ABSTRACT BOOK

Keynote Address
100 - Who Owns Autism? Exceptionalism, Stigma, and Stakeholders
9:00 AM - 10:00 AM - Grand Ballroom

Speaker: R. R. Grinker, George Washington University, Washington, DC

This presentation focuses on critical themes and challenges in the cultural study of autism spectrum disorder (ASD). First, in clinical, research, and advocacy settings ASD has emerged as a singular and powerful construct that encompasses an increasing number of heterogeneous phenomena. What forces made this category possible? How did it become both a valid and unstable construct? Second, the growth of genetic and other biomedical perspectives on ASD risks reducing ASD to biology alone, and, as a consequence, masking the fact that scientific representations express cultural values about diversity and disability. Difference constructed on the molecular level is still difference, no less stigmatizing and socially consequential because of its biological source (and perhaps even more so). How can we integrate both the biological and sociocultural aspects of ASD into research? Third, ASD is now, in some respects, a commodity that circulates in an industry of "stakeholders," such as therapists, producers of high-cost diagnostic tools, and advocacy organizations. Indeed, as health professionals are discovering in low- and middle-income countries, few diagnostic categories cost as much as ASD. How does the economy of ASD influence the science of ASD?

9:00   **100.001**   Who Owns Autism? Exceptionalism, Stigma, and Stakeholders
        R. R. Grinker, *George Washington University, Washington, DC*

> This presentation focuses on critical themes and challenges in the cultural study of autism spectrum disorder (ASD). Panel Session
101 - Autism and Society: Taking Stock of the History and Meaning of Autism Research
10:30 AM - 12:30 PM - Grand Ballroom B

Panel Chair: Roy Grinker, *George Washington University, Washington, DC*

Current debates about the present and future of autism research generally focus on scientific discovery and are fitted into the framework of the scientific method. This panel departs from convention to "take stock" of the field, and explore autism research as a system of knowledge and practices in social, historical, and economic context. The questions at the core of this panel concern the various and sometimes contradictory aspects of the field of autism research: How has the definition of autism changed over time for a range of individuals, communities, and audiences, and what factors led to those changes? What kinds of authority (e.g., institutional, bureaucratic, academic, legislative, familial) have structured, and been structured by, scientific representations of autism? Is autism a disease, a disability, or an aspect of a 'normal' range of human variation? Is autism singular, or do the boundaries and definitions of the category constrain the ability of researchers and clinicians to address the dimensions of autism as outcomes of a common set of developmental pathways shared by all humans? Speakers from the fields of anthropology, disability rights, linguistics, and epidemiology will employ historical, ethnographic, philosophical, and public health perspectives to explain the dramatic changes in the field of autism research over the past several decades and outline possibilities for the future.

10:30   **101.001**   Trends in the Prevalence of Intellectual Disability and Autism Spectrum Disorder
        M. S. Durkin, *Population Health Sciences, University of Wisconsin-Madison, Madison, WI*

> Background: Changes in the diagnosis and treatment of just one psychiatric condition can have an important effect on the diagnosis and treatment of others. This presentation provides a historical review of the epidemiology of intellectual disability (ID) and autism (ASD) in relation to each other. Objectives: We discuss possible explanations for declines in ID prevalence include the expansion of

proven interventions for the prevention of ID, such as newborn screening, early interventions to boost intellectual functioning, and numerous other public health interventions. Declines in the prevalence of ID could also be related to gradual, population-level improvements in intellectual functioning over time.

Methods: Evidence from around the globe, primarily from developed countries, suggests that the recent rises in the prevalence of autism spectrum disorder (ASD) have corresponded with declines in the prevalence of intellectual disability (ID), and with declines in the proportion of ASD cases with co-occurring ID.

Results: Possible explanations for declines in ID prevalence include the expansion of proven interventions for the prevention of ID, such as newborn screening, early interventions to boost intellectual functioning, and numerous other public health interventions. Declines in the prevalence of ID could also be related to gradual, population-level improvements in intellectual functioning over time. Other developments that could contribute to both the decline in ID and rise in ASD prevalence include: improvements in the precision of diagnostic assessment tools, training of professionals and general awareness of ASD; the expansion of diagnostic criteria for ASD; less stigma and better access to services associated with ASD relative to ID; the effectiveness of early autism interventions in raising IQ, but without necessarily eliminating ASD; and possible selective effects of the information age and technology on brain development and behavior. In sum, it is difficult to understand either one of these conditions without understanding the other. An evaluation of trends in the prevalence of ID and ASD challenges the exceptionality of ASD as a condition isolated from the broader history of childhood onset disabilities and suggests a number of important implications for future research and policies related to intellectual development and ASD across the lifespan and the globe.

Conclusions: An evaluation of trends in the prevalence of ID and ASD challenges the exceptionality of ASD as a condition isolated from the broader history of childhood onset disabilities and suggests a number of important implications for future research and policies related to intellectual development and ASD across the lifespan and the globe.

11:00 **101.002** The Lived Experience of Autism

J. E. Robison, The College of William and Mary, Springfield, MA

Background: In the past few years we have begun to speak of "autisms" as we describe a range of conditions that include symptoms clinicians deem autistic. At the same time, the interpretative latitude for the words used to describe autism has broadened enormously.

Objectives: One result of broadening is an increase in the identified autistic population. As this has unfolded, biological studies show that we have identifiable differences, and more of us are loosely bound together by a group of shared biomarkers. Some possible biomarkers are de novo – and those tend to accompany the gravest disability. That leaves a large number of us – me included – whose impairments are less severe. We are the ones who inherit our difference from our parents, and pass it on to our children.

Methods: Hans Asperger recognized this family clustering when he described our population in 1938. Perhaps we are a lost tribe of history, now being identified and brought together by genetics and brain imaging studies. Behavioral observations were the first clue, and biomarker tests prove the case. What does this mean for science and society today?

Results: If autism touches 1% of our population there are more than three million autistic Americans. That's a big population, one that until recently has had no voice. But that is changing, and it's important for scientists to work with us as we begin to speak out and assert ourselves. While it's true that autism delivers crushing disability to many, it also delivers extraordinary gifts to others. Many of us live with both gifts and disability. However, the medical and educational communities – indeed, most of society – tend to see us as broken. We are evaluated by the ways in which we are less than typical people. What about seeing the ways in which we are more? As functional as I seem to you now, I have lived my whole life with this double-edged sword of autism – gift and disability – with the disability largely invisible to everyone but me. I isolated myself through my blindness, society rejected me for the inappropriate behaviors they didn't understand, and I felt like a failure. Yet today I see I am a success.

Conclusions: Cancer is a disease to be cured. Smallpox is a scourge to be eradicated. Autism is neither. We must embrace a more balanced view. We need to find a balance between the extreme views of cause, accommodation, and cure that divide our community. The nature of our population is emerging and the goal of autism science should be to maximize our success and remediate our disability. There is a great risk that the young people who are emerging as spokespersons for the autistic identity and neurodiversity movements will reject autism science if we do not recognize and embrace the complexity and range of the experience of being autistic. Scientists must understand and appreciate our gifts, and relieve our suffering. We have a great challenge and a great opportunity, together.

11:30 **101.003** Emic and Etic Perspectives in the Construction of Authoritative Knowledge on Autism

O. Solomon, University of Southern California, Los Angeles, CA

Background: The distinction made in medical anthropology between an etic term 'disease' and an emic term 'illness', signifying the duality of the biomedical and the experiential phenomena (Good, 1977; Good & Delvecchio Good, 1980, 1985; Kleinman, 1989; Kleinman et el., 1978) is especially

relevant to understanding how authoritative knowledge of autism has evolved since the demise of psychogenic theories. Temporarily putting aside the question whether autism is or should be defined as a 'disease', the value of the emic and etic distinction lies in explicating how the dialogue between the biomedical and the social science perspectives has engendered a system of knowledge and practices that is called 'autism research' today.

Objectives: In recent years, autism has been the subject matter of psychiatry, psychology, epidemiology, genetics, neuroscience and occupational science, but also of anthropology, sociology, disability studies, education, linguistics and philosophy. Although these disciplines employ diverse theories and methods, and interdisciplinary approaches and mixed methods are common, research on autism tends to cluster around the etic view of autism as a neurodevelopmental disorder (e.g. Amaral et al., 2008; Courchesne et al., 2007; Dapretto et al., 2006; Geschwind & Levitt, 2007; Hirstein et al., 2001; Kasari et al., 2008; Levitt & Cambell, 2009; Moldin & Rubenstein, 2006; Sigman & Capps, 1997; Striano & Reed, 2009; Volkmar, 2005) and the emic view of autism as a personal, family, and community experience (Angell & Solomon, 2014; Bagatell 2007, 2010; Grinker 2007, 2010; Grinker & Cho, 2013; Prince 2010; Kaufman 2010; Lawlor 2010; Maynard 2005, 2006; Ochs et al., 2001, 2004, 2005; Ochs & Solomon, 2004; Park, 2008; Solomon, 2008, 2010, 2013; Solomon & Lawlor, 2013; Sterponi 2004; Sterponi & Fasulo 2010).

Methods: As Grinker and Cho (2013) have agued, although psychiatric diagnoses are social constructions that are situated in social, historical, and economic contexts, the constellations of symptoms that these diagnoses signify are experienced as real and disabling by the affected individuals and their families independently of what diagnostic categories or clinical terms are assigned to these symptoms.

