mixed model ANOVA. A significant main effect was found for stimulus type, where both groups made more judgement errors for the emotion stimuli. A within-group post-hoc analysis showed that the TD group made more errors for the positive affect versus negative affect, *t*(1,29)=2.467, p=.019, while the ASD group made equal mistakes on both types of the EH stimuli.
Errors were also separated out by synchrony type: that is, responding as synchronous when the stimulus was asynchronous, and vice versa. A 2-way mixed model ANOVA with error types and group yielded a significant main effect of error type. Both groups were less likely to misidentify a synchronous stimulus as asynchronous. A within-group post-hoc analysis showed that the ASD participants were more likely to erroneously respond that an asynchronous visual-leading stimuli was synchronous than for audio-leading stimuli, *t*(1.19)=2.658.This difference was not observed in the TD group.
Conclusions:
The more explicit judgements required in this task were expected to help participants with ASD overcome their difficulties with audiovisual IMP in more subtle tasks. However, the ASD group made significantly more errors in a synchrony judgement task, even though the asynchronous stimuli were offset by 1 second, a very large offset.Â The present findings indicate that helping to focus the participants' attention to the task by requesting a concrete motor response was not sufficient to help overcome the underlying audiovisual IMP issues. Further research is needed to better understand these challenges.

68 **161.068** Examining the Mathematical Abilities of Children and Adolescents with Autism Spectrum Disorders: A Meta-Analysis

H. M. Brown[1]*, N. Ansell*[1]*, A. Altani*[1] *and J. MacCormack*[2]*, (1)Educational Psychology, University of Alberta, Edmonton, AB, Canada, (2)Educational Psychology and Inclusion, University of Lethbridge, Lethbridge, AB, Canada*

Background: To date, there is a great deal of uncertainty about how Autism Spectrum Disorder (ASD) influences the mathematical skills of individuals in this population. Researchers have found that the rates of math giftedness and math disability in ASD are much higher than in the typically developing (TD) population with up 46% of a particular sample of individuals with ASD categorized by math disability and up to 34% categorized by math giftedness (Brown, 2013). The high levels of both math giftedness and disability found in the ASD population could suggest that some unique factor or set of factors associated with autism leads to either extreme math strengths or weaknesses.
In order to develop appropriate interventions, remediation and even enhancement activities, we need to be able to predict which individuals with ASD may have math strengths versus weaknesses. In order to make these predictions, we must investigate possible variables that have been previously shown to predict math success in other populations. Four variables that we propose to examine in relation to the math skills of the ASD population are: visual-spatial/motor ability (VSM), executive functioning (EF), general knowledge (Gk) and vocabulary knowledge (Vk).
Objectives: Â 1. To determine the size of the difference between individuals with ASD and their TD peers in two measures of math ability—arithmetic and math problem solving (Ps)—as well as the direction and the consistency of this effect. 2. To examine four predictors of math ability in the ASD population.
Methods: After a comprehensive database search, we collected data on 1056 children and adolescents with ASD across 35 studies. Using the metafor package in R (Viechtbauer, 2010), we derived the standardized mean differences (SMD; Hedge's g) between the math scores of individuals with ASD and their TD peers along with meta-regression models examining predictors of their math ability.
Results: The models demonstrated that individuals with ASD performed significantly lower (g = -0.5) than their TD peers in both arithmetic and Ps and the resultant prediction intervals were -2.26 to 1.30SD and -2.76 to 1.95SD, respectively. Secondly, the SMDs across the two math areas were highly variable and this variability was not only due to random error. The meta-regression model for arithmetic demonstrated that EF and VSM were significant predictors of math ability (ß = 0.028, ß = 0.031, respectively; p < .001), yet Gk and Vk were not.
Conclusions: Our findings reject the stereotype of mathematical prowess among individuals with autism, as their average performance was lower than their TD peers. As well, the range of the prediction intervals were wide, but positively skewed, indicating that students with ASD were more likely to struggle in math than to excel. Finally, the outcome of the meta-regression model was generally in line with the Pathways model of numerical development, according to which mathematical ability is influenced in distinct ways by different neural pathways (LeFevre et al., 2010). The current analyses suggest that VSM and EF may be critically important to understanding how the autistic mind processes mathematical information.

69 **161.069** Executive Function: Cognition and Behaviour in Adults with Autism

A. J. Russell[1]*, K. Johnston*[2]*, K. Murray*[3]*, D. Spain*[4] *and I. Walker*[5]*, (1)University of Bath, Bath, United Kingdom, (2)Psychology, Kings College London/South London & Maudsley NHS Trust, London, United Kingdom, (3)King's College London, London, UNITED KINGDOM, (4)King's College London, Institute of Psychiatry,, London, UNITED KINGDOM, (5)Psychology, University of Bath, Bath, United Kingdom*

Background: Executive function (EF) is a complex cognitive construct incorporating a number of processes associated with higher-level thought and behaviour across the life-span. EF has been much studied in Autism Spectrum conditions with inconsistent findings reported in terms of impairment across the different facets of EF. It is thus not clear if impairments in EF are truly characteristic of ASD in respect of cognition and if cognitive deficits are consistently related to behavioural features. Co-morbidity and individual heterogeneity are important factors to take account of in study design.
Objectives: The study aimed to investigate the performance of high functioning adults without intellectual disability with robust diagnosis of Autism Spectrum Disorder (ASD) across a range of EF tasks, and particularly to consider the issue of heterogenity. The study also explored whether EF impairments impact on (a) everyday function and (b) ASD symptomatology including repetitive behaviours.
Methods: Participants with ASD (n=110) were compared with age and IQ matched healthy controls (n=31) on a battery of well validated clinical neuropsychology tasks assessing planning, cognitive flexibility, inhibition, generativity/fluency and speed of task completion. Information about the behavioural characteristics associated with EF difficulties was collected using standardised informant and self-report. Participants with co-morbid ADHD, psychosis and neurological disability were excluded from the study. Group differences across the main test indices were investigated. Exploratory factor analysis was employed to consider the universality of impairment across EF function.
Results: Participants with ASD were significantly more likely to score in the impaired range across all the EF tasks, although notably approximately 1/3 of the ASD group were not impaired on any of the EF test indices. Significantly higher levels of behavioural, cognitive and emotional characteristics associated with EF were reported in the ASD group. Exploratory factor analysis confirmed a single underlying construct or 'EF factor' consistent with the theoretical account in the literature of a single over-arching executive process. This 'EF factor' was not related to ASD symptoms or behavioural characteristics. Behavioural characteristics associated with ASD could also not be accounted for by co-morbid psychiatric difficulties such as anxiety.
Conclusions: The majority of high functioning adults with ASD are impaired across a number of tests of executive function when compared to adults without ASD. Performance across EF tests was found to represent a single underlying construct. Everyday difficulties associated with EF impairment are common in adults with ASD but on the basis of these findings are not accounted for by performance on neuropsychological tests, ASD symptoms or psychiatric co-morbidity. The findings of this study suggest executive function is an important domain to consider when assessing adults with ASD in respect of formulating difficulties and modifying interventions to reduce executive demands. Further investigation into 'dysexecutive' difficulties in everyday function in ASD is warranted. Notably one third of adults with ASD in this study were not impired on any of the EF measures.

70 **161.070** Eye Avoidance in Young Children with Autism Spectrum Disorder When Scanning Emotional Faces

Q. Wang[1]*, L. Lu*[1]*, X. Zou*[2] *and L. Yi*[1]*, (1)Peking University, Beijing, China, (2)The Third Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China*

Background: Abnormal face scanning patterns have been consistently found in individuals with autism spectrum disorders (ASD) (see Falck-Ytter & von Hofsten, 2011, for a review), which may be associated with their face processing deficits. Particularly, some studies have found that participants with ASD spent less time looking at the eye region when scanning faces compared to typically developing (TD) counterparts (e.g., Pelphrey et al., 2002; Yi et al., 2013). Tanaka and Sung (2013) proposed an “eye avoidance’’ hypothesis of autism in face processing, which suggested that individuals with ASD avoid the eye region because it is perceived as socially threatening. In line with this hypothesis, individuals with ASD may show stronger tendency to avoid looking at eyes of faces with threatening expressions (e.g., anger) than other expressions.
Objectives: The current study aimed to further examine the “eye avoidance” hypothesis by comparing the eye looking time of children with ASD to that of TD children when viewing faces with different expressions.
Methods: We showed faces with different emotional expressions (joy, anger, sadness, and neutral) to 2- to 5-year-old ASD (*n* = 28) and age-matched TD (*n*= 31) children for 5 seconds when their eye movements were recorded using a Tobii T60 eye tracker. Sad facial expressions were included to avoid a possible confound between threat-relatedness and negativity of the displayed emotion. We used temporal course measures to examine the proportional fixation time on the eyes in three continuous phases: the 5-second looking time (300 sample data in total) was divided equally into three phases (early, middle, and late phases, each of which was about 1667 ms) and we wanted to determine whether and when effects of different scanning patterns to the eyes appeared. This analysis allowed us to test whether the patterns observed in the current study are stable or more dynamic across viewing time and thus it may provide a more complete picture into face scanning.
Results: We found that: (1) children with ASD fixated less on the eyes than TD children only for angry and neutral faces, but the two group scanned similarly for happy and sad faces; (2) children with ASD scanned less on the eyes of angry faces than that of happy and sad faces, while TD children scanned more on the eyes of angry and sad faces than that of happy faces; (3) temporal course analysis revealed that: for neutral faces, children with ASD showed an attention avoidance toward eye region than TD children in the early, middle phases but not in the late phase; whereas for angry faces, children with ASD showed more avoidance to the eyes than TD children in all the three phases.
Conclusions: Our study demonstrates that facial expressions moderate eye avoidance pattern in children with ASD when scanning faces. These results suggest that young children with ASD do not have a general eye avoidance pattern in face scanning, rather, this pattern is limited to the threat-related expressions.

71 **161.071** Eye Tracking on an Unmodified Ipad for Visual Attention of Children with and without ASD: A Feasibility Test

Q. Wang[1]*, C. Foster*[2]*, B. Li*[3]*, J. Snider*[2]*, M. Utheim*[4]*, R. Øien*[5]*, P. E. Ventola*[2] *and F. Shic*[6]*, (1)Yale University School of Medicine, New Haven, CT, (2)Yale Child Study Center, New Haven, CT, (3)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Superplus., Tromsø, Norway, (5)Psychology, The Arctic University of Norway, Tromsø, Norway, (6)Seattle Children's Research Institute, Seattle, WA*

Background: Eye tracking is widely used in autism research to study visual social cognition. However, most studies depend on expensive commercial eye-tracking devices, which dramatically restricts accessibility. In this study, we used video-based eye tracking-algorithms to implement and validate eye tracking on an unmodified tablet, an advance which could increase the accessibility of eye tracking for researchers and families.
Objectives: 1) To implement eye tracking on an unmodified iPad, 2) To validate calibration and looking time by using smooth pursuit, 3) To compare looking behaviors of children with Autism Spectrum Disorder (ASD) with controls.
Methods: Participants were 21 children (4 to 8 years old: 6 typically developing (TD), 4 developmentally delayed (DD), and 11 children with autism spectrum disorder (ASD)) and 6 TD adults. Participants watched three 5-minutes videos on an iPad; each video video contained three 5-point calibrations and two animated smooth pursuit trajectories. Using front facing camera recordings, we applied image processing to track head and eye movement for use in eye tracking calculations. Calibration errors and proportion of valid looking on screen (Valid%) were calculated. Percentage of looking during smooth pursuit was calculated as a validation and measure of sustained attention. Repeated measures ANOVA was conducted to examine between group differences.
Results: Adults failed 5.6% of calibrations (failure defined as looking at fewer than 3 of 5 calibration target points), and had an average calibration error (1.1 deg) and Valid% (81.7% ±4.0%) significantly better than children ($p = .005$, $F = 4.364$; $p<.001$, $F = 21.6$). Similarly adults looked more during smooth pursuit trajectory validations compared to children (83.3% ±2.9%, $p<.001$, $F =12.3$).
The TD group failed 11.1% of calibrations, DD failed 30% and ASD 22.2%. However, in passed calibrations errors were comparable between the three groups: TD 1.5 deg, DD 1.3 deg and ASD 1.4 deg. Valid% was not different between the three groups of children (58.7% ± 4% in TD, 52.3% ± 4.7% in DD with $p = .303$, and 53.2% ± 3% in ASD with $p=.280$ between TD and ASD). Both TD (56.0% ± 3%, $p = .049$) and DD (59.8%±3.5%, $p = .007$) groups exhibited significantly higher proportions of following the smooth pursuit trajectory than the ASD children (48.6%±2.3%). There was no performance difference between DD and TD ($p=.397$).
Conclusions: The preliminary data found that children with ASD and DD looked at less at calibration points than their TD peers, and that the ASD group showed lower percentage of valid looking while following smooth pursuit trajectories than TD and DD groups. This study provides evidence for the application of iPad eye tracking as a viable option for tracking eye movements and studying visual attention in children with and without ASD, but also points towards tablet-based eye tracking as a method for understanding potentially broader issues in sustained attention in children with ASD.

72 **161.072** Frontal Midline Theta Activity Explains Differences in Reaction Time Variability Between ASD and ADHD

G. McLoughlin[1,2], *J. A. Palmer*[3], *B. Azadi*[4], *K. L. Ashwood*[5], *P. Asherson*[1], *P. F. Bolton*[4] *and C. Tye*[4], *(1)Social, Genetic & Developmental Psychiatry, King's College London, London, United Kingdom, (2)King's College London, London, United Kingdom, (3)Department of Information and Communications Engineering, Tokyo Institute of Technology, Yokohama, Japan, (4)Child & Adolescent Psychiatry, King's College London, London, United Kingdom, (5)Forensic & Neurodevelopmental Disorders, King's College London, London, UNITED KINGDOM*

Background: Reaction time (RT) measures have long been recognised as a valuable indicator of cognitive performance in ASD (e.g. Jensen, 1992). RT data as it currently stands lacks specificity to a single psychiatric population and so has not been seen as a particularly useful marker for ASD. Our previous findings have shown that RT data, in particular, variation in reaction times (RT variability/RTV), may show some specificity between autism spectrum disorders (ASD) and attention deficit hyperactivity disorder (ADHD) (Tye et al. 2016) but this is not always clear (Tye et al. 2013). Brain function studies point towards a relationship between RT measures and medial frontal (MF) brain activity (Bellgrove et al. 2004; McLoughlin et al. 2014). Our recent work showed a strong relationship between RT measures and an EEG source signal from the MF region of the brain in the 5-7 Hz frequency range (theta) (McLoughlin et al. 2014). However, there is little research into the neurophysiological underpinnings of this relationship, nor of the relationship between theta activity and ASD.
Objectives: To understand the underlying neurophysiology of RT data in ASD, and further to examine if theta-indexed neurophysiological measures can clarify differences and similarities between ASD and ADHD in RTs.
Methods: Children with ASD (n=19), ADHD (n=18) and typically developing controls (TDC; n=26) completed the CPT-OX task, with concurrent EEG recording, which was identical to that used in our previous studies (McLoughlin et al. 2010, 2011; Tye et al. 2014.). Instructions indicated to respond only to the target in cue-target sequences (XOX-OXO). The remainder were attentional stimuli (e.g. XOX-OXO) or distractors. Power and phase were calculated in the theta frequency band to compare inhibitory stimuli (e.g. XOX-ODO) to other stimuli (e.g. XOX-OXO) using independent components (IC) of the EEG data.
Results: We showed alterations in only ADHD children for RTV and mean RTs, However, we found abnormalities in both ASD and ADHD for theta power compared to TDC across all stimuli. We also found abnormalities in the phase onset of theta time-locked to inhibitory stimuli in ADHD compared to the ASD and TDC group. Greater theta phase variability was associated with increased RT variability across all groups.
Conclusions: Our results suggest that children with both ASHD and ASD have altered cognitive control, indexed by decreased theta power localised to a source in the MF cortex. However, we show that the integrity of MF systems may be more compromised in ADHD compared to both ASD and TDC indicated by increased RTV and theta phase variability. Our findings may suggest disparate cortical sources for RT abnormalities in ASD and ADHD. Cognitive theories differ in whether they propose shared underlying causes between the disorders or disparate etiological pathways. Our findings confirm the importance of cognitive control in both ASD and ADHD pathophysiology but also suggest that some abnormalities in ASD may be independent of demands on the cognitive control system in ADHD, consistent with a model of limited shared causal pathways to the disorders.

73 **161.073** Gaze Abnormality Can Distinguish Between Autism Spectrum Disorder and Typically Developing Children through Screening in 5-Year-Old Children By a Double Blind Study in a Japanese Community Based Population

M. Saito[1], *M. Adachi*[2], *S. Yoshida*[3], *S. Yasuda*[4], *M. Kuribayashi*[5], *Y. Sakamoto*[6], *K. Nakamura*[7] *and N. Takayanagi*[2], *(1)Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, Hirosaki, Japan, (2)Hirosaki University, Hirosaki, JAPAN, (3)Research Centre for Child Mental Developmenta Hirosaki University Graduate School of Medicine, Hirosaki, JAPAN, (4)Research Center for Child Mental Development Graduate School of Medicine, Hirosaki University, Hirosaki, JAPAN, (5)Hirosaki University Research Center for Child Mental Development, Hirosaki, Aomori, JAPAN, (6)Graduate School of Medicine, Hirosaki University, Hirosaki, JAPAN, Hirosaki, Japan, (7)Hirosaki University, Aomori-Ken, JAPAN*

Background: A number of studies have identified unique visual gaze patterns in individuals with autism spectrum disorder (ASD) using eye-tracking systems. Such gaze fixation patterns in individuals with ASD are considered to be associated with social attention. However, the past studies show different results between ASD and typically developing (TD).
Objectives: Using Gazefinder, an all-in-one eye-tracking system for early detection of ASD in toddlers, we examined the gaze characteristics of toddlers to specific objects in individuals with and without ASD in a 5-year-old children by a double blind study in Japanese community based population.
Methods: We measured the percentage of eye fixation time allocated to particular objects depicted in movies by five-year-old children in a community health check-up (n=438) by double blind study. In the community health check-up spanning three years (2013-2015, N=3804), the participants screened in the community health check-up were 2923 children. The local government officers invited 440 children (included 31 applicants) to additional assessments and an interview based on the results of the screening. Subjects of analysis are ASD (n=84) who diagnosed by DSM-5 criteria and TD (n=98) who had no abnormalities in all the experiment. We compared these percentages between the two groups. Gazefinder incorporates movies of human faces, biological motion, and people and geometric shapes, and it provides almost instantaneous data by automatically calculating the percentage fixation time allocated by the participants among regions of interest in the movie. In addition to the total trial time is short (approximately 2 min), and instructions or verbal answers are not required; the participant simply views a video monitor.
Results: Compared with the TD group, the ASD group showed significantly less fixation time at locations of salient social information (the available percentage fixation time, 'eyes' region in the movie of human faces without lip movement, 'mouth' region with talking and 'people' region in the movie of people and geometry), while there were no significant group wise differences in the responses to biological motion. However, the percentage fixation times exhibited small effect sizes for the group difference. In ROC analysis in each area of interest, the significant AUCs wereÂ .600 ('eyes' region, silent), .590 ('mouth region',Â talking), .652 and .586 ('people' region, same size and small size).Â AUCs were low accuracy (<0.7).
Conclusions: This study showed gaze abnormalities can distinguish ASD and TD through screening, in order to improve the accuracy of screening, it is necessary to examine further these contents.

74 **161.074** Hot and Cool Executive Function and Theory of Mind in Children and Adolescents with Autism Spectrum Disorder: Cross Sectional Developmental Trajectories

***E. C. Kouklari**, S. Tsermentseli and C. Monks, Psychology, Social Work, and Counselling, University of Greenwich, London, United Kingdom*

Background:
Research on the development of Executive Function (EF) has indicated that the emergence of EF occurs in the early years of life, followed by critical changes throughout the preschool era. There is significant evidence suggesting that it continues to develop at least during the adolescence, protracted to the development of the prefrontal cortex. Despite research supporting separate domains of cool and hot EF, traditionally, the development of EF in ASD has been investigated mainly using tasks tapping only the "cool"-purely cognitive- aspects of EF. Thus, minimal is known about the developmental trajectories of "hot"-affective EF processes and whether cool and hot EF follow a similar developmental pathway in ASD. Finally, although the development of cool EF and its links to Theory of Mind (ToM) have been widely examined, understanding of the development of hot EF and its relation to ToM in ASD is very limited.
Objectives:
The present study sought to examine the age-related changes in both cool and hot EF of ASD participants from middle childhood to adolescence, shedding more light on the hot-cool EF organisation. It also explored the interrelation between the developmental trajectories of cool & hot EF and ToM in ASD.
Methods:
The current study employed a cross-sectional developmental trajectories approach to compare the hot and cool EF profiles as well as ToM, relative to chronological age between children and adolescents with ASD and typically developing peers. 170 participants (91 controls and 79 with ASD) between 7 and 16 years old were assessed on measures tapping cool EF (*working memory*, *inhibition*, *planning*), hot EF (*affective decision making*, *delay discounting*) and ToM (*emotion understanding*, *false no false belief knowledge*).
Results:
Results demonstrated that the developmental trajectories of selective cool EF (working memory, planning) differed significantly as a function of age (age-related changes) in participants with ASD relative to typically developing participants. Cool EF inhibition followed the same developmental pattern as in the control group (improvements with age) while for the hot EF, both ASD and control groups presented no significant changes across younger and older participants. Gains were also reported in both ToM measures for both groups. Developmental trajectories of cool and hot EF skills were related to ToM developmental trajectory in ASD.
Conclusions:
Theoretical implications are discussed as the examination of the developmental trajectories of the EF cognitive processes and their effect on social cognition such as ToM could contribute to our better understanding of the phenotypes of children and adolescents with ASD. These findings highlight the need to assess both hot and cool EF developmental trajectories in clinical practice as they may aid in enhancing diagnosis or better informed intervention programs.

75 **161.075** Impulse Control to Specific Interests in Children with Autism Versus Typical Development

***M. R. Silverman**[1], D. J. Bos[2], E. L. Ajodan[3], A. Hamo[4], C. K. Carberry[5] and R. M. Jones[6], (1)Sackler Institute for Developmental Psychobiology of Weill Cornell Medical College, New York, NY, (2)Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Utrecht, NETHERLANDS, (3)CADB, Great Neck, NY, (4)Weill Cornell Medicine, New York, NY, (5)Educational Psychology, University of Texas at Austin, New York, NY, (6)Weill Cornell Medical College, White Plains, NY*

Background: Deficits in impulse control and behavioral regulation are characteristic of autism spectrum disorder (ASD). Impulsivity negatively impacts learning and interferes with behavioral interventions in ASD. In typical development (TD), prior work has shown increased impulsivity to happy faces but in ASD, social cues have less significance. It is unknown how cues that are salient to children with ASD, such as special interests, influence impulsivity.
Objectives: The goal of this study was to examine impulse control to interests versus social cues in ASD and TD. We hypothesized that impulsivity in children with ASD would be greatest to special interests versus faces and the opposite pattern would be observed in TD.
Methods: 34 children participated: 15 children with ASD (13 male, mean age 9 (7-12 yrs), mean VIQ = 97; mean NVIQ = 94; mean ADOS CSS Total = 8.4) and 19 TD children (18 male, mean age 9 (5-12 yrs), mean VIQ= 115, mean NVIQ = 115). Children performed a novel go/nogo task on an iPad with 5 different conditions. For non-social conditions, children chose their favorite hobby (interest) and their least favorite hobby (non-interest). For social conditions, children were presented with happy or calm faces. A control condition presented colored shapes. Children were instructed to touch 'go' cues and to withhold responses to 'nogo' cues. All 5 conditions served as both go and nogo cues and were counterbalanced across participants. D-prime was calculated as the normalized hit rate (go-accuracy) minus normalized false alarm rate. Reaction time variability was assessed with ex-Gaussian distribution functions.
Results: Go-accuracy did not differ by group, demonstrating all children attended to the conditions. For d-prime using linear mixed effects models there was an interaction between condition and group (F(105.84) =4.993,Â p = 0.001) demonstrating in TD there was lower d-primes (greater impulsivity) to happy faces relative to interests (p=0.023) and lower d-prime to neutral faces relative to interests (p=0.008). As hypothesized, children with ASD demonstrated a trend of lower d-prime to their interests relative to TD (p=0.093), with no differences between groups to faces or non-interests, suggesting that children with ASD may be more biased and distracted by their interests relative to TD. There were no significant differences between conditions in the ASD group and no significant interactions between condition and diagnosis on the ex-Gaussian functions. These parameters will be explored further as data collection is ongoing.
Conclusions: Children who were typically developing were more impulsive to socials cues than their interests, suggesting that interests elicited greater attention and facilitated inhibition. In contrast, there was a trend that children with ASD were more biased by their interests relative to TD, suggesting that interests may be particularly distracting for children with ASD and decrease inhibition. Ultimately identifying cues that are salient to children with ASD and thus increase impulsivity and distraction will be important for improving interventions that target attention and behavioral regulation.

76 **161.076** Increased Access to Information, but Not Increased Feedback, Enhances Category Learning in Autism

A. M. Nader[1], *D. Tullo*[2], *V. Bouchard*[3], *J. Degré-Pelletier*[4], *E. Danis*[1], *A. Bertone*[2], *M. Dawson*[5] *and I. Soulières*[3], *(1)University of Quebec in Montreal, Montreal, QC, Canada, (2)McGill University, Montreal, QC, Canada, (3)University of Quebec in Montreal, Montréal, QC, Canada, (4)University of Montreal Center of Excellence for Pervasive Developmental Disorders (CETEDUM), Montreal, QC, Canada, (5)Centre d'excellence en Troubles envahissants du développement de, Montréal, QC, CANADA*

Background: Popular autism interventions often feature high levels of feedback as well as the breaking down of tasks or information into numerous small increments presented sequentially. However, these practices are not necessarily consistent with a small but growing literature on how autistics learn well (Foti et al., 2015), including by spontaneously extracting regularities from large arrays of information (Mottron et al., 2009, 2013). Autistics have shown a range of performance in category learning tasks (Gastgeb et al., 2012; Schipul et al., 2012; Soulières et al., 2010), suggesting that changes in how and how much information is presented may affect how well autistics learn.
Objectives: Assess how access to information (sequential vs. simultaneous presentation) and level of feedback (high vs. low intensity) during learning affects the probabilistic categorization performance of autistic and typical children.
Methods: 108 children were tested on one of two probabilistic categorization tasks (Shohamy et al., 2004; Brown et al. 2010). To date, data have been analysed for 11 autistic (age=9.0 years, *SD*=1.5; WISC-IV PRI=108.0, *SD*=16.09) and 16 typical (age=9.0 years, *SD*=1.4, *p*=1.0; PRI=115.4, *SD*=12.0, *p*=0.17) children tested on the *feedback* task; and for different groups of 16 autistic (age=10.3 years, *SD*=2.0; PRI=105.9, *SD*=15.8) and 18 typical (age=9.2 years, *SD*=1.2, *p*=0.08; PRI=115.0, *SD*=11.0, *p*=0.06) children tested on the *presentation* task. 14 artificial stimuli varying across 4 dimensions had to be classified into 2 categories based on 5 different probabilities. Each stimulus was probabilistically associated with an outcome. Tasks varied either in information *presentation* (sequentially, one stimulus at a time vs. simultaneously, all stimuli together) or *feedback* level (*low* vs. *high* intensity nonsocial informative feedback) in the 200-trial learning phase, which was followed by two 70-trial test phases. Test1 used learning-phase stimuli, while Test2 used equivalent but new stimuli requiring generalization of learning.
Results: Â Preliminary analyses were conducted of test-phase accuracy, reported here as mean number of correctly classified stimuli out of 70. Intensity of feedback (*low* vs. *high*) did not affect Test1 accuracy in either group (typical: *low*=42.2, *SD*=9.3, *high*=42.4, *SD*=7.2; autistic: *low*=40.0, *SD*=12.4, *high*=46.3, *SD*=9.3), *p's*>.05. The same was true for Test2 (typical: *low*=42.0, *SD*=12.6, *high*=44.5, *SD*=11.4; autistic: *low*=45.8, *SD*=10.3, *high*=46.3, *SD*=12.0), *p's*>.05. However, autistic children's Test1 accuracy was significantly better when information was presented simultaneously during learning (46.9, *SD* 5.6) versus sequentially (36.8, *SD* 8.3, *p*=.01), while this made no difference in typical children (43.9, *SD*=8.2 vs. 49.6, *SD*=7.07, *p*=.176). In Test2, autistics again benefited from simultaneously (51.7, *SD*=6.21) versus sequentially (42.4, *SD*=4.7, *p*=.01) presented information during learning, with no difference in typical children (40.5, *SD*=13.2 vs. 48.2, *SD*=12.6, *p*=.125). Further analyses are ongoing.
Conclusions: In a probabilistic category learning task, increased access to information enhanced autistic children's category learning and generalization, while increased feedback had no effect. Our preliminary results suggest the relative non-importance of feedback intensity to autistic learning, and that limiting autistic children to small increments of information, presented one at a time, may impede or undermine their learning. Increasing autistic children's access to information they can process well should be a priority.