Results: Based upon almost two decades of ethnographic research that spans linguistic and medical anthropology and occupational science, this presentation explores the tensions between the particularities and uniqueness of individual and family experiences of autism, and the experience-distant notions (e.g. "heterogeneity", "elopement and wandering") that frame these particularities as part of a larger, generalized pattern.

Conclusions: The presentation will argue that this tension resides not only between the research arena and personal or family experiences, but as a 'double vision' (Mattingly 1994) in individual stakeholders' perspectives on autism as both a biomedical condition/ syndrome/ disorder, and a lived experience and a way of being in the world.

12:00 **101.004** ASD vs. ASC: Is One Small Letter Important?

S. Baron-Cohen, Autism Research Centre, University of Cambridge, Cambridge, United Kingdom

Background: The term "disorder" is defined as a "lack of order or intelligible pattern" or "randomness" whereas the term "condition" is simply "a state of being. Those who prefer the term ASD (autism spectrum disorder) argue that "disorder" implies severity and suffering, and thus is necessary to trigger medical services.

Objectives: The term "disorder" may be appropriate for comorbid symptoms such as epilepsy, self-injury, mutism, gastro-intestinal pain, and perhaps general learning difficulties. However, it can be also be argued that most individuals on the autism spectrum do not have these comorbid features, and that a term denoting something broken is harsh, stigmatizing, and inaccurate.

Methods: Scientific evidence from both neurobiology and psychology shows difference, not dysfunction.

Results: Those who argue in favour of the term ASC (autism spectrum conditions) propose that the term "condition" still succeeds in signaling that autism is biomedical, entails disability and vulnerability, and thus can serve as a trigger for services. But "condition" is a less hard-hitting and more respectful concept that can comprise a range of levels of severity, whilst acknowledging both cognitive deficits and assets – in short, a different 'cognitive style.' The more neutral term ASC carries fewer value judgments.

Conclusions: The DSM (editions I through to 5) uses the term "disorder" (not just for autism but for any atypical behaviour), but that word may be a legacy from an earlier period in the history of psychiatry. It may be time to consider the emotional and social impact of the conventional language used to describe autism, and rethink our categories. Certainly, whether we opt for ASD vs. ASC, it should not affect insurance cover.

Panel Session
102 - An Update on Vocal Complexity in Infants and Children with ASD
10:30 AM - 12:30 PM - Grand Ballroom A

Panel Chair: Tiffany Woynaroski, *Hearing and Speech Sciences, Vanderbilt University, Thompsons Stn, TN*

Research spanning several decades has demonstrated that vocalizations differentiate young children with ASD from their typically developing peers and predict spoken language and other developmental outcomes in ASD. This panel presents recent findings from several different research groups on vocalization in infants and children with ASD. We open with a presentation that: a) highlights several ways in which the vocalizations of

children with ASD differ from their typically developing peers, b) examines associations between these aspects of vocal development and other key domains of deficit in ASD, and c) explores how these differences in vocal development and other domains relate to later cognitive and communication outcomes in ASD. The subsequent series of talks draws on a large database from the LENA Research Foundation, as well as an independent sample of children with ASD who are in early stages of language development, to test the stability and/or validity of several current options for automated analysis of child vocalizations. Implications of the findings for research and clinical practice will be discussed.

10:30 **102.001** Relations Among Canonical Babbling and Volubility in Infants Later Diagnosed with ASD and Other Markers Predictive of Outcome

E. Patten[1], G. T. Baranek[2], L. R. Watson[3], K. Belardi[4], E. R. Crais[5], K. Poon[6] and D. K. Oller[7], (1)Department of Audiology and Speech Pathology, University of Tennessee Health Science Center, Knoxville, TN, (2)Division of Occupational Science and Occupational Therapy, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Division of Speech and Hearing Sciences, University of North Carolina, Chapel Hill, NC, (4)Speech & Hearing Sciences, University of Noth Carolina, Chapel Hill, Chapel Hill, NC, (5)Division of Speech and Hearing Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)National Institute of Education, Nanyang Technological University, Singapore, Singapore, (7)Konrad Lorenz Institute for Evolution and Cognition Research, Klosterneuburg, Austria

Background:

Onset of canonical babbling is a key milestone for speech development in typically developing infants. Delays in canonical babbling and decreased volubility (density of vocalizations) are often indicative of poor communication outcomes (Oller, 2000).
A retrospective study of audio-video samples of 9-12 and 15-18 month old infants later diagnosed with ASD has suggested early potential diagnostic markers. Watson et al. (2013) found that children with autism were less likely to use communicative gestures during both age ranges than typically developing children, and Colgan et al. (2006) found that variety of type of gesture was significantly associated with ASD status. Poon et al. (2012) evaluated imitation, play and gesture, finding these predicted communication and intellectual functioning at 3-7 years. A subsequent study by Patten et al. (2013) of overlapping samples showed that vocalization variables (canonical babbling and volubility) also differed in the ASD group. The associations among these variables has not yet been evaluated.

Objectives:
We will present data exploring associations between vocal development and these other key features of development and examine later cognitive outcomes in the ASD children, comparing predictions based on multiple regression models.

Methods:
This series of studies is derived from an extant data set that includes home movies recorded during infancy and developmental measures acquired during early childhood. Vocal behaviors of 37 infants, 23 who were later diagnosed with ASD and 14 who were typically developing were analyzed using a total of 20 minutes of video randomly extracted from home movies at 2 time points (10 minutes at each age-range). Gesture, imitation, and play behaviors were previously coded for each of the age ranges. For the vocalization study, a naturalistic real-time listening technique with coding of vocalizations on a single pass for canonical and non-canonical syllables was used. These data will be analyzed using multiple regression to evaluate associations between independent variables (at least one vocal variable along with at least one other potentially aggregated developmental skills variable) and outcome variables (communication and intellectual functioning).

Results:

1. Infants later diagnosed with ASD were less likely than typically developing infants to engage in key gestural, imitative, and play behaviors at both age ranges.
2. Infants later diagnosed with ASD were less likely to have reached the canonical babbling stage, produced significantly lower canonical babbling ratios, and produced significantly lower volubility at both age ranges.
3. The gestural, imitative and play behaviors significantly predicted later cognitive development in the ASD group.
4. Associations between the vocal development and other features of development are currently being analyzed along with prediction of cognitive outcomes as determined by multiple regression.

Conclusions:
Assessment of vocal patterns and other key developmental features in infants as young as 9-12 months may well provide useful components in diagnosing ASD in infancy. The current effort will illuminate potential relations among these markers.

11:00 **102.002** Stability and Validity of Automated Vocal Analysis As a Measure of Vocalization Complexity in Preschoolers with ASD in Early Stages of Language Development

T. Woynaroski[1], D. K. Oller[2] and P. J. Yoder[3], (1)Hearing and Speech Sciences, Vanderbilt University, Thompsons Stn, TN, (2)Konrad Lorenz Institute for Evolution and Cognition Research, Klosterneuburg, Austria, (3)Special Education, Vanderbilt University, Nashville, TN

Background:

Explaining individual differences in spoken word use of preschoolers with ASD increases our understanding of variability in this population and helps us predict the extent to which children with ASD will use spoken words to communicate. Theory and research suggest that vocalization complexity explains individual differences in spoken word use in ASD.

Objectives:

This longitudinal correlational study examines the relative validity and reliability of three estimates of vocalization complexity in preschoolers with ASD who are preverbal or just beginning to use words to communicate. Two estimates were derived via automated vocal analysis of day-long samples of child vocalizations collected in natural settings, and another was derived from human coded, brief conventional communication samples collected in the lab.

Methods:

Participants were 33, 24-48 month old children with Autistic Disorder who were reported by their parents to use <200 words at entry to the study (Time 1). Our index of vocalization complexity from conventional communication samples was the proportion of communication acts including canonical syllables aggregated with the number of different consonants used communicatively across samples. The first automated index of child vocalization complexity, the infraphonological vocal complexity score, was derived using software developed for research by Oller et al. (2010) that can be applied after standard utterance labeling by LENA software. The additional automated index of vocalization complexity, the Automated Vocal Analysis (AVA) developmental age equivalency score, was provided directly by the standard LENA software. Parents reported children's spoken vocabulary use on the MacArthur-Bates Communicative Development Inventories: Words and Gestures (MBCDI) checklist at Time 1 and four months later at Time 2.

Results:

The infraphonological vocal complexity score reached our criterion for acceptable stability with one day-long audio recording (g = .82) and covaried with Time 1 (r = .46) and Time 2 (r = .51) spoken vocabulary. Associations for the infraphonological vocal complexity score with concurrent and future spoken vocabulary were non-significantly different from the analogous associations for the variable from conventional communication samples (Z = -1.12, p = .26; Z = -1.02, p = .31, respectively). The AVA developmental age equivalency score was similarly stable, but was not significantly correlated with concurrent or future spoken vocabulary in our sample. Results were similar for the subset of our sample reported to use <20 words on the MBCDI at Time 1.

Conclusions:

Results suggest the infraphonological vocal complexity score from automated vocal analysis is a valid and reliable alternative to the more expensive vocal complexity measures from conventional communication samples and may thus provide a cost-effective method for measurement of vocal complexity in clinical practice. However, at present the infraphonological vocal complexity score is not publicly available in the standard LENA software package.