77 **161.077** Inhibitory Control Deficits in ASD Reflect Failures to Strategically Delay Behavioral Responses

L. M. Schmitt[1], *M. E. Ragozzino*[2], *E. H. Cook*[3], *S. P. White*[4], *J. A. Sweeney*[5] *and M. W. Mosconi*[1], *(1)University of Kansas, Lawrence, KS, (2)University of Illinois at Chicago, Chicago, IL, (3)Psychiatry, University of Illinos at Chicago, Chicago, IL, (4)UT Southwestern Medical Center at Dallas, Dallas, TX, (5)University of Cincinnati, Cincinnati, OH*

Background: Deficits of behavioral response inhibition, including reduced abilities to suppress contextually inappropriate behaviors, have been repeatedly documented in ASD. We recently demonstrated that healthy individuals are more likely to inhibit unwanted behavioral responses when they strategically delay their onset. Determining the extent to which individuals with ASD use similar cognitive strategies to support response inhibition across childhood and into adulthood may provide important insights into cognitive processes underlying reduced inhibitory control in ASD.
Objectives: To characterize behavioral response inhibition and underlying neurocognitive strategies in children, adolescents, and adults with ASD using a stop-signal task (SST).
Methods: One hundred twenty-two individuals with ASD and 76 healthy controls matched on age (5-28 years), gender, and nonverbal IQ completed a manual motor SST. Participants were instructed to press a button when a peripheral target appeared ('GO' trials) or inhibit these responses when a central stop-signal appeared following the peripheral cue ('STOP' trials). A baseline reaction time (RT) task consisting of a block of GO trials was administered to assess adaptive RT slowing during SST GO trials. Non-linear regression models were used to assess the relationship between SST accuracy and slowing as function of age. The Repetitive Behavior Scale-Revised (RBS-R) was used to assess the relationship between SST performance and repetitive behaviors in patients.
Results: Â Individuals with ASD showed reduced rates of successfully inhibiting motor responses on STOP trials compared to controls. Participants slowed their RTs during SST GO trials compared to baseline, but individuals with ASD slowed their RTs less than controls. Greater RT slowing was associated with reduced inhibition error rates for participants, and this relationship was stronger for controls than patients. Participants demonstrated age-related increases in stopping accuracy and RT slowing that were best modeled as a cubic function. Individuals with ASD showed less age-related increases in SST accuracy and slowing. Reduced stopping accuracy and RT slowing were associated with more severe repetitive behaviors, including compulsive, self-injurious, and ritualistic behaviors.
Conclusions: Our results provide novel evidence that deficits inhibiting behavioral responses in ASD may reflect a reduced ability to strategically delay the onset of motor responses. Whereas healthy individuals slow their behavioral responses in uncertain conditions and thereby increase their ability to suppress inappropriate responses, individuals with ASD are less able to use this strategy and therefore have greater difficulty suppressing unwanted responses when they are cued to stop. Our findings that deficits of inhibitory control are related to repetitive behaviors suggest that patients' failures to suppress attention to or engagement in a particular behavior may contribute to their compulsive and ritualistic actions. Our findings also suggest that treatments aimed at slowing behavioral responses may mitigate impulsive behavioral responses and repetitive behaviors in ASD, and that these treatments may continue to be effective if implemented in later childhood or adolescence.

78 **161.078** Internal Noise and Global Motion Pooling and Their Relationship with Autistic Traits in Typically Developed Adults.

E. Orchard *and J. van Boxtel, Monash Biomedical Imaging, Monash University, Melbourne, Australia*

Background:
People with autism spectrum disorder (ASD) display abnormalities in motion processing. Motion perception abnormalities in ASD have been linked to high levels of internal noise (unreliable neuronal fluctuations), and deficits in global motion pooling (integrating local motion into a global percept). There are two types of internal noise: additive ('baseline' that is constant across different amounts of external, i.e. stimulus, noise); and multiplicative (proportional to external noise). Previously, internal noise in ASD has been investigated through additive internal noise, comparing ASD and control groups. However, multiplicative noise has not yet been investigated in terms of ASD and neither type of internal noise has been investigated in terms of traits of autism in typically developed populations.
Objectives:
To investigate how additive and multiplicative internal noise and global motion pooling vary across number of autistic traits in typically developed adults.
Methods:
To achieve these aims, we employed a visual motion integration task with a typically developed population, measuring autistic traits with the Autism Spectrum Questionnaire (AQ). Forty-five adults (M_{age}= 22.18, SD_{age}= 4.96) indicated average direction (left or right) of 200 dots across eight external noise levels (varied with increased directional noise). Additive and multiplicative internal noise and global motion pooling were calculated from task accuracy and consistency across external noise levels, using equivalent noise analysis (ENA), within a double-pass paradigm. ENA compares human performance to an 'ideal observer' with known levels of additive internal noise and pooling (Lu & Dosher, 2008). An equivalent noise function is then fit to these data to estimate internal noise and pooling (Manning et al., 2014). This method of analysis has been used within populations of both ASD (Manning et al., 2015) and typically developed individuals (Burgess & Colborne, 1988).
Results:
A Mann-Whitney U test revealed no significant difference in additive noise between those with high (Mean Rank = 22.45, n = 20) and low (Mean Rank = 20.64, n = 22) AQ scores, U = 201.00, p= .56, two-tailed. No significant correlation was found between multiplicative noise and AQ score: r= -0.03, p= .84, or between global motion pooling and AQ score: r= 0.12, p= .448. Bayesian statistics indicate these values give moderate support for the null hypothesis, with BF_{10}=0.12, and 0.16, for multiplicative noise and global motion pooling, respectively.
Conclusions:
Our results suggest that differences in internal noise and global motion pooling may not be present across a sub-clinical spectrum of autistic traits. In support of Manning et al. (2015), who found no difference in internal noise between ASD and control groups using similar methods, our results may be tentatively extrapolated to clinical ASD populations. We offer support for the *absence* of a difference in internal noise and global motion pooling between clinical ASD and typically developed populations.

79 **161.079** Intuitive and Reflective Reasoning in Autism Spectrum Disorder

M. Brosnan[1]*, M. Lewton*[2] *and C. Ashwin*[1]*, (1)University of Bath, Bath, UNITED KINGDOM, (2)University of Bath, Bath, United Kingdom*

Background:
Dual Process Theory has been a major theory within psychology for over 50 years. It proposes that there are two distinct types of reasoning process: Type 1 which is autonomous and typically rapid and nonconscious ('intuition'), and Type 2 which is typically slower and conscious ('reflective') and dependent upon working memory capabilities. Recently a Dual Process Theory of Autism has been proposed to suggest that reasoning in Autism can be characterised as Type 2 processing dominating over Type 1 processing (Brosnan et al., 2016). This can be assessed through the Cognitive Reflection test (CRT) which is a series of three apparently simple questions that have a correct reflective response but also an incorrect response that is argued to be an intuitive response. The task is not purely ipsative as it is also possible to make random errors. The typical dominance of the intuitive response in this task is reflected in only 17% of over three thousand American college students getting all the questions correct.
Objectives:
Investigate the relationship between autistic traits and autism diagnosis upon intuitive and reflective responses on the CRT – controlling for an index of non-verbal IQ.
Methods:
Participants were 26 people with a diagnosis of autism (17M, 9F) and 22 Typically Developing (TD) controls (11M, 11F), with the proportion of males and females not significantly different between the groups (Chi=1.16, p>.05). Participants were 16-24 years old (mean = 18.31, sd=1.40), and age did not significantly differ between the groups. Participants completed the AQ, the CRT and 12 items (subscale I) of Ravens Matrices as an index of non-verbal IQ (NVIQ).
Results:
The means (standard deviations) for both groups are reported in Table 1. A MANOVA was conducted with CRT-Intuitive and CRT-Reflective responses as the dependent variables and Group (ASD/TD) as the independent variable with sex (Male/Female) and NVIQ as covariates. The ASD group made significantly less intuitive responses ($F(1,44)=4.43$, $p<.05$), with no significant difference in reflective responses ($F(1,44)=2.38$, $p>.05$). The covariates were not significant. Finally a partial correlation controlling for group (ASD/TD) and sex (Male/female) revealed a significant negative correlation between autistic-like traits and CRT-Intuitive ($r(44)= -.29$, $p<.05$) and a significant positive correlation between autistic-like traits and CRT-Deliberative ($r(44)= +.25$, $p<.05$).

Table 1	ASD	TD	
AQ (max 50)	29.42 (5.48)	14.73 (4.91)	t(46)=9.71, p<.001
NVIQ (max 12)	9.58 (1.72)	9.91 (1.44)	ns
CRT_Intuitive (max 3)	0.54 (0.71)	1.14 (1.04)	t(46)=2.36, p<.05
CRT_Reflective (max 3)	1.38 (0.85)	1.82 (1.10)	ns

Conclusions:
Consistent with the Dual Process Theory of Autism, higher autistic-like traits and a diagnosis of ASD related to fewer intuitive responses. Higher autistic-like traits related to more reflective responses, although there were no group differences in this measure. Together, the results support the Dual Process Theory of Autism and suggest ASD is characterised as being less intuitive and more deliberative than controls. Intuitive responses are incorrect responses, however, the group difference was identified controlling for NVIQ, indicating that more intuitive responding is not solely due to generally lower levels of reasoning ability in ASD.

80 **161.080** Investigating the Predictive Impairment in Autism Hypothesis.

W. Jamal[1]*, N. Hadjikhani*[2]*, J. A. Christodoulou*[3]*, A. Cardinaux*[1]*, L. Vogelsang*[4]*, M. M. Kjelgaard*[5] *and P. Sinha*[1]*, (1)Massachusetts Institute of Technology, Cambridge, MA, (2)Martinos Center for Biomedical Imaging, Charlestown, MA, (3)Dept. of Communication Sciences and Disorders, MGH Institute of Health Professions, Boston, MA, (4)University of Osnabrück, Osnabrück, Germany, (5)MGH IHP, Arlington, MA*

Background: The human brain extracts probabilistic information from relations between events in the environment. Such learning underlies our ability to anticipate changes. The Predictive Impairment in Autism (PIA) hypothesis, recently proposed by Sinha and colleagues, posits that impaired ability to detect probabilistic regularities over time may be a key cause of seemingly unrelated symptoms in autism (e.g., social, language, and motor impairments). The Weather Prediction Task (WPT) is a probabilistic learning task that serves to test this hypothesis. Besides revealing behavioral performance differences, it also allows the study of the function of cerebellar and frontostriatal circuits in prediction while eliminating the potential confounds of social rewards. The functional integrity of neural substrates of skill- and probabilistic-learning in autism are not known.
Objectives: To assess: 1) Performance of individuals with autism spectrum disorders (ASD) on the WPT and 2) Differences between prediction-evoked neural activations in ASD and typically developing (NT) participants.
Methods: Participants were age and gender-matched ASD and NT adults with average range IQ. Each participant completed the WPT, which requires gradual integration of probabilistic information, outside and in an MRI scanner. During behavioral trials, the participant sees a combination of 1-3 cards from a set of 4 cards and indicate via button press either sunny or rainy weather outcomes with immediate feedback. Each card is probabilistically associated with a unique predictive value (likelihood) of sunny weather. Some cards have high predictive value, but none is a deterministic indicator of outcome. Through repeated presentations, participants learn the predictive value of cards to estimate weather outcomes. Responses are considered accurate when a participant selects the weather most highly associated with the probability of the combination of cards presented. Thus the accuracy reported represents the ability to build a probabilistic model for each card across a number of trials. Participants first complete a 200 trial behavioral training session, followed by 64 trials (without feedback) during fMRI scanning.Â A deterministic control task in the scanner presents a combination of 1-3 cards with either sunny or rainy symbols and requires participants to choose the weather in a 2AFC setting.
Results: During training, group performance significantly differed [$t(14)=2.70$, $p = .0097$] favoring NTs (M=66%, SD=0.06) compared to ASDs (M=58%, SD=0.06). During fMRI, the NT group showed greater activation for experimental vs control tasks, and increased activation compared to ASD in the thalamus, the basal ganglia (caudate and putamen), and in the 'social brain' (TPJ, STS, vmPFC, IFG, anterior insula, temporal pole, and amygdala). Importantly, this finding was partly driven by greater activation during the control task in ASDs versus NT participants.
Conclusions: The WPT is a non-social prediction task that can reveal both behavioral and functional differences in ASD. This task did not reveal cerebellar differences in the pilot group, but revealed decreased activation in frontostriatal circuits and in the so-called social brain in ASD. This study offers preliminary evidence for PIA hypothesis by demonstrating prediction deficits behaviorally and hypoactivation in systems that rely on predictive learning capacity distinct from known deficit areas in ASD.

81 **161.081** Looking Beyond Looking Time: A Systematic Review of Eye-Tracking Measures of Social Attention in ASD

M. Chita-Tegmark*, Boston University, Winchester, MA*

Background:
Eye-tracking technology has been a powerful tool for investigating social attention in ASD (Guillon et al., 2014). The majority of measurements of social attention have relied solely on looking time measures, interpreting longer looking times as an indication of preference for a certain area of interest (AOI). Based on this measurement it has been shown that social attention is reduced in individuals with ASD as compared to typically developing controls, ASD individuals directing less of their visual attention to social stimuli than typically developing controls (for a meta-analysis see Chita-Tegmark, 2016). However, there are many questions regarding social attention that cannot be answered through looking time measures, such as: do individuals with ASD prioritize social attention in the same way and to the same degree as typically developing controls? Do individuals with ASD explore the visual social world to the same extent? Do individuals with ASD maintain the same kind of focus on social stimuli as typically developing controls? Fortunately, eye-tracking technology makes possible a large number of different kinds of measures that can be used to tackle a variety of questions related to social attention in ASD.
Objectives:
The objective of this research is to systematically examine the eye-tracking literature in order to create an inventory of the available eye-tracking measures and to synthesize the findings they have enabled pertinent to social attention in ASD.
Methods:
A thorough search of the PubMed database was performed using the Boolean phrase ((ASD) OR (autism) OR (Asperger)) AND ((eye-tracking) OR (eye tracking) OR (eye gaze)). Articles meeting the following criteria were selected: 1) the article was an empirical study 2) the study compared individuals with ASD with TD controls 3) the study used eye-tracking technology 4) the study involved social stimuli 5) the study had a free viewing task and 6) the study included a measure in addition to and/or other than looking time. All eye-tracking measures of social attention were catalogued and the results obtained by means of these measures were synthesized.
Results:
The measures fell into three major categories: measures of prioritization of social attention (including: location of first fixation, latency to first fixation and progression of exploration over time), measures of persistence of social attention (including: average fixation time, characteristics of first fixation and visual perseverance) and measures of exploration of social information (including: saccade length, saccade paths characteristics, number of saccades and spread of fixation). A preliminary synthesis of findings suggest differences between individuals with ASD and typically developing controls for each of these major features of social attention, with less prioritization of social information, less persistence of social attention and less exploration of social information.
Conclusions:
By harnessing the full potential of eye-tracking technology and research in terms of available measures it is possible to gain a more nuanced understanding of social attention in ASD.

82 **161.082** Memory Deficits for Faces and Non-Social Stimuli in Children with ASD

***Y. B. Choi**, L. Chen, S. Qin and V. Menon, Stanford University School of Medicine, Stanford, CA*

Background: The ability to remember faces is important for normal social communication. Despite mounting research on face processing deficits in children with autism spectrum disorder (ASD), little is known about their face memory deficit, particularly regarding its domain-specificity and the impact of memory demand. Moreover, the relation between the face memory deficit and affect processing in ASD has not been thoroughly researched, although the emotion recognition deficit is a key diagnostic criterion. Hence, a systematic investigation of the face memory deficit and its relation with affect processing in ASD is desired for improving diagnosis and treatment of affected individuals.
Objectives: This study aimed to investigate (a) whether children with ASD show a specific memory deficit for faces compared to non-social objects, (b) whether memory demand (i.e., time delay) affects memory performance in children with ASD, and (c) whether memory for faces is associated with affect processing.
Methods: Preliminary analysis on a sample of 8 children with ASD and 10 typically-developing (TD) controls (age range=8-12 yrs, *M*=10.72 yrs) is presented below.Â Memory for faces and non-social stimuli was assessed using (a) Memory for Faces and Memory for Designs subtests (both immediate and delayed) from the Developmental Neuropsychological Assessment Battery (NEPSY-II), and Faces and Dot Locations subtests (both short and long delay) from the Children's Memory Scale (CMS). Affect processing was assessed using the Affect Recognition subtest from NEPSY-II. Standardized scores of all these assessments were used.
Results: Â A 2x2x2 ANOVA with Domain (Face vs. Non-social), Delay (Short vs. Long), and Group (ASD vs. TD) on the NEPSY-II Memory for Faces and Memory for Designs subtests revealed a significant effect of group, $F(1,16)=15.13$, $p<0.001$, indicating overall lower memory ability in children with ASD ($M=9.47$) compared to TD children ($M=12.63$). No other main effects or interactions were significant. This result was replicated on the CMS Faces and Dot Locations Memory subtests; a 2x2x2 ANOVA with Domain (Face vs. Non-social), Delay (Immediate vs. Long), and Group (ASD vs. TD), $F(1,16)=6.71$, $p<0.02$, showed inferior memory performance in ASD children regardless of domain and time delay. Further correlation analysis found a significant correlation between long delayed face memory and affect recognition scores on NEPSY-II across all individuals, $r(16)=0.647$, $p<0.004$, and a significant relation was only observed in TD, $r(8)=0.774$, $p<0.009$ but not ASD, $r(6)=0.058$, $p=0.891$.
Conclusions: Although further analysis with a larger sample size is needed to corroborate these findings, current preliminary analysis revealed impaired memory for faces in children with ASD compared to their TD peers. However, this deficit was not specific to faces, and memory demand had no effect on its severity. Rather, children with ASD appear to have a general memory deficit across social and non-social domains. Furthermore, face memory seems to associate with affect processing in TD, but this relationship is likely to be disrupted in children with ASD.

83 **161.083** Memory Profiles Between Individuals with ASD with High or Low Cognitive Abilities: A Cautionary Tale about Generalizing Across the Autism Spectrum.

***N. Shea**[1], T. Flanagan[2], J. A. Burack[3] and N. Russo[1], (1)Syracuse University, Syracuse, NY, (2)Counselling and Educational Psychology, McGill University, Montreal, QC, Canada, (3)McGill University, Montreal, QC, CANADA*

Background: Findings from studies of individuals with high functioning autism are often generalized to the entire spectrum that includes individuals with a broad range of intellectual abilities, as well as varying levels of symptoms.
Objectives: The aim of the present study was to add to the discussion about the practice of generalizing across the autism spectrum by directly comparing the memory profiles of individuals with autism who were grouped according to cognitive abilities on a standardized measure of memory.
Methods: 37 children with an autism spectrum disorder with both high (HCA) and low cognitive abilities (LCA) were tested on a non-verbal IQ test, and a subset of these (n = 17) also completed the conormed attention and memory battery of the Leiter-R (Roid & Miller, 1997).
Results: Profiles of scores were examined via both traditional null hypothesis testing, as well as Bayesian analysis, since evidence of group differences in patterns of performance would be reflected in a lack of differences between the HCA and LCA participants. The findings suggest similarities in patterns of cognitive strengths and weaknesses but clear difference in terms of memory profiles. Using Bayesian analyses, we confirm that HCA and LCA did not differ in terms of their recognition memory skills. Examination of standard scores suggest that while recognition memory might be a weakness for HCA participants, this was not the case for the LCA group.
Conclusions: These findings suggest that researchers should be cautious when making generalizations to the entire spectrum, as recognition memory weaknesses noted in the HCA group were not reflected in the LCA group. These findings also provide further support for the use of non-verbal tests in assessing the performance of individuals with autism with lower cognitive abilities.

84 **161.084** Memory for Items, Contexts and Relations in Adults with Autism Spectrum Disorder

***M. Ring**, S. B. Gaigg and D. M. Bowler, Psychology, City, University of London, London, United Kingdom*

Background:
Two prominent accounts of memory difficulties in adults with Autism Spectrum Disorder (ASD) suggest difficulties in episodic memory (Bowler et al., 2007) and complex memory (Williams et al., 2015). Both accounts implicate problems remembering relations between items or between items and their context (Bowler et al., 2015), and difficulties in these areas may be the result of problems in binding items to one another, in binding items to their context, or in forming a three-way relation between two items and their context (ternary relations; Halford, 1992). Recent research has shown a developmental progression in typical children's ability to recombine items and context as well as to form relations between three components such as two items and their context (Yim et al., 2013). Forming and retaining connections between items and context have recently been identified as the prerequisites for the development of episodic memory (Yim et al., 2013), and they may be a component of autistic individuals' difficulties in this area.
Objectives:
This study aimed to use Yim et al.'s (2013) paradigm to identify the components in the memory binding process that are most difficult for ASD individuals and to point to potential compensatory mechanisms.
Methods:
Fifty-four pairs of ASD and typically developing (TD) individuals matched on gender, chronological age (CA; M_{CA} = 43.19), and intelligence quotient (IQ; M_{FIQ} = 111) were tested on one of three associative learning tasks that varied in the number of bindings between items and context to be formed for task success. One group of participants studied lists of word pairs in the form of AB CD, where each list contained different pairs of items such as *tree-shoe* (AB) and *strawberry-sofa* (CD). A second group of participants studied lists of the form AB AC, which recombined familiar items from the first list with new items in the second list, for example, *bicycle-cup* (AB) and *bicycle-nail* (AC). A third group studied AB ABr lists, where the first studied list (AB) contained pairs such as *door-glass* and *flag-balloon*, and the second set (ABr) presented a recombination of item-pairs from the first list introducing no new items, for instance, *door-balloon*. Each list was accompanied by a specific contextual cue.
Results:
Overall accuracy was lower for persons with ASD compared to TD individuals on all tasks ($F(1,102) = 12.49$, $p = .001$). A multinominal model (Kim et al., 2013), using error rather than accuracy data showed that ASD participants named more items that were unrelated to the studied items, they more often confused item-item relations, and they showed particular difficulties in binding item-pairs to their contextual cue. These last two findings reflect ternary binding difficulties. However, ASD participants performed better than TD individuals in distinguishing between the two studied lists, i.e., identifying whether individual items belonged to a cue or a target list.
Conclusions:
This study confirms particular difficulties in ASD in forming ternary relations in memory. However, it also suggests that persons with ASD rely on their superior capacity to remember item-list relations as a compensatory mechanism.

85 **161.085** Meta-Analysis of Eye Gaze Differences to Social and Non-Social Information Between Individuals with and without Autism

***E. E. Zetzer**[1], E. W. Klingemier[1], A. Y. Hardan[2], M. S. Strauss[3], C. Eng[4], E. A. Youngstrom[5] and T. W. Frazier[1], (1)Cleveland Clinic Center for Autism, Cleveland, OH, (2)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (3)University of Pittsburgh, Pittsburgh, PA, (4)Genomic Medicine Institute, Cleveland Clinic, Celeveland, OH, (5)University of North Carolina, Chapel Hill, NC*

Background:
Numerous studies have emphasized abnormal eye gaze as a key characteristic in individuals with autism. However, a limited number of findings have been replicated, the magnitude of effects is unclear, and the pattern of gaze differences across stimuli requires further investigation. Eye gaze studies offer a unique window into the selection of information for attention and cognitive processing. As such, findings across studies can inform disparate cognitive theories of autism, including the distinction between specific deficits in social-emotional cognitive processing versus more general non-affective cognitive dysfunction.
Objectives:
The first aim of the present study was to conduct a comprehensive multivariate meta-analysis of autism eye tracking studies to establish whether gaze differences relative to healthy and developmental disability controls are present and to determine the magnitude of these differences. The secondary aim was to evaluate the influence of specific study demographic and methodological factors influencing eye gaze differences. Specifically, we were interested in the magnitude of differences across different stimuli and regions-of-interest (ROIs) as this may inform cognitive theories of autism.
Methods:
A comprehensive search was completed using PubMed supplemented by a manual search. 1132 publications were initially identified for closer inspection. Inclusion and exclusion criteria were applied to identify only those studies reporting sufficient information to compute effect sizes comparing individuals with autism to healthy or developmental disability controls on eye gaze measures of fixation or looking time. A wide range of study demographic, clinical, methodological, stimulus, and ROI characteristics were coded. A blinded second rater coded 10 studies representing 62 group comparisons. Inter-rater reliability was consistent for each variable (K=.81-1.00, absolute agreement=91.3%-100%).Â An initial methodological mixed-effects meta-regression model was estimated with study characteristics as moderators. Next, a conceptual multivariate mixed-effects meta-regression model examined the impact of stimulus and ROI features while adjusting for significant methodological characteristics from the initial model.
Results:
The search revealed 122 independent studies with 1155 comparisons. Estimated effect sizes tended to be small-to-medium, but varied considerably across studies. Meta-regression of methodological factors indicated lower effect sizes for studies with higher method quality, later publication years, and using developmental disability control comparisons. Effect sizes did not vary as a function of sample age. The conceptual meta-regression identified that non-social ROIs yielded larger effect sizes than social ROIs (Figure 1). However, eye and whole face regions within stimuli depicting human interaction produced the largest effects (Hedge's g=.47 and .50). Overall, studies with weaker methodology obtained larger effects, but effects remained significant and medium-sized for studies with moderate and high rigor designs.
Conclusions:
Individuals with autism show a reliable pattern of eye gaze abnormalities that suggests a problem with basic discrimination of irrelevant non-social from socially-important information. This difference appears to be persistent across age and worsens during observation of human interactions. These findings support social processing deficits as a core feature, consistent with social cognitive theories of autism. Eye gaze abnormalities in autism were of sufficient magnitude that, if combined across stimuli and ROIs, could yield clinically-useful risk assessment and serve as quantitative, objective outcome measures.

86 **161.086** Metacognition, Mindreading, and the Hypercorrection Effect in ASD

D. M. Williams[1]*, C. S. Grainger*[2]*, T. Nicholson*[3] *and Z. Bergstrom*[3]*, (1)School of Psychology, University of Kent, Canterbury, United Kingdom, (2)School of Psychology, University of Stirling, Stirling, UNITED KINGDOM, (3)University of Kent, Canterbury, United Kingdom*

Background: Â Among neurotypical adults, errors made with high confidence (i.e., errors a person strongly believed they would not make) are corrected more reliably than errors made with low confidence.Â This "hypercorrection effect" is thought to result from enhanced attention to information that reflects a "metacognitive mismatch" between one's beliefs and reality.Â This effect is thought to be tied to metacognitive monitoring ability (awareness of one's own thoughts/cognitive states).Â Theoretically, metacognitive monitoring is itself considered to be related to mentalizing/mindreading ability (awareness of others' mental states).Â Although mindreading is well-known to be impaired in ASD – thus providing grounds to predict metacognitive monitoring and the hypercorrection effect will be also – studies have only recently begun to explore metacognition, and its relation to mindreading and ASD features/traits, in this disorder.
Objectives: Â This study addressed three central questions, two of which were entirely novel (1 and 3) and one of which (2) provided new evidence about a phenomenon only recently-studied in ASD:
1) What is the relation between metacognitive monitoring ability and a) mindreading ability, and b) ASD traits?
2) To what extent is metacognitive monitoring is impaired in ASD?
3) To what extent do children with ASD show a hypercorrection effect?
Methods: In Experiment 1, n = 83 neurotypical participants answered general knowledge questions and provided confidence judgements about how likely each answer was to be correct, after which feedback (i.e., the correct answer) was given. Finally, participants were retested on all questions answered incorrectly during the initial phase. Mindreading ability (Reading the Mind in the Eyes) and ASD-like traits (Autism-spectrum Quotient) were also measured. In Experiment 2, so far 11 children with ASD and 11 age- and IQ-matched comparison participants have completed the hypercorrection task.
Results:
In Experiment 1, participants made accurate confidence judgements (i.e., a close correspondence between confidence in their answers to questions and actual success on those questions, reflecting good metacognitive monitoring) and showed the hypercorrection effect (high confidence errors initially more likely to be corrected at retest than initial low confidence errors). Mindreading ability was associated significantly with metacognitive monitoring ($r = .27$, $p < .01$) and ASD-like traits ($r = -.35$, $p < .001$). However, the hypercorrection effect was non-significantly associated with mindreading ($r = -.16$, $p = .88$) and ASD-like traits ($r = .08$, $p = .45$). In Experiment 2, children with ASD children are showing a large and significant diminution of metacognitive monitoring ability, $t(20) = 2.00$, $p = .03$, $d = 0.86$, yet a non-significantly larger hypercorrection effect than comparison participants, $t(20) = 0.57$, $p = .58$, $d = 0.25$. The evidence in favour of an undiminished hypercorrection effect (null result) is moderate, according to Bayesian analysis (Bayes factor = 0.21).
Conclusions: These results provide support for the theory that metacognitive monitoring and mindreading are linked, and confirm that both are diminished in ASD. The hypercorrection effect appears normal in ASD, however, and does not rely on the same metarepresentational resources as metacognitive monitoring and mindreading. The implications for theory and educational practice will be discussed.