11:30 **102.003** Looking Under the Hood of the Infraphonological Vocal Complexity Score

P. J. Yoder[1], T. Woynaroski[2], D. Xu[3], J. A. Richards[4], S. Hannon[5], S. S. Gray[6] and D. K. Oller[7], (1)Special Education, Vanderbilt University, Nashville, TN, (2)Hearing and Speech Sciences, Vanderbilt University, Thompsons Stn, TN, (3)Department of Speech, Language and Hearing Sciences, University of Colorado, Boulder, CO, (4)LENA Research Foundation, Boulder, CO, (5)LENA Research Foundation, Denver, CO, (6)Mobility Core Research, Nuance Communications, Dracut, MA, (7)Konrad Lorenz Institute for Evolution and Cognition Research, Klosterneuburg, Austria

Background:
The infraphonological vocal complexity (IVC) score is derived from computer-automated analysis of day-long samples of children's vocalizations according to 12 acoustic properties intended to describe the degree to which vocalizations are speech-like (Oller et al., 2010). The original IVC is the sum of these 12 properties weighted by regression coefficients from a multiple regression model that predicted concurrent chronological age of children who were typically developing (TD). Because we wish to derive a measure of the degree to which vocalizations are speech-like, IVCs with regression weights based on predicting productive language might be more valid than the original IVC. Because a valid measure of speech-likeness of vocalizations might have clinical value in minimally-verbal children with ASD, we need to test the validity of such measures in minimally-verbal children with ASD.

Objectives:
We sought to identify (a) the set of acoustic properties of child vocalizations with zero-order correlations with productive language at or above a moderate effect size (i.e., *language-related*

properties), (b) the participant sample providing the most useful weights (i.e., typically developing, TD, or autism spectrum disorder, ASD), and (c) the relative predictive validity for later productive language in a separate sample of initially minimally-verbal children with ASD.

Methods:
The model building samples were from the LENA Research Foundation (LENA TD, n = 30; LENA ASD, n = 43) and had mean expressive language ages of 28 months (*SD* = 6) and 22 months (*SD* = 9), respectively. The productive language measure in the LENA samples was an aggregate of the Language Development Survey raw score and the Child Development Inventory Expressive age equivalent. The test sample of preschoolers with ASD (n = 20) had a median of 4 and mode of 0 words said according to parents when day-long vocal samples were recorded. In the test sample, the interval between vocal samples and the productive vocabulary measure (i.e., MacArthur-Bates Words and Gestures checklist) was 4 months.

Results:
Results indicate that 8/12 and 9/12 properties had at least medium-sized associations with concurrent measures of productive language in the LENA ASD and LENA TD samples, respectively. Different properties predicted productive language in the two groups (e.g., Squeals in the ASD, Growls in the TD). In the test sample, the IVC variant based only on the language-related acoustic properties in the LENA ASD sample was the best predictor of later productive vocabulary (r = .54), relative to that based on language-related properties in LENA TD sample (r = .37).

Conclusions:
In the minimally-verbal sample of children with ASD, the size of the association between the selected variant of IVC and later productive vocabulary was similar in magnitude relative to that for the original IVC (r = .51) (Woynaroski, 2014). Future research with a larger ASD sample to derive more precise regression weights is needed to determine whether the selected variant on the IVC improves the association with productive language over the original IVC.

12:00 **102.004** Toward Improved Clinically Useful Automated Vocal Assessments for the Prediction of ASD

D. K. Oller[1], P. J. Yoder[2], D. Xu[3], J. A. Richards[4], J. Gilkerson[3] and S. S. Gray[5], (1)Konrad Lorenz Institute for Evolution and Cognition Research, Klosterneuburg, Austria, (2)Special Education, Vanderbilt University, Nashville, TN, (3)Department of Speech, Language and Hearing Sciences, University of Colorado, Boulder, CO, (4)LENA Research Foundation, Boulder, CO, (5)Mobility Core Research, Nuance Communications, Dracut, MA

Background:

Oller et al. (2010) , Xu et al. (2014), and Richards et al. (2008) have provided three alternatives for automated analysis of child vocalizations measured in day-long home recordings. The three methods vary by theoretical orientation, method of derivation, and number of vocal characteristics considered, but all three used the massive quantities of data available from the LENA Research Foundation and have been shown to predict age and to differentiate groups that differ on presence and type of disability (including ASD). Clinical utility of the measures would be enhanced by testing which of the three measures is most strongly associated with variables more directly relevant to language level.

Objectives:

We test which of the three methods of automated vocal analysis is most strongly associated with communication and language in three groups of preschoolers who differ on presence and type of disability.

Methods:
The dataset is based on multiple day-long recordings from 106 typically developing (TD) children, 77 children diagnosed with ASD, and 49 children diagnosed with language delay (LD) but not ASD (a total of 1486 day-long recordings). Children's ages ranged from 20-48 months. Communication and language measures were collected via parent report at approximately the same time as the day-long recordings. The communication measure, the LENA Developmental Snapshot (LDS) developmental age, correlates highly with age and other measures of early cognitive, social, and language development (Gilkerson, et al., 2008). Ninety-five percent of parents also completed the Child Development Inventory (CDI; Ireton & Glascoe, 1995). We used the developmental age scores from expressive language (CDI-Exp) and language comprehension (CDI-Comp) subscales as our language measures. The three models of vocal analysis are: (a) the linear combination of 12 vocal characteristics (here called *parameters*), mostly based on infraphonological theory (12P; Oller, et al., 2010), (b) the linear combination of 4 variables derived from the Sphynx automated speech recognition system (SASRS; Xu, et al., 2014), and (c) a single variable derived from SASRS with mathematical adjustments based on the relation of the earlier scores with age and language measures (AVA developmental age score; Richards et al., 2008).

Preliminary Results:

All three models are significantly associated with age and the communication/language variables. The 12P model is more strongly associated with the communication and language variables than with age. In the TD group, the 12P and the AVA models are most strongly associated with the CDI language variables, adjusted R^2 values ≥ 0.74. In the LD group, 12P and AVA yield lower, but still excellent

adjusted, R^2 values > .5. In the ASD group, the 12P model is most strongly associated with the CDI-Exp and CDI–Comp, adjusted R^2 = 0.61 and 0.54, respectively.
Conclusions:

Combined models using 12P and SASRS have as yet not been thoroughly evaluated, but may yield a much improved score that can be made available publicly for clinical work. The potential for improved clinically relevant automated tools of vocal analysis is clear. A new generation of vocal assessment with no human intervention seems just around the corner.

Panel Session
103 - Approaches to Examining and Identifying Neural Biomarkers for Autism: Progress and Challenges
10:30 AM - 12:30 PM - Grand Ballroom C

Panel Chair: Joseph McCleery, *Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA*

Discussant: Timothy Roberts, *Children's Hospital of Philadelphia, Philadelphia, PA*

Clinicians involved in treating heart disease, diabetes, and cancer, are all able to utilize a number of scientifically validated biomarkers to better understand the origin and nature of their patients' diseases, and to initiate tailored interventions. One of the greatest current challenges to understanding and treating autism and other psychiatric conditions is the relative absence of such biomarkers. The current panel presents four research programs involving differing approaches to the search for brain-based biomarkers for autism spectrum disorders. Bartley and colleagues present data utilizing arterial spin labelling to establish voxel-based reliability of activity across 10 weeks in a brief biomarker assessment; Stefanidou and colleagues present evidence that event-related potentials biomarkers for core social processing atypicalities may differ across development and/or intellectual ability levels in autism; Hudac and colleagues describe evidence for a significant role of genetic variability in defining an electroencephalography-based biomarker for social processing within individuals diagnosed with autism; finally, Roberts and colleagues describe a robust, multi-modal set of biomarkers for variability in language-related functioning in individuals with autism. Together, these presentations describe both challenges and successes in the field's application of cutting edge neuroimaging procedures and approaches to the identification of meaningful, clinically-relevant biomarkers for individuals with autism.

10:30 **103.001** Cerebral Blood Flow Biomarkers of Autism during a Passive Viewing Task

G. K. Bartley[1], *H. S. Liu*[2], *J. D. Herrington*[3], *B. E. Yerys*[4], *J. A. Detre*[5] *and R. T. Schultz*[3], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)Psychiatry, University of Pennsylvania, Philadelphia, PA, (5)Neurology, University of Pennsylvania, Philadelphia, PA*

Background: Changes in the cerebral blood flow (CBF) reflect underlying neural activation (Sokoloff, 1981). One MRI based-method for characterizing CBF, Arterial Spin Labeling (ASL), relies on the magnetic tagging of cerebral blood water for weighted measures of relative CBF across the entire brain. Compared to the fMRI based BOLD signal, ASL is more sensitive to small changes in CBF over the course of several minutes (Aguirre et al., 2002; Wang et al., 2003). Despite this advantage, there are no published brain imaging studies of autism using ASL.
Objectives: Evaluate brain perfusion in ASD compared to matched typically developing controls (TDC) during passive watching of a nature video.
Methods: Thirty-three males with ASD and 26 TDC males, matched on age (ASD=14.9 ± 1.7, TDC=14.9 ± 1.64, p=0.97) were scanned with pseudo-continuous ASL (pCASL) at 3T, while watching without sound the Discovery Channel video ("Planet Earth: Pole-to-Pole") on a projection screen. All participants were re-scanned while watching this video about 10 weeks later (ASD= 9.68 ± 2.64, TDC=11.08 ± 4.28) in order to assess per-voxel regional CBF (rCBF) reliability via intra-class correlation (ICC). rCBF (mL/100g/min) was measured using pCASL with 2D gradient-echo echo-planar imaging (GE EPI). The labeling and control RF duration was 1.5 sec with post-labeling delay of 1.2 sec. Multi-slice perfusion maps with 40 label/control pairs were acquired with: TR/TE = 4000/17 ms, flip angle=90^0, bandwidth = 3005 Hz/pixel, slice thickness = 5mm, matrix size = 64×64, FOV = 220×220 mm^2 and slice number = 20).
Results: Gray matter signal was moderate-to-highly reliable (ICCs: 0.5 to > 0.9), with no significant group differences in ICC values. Per-voxel group comparisons of rCBF averaged across both time points revealed robust ventral pathway deficits in ASD (p < 0.05 corrected) extending posteriorly from the temporal pole to the fusiform and middle temporal gyri in both hemispheres (Fig 1). Left hemisphere reductions in rCBF were particularly robust, especially the left temporal pole (p<0.006 corrected). No evidence of ASD hyper-perfusion (ASD > TDC; p < 0.05 corrected) was observed. Group differences were found for several phenotypic measures of behavior (e.g. SRS, Vineland), and these metrics strongly correlated (r's > .68) with left temporal pole rCBF.