87 **161.087** Minecraft Working Memory Task: Considering Content in the Working Memory Abilities in School-Age, Higher-Functioning Children with Autism Spectrum Disorders

M. C. Zajic[1]*, N. S. McIntyre*[2]*, L. E. Swain-Lerro*[3]*, J. McCauley*[4]*, H. K. Schiltz*[5]*, T. Oswald*[6] *and P. C. Mundy*[7]*, (1)University of California at Davis MIND Institute, Davis, CA, (2)University of California at Davis, Davis, CA, (3)UC Davis, Santa Rosa, CA, (4)UC Davis MIND Institute, Sacramento, CA, (5)Marquette University, Milwaukee, WI, (6)University of California at Davis MIND Institute, Sacramento, CA, (7)University of California at Davis, Sacramento, CA*

Background: Higher-functioning children with ASD (HFASD) often experience working memory (WM) problems (Geurts, de Vries, van den Bergh, 2014). These difficulties can be similar to those observed in children with ADHD (Geurts et al., 2004). Incorporating specific interests—such as video game content—into WM tasks may affect WM outcomes in both clinical groups but for possibly different reasons.
Objectives: Our study examined WM abilities in 9–18-year-old school-age children with HFASD compared to children with ADHD or typical development (TD) across two types of memory tasks—two standardized WM tasks and an experimenter-constructed task based off the video game Minecraft. This study examined the hypothesis that children with HFASD will perform better than controls on a memory task incorporating items of interest compared to performance on content-irrelevant WM measures. An alternative hypothesis is that children with HFASD demonstrate difficulties on a content-specific task due to syndrome-specific difficulties in WM.
Methods: The participants were 71 children with HFASD, 31 children with ADHD, and 38 children with TD. ASD symptoms were confirmed with the ADOS–2; ADHD symptoms were confirmed with the Conners-3. IQ was assessed with the WASI-II. WM abilities were assessed with Story and Verbal WM assessments of the Wide Range Assessment of Memory and Learning-2. The Minecraft WM task required participants to watch a 2-minute clip of Minecraft gameplay and to retell the video to an experimenter; participants were scored across a list of 35 possible items. Minecraft familiarity was assessed by self-report on a questionnaire.
Results: A MANCOVA controlling for IQ revealed a Diagnostic Group effect on WM measures, $F(4,270)=3.84$, Wilks' $\Lambda=.90$, $p=.005$, partial $\eta^2=.05$. Univariate effects were observed for Story Memory, $F(2,136)=5.61$, $p=.005$, partial $\eta^2=.08$; pair-wise comparisons with Sidak corrections indicated that the HFASD group performed significantly lower than the TD group ($p=.003$). No univariate effects were observed for Verbal WM. Almost all participants across groups reported being familiar and knowing about Minecraft (97%, 100%, and 100% for HFASD, ADHD, and TD, respectively). Within the HFASD group, VIQ ($r=.43$, $p<.002$), ADOS-2 Total score ($r=-.41$, $p<.002$), and Story Memory ($r=.55$, $p<.002$) were correlated with the Minecraft Recall score; these significant correlations remained after controlling for age. Within the ADHD group, only age ($r=.44$, $p=.02$) and Story Memory ($r=.58$, $p=.001$) were significant. An ANCOVA controlling for age revealed a Diagnostic Group effect on Minecraft recall score, $F(2,136)=5.53$, $p=.005$, partial $\eta^2=.08$; the HFASD group performed significantly lower than the TD group ($p=.003$) but did not differ from the ADHD group.
Conclusions: This study demonstrated that children with HFASD display syndrome-specific WM difficulties regardless of the content of the WM task. The HFASD group demonstrated significantly lower performance on both the Story Memory scale and the Minecraft Recall task; Minecraft Recall performance in HFASD was related to verbal IQ, story memory, and ASD symptoms, while the performance in ADHD was related to story memory and age. Our study suggests that the memory difficulties observed in HFASD may be due to syndrome-specific impairments regardless of the task content.

88 **161.088** Predicting Math Achievement from Attentional Ability and Perceptual Reasoning in Students with Autism Spectrum Disorder

***E. L. Clark**, D. Tullo and A. Bertone, McGill University, Montreal, QC, Canada*

Background: Children and adolescents with Autism Spectrum Disorder (ASD) often present a profile that includes academic difficulties compared to their typically developing peers (Ashburner, Ziviani, & Rodger, 2010). Early math skills are an integral component to academic success and can be used to predict future achievement (Claessens & Engel, 2013). Although domain-specific numerical skills and knowledge are critical for success in mathematics, cognitive factors also play important roles in math proficiency. In particular, domain-general attentional skills, such as concentration and working memory, have been found to be factors contributing to differences in mathematics achievement (Cragg & Gilmore, 2014). Research involving these skills can clarify the degree to which attention contributes to the math abilities of individuals with ASD. A better understanding of this relationship can lead to the development and implementation of academic interventions in the form of attention training programs aimed at far-transfer to improvement of mathematics ability.
Objectives: Â The purpose of this study is to assess the contribution of attention to math achievement within the context of a school-based study, and to determine the role of perceptual reasoning in this relationship. The objectives are two-fold: (i) determine whether the math proficiency of children with ASD can be predicted by performance on a clinical test of attention, and (ii) measure whether perceptual reasoning intelligence acts as a covariate in the relationship between attention and math.
Methods: All participants (N = 99) completed measures of attention, intelligence and math. The participants were grouped by diagnosis; ASD and non-ASD neurodevelopmental disorder. Attention was assessed using the Conner's Continuous Performance Task, Third Edition (CPT-3). The Wechsler Abbreviated Scale of Intelligence (WASI)-II was used to assess intelligence, Non-Verbal Perceptual Reasoning Index (PRI) and Verbal Comprehension Index (VCI). Lastly, the Pearson KeyMath was used to assess math ability.
Results: The results of a one-way ANOVA indicate that students diagnosed with ASD performed significantly higher on KeyMath than students with a non-ASD neurodevelopmental disorder, $p = .016$. The results of a separate ANOVA indicate that individuals with ASD also performed significantly higher on tests of attention, $p = .014$, as well as perceptual reasoning, $p < .001$. All variables were significantly correlated with each other (PRI, CPT-3 and KeyMath), $p < .001$ for all correlations. The PRI score of the WASI-II (a measure of non-verbal fluid abilities) served as a significant mediator in the relationship between attention and math ability in students with ASD, but not for students with a non-ASD diagnosis.
Conclusions: The results of this study indicate that math proficiency can be predicted by attention for students diagnosed with ASD. Furthermore, PRI serves as a significant mediator in the aforementioned relationship for students with ASD only. The results help to gain a better understanding of the cognitive and academics profile of individuals with ASD, specifically in terms of the selective influence of attention capability and non-verbal intelligence. These results provide the theoretic foundation for choosing non-verbal assessment and remediation approaches for students with ASD.

89 **161.089** Preference for Nonsocial Realistic Movement in Children with ASD

***C. McCormick**[1,2], H. Tokadjian[1] and S. J. Sheinkopf[1,3], (1)Brown Center for the Study of Children at Risk, Women and Infants Hospital, Providence, RI, (2)Department of Psychiatry and Human Behavior, Brown University, Providence, RI, (3)Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI*

Background: From infancy children orient to social information as supported by evidence of preference for and orienting to both faces and biological motion. In ASD, patterns of visual attention for socially based stimuli often differ from typically developing peers. In particular there is evidence for a lack of orienting to biological motion (Klin et al., 2009) and a preference for non-biological motion in the form of geometric patterns (Pierce, et al., 2011).
Objectives: To examine whether diminished orienting to motion is specific to socially based motion or a general diminished orienting to realistic motion.
Methods: Participants were 19 children (Female = 4) with ASD ranging in age from two to five years (M = 4.24, SD = 1.12). Stimuli consisted of a total of 20 5-second movie clips of social or object based motion with no sound. Social movies were male and female children in the age range of the study sample engaging in a variety of movements like jumping, dancing, and waving their arms. Object movies were a range of objects moving independently like a remote control bus driving, a record spinning, and marbles going down a marble tower. Control stimuli were created by blurring the social and object movies, retaining color, brightness and amount of movement, but were not obviously movement from everyday life. Participants viewed each clip simultaneously (side by side) with the blurred version of itself on a 22"" computer screen. Children's gaze shifts were monitored with an SMI REDn Remote Eye-Tracking system. Looking time was measured as visual fixations, defined as ≥100 ms of continuous gaze to a 100 pixel area, and saccades within the visual area of each video presentation. Preference for the blurred video was calculated as looking time to the blurred video over looking time to both the blurred and real movement videos. Preference was averaged across 10 trials within each condition. Trials with less than 200 milliseconds of looking to either video were excluded.
Results: One-sample t-tests with a test value of .5 revealed that in the object condition, participants demonstrated a preference for the object movement versus the blurred video (M = 0.38, SD = 0.11, t(18) = -4.79, p < .0001). In the social condition participants' preference was not significantly different from chance (M = .52, SD = 0.15, t (18) = 0.71, p = .49).
Conclusions: This paradigm demonstrated the presence of a preference for realistic motion when that motion is non-biological. These results suggest that orienting to biological motion may be a domain specific deficit. Next steps are to examine relationships between preference and measures of ASD symptoms, as well as to compare performance on this task to children with developmental delays and typically developing children.

90 **161.090** Preliminary Findings in Adolescents with ASD: Pupil Diameter As a Proxy for Cognitive Load during Passive Viewing of Facial Expression Stimuli

G. T. Lynch[1]*, S. M. James*[2]*, M. VanDam*[1] *and R. Hyslop*[3]*, (1)Dept. of Speech and Hearing Sciences, Elson S. Floyd College of Medicine, Washington State University, Spokane, WA, (2)Sleep and Performance Research Center, Elson S. Floyd College of Medicine, Washington State University, Spokane, WA, (3)Dept. of Speech and Hearing Sciences, Elson S. Floyd College of Medicine, Spokane, WA*

Background: Â Pupillometry, a method for indirectly measuring neural firing within the locus-coeruleus norepinephrine (LC-NE) system, has long been usedÂ as aÂ proxy for measuring arousal and visual attention. In recent years, it has been established that changes in pupil dilationÂ are associated with cognitive demand in typical populations. Pupil diameter increases as demands on visual attention increases, and as general cognitive tasks increase in complexity. As cognitive load increases, pupil diameter will increase regardless of accuracy of the participant's response. Within ASD, it is well known children and adolescents demonstrate diminished attention to faces. It is not clear, however, whether there is a difference in cognitive demand between typically developing individuals and those with ASD while visuallyÂ processing facial stimuli depicting emotion.
Objectives: Â This study examined theÂ pupillary changesÂ in two groups of adolescents, typically developing (TD), and those with ASD without language impairment, upon passive viewing of facial expressions. The aim of the study was to demonstrate differences in pupil diameter between groups, serving as a proxy for measuring the cognitive demand associated with passive visual processing of facial expression stimuli. We hypothesized that the ASD group would demonstrate greater average pupil diameter while passively viewing facial expressions when compared to average pupil diameter within the typically developing group.
Methods: Participants sat at a stationary eye-tracking station with chin positioned in a chin rest. NimStim photos (Tottenham, 2009) were presented on a computer monitor for 4000 ms each, within 2 randomized blocks. Participants were told to look at the face on the monitor. Binocular infrared eye tracking recorded the changing pupil diameter in response to passive viewing of the facial expression stimuli.
Results: A significant difference in average pupil diameter was observed between groups. We ran a two-tailed, bi-directional t-test, which suggested the mean pupil size was smaller for the TD group (M=.0043, SD=.00040) than for the ASD group (M=.0052, SD=.00051) (t(38)=6.408, p<.000001). When considered in the context of cognitive demand and pupillary dynamics, this observation suggests the likelihood of greater allocation of cognitive resources by the adolescents in the ASD group during visual processing of facial expressions. The ASD group demonstrated greater average pupil diameter, suggesting the increase in pupil dilation may be associated with greater demands of attentional resources while examining the human face.
Conclusions: The relative increase in average pupil diameter within the ASD group suggests measurement of changes in pupil diameter may serve as a proxy for cognitive load when viewing visual stimuli. This population may use increased cognitive effort to process common facial expressions and the pupil response provides a physiologic measure of visual processing in relation to cognitive demand. These results have implications for treatment targeting non-verbal language use. These findings also support further analysis using an "index of cognitive ability" algorithm (Bartels & Marshall, 2012)Â to measure changing pupil diameter as a covariate when examining visual processing of facial expressions within the ASD population.

91 **161.091** Profiles of Academic Achievement in Children with Autism Spectrum Disorders with Monolingual and Bilingual Language Experience

S. B. Vanegas*, K. Acharya and S. Magana, Disability and Human Development, University of Illinois at Chicago, Chicago, IL*

Background:
Although research has shown that children with ASD with can demonstrate comparable academic skills with their typically developing peers (Mayes & Calhoun, 2008), no research to date has assessed the impact of diverse experiences on academic achievement in children with ASD. Research with typically developing bilingual children find that although English-language learners may lag behind their monolingual peers on measures of academic achievement (Han, 2012), these gaps can be minimized with bilingual programs (Rolstad, Mahoney, & Glass, 2005). Despite these studies on academic achievement in children with ASD and bilingual children, it is unclear whether these patterns will hold for bilingual children with ASD.
Objectives:
The present study aims to clarify the impact of diverse language experiences on academic achievement in diverse children with ASD.
Methods:
The current study is part of a larger study evaluating developmental profiles of diverse children with ASD who visited a developmental disabilities clinic located in an urban city in the United States. Clinic records of children between 3 and 12 years of age with clinical diagnoses or educational classifications of an Autism Spectrum Disorder were reviewed. Information about demographics, language experiences, nonverbal IQ, and subtest scores for Wechsler Individual Achievement Test (WIAT; Wechsler, 2001) were extracted from the clinic records. Children were grouped by their language use as monolingual or bilingual based on clinician observations, parent-report of language use in the home and school and language use reported in children's IEP reports.
Results:
Cases were included in the current analyses if children with ASD had data available for at least three WIAT subtests: Word Reading, Numerical Operations, and Spelling. Preliminary analyses included 17 monolingual children and 11 bilingual children. No differences were found in age, age of first diagnosis, and nonverbal IQ (all *p*'s > .05) between groups. Additionally, the two language groups were comparable in the proportion of males and percentage receiving public aid, see Table 1. To examine academic achievement profiles of monolingual and bilingual children with ASD, a repeated measures ANOVA was conducted with WIAT subtests (Word Reading, Numerical Operations, Spelling) as a within subjects variable, and Language Group as a between subjects variable. These analyses found a significant WIAT subtest X Language Group interaction, $F(2, 52) = 3.62$, $p = .034$, partial $\eta^2 = 0.12$. The results of the significant interaction are displayed in Figure 1. Follow-up t-tests found no significant differences between monolingual and bilingual children with ASD on individual WIAT subtests (all *p*'s > .05).
Conclusions:
Although the preliminary results found a significant interaction between language group and WIAT subtests, follow-up tests revealed no differences between groups. However, the results also indicate that monolingual and bilingual children perform similarly on standardized measures of academic achievement, indicating that learning two languages may not have a detrimental effect on the cognitive development of children with ASD. These results provide initial evidence on the impact of language experience on academic achievement, adding to the limited literature on bilingual language development in ASD.

92 **161.092** Pupil Adaptation Corresponds to Quantitative Measures of Autism Traits in Children

A. S. DiCriscio[1] *and V. Troiani*[2]*, (1)Geisinger ADMI, Lewisburg, PA, (2)Geisinger-Bucknell Autism & Developmental Medicine Institute, Lewisburg, PA*

Background:
The pupil is known to reflect underlying neurologic function as well as a range of psychological and physiological variables, including cognitive effort, arousal, attention, and even learning. Within autism spectrum disorder (ASD), several studies have found atypical pupil size and/or atypical pupil response profiles relative to control populations. As we have come to understand the heterogeneity of ASD and other neurodevelopmental disorders, the relationship between quantitative traits and physiological markers has become increasingly more important, as this may lead us closer to the underlying biological basis for atypical responses and behaviors.
Objectives:
Here, we implement a novel paradigm designed to capture patterns of pupil adaptation during sustained periods of dark and light conditions. We also investigate the relationship between pupil metrics derived from this novel task and quantitative behavioral traits associated with the autism phenotype.
Methods:
Our sample included children seen at a neurodevelopmental clinic, including those with and without an ASD diagnosis, as well as those with other diagnoses (ADHD, ODD, fetal alcohol syndrome); N=42 children, ages 5 to 16 years (mean age= 8.95 ± 2.59; n=21 males; average FSIQ= 104.45 ± 17.60). Participants were characterized using a phenotyping battery that included the Social Responsiveness Scale-2nd Edition (SRS), a parent-report measure that assesses quantitative impairments in social awareness, cognition, communication, motivation, and repetitive behavior/restricted interests that define ASD. Participants completed a passive viewing eye tracking task during which alternating dark (black screen) and light (white screen) stimuli were displayed. Stimuli included a 5-second black screen and a 5-second white screen that alternated across trials. Dependent variables of interest included: (1) the amplitude of dilation or constriction across each condition and (2) the latency to reach maximum dilation or constriction across each condition. Baseline pupil diameter was also extracted for each participant.Â
Results:
This task evoked characteristic constrictions and dilations during light and dark conditions, respectively, as expected based on pupil physiology. Further, the amplitude of dilation was correlated with SRS Total t-score (p=0.007), as well as SRS subscores (all p's<0.02). The amplitude of constriction showed a similar relationship with SRS scores (all *p*'s<0.02). Latency was not as reliable in predicting SRS scores. Importantly, baseline pupil diameter was not related to SRS scores (all p's > 0.16).
Conclusions:
These results suggest that using our novel, yet simple, paradigm can result in meaningful pupil metrics that correlate with individual differences in autism traits, as measured by the SRS.Â One key difference between our paradigm and studies of the pupillary light reflex is the sustained nature of our stimulus presentation. This sustained presentation may contribute to capturing meaningful individual differences in pupillary physiology that is relevant to quantitative traits associated with the autism phenotype. These results contribute to a growing body of literature that implicates basic visual sensory anomalies in atypical social-communication deficits associated with autism.