Conclusions: To our knowledge this is the first demonstration of rCBF perfusion deficits in ASD. This method is very promising for characterizing biomarkers, as it is reliable across the duration of a typical drug trial, takes only ~ 8 minutes to collect, does not require compliance with an active task, and yields robust group differences. Findings were concentrated in the temporal lobes, and include hypoperfusion of the fusiform face and word form areas (with the former being localized individually via fMRI for each participant). These results also highlight the role of the temporal pole in socially relevant integrative processes (See Olsen et al., 2007 review).

10:55 **103.002** Evaluation of Atypical Human Action Sound Processing As an Early Biomarker for Autism

C. Stefanidou[1], *R. Ceponiene*[2] *and J. McCleery*[3], *(1)School of Psychology, University of Birmingham, Birmingham, United Kingdom, (2)UCSD Medical Center, California, CA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Previous behavioural and neuroimaging studies have revealed reduced attention to social orienting cues, such as eye-gaze and pointing gestures, as well as atypical visual perceptual processing of biological motion and human actions in children with autism spectrum disorders.
Objectives: Examine human versus non-human action sound processing as a putative biomarker for autism in young children diagnosed with autism without intellectual disability, high-risk toddler siblings of children with autism, and toddlers diagnosed with autism with intellectual disability.
Methods: Human and non-human action sounds were presented using a Rapid Auditory Mismatch event-related potentials (ERPs) procedure. The autism without intellectual disability group and high-risk toddler group were each matched with a group of typically developing children/toddlers who were matched for gender, chronological age, and verbal ability. The autism with intellectual disability group was matched with a typically developing toddler control group matched for gender and chronological age.
Results: Children with autism without intellectual disability exhibited atypical processing of non-human action sounds at an early cognitive stage of processing, as well as reduced habituation to human action sounds at a later stage of processing, both over posterior parietal cortex. High-risk toddlers also exhibited atypical processing of non-human action sounds at an early cognitive stage over posterior parietal cortex. However, toddlers with autism with intellectual disability exhibited reduced right frontal activity specifically in response to human action sounds, with no apparent atypicalities in either human or non-human action sound processing over posterior parietal cortex.
Conclusions: The current findings indicate that atypicalities in human action sound processing are present in individuals with autism both with and without intellectual disability. However, these atypicalities were differentially expressed as reduced habituation over parietal cortex in individuals without intellectual disability versus reduced activation over right frontal cortex in the individuals with intellectual disability. These findings suggest that the nature of neurobiological markers for core impairments in social processing may differ across levels of intellectual disability in this population.

11:20 **103.003** Biomarkers of Social Perception in Children with ASD and Loss of Function Gene Mutations

C. Hudac[1], *A. Kresse*[2], *T. DesChamps*[2], *S. J. Webb*[3] *and R. Bernier*[2], *(1)University of Washington, Seattle, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background: Recurrent disruptive mutations in genes such as *CHD8* and *DYRK1A* have been implicated as contributing to approximately 1% of autism spectrum disorders, (ASD; O'Roak et al., 2012; Devlin & Scherer, 2012). Work has begun to identify ASD subtypes associated with specific loss-of-function genetic mutations (e.g., Bernier et al., 2014). Despite the hallmark social impairments of ASD, to date, no one has characterized the impact of genetic mutations associated with ASD on social cognition. Social perception biomarkers are ideal for assessing social cognition in children with widespread behavioral capacities, given the robust nature of passive viewing tasks (e.g., Kaiser et al., 2010). Reduction of mu attenuation in response to viewing social versus nonsocial motion is one such biomarker of social perception. However, discrepant results of mu rhythm in ASD are reported (e.g., Bernier et al., 2007; 2013; Oberman et al., 2005; 2013), potentially highlighting existing heterogeneity that may be driven by etiological differences.
Objectives: We aimed to compare the biomarkers of social perception in children with ASD with recurrent, ASD associated, loss of function mutations (e.g., *CHD8*, *DYRK1A*) to children with idiopathic ASD and typically developing children.
Methods: Children completed an EEG session during which they watched videos of social and nonsocial motion. Mu attenuation was computed across electrodes surrounding C3 and C4 as Fast Fourier transformed power (8-13 Hz), relative to resting. We targeted children with ASD and loss-of-function gene mutations falling into an interactive protein network (ASD-LOF). Comparison groups included age- and gender-matched children with idiopathic ASD (ASD-NON) and typical development (TYP). See participant characterization in Table 1. Single-trial analysis conducted in SAS 9.3 used REML multilevel models and Bonferroni correction for pair-wise comparisons.
Results: Observed mu attenuation for each group is presented in Figure 1 across trial and on average for social (green) and nonsocial stimuli (orange). First, a model comparing both ASD groups to TYP indicated no group differences of condition, $F(1,7023)=.94$, $p=.33$. Second, a model comparing all

three groups indicated a group effect of condition, $F(1,7031)=30.93$, $p<.0001$, such that ASD-NON group did not exhibit mu attenuation condition differences, $t=2.49$, $p=.19$. The ASD-LOF and TYP groups exhibited more mu attenuation for social than nonsocial stimuli, respectively, $t=5.39$ and $t=6.09$, p's$<.0001$. *Post-hoc* ANOVAs indicated that the children with *CHD8* and the *DSCAM* genetic events exhibited equivalent mu attenuation to both social and nonsocial stimuli, $F(1,58)$'s<3.4, p's$>.068$. The other ASD-LOF children exhibited greater mu attenuation to social compared to nonsocial stimuli, similar to the TYP group. There were no significant effects of IQ, age, or gender. Conclusions: Traditional analysis of TYP versus ASD suggested no difference in mu attenuation (e.g., Bernier et al., 2013). Implementation of a "genetics-first" approach specified that ASD-LOF children exhibit patterns of mu attenuation similar to TYP. However, children with specific genetic mutations (*CHD8*, *DSCAM*) exhibit mu attenuation more similar to ASD-NON. These results indicate the necessity of careful consideration for genetic mutations contributing to phenotypic social cognition profiles of ASD.

11:45 **103.004** Electrophysiological Signatures for ASD: Putting the "Bio" into Biomarker

T. P. Roberts[1], W. C. Gaetz[2], J. I. Berman[1], L. Blaskey[1] and J. C. Edgar[1], (1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)The Children's Hospital of Philadelphia, Bala Cynwyd, PA

Background: Electrophysiological signatures recorded by EEG and MEG are increasingly recognized as distinctive features of ASD, offering neurobiologic insight as well as potential diagnostic/prognostic utility. As such they increasingly attract the label "biomarker". However, the mechanistic basis implied in this moniker is often left unspecified. Furthermore, by establishing a biological component to the signature, and justifying the term "biomarker", an additional potential axis is offered for stratification of the heterogeneous autism spectrum.

Objectives: To evaluate the interpretation of auditory evoked electrophysiologic responses as biomarkers for ASD, using converging evidence form multimodal imaging/spectroscopy studies to provide a biological basis for defining sub-populations for future use as inclusion/enrichment criteria for targeted pharmaceutical trials.

Methods: Approximately 200 school-aged (6-15yrs) children on the autism spectrum, and typically-developing control subjects have been recruited for multimodal imaging studies including magnetoencephalography (MEG) during auditory stimulation, as well as diffusion-magnetic resonance imaging (both DTI and HARDI) and , in a subset, spectrally-edited magnetic resonance spectroscopy (MRS). While MEG measures auditory evoked cortical response component latency (M50 and M100), diffusion measures focus on the microstructure of thalamocortical projections to superior temporal gyrus, and MRS measures address levels of neurotransmitters GABA and glutamate in superior temporal lobe. Clinical assessments include ADOS and ADI-R, as well as dimension scales such as the social responsiveness scale (SRS) and domain-specific measures such as the clinical evaluation of language fundamentals (CELF-4).

Results: Auditory evoked response components M50 and M100 are characterized by significantly delayed latencies in ASD of magnitude ~5ms and ~10ms respectively (p's <0.05). While the developmental trajectory of these response components shows a maturational slope similar to that observed in typical development, the absolute delay persists. This pattern of atypical maturation is reflected in quantitative diffusion imaging of the thalamocortical white matter in which the mean diffusivity shows a developmental slope similar to neurotypical, but of differing underlying (eigenvalue) basis. As such strong associations between properties of the white matter (such as fractional anisotropy) and cortical response latencies that are significant in typical development (p<0.05) are lost in ASD. Similarly evidence for atypical neurochemistry in ASD is revealed in an approximately 15-20% decrease in levels of inhibitory neurotransmitter GABA in the superior temporal lobe of children with ASD compared to TD (p<0.05). Nonetheless, both diffusion and spectroscopy findings are associated with significant inter-individual variability, perhaps representing a brain level embodiment of autism spectrum heterogeneity, and suggesting their combined use in definition of sub-populations.

Conclusions: Delays in the latency of auditory cortical responses such as the ~100ms M100 component have been consistently observed in ASD (although to varying degrees) and speculatively attributed to both white matter conduction anomalies as well as deficits in synaptic transmission. Support for both of these explanatory neurobiological hypotheses can be found in diffusion imaging of thalamocortical white matter and MRS assays of temporal lobe neurotransmitter balance. Since the potential therapeutic management of these etiologies differs, we propose that such biological measures form the basis of stratification biomarkers, appropriate for tailoring clinical trial inclusion, and subsequently directing patient management.

Panel Session
104 - Attending to Attention Among Persons with Autism Spectrum Disorder: Perspectives on Strengths, Weaknesses, and Goodness-of-Fit
10:30 AM - 12:30 PM - Grand Ballroom D

Panel Chair: Oriane Landry, *La Trobe University, Bendigo, Australia*

Throughout the lifespan, where and how visual attention is allocated affects what we learn about the world, how we interact with others, and how we plan goal-directed behaviors. Several "atypicalities" in visual attention are cited among persons with ASD. Under some circumstances, such as visual search, this atypicality takes the form of enhanced performance. In other circumstances, such as attentional disengagement, the abnormality is characterized as impairment. But in many other aspects of visual attention, the differences that emerge between individuals with autism can simply be identified as superior or inferior. For example, the processes involved in the modulation of attentional focus, such as needed under varying conditions of perceptual load or when the task necessitates efficient attending to target information in dynamic complex environments, can involve diminished performance in one circumstance and enhanced performance on another. Across all these permutations of strengths and weaknesses, the understanding of the subtle nuances of attentional processing provides considerable insight into context-specific cognitive and social styles and level of performance of persons with ASD. In this panel, we will explore the nuances of visual attention of persons with ASD within the frameworks of both strength and weakness within the demands of the environment.

10:30 **104.001** Attentional Priority for Special Interests in Autism Spectrum Disorder (ASD) and Neurotypical Passions

A. Remington[1], O. E. Parsons[2] and A. P. Bayliss[3], (1)Institute of Education, London, United Kingdom, (2)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (3)School of Psychology, University of East Anglia, Norwich, United Kingdom

Background: Autism Spectrum Disorder (ASD) is characterized by impairments in social interaction. A component of this deficit is lack of expertise for face processing (Grelotti et al., 2002). For typical individuals, faces are prioritized for processing over non-social items however our research previously demonstrated that this is not the case in ASD – where equal preference for social and non-social images is seen (Remington et al., 2012).
Why is that the case? It has been suggested that the specialized face processing system is not innately assigned in typical infants but becomes specific due to strong interest and experience of faces, and therefore has the potential to become specialized for any category (Gauthier et al., 2000). It is therefore striking that autistic individuals often hold an obsessive interest in a specific category.
Objectives: We aimed to establish whether in autistic people, their category of choice has adopted the expertise system and is afforded prioritized processing resources.
Methods: A selective-attention paradigm was used with autistic adolescents who hold obsessional interests, and neurotypical controls with similar passions/interests. Participants classified a target word based on category (e.g. for trains: 'Steam or Electric'?). The target (e.g. 'Bullet Train') was presented alone or in a list of 1 or 5 non-words, thereby varying the 'perceptual load' (amount of potentially task relevant information) of the task. A distractor (photograph of special interest item) was presented next to the words and participants were explicitly told to ignore it. The distractor was either congruent or incongruent (same or alternative sub-category to target). Each participant performed the task with personalized stimuli related to their special interest. All pictures were non-social (i.e. did not contain faces).
By comparing RTs we can establish to what extent distractors are processed under various levels of load, allowing us to index the degree to which a particular stimulus category is prioritized in the information processing system. Load Theory (Lavie, 1995) suggests that distractor processing of non-social items only occurs if perceptual load does not exhaust processing capacity. Conversely social stimuli are afforded a 'special saliency' and are processed at all levels of load. Our study examined whether stimuli related to each participant's area of interest would be processed in a similar manner to other non-social stimuli, or would show a 'special saliency' in ASD.
Results: Preliminary results indicate that, as with other non-social items (Lavie et al., 2003; Remington et al., 2012), neurotypical controls showed a congruency effect that was eliminated at high levels of load: greater distractor-impact under lower load levels. Conversely, for ASD, the congruency effect did not differ across load levels. This indicates that the autistic participants processed the pictures of their special interest to the same degree under all load levels, despite the fact that this slowed their performance on the central task.
Conclusions: This research begins to elucidate a potential link between social and non-social symptoms in ASD. Moreover, the findings will have crucial practical implications for intervention programs that aim to improve social skills of individuals with ASD.

11:00 **104.002** Visual Search in Time Among Persons with an Autism Spectrum Disorder

N. Russo[1], W. R. Kates[2] and B. Wyble[3], (1)Syracuse University, Syracuse, NY, (2)SUNY Upstate Medical University, Syracuse, NY, (3)The Pennsylvania State University, University Park, PA

Background: Individuals with an Autism Spectrum Disorder (ASD) demonstrate specific strengths in attention that includes the ability to detect visual stimuli among distractors. This visual search strength has generally been studied using static conjunctive search tasks, in which participants search for a target (e.g. orange squares) among distractors that share features with it (e.g. orange circles and blue squares). Here we look at the integrity of *temporal* visual search through single and dual target search tasks, and focus on the attentional blink (AB) in dual target searches. The AB is a phenomenon whereby the second of two targets is often missed when it follows the first target by 200-500ms.

Objectives: To extend findings on enhanced visual search from the spatial domain to the temporal domain in both single and dual target search experiments and to assess the integrity of the AB, and it's associated characteristics.

Methods: 15 participants with an ASD (ADOS and ADI-R confirmed) and 15 typically developing (TD) children and adolescents matched on the basis of age and IQ completed 4 experimental tasks in counterbalanced order. On the multispeed tasks (current N = 7, analysis underway for the remaining participants), participants were asked to detect 1 target (either a purple letter among white letters: featural task (exp 1.), or a letter among numbers: category task, exp.2). 29 distractors, and 1 target were presented at slow (135ms/stimulus), medium (102.5ms/stimulus) and fast (83ms/stimulus) speeds and participants had to report the correct target at the end of the stream. In the AB tasks (exp 3 and 4, N = 15 participants anlayzed), participants reported two targets (the T1 and T2), which consisted of either 2 purple letters among white letters (featural AB task) or 2 letters among numbers (categorical AB task).

Results: Performance on experiments 1 and 2 was more accurate among individuals with an ASD compared to TD participants, and this was especially evident at the fastest speed. On the AB tasks, participants' ability to detect the first of 2 targets did not differ between the groups for either experimental task. For T2|T1 (conditional accuracy: the accuracy with which participants correctly identified the T2 given correct T1 identification), task and group differences emerged. The AB was more pronounced overall in the category task compared to the feature task for both groups, and was less pronounced in ASD on the feature task and more pronounced on the category task relative to the TD participants. Additional characteristics of the AB, including swaps (in which participants identify both targets correctly but reverse their order) appeared over longer lags among persons with ASD, whereas binding errors, in which participants falsely report the target as the distractor preceding or following the target (by 1 or 2 lags) did not differ between the groups.

Conclusions: Strengths in visual search were noted for the multispeed tasks however more subtle group differences were noted on AB tasks. These findings will be discussed with respect to current theories of the AB and ASD.

11:30 **104.003** Challenging the Myth of Attentional Overfocus Among Persons with Autism Sprectrum Disorder

J. A. Burack[1], *D. A. Brodeur*[2], *J. Stewart*[3], *J. Querengesser*[4] and *O. Landry*[5], (1)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada, (2)Department of Psychology, Acadia University, Wolfville, NS, Canada, (3)McGill University, Montreal, QC, Canada, (4)Educational and Counselling Psychology, McGill University, Montreal, QC, Canada, (5)La Trobe University, Bendigo, Australia

Background: Overfocused attention is often considered, at least implicitly and often explicitly, as central to essential theories of cognitive style of persons with ASD. The idea of an excessive focus on one piece, part of a piece, or group of pieces of information in the environment at the expense of processing others is consistent with various theories about the ways that persons with ASD process and respond to information. For example, the theory of mind deficit might be seen as an overfocus on objects and events from an egocentric view rather than on those from others' viewpoints; the theory of executive function deficit as an overfocus on ideas in the here and now rather than on those for the future; and the theories of weak central coherence and enhanced perceptual functioning as an overfocus on details rather than on global objects. These conceptual extrapolations from theory and behavior are consistent with historical depictions of attentional processing among persons with ASD as overfocused (Rincover & Ducharme, 1987; Wainwright-Sharp & Bryson, 1993) and overselective (Townsend & Courchesne, 1994; Townsend et al., 1996), but not as distractibile (Burack, 1994; Burack et al., 1997).