93 **161.093** Reaching the Other Half: Executive Function Deficits in a Community Based Sample

A. D. Verbalis[1]*, C. K. Kraper*[1]*, A. B. Ratto*[2]*, S. Seese*[1]*, J. L. Martucci*[1]*, J. Safer-Lichtenstein*[3]*, K. Tiplady*[1,4]*, B. J. Anthony*[3]*, L. G. Anthony*[1]*, L. Kenworthy*[1] *and K. Hardy*[1]*, (1)Children's National Health System, Washington, DC, (2)Children's National Medical Center, Washington, DC, (3)Center for Child and Human Development, Georgetown University, Washington, DC, (4)University of Florida, Ashburn, VA*

Background: Most ASD research recruits individuals with prior diagnoses, limiting generalizability to families who have sought care, which is particularly problematic for low resource families (Durkin et al., 2015). Our group has previously reported on children recruited based on symptomology, rather than prior diagnosis (Kraper et al., poster at 2016 IMFAR conference), finding that while clinician observation of ASD symptoms was similar between children previously diagnosed with ASD and those who were not, parents of children without any prior diagnosis reported fewer symptoms. The current study follows up on that same group of children to report the degree that parents recognized problems with executive functioning (EF).
Objectives: To compare EF skills in children meeting criteria for ASD on the ADOS-2 with a prior ASD or comorbid ASD and ADHD diagnosis to those with a prior ADHD diagnosis or no prior diagnosis.
Methods: Families at high-poverty schools in the broader Washington, DC area were referred to participate in a comparative effectiveness trial of two school-based EF interventions. The current study uses a subsample of this population meeting criteria for ASD on the ADOS-2 for whom parents reported on prior diagnostic status. Specifically, this included 39 children (mean age=9.8 years, SD=0.79) of whom 12 had a prior ASD diagnosis, 7 had prior comorbid diagnoses of ASD and ADHD, 10 had a prior ADHD diagnosis, and 10 had no prior diagnosis. EF was measured by parent report on the BRIEF, clinician observations of skills in the classroom, and teacher report of classroom performance.
Results: Clinician Comparison Score rating of social communication and restricted interests/repetitive behaviors on the ADOS-2 did not differ between the four groups ($F_{3,35}$=1.67, *p*>.05). The groups also did not differ on age, Full Scale IQ, family income, or child's ethno-racial category. Parent-reported level of EF problems on the BRIEF differed significantly between groups ($F_{3,35}$=8.443, p<.01). Post-hoc comparisons showed children with prior comorbid diagnoses had significantly higher levels of parent-reported EF problems than children with a prior ASD diagnosis (Sheffe's *p*=.004) or no prior diagnosis (Sheffe's *p*=.002). The children with a prior ADHD diagnosis had significantly higher levels of parent-reported EF problems than children with no prior diagnosis (Sheffe's *p*=.047). Despite differences in parent report of EF problems, there were no differences in clinician observations of classroom behaviors ($F_{3,35}$=.365, p>.05) nor in teacher report of classroom performance ($F_{3,24}$ =.665, p>.05).
Conclusions: Greater levels of EF problems were reported by parents of children with prior comorbid diagnoses of ASD and ADHD or a prior ADHD diagnosis, suggesting that parent-report of EF problems resulted in a diagnosis of ADHD, either alone or in combination with ASD. In contrast, blind observations of classroom behaviors and teacher report of concerns were similar, indicating comparable functional impairment from EF problems at school across groups. This suggests the importance of multiple methods of gathering information for accurate diagnosis (e.g., parent-report, teacher-report, observations). Further research should continue exploring factors related to difficulty accessing specialized ASD assessment and methods to identify children most likely to require those assessments.

94 **161.094** Retest Reliability of the N2 Event-Related Potential Component and Conflict Processing Behavioral Task in Children with High Functioning ASD

A. Vaidyanathan[1]*, S. Faja*[2] *and T. Clarkson*[3]*, (1)Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)Psychology, Stony Brook University, Stony Brook, NY*

Background:
Evidence indicates good retest-reliability of electrophysiological measures of performance monitoring in the anterior cingulate cortex (ACC) over time in healthy adolescents and young adults and moderate retest reliability of the conflict monitoring N2 component in a large group of healthy individuals (Segalowitz et al., 2010; Clayson & Larson, 2013). However, to our knowledge, no investigations have explored the retest reliability of this component in children, particularly those with autism spectrum disorders (ASD), which is important considering its recent uses as neural developmental measure of executive control (EC) (Espinet et al., 2011). In addition, we will investigate the retest reliability of a modified version of the Change Task as a behavioral measure of EC within the same subjects. Ultimately, it is critical to examine the retest reliability of both the N2 component and the Change Task as the psychometric properties of EC measures are often poorly understood but represent an important domain in the exploration of intervention and biomarkers of treatment response.
Objectives:
To determine the retest reliability of the N2 event-related potential component and a conflict processing behavioral task in children with ASD.
Methods:
The test-retest reliability was evaluated for the conflict monitoring N2 event-related potential (ERP) and for an adapted version of the Change Task, which measures inhibitory control, shifting and monitoring behaviors. ERPs were obtained from 10 children diagnosed with ASD between the ages of seven and eleven, while they completed a modified version of the Eriksen Flanker Task (Rueda et al., 2004). The N2 ERP was calculated from the mean amplitude in electrodes Fz and those directly adjacent (EGI GSN: 19, 4). All participants completed the Flanker task at two time points, around ten-weeks apart and eight of these participants completed the change task at two time points, also around ten-weeks apart.
Results:
Results showed that the differential N2 amplitude between congruent and incongruent trials was not reliable over the two time points, while evidence showed that N2 amplitude in congruent trials was reliable over the 10-week period (ICC of .88, $p < .05$). In terms of behavior, the modified change task showed strong 10-week test-retest stability in measures of inhibitory control (ICC of .74, $p < .05$), shifting (ICC of .85, $p < .05$), and monitoring behavior (ICC of .98, $p < .05$).
Conclusions:
Although we found that the differential N2 amplitude was not stable over the 10-week time period, we found the general N2 amplitude in congruent trials was. In addition, the Change Task showed retest reliability over the 10-week period within these same subjects. This suggests that that behaviorally these subjects did not exhibit improvements in EC as measured by the Change task, despite changes in the differential N2. This could suggest that the N2 measure isn't stable over time, or that the changes in neural EC perhaps, precipitate changes in behavior. Implications of this finding might be limited by our small sample size, which we anticipate will increase by at least a factor of two over the next few months.

95 **161.095** Sex Differences in Autistic Profiles in Preschool Children with Autism Spectrum Disorders.

H. Kumazaki[1]*, M. Kikuchi*[1]*, Y. Yoshimura*[1]*, C. Hasegawa*[1]*, S. Kitagawa*[1]*, T. Hirosawa*[2]*, T. Ikeda*[1]*, D. Saito*[1] *and Y. MInabe*[1]*, (1)Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan, (2)Research Center for Child Mental Development, Department of Psychiatry and Neurobiology, Graduate School of Medical Science, Kanazawa University, Kanazawa,, Kanazawa, JAPAN*

Background: Epidemiological studies have consistently shown that autism spectrum disorders (ASD) affect more males than females. Studies have reported that females with ASD have a different behavioral phenotype from that of their male counterparts. Females with ASD have a lower frequency of comorbid challenging behaviors and fewer abnormal special interests and concurrent socio-communication symptoms than males with ASD. They also have less externalizing and social problems and present fewer socio-communication symptoms. It has been suggested that there is a relative failure to diagnose females with ASD because of differences in the clinical presentation of ASD. The delay in (or complete absence of) diagnosis results in a failure of necessary support for females with ASD, which could create serious identity issues and higher levels of internalizing symptoms (i.e., withdrawal, somatic complaints, anxiety, and depression). Early identification and diagnosis of ASD in females are important, as they lead to earlier treatment, which is associated with improved developmental outcomes.
Objectives: The purpose of this study is to examine the sex differences in young subjects with ASD.
Methods: We examined sex differences in ASD among children under 6 years, using the Kyoto Scale of Psychological Development and the Childhood Autism Rating Scale-Tokyo Version (CARS-TV). Seventeen females with ASD were compared with 100 similarly diagnosed males.
Results: Although females and males with ASD showed similar cognitive profiles on the Kyoto Scale of Psychological Development, females with ASD demonstrated a different symptom profile from males with ASD on the CARS-TV. Females with ASD had a significantly higher "Taste, Smell, and Touch Response and Use" score than males with ASD.
Â Conclusions: The notable finding in this study was found in the CARS-TV, in which female subjects scored significantly higher than male subjects on "Taste, Smell, and Touch Response." This result may assist in planning early diagnosis as well as intervention methods for females with HFASDs who might have been under-recognized. Some researchers consider sensory symptoms to be a component of core ASD deficits. We propose that "Taste, Smell, and Touch Response and Use" may be useful for the early identification of ASD in females. The sex differences in "Taste, Smell, and Touch Response and Use" in our study, if replicated in other samples, could lead to the development of useful diagnostic tools, increasing service and therapeutic efficacy for female children with HFASDs. The presence of the unique autistic features identified in this sample of females should be replicated with a larger sample, and future research should clarify possible behavioral, neurological, and genetic links to these sex differences.

96 **161.096** Sex-Differences in Self-Reported Executive Functioning Problems in Youth with Autism Spectrum Disorder

M. A. Collins[1], *J. B. Crutcher*[1], *A. C. Armour*[2], *C. D. Riddell*[1], *Y. Granader*[2], *G. Wallace*[1,3], *A. Martin*[1] *and L. Kenworthy*[1,3,4], *(1)National Institutes of Health- National Institute of Mental Health, Bethesda, MD, (2)Children's National Medical Center, Washington, DC, (3)The George Washington University, Washington, DC, (4)Children's National Health System, Washington, DC*

Background: Although the literature contains rich autobiographical accounts by individuals with autism spectrum disorder (ASD), there has been relatively little quantitative research utilizing self-report measures to describe the experience of having ASD. Such research amongst females with ASD is particularly rare, as it is estimated that ASD is diagnosed four times more often in males than in females. The Behavior Rating Inventory of Executive Function (BRIEF) is a questionnaire that has consistently revealed everyday executive function deficits, particularly inflexibility, in ASD. However, there are no prior studies examining self-reported real-world executive functioning utilizing the BRIEF in ASD. We have previously found sex differences in everyday executive functioning utilizing parent ratings from the BRIEF (White et al., IMFAR Panel, 2016).
Objectives: Examine sex differences in everyday executive functioning in ASD based on scores from the youth self-report version of the BRIEF. Compare parent and self-reports of everyday executive functioning using the BRIEF to look for discrepancies in self and informant ratings that may be sex related.
Methods: The present study included 22 females and 22 males with ASD who completed the BRIEF youth self-report, and who had a parent/guardian complete the BRIEF informant report. Females (mean age = 14.39 ± 2.18, IQ = 106.41 ± 17.46) and males (mean age = 14.38 ± 2.24, IQ = 106.14 ± 17.28) were individually matched within 5 full-scale IQ points. All subjects received an ASD diagnosis from trained and experienced clinicians applying DSM-IV/5 criteria which were confirmed based on scores from the Autism Diagnostic Observation Schedule and/or Autism Diagnostic Interview. Two mixed-model ANOVAs were run as follows:
1) sex (female, male) x BRIEF self-report scale (8)
2) sex (female, male) x rater (self, parent) x BRIEF scale (8)
Results: On the BRIEF self-report a significant interaction between BRIEF scale and sex (F = 2.75, p = .025) was observed. There were not sex differences on any given scale, indicating that the interaction effect reflects a diverging profile of BRIEF scores between males and females (see Figure 1). Comparing BRIEF self and parent reports, there is a strong main effect of rater (F = 55.19, p <.001), with parents rating significantly more executive function challenges across scales than did youth with ASD. However, there were not any sex-related differences in the degree of self vs. parent rated impairments.
Conclusions: In this report, we found evidence of sex differences on the BRIEF self-report in a well matched sample of youth with ASD. In line with previous findings on the BRIEF parent informant report, both males and females with ASD exhibited the highest scores on the Shift scale from the self-report measure. However, this finding is qualified by emerging sex differences in the profile of impairments across BRIEF subtests. As we continue ongoing data collection, we aim to delineate the intricacies of everyday executive functioning patterns in males and females with ASD.