Objectives: To provide a more precise understanding of attentional functioning and modulation, specifically in relation to the notion of focus and its relevance to understanding cognitive styles among persons with ASD.

Methods: A critical analysis of the studies of attentional focus and filtering among persons with ASD based on the premise that two aspects of functioning should be especially heightened if attention were really overfocused – one, "zooming-in" the focus of attention to a meaningfully restricted spatial area, and two, maintaining that focus despite the occurrence of events or appearance of objects in the environment.

Results: Proponents for the overfocused approach cite evidence that individuals with ASD experience difficulty in broadening the focus of attention (Mann & Walker, 2003), deploy a narrower than typical attentional spotlight suggesting a prolonged zoom-in lens but a sluggish zoom-out one (Ranconi et al., 2013), and display "tunnel vision" (Robertson et al., 2013). However, in a study with a dynamic version of the Erikson flanker task, children with ASD, as compared to MA-matched TD children, met neither of the essential criteria of over-focus but rather displayed behavior indicative of under-focus – they were distracted by targets quite distant from the target and by distractors that appeared considerably after the presentation of the target stimulus (Stewart et al., submitted). Although detrimental to performance on a flanker task, this type of underfocus might better be interpreted with regard to the hypothesis that increased distractor processing among persons with ASD results from enhanced perceptual capacity rather than an attentional deficit in filtering or focus (Remington et al., 2012).

Conclusions: A model that involves underfocus and increased perceptual capacity, rather than the

common characterization of overfocus, might better represent the attentional and cognitive styles of persons with ASD. We offer new evidence to support this assertion and an alternative explanation for the findings typically cited to support the overfocus hypothesis.

12:00 **104.004** The Curious History of the Gap/Overlap Procedure
J. T. Elison, Institute of Child Development, University of Minnesota, Minneapolis, MN

Background: Impaired attentional disengagement is widely considered a key cognitive mechanism in the pathogenesis of autism (Elison & Reznick, 2012; Keehn, 2013). Disengagement is often examined with the gap/overlap procedure (also referred to as a shift/disengagement procedure or competition/non-competition procedure). The translational potential of this construct holds much promise, and as such, requires careful scrutiny.
Objectives: To trace the use of this procedure since its inception (Saslow, 1967) to identify interpretational pivot points within and between separable bodies of literature (i.e., an infant cognition line and an adult cognition line). More specifically, I will attempt to identify papers that offered interpretations that subsequently altered researchers conceptualization of performance in this procedure within a given line of research. I will also identify convergence/divergence between disparate bodies of literature that have employed this task.
Methods: As of November 1, 2014, Web of Science identified 382 papers that cited the original report of the gap/overlap paradigm (Saslow, 1967). Each abstract was examined and dichotomously classified according the age of the sample studied. Those papers that examined infants and/or children were tagged for further examination in order to characterize citation patterns in the developmental line of research, which I suspected to be the line of research adopted by the autism field.
Results: Two, essentially non-overlapping bodies of work (with very few exceptions, e.g., Farroni et al., 1999; Masuzawa & Shimojo, 1997; Ross & Ross, 1980; Senju & Hasegawa, 2005) with different emphases stemmed from the original Saslow (1967) report, one in the adult cognition literature (encapsulating cognitive/systems neuroscience) and one in the infant cognition literature. In the adult literature, effort was primarily focused on understanding/characterizing the mechanism(s) responsible for reduced latencies in the gap condition (e.g., disengagement of attention facilitating express saccades, the premotor theory, etc.). On the other hand, with very few exceptions (c.f. Aslin & Salapatek, 1975), the infancy literature focused on the overlap condition and its service to understanding 1) the extent of the visual field during infancy, and 2) the phenomenon of obligatory attention observed in very young infants. The emergence of cognitive neuroscience and its merger with developmental science in the late '80's and early '90's yielded new interpretations of performance in the gap/overlap paradigm that were adopted by the autism field (with few exceptions, see Goldberg et al., 2002) at the expense of including emerging data from the adult line of research.
Conclusions: Building a cumulative developmental science requires conceptual and methodological precision coupled with innovation. This inquiry into the history of the gap/overlap procedure yields evidence that important findings from adults (and non-human primates) have been neglected in current interpretations of gap/overlap performance. Whether performance in the overlap condition (or difference between overlap condition and baseline condition) reflects "attentional disengagement" as originally conceived remains open for debate and requires further examination.

Panel Session
105 - Pivotal Response Treatment: Novel Intervention Models to Optimize Outcome
10:30 AM - 12:30 PM - Grand Salon

Panel Chair: Antonio Hardan, *Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA*

Discussant: Laura Schreibman, *University of California, San Diego, La Jolla, CA*

This panel will review new research into state-of-the-art models for disseminating evidence-based Pivotal Response Treatment (PRT) for ASD across key contexts and stakeholders. The first presentation examines results of a large randomized controlled trial of PRT Group (PRTG) and reviews data on the effects of group parent education on child language and parenting stress and empowerment. The second talk introduces the novel Classroom PRT (CPRT) approach for training teachers and will present preliminary teacher outcomes and child characteristics from large-scale application of CPRT in school settings. The third presentation reviews preliminary data on the effects of brief individually-administered PRT on child language use, as well as neurophysiological function measured with EEG for a small subsample. Finally, our fourth panelist will discuss a package treatment model which combines both parent training and clinician-delivered intervention in home settings to maximize treatment effects and data supporting this model will be shared. Overall, this panel offers a review of innovative research in intervention models of PRT to optimize outcome across multiple universities, documenting novel approaches for community implementation of evidence-based motivational treatment practices. We seek to stimulate further research interest in the development of high-quality autism interventions and in effective strategies for wide-spread dissemination.

10:30 105.001 Pivotal Response Treatment Parent Training Group: Effects on Parent Factors and Child Outcomes from a Randomized Controlled Trial

K. L. Berquist[1], *G. W. Gengoux*[2], *M. B. Minjarez*[3], *J. M. Phillips*[2], *T. W. Frazier*[4] and *A. Y. Hardan*[2], (1)Stanford University, Stanford, CA, (2)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, (3)Psychiatry and Behavioral Sciences, Seattle Children's Hospital, Seattle, WA, (4)Cleveland Clinic, Center for Autism, Cleveland Clinic Children's, Cleveland, OH

Background: As rates of autism spectrum disorder have increased in recent years, the need for effective and efficient service delivery models continues to expand. In previous studies of Pivotal Response Treatment (PRT), research has documented that parents can learn this evidence-based treatment and that their children show associated benefits in language. Recent research has also provided preliminary evidence that group parent training in PRT may reduce parenting stress and improve parent empowerment. However, this hypothesis has not yet been evaluated in a controlled trial.

Objectives: This presentation will review research on the effects of parent training on levels of parenting stress and family empowerment, as well as children's language outcomes. Evidence will be presented from a recently completed randomized controlled trial of group parent training in PRT (PRTG) compared to a parent psychoeducational group (PEG).

Methods: Participants included 53 children (2-6.11 years) with autism and significant language delay. Children were randomized into either the PRTG (N=27) or PEG (N=26). The PRTG taught parents PRT to facilitate language development. The PEG addressed general topics related to the assessment and treatment of autism. Measures of parental empowerment and stress and children's language outcomes were obtained at baseline and at the end of the 12-week trial.

Results: Results suggest that group parent education is an effective method for teaching parents to implement PRT with their children and that a majority of parents (84%) in the PRTG met PRT fidelity of implementation criteria after 12 weeks of treatment. Analysis of parents who participated in PRTG and PEG indicated that they endorsed strong empowerment on the Family and Service System subscales of the Family Empowerment Scale (FES). Results also showed that parents who participated in the PEG showed a trend toward greater improvement on the Community/Political subscale (t=3.942; df 43; p=0.054). Consistent with the literature reporting high levels of parenting stress in this population, 75% of parents across groups showed clinically significant levels of stress on the Parenting Stress Index, Short Form (PSI-SF). Furthermore, changes in child communication for families who completed the trial (PRTG N=26; PEG N=20) revealed that children whose parents participated in the PRTG exhibited a significant increase in the number of utterances compared to those whose parents participated in the PEG (F= 3.53; df 44; p= 0.038; d=0.42). Changes on a standardized measure of adaptive communication were also observed following PRTG: Receptive Communication V-Scale score (F= 4.27; df 40; p= 0.028; d=0.23) and overall Communication Standard Score (F=3.80; df 40; p=0.041; d=0.34).

Conclusions: These findings suggest that specific instruction in PRT results in strong skill acquisition for both parents and children and may also have a positive impact on feelings of empowerment related to direct teaching interactions. Parents participating in a general psychoeducation group benefited more in terms of their empowerment related to community and political advocacy. These findings will be discussed in the context of programs which combine parent education in specific intervention strategies with education related to community advocacy, and recommendations for future research in this area will be reviewed.