97 **161.097** Sleep Related Behavioural and Cognitive Functioning

M. M. Chadiarakos[1], *G. Pavlopoulou*[2] *and D. Dimitriou*[1], *(1)Lifespan Learning and Sleep Lab, Institute of Education UCL, London, United Kingdom, (2)Lifespan Learning and Sleep Lab, UCL, Institute of Education, London, UNITED KINGDOM*

Background:
Several factors have been outlined as having a negative impact on cognitive and behavioral functioning of individuals with Autism Spectrum Disorders (ASD). Sleep is the main focus of the current study since a number of studies reported that children with ASD experience severe sleep problems. Since sleep has been found to play an active role in children's memory consolidation, it is vital to assess the impract of sleep on children's functioning.
Objectives:
The study had two chief aims: primarily to examine sleep-dependent memory consolidation on children with ASD, and furthermore to provide insights on children's nocturnal sleep habits in relation to their cognitive abilities. Additionally, as Greece is a country in which napping is a common practice, diurnal sleep habits of children were assessed. Participants included, 12 typically developing (TD)and 12 children with ASD (5-16 years of age).
Methods: Sleep dependent memory consolidation was assessed using Animal Names task, a recently developed child-friendly and engaging declarative memory task. Sleep was further assessed using Childhood Sleep Habits Questionnaire, a napping questionnaire and actigraphy.
Results: Repeated measures ANOVAs were conducted to assess performance between the Animal Names task sessions (Test 1, 2, 3) across each group (TD, ASD) and sleep and wake condition. TD children had higher scores than the ASD children on all tests.
TD children had higher scores on the Animal Names task following intervals of sleep, rather than wake, indicating that during periods of active sleep children's memory traces of the animal's names were strengthened. The new memories the children had made of the non-words improved following periods of sleep irrespective of whether the training had happened in the morning or in the evening. Contrary to expectations, despite the challenges that children with ASD experience during sleep, the positive effects of sleep remained. New memories were not merely protected and strengthened, but were also maintained after a period of 24 hours. Sleep-dependent memory consolidation was possible for children with ASD, regardless of whether the training had occurred in the morning or evening. Significant differences in Sleep Duration, Night Wakings were found between the groups. Moreover, ASD children had higher CSHQ total scores than TD children. Children with ASD had significantly higher sleep onset delay and decreased sleep.
Conclusions: The findings suggest that sleep, does in fact play an active role in children with ASD, despite the reported sleep problems which are suggested to characterize them. Due to the scarcity of previous research on the area, the findings of the study emphasize the importance of sleep in children with ASD and stress its role in the process of learning. It is concluded, that sleep had a strengthening and stabilizing effect on the memories of both TD and children with ASD.
Gaining better understanding of the influence of sleep on children with ASD is important for the creation of teaching interventions. Such understandings will aid children's learning and development. It is therefore essential that teachers, educators and researchers focus on transmitting to parents and children the prominent role of sleep.

98 **161.098** Stratifying Working Memory Ability in ASD

J. Ahmad[1], *D. V. Crawley*[2], *H. L. Hayward*[3], *A. San Jose Caceres*[4], *B. Oakley*[4], *T. Charman*[1], *J. E. Tillmann*[1], *J. K. Buitelaar*[5], *D. G. Murphy*[6], *G. Dumas*[7] *and E. Loth*[8], *(1)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Karakter Child and Adolescent Psychiatry University Centre, Nijmegen, Netherlands, (6)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Institut Pasteur, Paris, France, (8)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background: Working memory (WM) refers to the short-term storage and manipulation of sensory information. The system is involved in a range of behaviours, from perception to higher level cognition and impairments have been reported in several neurodevelopmental and neuropsychiatric conditions. Some studies found WM impairments in autism spectrum disorder (ASD) relative to typically developing (TD) controls while others failed to find group differences. These discrepancies may be due to variability in performance among individuals with ASD. Furthermore, mean group differences alone do not enable inferences on individual performances. Therefore, we need to better understand the frequency and severity of WM deficits in ASD, and the impact of WM on symptom severity or adaptive functioning.
Objectives: (1) To identify case-control differences between ASD and control participants in a diverse sample, ranging in IQ between 50-120, and 6-30 years of age. (2) To stratify the ASD group by whether, and how far, each individual diverges from their age expected performance. (3) To link WM ability with autism symptomatology (social responsiveness SRS-2, repetitive behaviour RBS-R) and adaptive behaviour (Vineland).
Methods: From 6 research centres in 4 European countries, 390 individuals with ASD and 293 individuals with typical development (or mild intellectual disability) were tested on a visual-spatial WM task. The task required participants to remember the location of 4, 6, or 8 telephones in a visual array. The dependent measure was between-trial errors: the number of times a participant re-selected a target phone from a previous trial. We classified the WM skills of ASD individuals using Gaussian process modelling (GPM) by first estimating WM ability across age for TD individuals. We derived the extent to which individuals with ASD deviated from the estimated TD mean (within 1 SD, 1-2SDs, or >2SDs of the estimated mean for their age).
Results: Case control analysis demonstrated overall higher between-participant errors in the ASD group, across the 4 (p<.001, d: 0.294), 6 (p<.001, d: 0.388), and 8 (p<.001, d: 0.422) conditions. However, when the sample was split by age groups, this effect was only significant for adolescents and adults. Individuals with mild intellectual disability performed similarly regardless of an ASD diagnosis. We then carried forward the load 8 condition as a discrimination tool for GPM stratification. Despite the significant between group differences, 62.82%, of the ASD sample performed within +/-1 SD of the TD range. Only 19.50% of the ASD cohort performed <1SD and 11.54% performed <2SD of the age-related means. WM performance correlated with symptom severity, SRS-2 (r= .34), RBS-R (r = .22) and adaptive functioning (r = -.27) (all ps <.01).
Conclusions: Across a large sample, we demonstrate that case control differences varied with age, with significant group differences for the adolescents and adults only. Despite this, stratification analysis demonstrated that the majority of cases fell within 1SD. These relatively small impairments may have greater clinical significance if they co-occur with difficulties in other areas. The small percentage who had WM impairments in a clinically significant range, might indicate a sub-group suitable for treatment targets.

99 **161.099** Susceptibility to Optical Illusions in Autism Spectrum Disorder Depends on Illusion Characteristics

K. Royals[1], ***O. Landry***[1], *A. S. Millard*[1], *I. Sperandio*[2], *S. G. Crewther*[3] *and P. A. Chouinard*[1], *(1)La Trobe University, Bendigo, Australia, (2)University of East Anglia, Norwich, United Kingdom, (3)School of Psychology and Public Health, La Trobe University, Melbourne, Australia*

Background: Chouinard et al (JADD, 2016) examined susceptibility to 13 optical illusions as a function of AQ traits in the general population. They demonstrated how one group of illusions with strong within-object relational properties (consisting of the Shepard's tabletops and square-diamond illusions) was associated with reduced susceptibility as a function of AQ whilst a different group of illusions with strong between-object relational properties (consisting of the Ebbinghaus and Delboeuf illusions) was not. From these results, the authors speculated that susceptibility to the former but not the latter group of illusions might also be reduced in ASD.
Objectives: Examine whether participants with a clinical diagnosis of ASD show reduced susceptibility to illusions with within-object relational properties, while simultaneously showing typical levels of susceptibility on illusions with between-object relational properties.
Methods: Â The participants included 15 children with ASD (11 males, mean age = 12.17 yrs, age range = 7.92 to 15.5 yrs) and 15 age and Performance IQ matched typically developing children (11 males, mean age = 12.21 yrs, age range = 8.45 to 14.7 yrs). The participants completed four trials of each illusion, in pseudorandom order (Shepard's tabletops, Square-Diamond, Ebbinghaus, Delboeuf illusions). Presentation was computerized, with participants adjusting one stimulus to match another. Eye-tracking was used to measure scan patterns while participants completed the task. To allow meaningful comparisons between illusions, we computed normalised indices of susceptibility for each illusion as: ((Perceived Size of Stimulus B - Perceived Size of Stimulus A) / (Perceived Size in Stimulus A + Perceived Size of Stimulus B)); B denoting the stimulus one would expect to see greater judgements in perceived size. Participants also completed control tasks to measure basic abilities in visual acuity and discrimination.
Results: The children with ASD (*M* = .14, *SD* = .10) were less susceptible to the Shepard's tabletops illusion than the typically developing children (*M* = .21, *SD* = .05), *t* (28) = 2.41, *p* = .023. There were no differences between groups on the other illusions.Â There were no differences between groups on any eye-tracking measures (saccade time, saccade distance, average saccade velocity, average saccade count, average pupil size, average block duration, time spent fixating).
Conclusions: We conclude that reduced illusory susceptibility in ASD is confined to certain groups of illusions, particularly those with strong within-object relational properties. We did not find any evidence to suggest that these differences could be driven by eye scan patterns.

100 **161.100** The Contribution of Visual Attention to Performance on Tests of Nonverbal Ability in Adolescents with Intellectual Disability with and without Comorbid Autism Spectrum Disorder

C. Mungkhetklang[1]*, S. G. Crewther*[2] *and E. L. Bavin*[3]*, (1)La Trobe University, Bundoora, Australia, (2)School of Psychology and Public Health, La Trobe University, Melbourne, Australia, (3)La Trobe university, Bundoora, Australia*

Background: Â Few studies have considered how visual attention contributes to solving the visual items on nonverbal IQ tests especially for individuals with Intellectual Disability (ID) with and without Autism Spectrum Disorder (ASD) where fast activation and maintenance of visual attention is characteristically problematic.
Objectives: Â To identify the contribution of rapid activation of visual attention to the nonverbal IQ tests scores of adolescents with ID and typically developing (TD) children of comparable mental age.
Methods: Â We compared the performance of both groups on the Raven's Coloured Progressive Matrices, the Test of Nonverbal Intelligence –Fourth Edition and the Wechsler Nonverbal Scale of Ability, nonverbal IQ (NVIQ) test and threshold performance on 4 visual tasks requiring rapid and maintained activation of attention i.e., motion coherence, inspection time (IT), contrast threshold for illusory figures, and change detection. Multiple regression analyses were utilized to compare the contribution of the 4 visual attention tests scores to variance on NVIQ scores. Furthermore, as it is well accepted that many adolescents with ID also show co-morbid symptoms of Autism Spectrum Disorder (ID+ASD), we compared the performance on all tasks of the individuals with ID non-ASD and those with ID+ASD.
Results: Performance of the ID group was worse than that of the TD group on all visual attention tasks especially the IT task, which contributed significant variance to nonverbal tests scores for the ID group but not for the TD group. Threshold visual attention scores also contributed substantial amounts of variance to NVIQ test scores for the ID+ASD but not for the ID non-ASD group.
Conclusions: Our results suggest that adolescents with ID are slower to activate visual attention and complete visual NVIQ test items than children with TD of a similar mental age. The finding that the ID+ASD performed less well than the ID non-ASD confirms earlier observations that attention deficits are greatest for those with more severe ID and co-morbid ASD.

101 **161.101** The Impact of Lures on Semantic and Visuospatial Analogical Reasoning in Autistic Children

E. Danis*, A. M. Nader, V. Bouchard and I. Soulières, University of Quebec in Montreal, Montréal, QC, Canada*

Background: Â In some fluid reasoning studies, children complete analogies like ''Hive is to bee as aquarium is to?'' by selecting the appropriate answer between response options. These can include a lure: an answer related to one item of the analogy, but which doesn't correctly complete it. Younger typically developing (TD) children have poorer performance than the older ones in analogies containing lures, reflecting their poorer inhibition skills and ability to manipulate multiple relations (Richland et al., 2006). Only Green and colleagues (2016) studied the effects of lures in analogical reasoning in autism spectrum disorder (ASD). They did so using a social analogical reasoning task and found that young and old autistic and TD children's performances were similarly impacted by lures. Autistic children were found as good as TD children to solve pictured analogical problems of visuospatial and semantic content (Morsanyi & Holyoak, 2010), but the effects of lures in analogies varying exclusively in content has not been studied in ASD.
Objectives: Â To investigate how young and old autistic and TD children are affected by the presence of lures in semantic and visuospatial analogical reasoning problems.
Methods: Â 37 autistic and 42 TD children matched on age (6-13 years; *M*=9.54, *SD*=1.95) and on Raven's Progressive Matrices (*M*=57.57 percentile, *SD*=24.50) completed 80 pictured analogical reasoning problems on a computerized task. Problems varied in content (semantic vs visuospatial) and consisted of 2x2 matrices with last entry to be filled with one of the three responses options presented. 20/40 semantic and 13/40 visuospatial analogies contained a lure in their answer choices. For the semantic problems, lures were semantically related to one item from the matrix, while for the visuospatial problems, lures were visually identical to one item from the matrix. Mixed ANOVAs with Content and Lure presence as within-subject factors and Group and Age (6-9, 10-13 years) as between-subject factors were conducted for accuracy and reaction time (RT).
Results: For both autistic and TD children, visuospatial content and younger age of the participants decreased accuracy and increased RT. In all children, lure presence decreased accuracy, but did not increase RT. Moreover, for the analogies containing a lure, performance was significantly higher for semantic problems (*M*=75.19, *SD*=17.09) than for visuospatial problems (*M*=65.24, *SD*=24.4) ($p<.05$), and older children (*M*=76.76, *SD*=16.30) were more accurate than the younger ones (*M*=61.10, *SD*=18.52) ($p<.05$). Interestingly, even though no significant difference in accuracy between autistic and TD children was found for any condition of the task, autistic children (*M*=5403.32, *SD*=2198.41) were faster than TD children (*M*=6775.07, *SD*=1960.45) to correctly solve visuospatial analogies with and without a lure ($p<.05$).
Conclusions: Autistic and TD school-age children are similarly affected by the presence of lure during semantic and visuospatial analogical reasoning, bringing further support to intact fluid reasoning skills and development in ASD. Also, the observed faster reaction time of autistic children relative to TD children for solving visuospatial analogies suggests superior visuospatial reasoning skills in autistic children, independently of the presence of a lure.

102 **161.102** The Relation Between Visual Disengagement and Autistic Traits: An Eye-Tracking Study of 410 Individuals

M. Siqueiros Sanchez[1], *D. P. Kennedy*[2], *S. Bolte*[1], *B. M. D'Onofrio*[3], *P. Lichtenstein*[4] *and T. Falck-Ytter*[1,5], *(1)Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Institutionen för kvinnors och barns hälsa (KBH), Karolinska Institutet, Stockholm, Sweden, (2)Psychological and Brain Sciences, Indiana University, Bloomington, IN, (3)Department of Psychological and Brain Sciences, Indiana University, Bloomington, IN, (4)Department of Medical Epidemiology and Biostatistics (MEB), Karolinska Institutet, Stockholm, Sweden, (5)Dept of Psychology, Uppsala University, Uppsala, Sweden*

Background: Â Attentional atypicalities are often found in individuals with ASD, and problems with reallocating attention have been proposed as a plausible explanation for the cognitive and social deficits characterizing the autism phenotype. Using the visual disengagement paradigm, where the task is to move one's gaze away from a central stimulus (CS) when a new stimulus appears in the periphery, several studies suggest that flexibility in visual orienting is impaired in adults and children with autism, as well as infants with a later diagnosis of ASD.Â ASD is commonly conceived as the extreme end of a phenotypic and etiological continuum. Yet, how visual disengagement relates to autistic traits in the typical population remains unknown. Furthermore, case-control differences have not always been replicated when visual disengagement is assessed in childhood (i.e., beyond infancy).
Objectives: Â To test the hypothesis that slower visual disengagement is related to higher ASD traits in a typical population sample of children.
Methods: The final sample consisted of 410 twins ranging age from 9-14 years recruited from the Child and Adolescent Twin Study in Sweden (CATSS). All twins were included in the analysis below, but all effects remained in a control analysis where one twin from each twin pair was removed. Twin modeling analysis is not reported at this point, but is an upcoming step of the analysis. ASD traits were assessed using the Social Responsiveness Scale (SRS). Visual disengagement was measured using the prosaccade (gap-overlap) paradigm on a Tobii T120 eye tracker. In the current analysis, our dependent measure, the disengagement effect, was defined as the difference in saccadic reaction times between the overlap (CS remained) and the baseline conditions (CS disappeared when peripheral stimuli appeared). Additionally, the relation between SRS and absolute performance in the aforementioned conditions as well as a third, the gap (CS disappears 200ms before the peripheral appears) is analyzed.
Results: We found the expected effect of condition on saccadic reaction times: gap (*M*=200.2ms, *SD*= 56.9ms), baseline (*M*=235.4ms, *SD*= 60ms), overlap (*M*=261.9ms, *SD*= 75.4ms; all pairwise comparisons p<.001). We found no indication that the disengagement effect was related to severity scores on the SRS (r = .01, p>.25). However, higher ASD traits were associated with slower visual orienting in all conditions (Gap: r = .178, p=.001; Baseline: r = .171, p<.001; Overlap: r = .140, p=.004). Neither age nor number of valid trials were related to the disengagement effect.
Conclusions: These data indicate that visual disengagement (as typically operationalized in the literature, e.g. Elsabbagh et al 2013) is not related to the level of autistic traits in typically developing children of 9-14 years. Rather, the correlations with absolute latencies (in all conditions) could suggest that higher autistic traits are associated with slower reactive eye movements. With the reservation that this was a study of traits and not a case-control study, these data from several hundreds of individuals do not support that visual disengagement is related to autism in late childhood.

103 **161.103** Too Little Strategy, Too Much Guessing: Problem-Solving in High-Functioning Adolescents with ASD

J. S. Beck[1], *M. South*[2] *and M. Solomon*[3], *(1)Psychology, Brigham Young University, Provo, UT, (2)Psychology and Neuroscience, Brigham Young University, Provo, UT, (3)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA*

Background: Twenty Questions is a game that requires the player to select a target object from an array using information gathered by asking only twenty or fewer yes/no questions. It allows the exploration of problem-solving abilities in a highly-motivating context. Successful performance requires concept formation (grouping by abstract concepts, such as "living things"), verbal abilities (asking a question), strategy (asking questions in an efficient order), verbal working memory (remembering answers), and inhibition (not guessing until obtaining enough information). Previous research has shown that individuals with ASD generate less efficient questions (despite unimpaired recognition of efficient questions), make more premature guesses, and correctly identify fewer items than their typically-developing peers. Manipulations of the task have revealed that their poor performance is likely not due to attention or working memory problems.
Objectives: First, we sought to replicate the performance findings of previous research. Second, while previous research manipulated the task to explore factors theorized to underlie poor performance, we utilized parent-report and neuropsychological measures to explore such factors, namely concept formation ability, VIQ, inattention, impulsivity, and verbal working memory. Finally, we sought to investigate relationships between task performance and autism symptomatology as no relationships have previously been reported.
Methods: The sample consisted of 26 high-functioning (FIQ > 80) adolescents with ASD and 27 age (*M* 14.8 years)- and VIQ (*M* 102.7)-matched typically-developing controls. We used the Delis-Kaplan Executive Function System (D-KEFS) Twenty Questions task. Concept formation, VIQ, attention problems, impulsivity, and verbal working memory were measured using the D-KEFS Card Sorting task, WASI-II, Conners Parent Rating Scale, and WRAML-2 respectively. One-way ANOVAs explored group differences on task performance variables. Two-tailed Pearson correlations explored relationships between task performance, the factors listed, and autism symptomatology measured using the SRS-2.
Results: Consistent with previous findings, our ASD sample identified fewer items (F[1,51] = 6.34, p = .02, η^2 = .11) and were less efficient in their questioning (F[1,51] =4.51, p = .04, η^2 = .08) than their typically-developing peers. In contrast to previous findings, our sample was not less efficient in their questioning when questions that did not constitute a guess were excluded (F[1,51] =.24, p = .63). Successfully identifying items and question efficiency were associated with concept formation ability (r = .41, p = .04; r = .47, p=.02) and VIQ (r = .56, p = .003; r = .57, p = .002), while only identification success was associated with verbal working memory (r = .56, p=.003). There were no significant associations between task performance variables and inattention, impulsivity, or autism symptomatology.
Conclusions: We confirm past findings of impaired performance on Twenty Questions in ASD and significant associations between performance and concept formation ability, VIQ, and verbal working memory. Our new finding of impaired performance despite unimpaired *generation* of efficient questions (after removing guesses) reinforces a previous finding of impaired performance despite unimpaired *recognition* of efficient questions. Together, these findings point to a strategy deficit. The lack of association between performance and autism symptomatology weakens the theoretical significance of concept formation deficits in ASD.

104 **161.104** Untapped Mathematical Learning Capacity in Children with Autism Spectrum Disorders

J. B. Kang[1], *M. Rosenberg-Lee*[1,2], *H. N. Wakeman*[1,3], *L. Chen*[1] *and V. Menon*[1], *(1)Psychiatry, Stanford University School of Medicine, Palo Alto, CA, (2)Psychology Department, Rutgers University, Newark, NJ, (3)University of Colorado - Boulder, Boulder, CO*

Background:
While mathematics is often cited as an area of preserved abilities for individuals with autism spectrum disorders (ASD), emerging research suggests this domain is not a universal strength for children on the spectrum. However, a child's current math achievement reflects, in part, their educational history and thus may not capture their full learning potential. Assessing mathematical learning in children of varying achievement levels has the potential to inform the design of educational interventions and impact employment opportunities for individuals with ASD.
Objectives:
We sought to investigate learning trajectories in an arithmetic training task in children with ASD and relate them to standardized measures of mathematical achievement. We then assess whether children with ASD show the same relationship between learning rates and math ability as their typically developing (TD) peers.
Methods:
21 children with autism ages 8-11 and 19 age- and IQ- matched TD children participated in a five session one-on-one math training program focused on memorizing 14 double- plus single-digit arithmetic problems (47+9=56). Each session involved 14 exposures to each problem in a variety of physical and computerized settings. In a physical flash card task, children completed three rounds, where they verbally solved all 14 training problems, twice. After the first round, children were encouraged to "beat their time" on two subsequent rounds. To identify distinct learning profiles within each group, we performed a latent class growth modeling (LCGM) analysis using the average daily performance of each participant. Mathematical skills were assessed prior to training using the Broad Math composite of Woodcock Johnson Tests of Achievement- III.
Results:
In the ASD group LCGM identified three classes: two with slow initial starting reaction times (11.7 vs. 10.6 sec per problem), and a third, much faster class (3.9 sec). Between the two initially slow groups, one had a much faster learning rate (-1.6 vs. -1.2). Notably, this group had poorer math skills (87 on Broad Math) than the slower learning group (103). This pattern of larger learning gains for lower math skills was also captured by a significant correlation between math achievement and learning slope in the ASD group as a whole (r =.62, p=.003). In the TD group, LCGM also identified three classes, but they had more similar initial performance (4.4, 6.4, 6.0) and learning rates (-.4, -.9, -.6), and notably learning rates did not correlate with math ability (r=.43, p>.05).
Conclusions:
Emerging research suggests that math skills are not a universal strength in children with ASD. However, it remains to be determined if children with poorer math achievement could excel if presented with more optimal learning environments. In the current study we used one-on-one training, and a variety of activities to engage children in a math fact learning task. While all children improved on the task, only among children with ASD did we find larger learning gains for children with the lowest achievement levels. Together, these results suggest that children with ASD who struggle in math may have untapped mathematical learning potential.

105 **161.105** Using a 3-D Multiple Object Tracking (MOT) Task to Assess Attentional Abilities in Autism

B. Levy[1,2]*, D. Tullo*[1,2]*, L. Mottron, M.D.*[3]*, J. Faubert*[4] *and A. Bertone*[1,2]*, (1)McGill University, Montreal, QC, Canada, (2)Perceptual Neuroscience Lab (PNLab) for Autism and Development, Montreal, QC, Canada, (3)University of Montreal Center of Excellence for Pervasive Developmental Disorders (CETEDUM), Montreal, QC, Canada, (4)Laboratoire de Psychophysique et de Perception Visuelle, Université de Montréal, Montréal, QC, Canada*

Background: Autism spectrum disorder (ASD) is characterized by differences in visuo-spatial perceptual and attentional abilities. Multiple object tracking (MOT) paradigms are useful in assessing both these abilities, as this task demands the use of sustained, selective, and distributed attention to dynamic visual information. Outcomes of previous MOT studies in ASD have been interpreted within either perceptual (e.g., van de Hallen, 2015) or attentional (e.g., Koldewyn et al., 2013) contexts. As suggested by the Flexible Resource Model (Alvarez and Franconeri, 2007), attentional capacity is increasingly taxed during MOT as the number of target items (i.e., load) of the task increases. We used a 3D-MOT task to manipulate load in an effort to assess dynamic visual attention in individuals on the autism spectrum. We also assessed whether typically beneficial trial-by-trial feedback differentially affected performance.
Objectives: (1) To assess the effect of cognitive load on 3D-MOT performance in individuals on the autism spectrum. (2) To investigate whether performance differs (a) at different levels of cognitive loading, and (b) with or without feedback.
Methods: Individuals on the autism spectrum of average intelligence (n=16; M_{age}=21.82 years; M_{FSIQ}=105.65) and neurotypicals (n=40; M_{age} =23.93 years; M_{FSIQ}=104.75) tracked two blocks of 1, 2, 3, & 4 target items (spheres) among 8 in 3-D virtual space using a wearable head-mounted display. Half were shown the correct answers for each trial (Feedback groups), and half were not (No Feedback groups). Performance was defined as the average speed at which participants could successfully track all target spheres (Speed Threshold) at each load level (1, 2, 3, & 4 target items).
Results: ANOVAs revealed significant differences across all levels of Load (# tracked items) for both the ASD (p < .001) and TD (p < .001) groups; collapsed across feedback condition. No load by feedback group interaction was found for either diagnostic group. Analyses also revealed no interaction effects between diagnostic and feedback groups and load levels. However, when collapsing across load levels, a significant effect of diagnostic group was found (p=0.008); with the TD group outperforming the ASD group. Feedback significantly hindered performance in the TD group when speed threshold was collapsed across load p=0.010). When comparing performance between the first and second test block (collapsed across load level), improved performance on the second block was found only for the ASD Feedback group (p=0.020).
Conclusions: Results support the use of our 3D-MOT task to target attentional abilities in ASD; as all groups demonstrated a decrease in performance as the number of tracked target items increased. Though a significantly lower overall average 3D-MOT performance was found in the ASD groups, we are not, at present, proposing that this difference is due to a differential ability to flexibly allocate attention across target items in ASD. The feedback-enhanced performance across test blocks does suggest that feedback may be important to consider in the study of attention in ASD. Our findings will be discussed within the context of current theories of the role of attention in perceptual abilities in ASD (e.g., Remington et al., 2009).

106 **161.106** Visual Detection and Decoding of Aerial Photographs in Adults with ASD

Y. S. Bonneh[1]*, H. Marciano*[2]*, K. Ruth*[3] *and E. Gal*[4]*, (1)Optometry and Vision Science, Bar-Ilan University, Ramat Gan, ISRAEL, (2)Institute of Information Processing and Decision Making, University of Haifa, Haifa, Israel, (3)Department of Psychology and Institute of Information Processing and Decision Making, University of Haifa, Haifa, Israel, (4)University of Haifa, University of Haifa, ISRAEL*

Background: People with High Functioning Autism Spectrum Disorder (HFASD) typically face difficulties in employment. One potential approach to this problem is to take advantage of their known strengths, such as the often observed enhanced perception of details and superior visual search. In the current study we investigated these potential strengths in a battery of real-worlds tasks of decryption of aerial and satellite photographs.
Objectives: Study visual detection and decoding skills for details embedded in aerial photographs in adults with HFASD compared to matched controls. Investigate the different components involved in these real-life skills by additional tests, including the classical visual-search, embedded figures and vigilance.
Methods: 40 young male adults (17-21 years), 20 with HFASD and 20 typically developed (control), participated in the experiments. The groups had comparable scores on the Raven Matrix test for intellectual abilities. They were tested in three one-hour sessions on a battery of visual tests. Five tests on aerial-photographs detection and decoding included: (1) "stamp detection", where observers had to locate a small patch (stamp) in a large image; (2) "change detection", where observers had to mark the change between two images presented side by side; (3) " identification by legend", where observers had to use a 6-vehicle legend to identify highly degraded photographs of the vehicles embedded in a terrain; (4) A similar "vehicle Identification", such as a truck, private car, and bus; (5) "contrast threshold", where observer had to detect and mark multiple low contrast natural objects (e.g. deer) embedded in a photograph. Additional tests included: (a) Visual Search, with the classical feature (color, shape) and conjunction search tasks; (b) Embedded Figure Test (EFT) with 12 complex figures; (c) Vigilance Test, where observers viewed a constantly changing display of multiple letters in color and had to search for one of 3 target letters.
Results: Overall, no significant differences between groups were found in most tests, including visual search. The HFASD group had a small significant advantage in the EFT and the “stamp detection” test, but a small disadvantage in the "identification by legend" and "vehicle identification" tests, as well as in the vigilance test.Â Correlation analysis between tests across observers showed that the Raven matrix test was significantly correlated with all other tests, while the Vigilance Test was correlated with most tests in the control but not HFASD group. Additional correlations were found between the visual search slopes and the EFT and "identification by legend" response times, but these effects differed between groups.
Conclusions: Contrary to expectations, no significant superiority of the HFASD was found, including in conjunction search. The conjunction search slopes in the HFASD group were very similar to previous studies, while our control group performed better than previously reported. The fact that the vast majority of our control group members were "video gamers" (>5 weekly hours of play) could explain some superior performance. Overall, the results indicate performance as good as controls by the HFASD participants and a potential successful employment in work related to decryption of aerial and satellite photographs.

107 **161.107** Visual Illusion Susceptibility in Children with Autism Spectrum Disorder: Local Versus Global Processing

K. Wiseman[1]*, J. Gillis*[1]*, R. G. Romanczyk*[1]*, R. E. Mattson*[1] *and M. sevlever*[2]*, (1)State University of New York at Binghamton, Binghamton, NY, (2)auburn university, Auburn, AL*

Background: Research by Happè (1996) showed that individuals with ASD demonstrated less susceptibility to visual illusions, which may suggest enhanced local processing abilities. However, subsequent studies have produced mixed results, and there is also debate as to whether superior local processing corresponds to difficulties in processing visual illusions at the gestalt level.
Objectives: The present study aimed to reconcile the discrepancy in results across studies by conducting a replication of Happè’s design and extending the measurement precision of previous research through the use of eye tracking instrumentation. Eye gaze data may help to reconcile contradictory findings by determining whether all children in the present sample demonstrate a local processing bias, and whether this local processing bias is the mechanism responsible for decreased illusion susceptibility.
Methods: Participants were 36 children (17 with ASD, 19 typically developing) ages 4-13 years matched on chronological age. Local global processing was measured using a visual illusion task conducted with eye tracking technology, as well as an existing measure of central coherence.
Results: In contrast to Happe (1996), analyses revealed no overall group differences in illusion susceptibility, but eye gaze data revealed that children with ASD attend to different areas of the visual scene depending on individual variability in illusion susceptibility.
Conclusions: These findings augment recent research on the nature of visual processing in ASD, specifically suggesting a local bias for some children with ASD rather than an overall deficit in the ability to process global information inherent to all ASD cases. For a subset of children with ASD that do demonstrate evidence of a local processing bias, this in part contributes to decreased susceptibility to visual illusions.