10:55 105.002 Examining Outcomes and Satisfaction in a Randomized Trial of Classroom Pivotal Response Training (CPRT)

A. C. Stahmer[1], *J. Suhrheinrich*[1] and *S. R. Rieth*[2], (1)Psychiatry, University of California, San Diego, San Diego, CA, (2)Child and Family Development, San Diego State University, San Diego, CA

Background:
Autism interventions that are shown to be efficacious in controlled research settings are often not well integrated into school settings, demonstrating the need for translation or adaptation for classroom use. Classroom Pivotal Response Teaching (CPRT) is a behavioral intervention for children with ASD adapted from Pivotal Response Training through an iterative process in collaboration with researchers, teachers, and school administrators. Although the effectiveness of the original PRT protocol is well established and pilot study data suggest that CPRT may be effective in classroom settings, it has not been rigorously tested in a controlled trial.
Objectives:
This presentation will describe an overview of a large-scale community effectiveness trail of the CPRT intervention and preliminary teacher, paraprofessional, and student outcomes.
Methods:
The current study uses a randomized waitlist-control design with 108 classrooms (including the lead teacher and paraprofessional educators) over three years. Preliminary data will be presented for the completed first year. Participant measures were collected in the beginning and end of the school year, across training and control conditions. Teacher measures included the Professional Development Assessment (PDA) for all teachers and fidelity of implementation of CPRT and satisfaction surveys for teachers participating in the training year. Child measures included the ADOS,

cognitive battery, Vineland Adaptive Behavior Scales (VABS) and Pervasive Developmental Disability Behavioral Index (PDDBI).

Results:

Thus far data representing 64 teachers, 43 paraprofessionals and 114 students have been analyzed. Teachers were 95% female, 54% with Masters' degrees and 60% with 5-15 years of experience teaching special education. Paraprofessionals were 98% female, 63% with high school degrees, and 65% with 5-15 years of experience in special education. Students were 83% male, with an average age of 5.8 yrs. All classrooms had generally high quality ratings on the PDA. Preliminary outcome data for teachers participating in training (n = 64) indicates 75% met fidelity of implementation mastery criteria for CPRT, 100% of teachers were satisfied or very satisfied with the overall quality of training they received and 89% of teachers report CPRT is a successful or very successful strategy for children in their class. On average, teachers reported using of CPRT for 50 min/day. Time to acquisition of CPRT varied by teacher/program. Student testing data demonstrate that 99% of students met criteria for autism spectrum on the ADOS. A total of 18% of students scored within one standard deviation of the mean on cognitive assessments (80% below; 2% above). A comprehensive description of teacher, paraprofessional and child characteristics including autism severity and adaptive functioning will be provided.

Conclusions:

Results indicate that CPRT is feasible to implement in classroom settings and is well received by participating teachers. Teachers learned to implement the strategies in the context of training. Collaborative adaptation of evidence-based practices may facilitate community fidelity of implementation. Variability in fidelity of implementation and use of CPRT will be discussed.

11:20 **105.003** Efficacy of Brief Pivotal Response Training on Language Outcomes and Neurophysiological Indices in Children with ASD

M. B. Minjarez[1], *T. DesChamps*[2], *A. Kresse*[3], *G. W. Gengoux*[4], *A. Y. Hardan*[4], *K. L. Berquist*[5], *S. J. Webb*[2] *and R. Bernier*[6], (1)Psychiatry and Behavioral Sciences, Seattle Children's Hospital, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Seattle Children's Research Institute, Seattle, WA, (4)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, (5)Stanford University, Stanford, CA, (6)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background: Behavioral interventions are robustly supported in the treatment of ASD, including those that are parent-administered. Few studies have explored the efficacy of brief parent training models and the effects on child functioning. Further, little is understood regarding the impact of behavioral treatments on neurophysiological functioning. Pivotal Response Training (PRT) is an empirically supported, naturalistic behavioral approach, typically delivered via 25 or more parent training hours. Few studies have examined more brief models of PRT. Additionally, while evidence suggests behavioral interventions alter brain functioning in animal models, recent work suggests behavioral interventions for ASD (e.g., Early Start Denver Model) may also change neurological functioning; however, studies examining the effects of PRT on brain function are just emerging.

Objectives: This study examined the effect of brief (12-week) PRT on child language functioning. As an exploratory objective, correlated brain activity was examined in an additional group of participants by assessing neurophysiological indices of language skills.

Methods: In this uncontrolled trial, efficacy of parent-delivered PRT was examined to address language impairment in children with ASD, ages 3 to 7 years. Thirteen families have completed the protocol across two sites to date. Data collection is ongoing. Parent-child dyads participated in 12 weekly, 60-minute PRT parent training sessions, with a focus on child language gains. Data were obtained at baseline and post-treatment, using systematic scoring by independent raters of target behaviors observed during 10-minute video-taped structured lab observations (SLO). The primary dependent variable was child functional utterances during the SLO. These data were analyzed using paired t-tests to examine changes from pre- to post-treatment. For a small number of additional participants, high density EEG was collected during observation of social and nonsocial videos. Cortical activation, as reflected in spectral power in alpha and theta bands during the observation of social and nonsocial stimuli, was assessed to examine changes over treatment. For these children, a multiple baseline design across participants was used to examine child functional utterances and EEG data.

Results: Preliminary findings suggest parent training in PRT was associated with child language improvements (N=9), with a significant increase in functional utterances from baseline (34.2 ± 31) to post-treatment (55.9 ± 34) (t = -2.922; df =8; p= 0.019). Adequate, artifact free EEG was obtained from three of four additional participants. A multiple baseline design across participants indicated similar improvements in functional utterances and preliminary EEG findings indicate more normalized cortical activation (decreased alpha power and increased theta power) when viewing faces relative to objects following intervention.

Conclusions: Findings from this pilot study suggest brief parent training in PRT is associated with improvement in child language skills. Further, EEG findings support that these behavioral changes, following short-term PRT, are mirrored in changes in neurophysiological functioning to more normalized neural activity. These findings are analyzed in light of the need for more cost-effective and efficient treatment models and better understanding the impact of behavioral interventions on neurophysiological functioning in children with ASD.

11:45 **105.004** Pivotal Response Treatment Package: Combined Parent Training with Clinician-Delivered in-Home Treatment

G. W. Gengoux[1], J. M. Phillips[1], C. M. Ardel[1], M. E. Millan[1], R. Schuck[1], T. W. Frazier[2] and A. Y. Hardan[1], (1)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, (2)Cleveland Clinic, Center for Autism, Cleveland Clinic Children's, Cleveland, OH

Background: Pivotal Response Treatment (PRT) is an evidence-based naturalistic behavioral intervention which is traditionally delivered via a parent training model. While there is some evidence in support of brief treatment models, some children and parents may need longer duration of treatment or greater intensity in order to make clinically meaningful progress. For instance, while parents are still learning to implement the treatment themselves, clinician-delivered intervention may help boost child language development.
Objectives: This presentation will review initial outcomes from a randomized controlled trial of a PRT package treatment (PRT-P) which combines parent training with clinician-delivered in-home treatment.
Methods: This study is a randomized controlled trial of PRT-P compared to a Delayed Treatment Group (DTG). The active treatment involves weekly parent training and 10 hours per week of in-home therapist-delivered treatment for 3 months, followed by a less-intensive phase with 5 hours per week of in-home treatment and monthly parent training sessions. Participants include children with ASD and significant language delay, ages 2-5 years. Dependent measures include Clinical Global Impression Improvement (CGI-I) ratings by trained raters blinded to treatment condition, as well as standardized parent questionnaires and structured behavioral observations.
Results: To date, 18 subjects have been randomized. The trial is ongoing and preliminary data are currently available from 14 participants. CGI-I ratings focused specifically on communication indicate 3 children rated as very much improved (0 in DTG), 4 children rated as much improved (2 in DTG), 1 child rated as minimally improved (3 in DTG) and no children rated "no change" (1 in DTG). Preliminary examination of changes with PRT-P revealed that children in the active group are acquiring language skills as evidenced by increased performance on the Vineland Adaptive Behavior Scales, Second Edition (Vineland-II) Expressive Language raw scores (Baseline: 28.55 ± 9.63 ; Post-treatment: 37.13 ± 14.93) and an average gain of over 100 words between baseline (M=70.67 ± 23.46) and post treatment (M=187.67 ± 46.97) on the MacArthur-Bates Communicative Development Inventories.
Conclusions: These preliminary data suggest that the PRT package approach shows promise for addressing communication deficits associated with ASD. Potential benefits and challenges of a combined parent training and clinician-delivered intervention approach will be discussed and areas in need of future research will be explored.

Poster Session
106 - Medical and Psychiatric Comorbidity
11:30 AM - 1:30 PM - Imperial Ballroom

1   **106.001** A Delphi-Procedure Study of Standards of Clinical Assessment and Treatment of Individuals with Co-Occurring Gender Dysphoria and Autism Spectrum Disorders

J. F. Strang[1], H. Meagher[2], L. Kenworthy[3] and L. G. Anthony[1], (1)Center for Autism Spectrum Disorders, Children's National Medical Center, Rockville, MD, (2)Catholic University of America, Washington, DC, (3)Children's Research Institute, Children's National Medical Center, Washington, DC

Background: An overrepresentation of autism spectrum disorders (ASD) among individuals with gender dysphoria (GD) has been reported, with rates of almost 1 in 10 gender referrals meeting full diagnostic criteria for ASD, and many others with the broader ASD phenotype (de Vries et al., 2010). There is also evidence that gender identity issues are more common among referrals for ASD (Strang et al., 2014). Nine published case studies highlight the diagnostic and clinical complexity of these individuals, but there are no clinical guidelines for their treatment/management. A gold-standard method for developing initial clinical practice standards in an emerging field is the Delphi research procedure, which facilitates the development of clinical consensus statements, as well as identifies where current experts differ (Linstore & Turoff, 2002).
Objectives: To obtain a set of clinical consensus statements from those clinicians and researchers experienced in working with individuals with co-occurring ASD and GD.
Methods: Experts in comorbid ASD and GD were identified through a four-step procedure: 1. comprehensive internet search for individuals involved in publications and clinical services related to the comorbidity, 2. comprehensive search for clinics serving individuals with gender dysphoria, 3. a "snowball" sampling procedure to allow identified expert participants to refer other experts in the field, and 4. an assessment for inclusion in the study that evaluated publication history related to the comorbidity, clinical experience with the comorbidity, and training. Twenty-eight experts in comorbid ASD and GD were identified internationally, and 22 completed the multi-step Delphi procedure. Participants each completed an initial round of questions about the clinical management of the comorbidity. Results were then coded for themes using the NVivo qualitative data analysis computer

software (QSR International, 2012). 36 clinical statements emerged, which were then evaluated and shaped using a rating system by the 22 participants.

Results: Participants were 45% medical doctors (37% psychiatrist, 9% endocrinologist, 5% pediatrician), 45% clinical psychologists, and 10% other clinical specialty. 42% of participants had previously published on the comorbidity. The Delphi procedure produced 28 consensus statements; for 6 items the expert panel was unable to come to consensus. The resulting Delphi statements include general principles for assessment of individuals with the comorbidity, a three-step assessment protocol, a checklist for treatment approaches (including approaches for both psychotherapy and, when appropriate, sex reassignment treatment), and identified primary risk areas. Principal themes include the need for and nature of the multidisciplinary team for working with these individuals, the need for a more extended diagnostic period in which clinical decisions unfold more slowly, and the importance of autism treatment adapted to include concrete psycho-education about gender identity and gender outcomes.

Conclusions: The expert international panel was able to achieve consensus for preliminary guidelines in the assessment and treatment of individuals with comorbid ASD and GD. The full guidelines will be presented at the meeting with opportunities for the INSAR membership to provide their input. Next steps for the project will include the perspective of individuals with ASD and GD.

2   **106.002** ASD in Sibling Pairs Discordant for ADHD

A. M. Reiersen and M. B. McGrath, Psychiatry, Washington University in St. Louis School of Medicine, St. Louis, MO

Background:
Symptoms of Autism Spectrum Disorder (ASD) and Attention-Deficit/Hyperactivity Disorder (ADHD) frequently co-occur in clinical and population-based samples, and there is evidence that this co-occurrence is largely due to overlap of genetic influences that contribute to the two disorders. The diagnosis of both disorders in one person is now allowed according to DSM-5 diagnostic criteria, so it is important to identify appropriate methods for determining which individuals should receive just one versus both diagnoses. Many existing reports of ASD symptoms in ADHD have been based on parent-rated questionnaires, but few studies have used the Autism Diagnostic Observation Schedule (ADOS) to investigate the presence of likely ASD among individuals with ADHD.

Objectives:
To examine evidence for ASD among individuals showing parent-reported lifetime symptoms of combined type ADHD and their "unaffected" siblings.

Methods:
The ADOS was administered to individuals classified as having a severe combined form of ADHD (n=96) and their siblings (n=91) with few if any lifetime ADHD symptoms. Subjects were selected from a population-based sample of large sibships (n=169) or recruited through study advertisements (n=18). In each case, ADOS module 3 (N=43) or module 4 (N=144) was administered and scored according to the original ADOS algorithm to determine the ADOS classification. The ADOS-2 module 3 algorithm was then also applied to all ADOS assessments (regardless of module administered) to determine an ADOS-2 (module 3) classification.

Results:
Subjects were 8-31 years old, 96% Caucasian (includes 4 Hispanic subjects), 4% African-American, and 59% male. Using the original ADOS algorithm, 17% of ADHD probands and 8% of siblings had a classification of either "autism" or "autism spectrum". Using the ADOS-2 module 3 algorithm, 19% of ADHD probands and 12% of siblings had a classification of either "autism" or "autism spectrum". When ADHD probands qualified for an ADOS-2 diagnosis, they were more likely to be classified as "autism" (n=13) rather than "autism spectrum" (n=5). This was not true of siblings, who were more likely to be classified in the less severe "autism spectrum" category (n=8) than the "autism" category (n=3).

Conclusions:
We estimate that approximately 17-19% percent of individuals with lifetime combined type ADHD may be classified as having a co-occurring ASD based on the ADOS or ADOS-2. Consistent with previous findings of genetic overlap between ADHD and ASD, a substantial proportion (8-12%) of "unaffected" siblings of ADHD probands may also be classified as having ASD by the ADOS or ADOS-2.

3   **106.003** Alexithymia As a Predictor of Dimensional Scales of Autism Symptoms

K. Stephenson[1], M. E. Maisel[1], J. C. Cox[2] and M. South[3], (1)Department of Psychology, Brigham Young University, Provo, UT, (2)Counseling and Psychological Services, Brigham Young University, Provo, UT, (3)Psychology and Neuroscience, Brigham Young University, Provo, UT

Background: Alexithymia is characterized by difficulties identifying, expressing, and feeling emotional states. In addition to core clinical symptoms of autism spectrum disorders (ASD), researchers have found high rates of comorbid anxiety, depression, and alexithymia symptoms. However, there is little research investigating the association between these constructs and how they relate to dimensional measures of ASD symptoms.

Objectives: The goal of this study was to explore the relationship between ASD symptoms and the related constructs of alexithymia, anxiety, and depression. Specifically, we hypothesized that alexithymia would remain a significant predictor of ASD symptoms even after controlling for anxiety

and depression.

Methods: Participants were 23 adults diagnosed with ASD as well as 20 neurotypical controls. All participants completed a battery of questionnaires including the Toronto Alexithymia Scale (TAS-20), the Autism Spectrum Quotient (AQ), the Social Responsiveness Scale (SRS-2), the State-Trait Anxiety Inventory (STAI), and the Beck Depression Inventory (BDI). We used multiple regression analyses to predict autism symptoms (i.e., AQ and SRS-2 scores) using alexithymia, anxiety, depression, and categorical diagnosis as predictors.

Results: Multiple regression analyses indicated that both alexithymia and diagnosis were significant predictors of both AQ and SRS-2 scores when controlling for anxiety and depression. Furthermore, alexithymia emerged as a better predictor of dimensional ASD symptoms than categorical diagnosis. Additional Pearson correlations showed differing patterns between the study variables among the two diagnostic groups. In particular there appears to be different relationships between subscales of the TAS-20 and the SRS-2 in individuals with ASD.

Conclusions: Alexithymia appears to be a robust predictor of dimensional measures of autism symptoms, even when controlling for related anxiety and depression symptoms. This evidence emphasizes the connection between autism and alexithymia and suggests the importance of the assessment of alexithymia in both clinical and research settings.

4 **106.004** Antipsychotic Medication Use and Metabolic Monitoring in an Integrated Outpatient Clinic for Individuals with Autism and Other Neurodevelopmental Disabilities

L. M. Ruiz[1], M. Damron[2], K. B. Jones[3], D. Weedon[2], P. S. Carbone[2], A. V. Bakian[1] and D. A. Bilder[1], (1)Psychiatry, University of Utah, Salt Lake City, UT, (2)University of Utah, Salt Lake City, UT, (3)Family and Preventive Medicine, University of Utah, Salt Lake City, UT

Background: Antipsychotic medications are frequently taken by individuals with neurodevelopmental disabilities to address co-occurring psychiatric conditions. These medications increase metabolic syndrome risk and subsequent cardiovascular complications. The American Diabetes Association and American Psychiatric Association have established metabolic monitoring guidelines, but low reported rates of monitoring for medical complications of antipsychotic medications demonstrate a substantial gap between recommendations and clinical practice. The Neurobehavior HOME program (HOME) is an outpatient clinic with integrated primary and psychiatric care, funded by Medicaid, for individuals across the lifespan with neurodevelopmental disabilities and co-occurring psychiatric disorders. The majority of HOME enrollees have autism spectrum disorder (ASD) with or without intellectual disability (ID). HOME provides a unique setting to study prescribing and monitoring practices for antipsychotic medications in this high risk population.

Objectives: This study aims (1) to describe antipsychotic use among children and adults with neurodevelopmental disabilities served in an outpatient clinic, and (2) identify subsequent metabolic monitoring rates.

Methods: Participants included all patients enrolled in HOME from January through June 2013. Participant characteristics (i.e., antipsychotic use, demographics, insurance coverage, and disability type, see Table 1) and metabolic monitoring were obtained from billing records, Medicaid pharmacy data, and electronic medical records. Multiple and single variable logistic regression models were fit to investigate the association between antipsychotic medication use, medication monitoring, and participant characteristics. The models that included HOME program enrollment duration, insurance category, and co-occurring metabolic conditions as independent variables were adjusted for age.

Results: HOME program enrollees totaled 832 participants (67% males; mean age: 29.1 years, range: 4-82). Disability types were as follows: 9.3% ASD only, 30.2% ID only, and 54.8% ASD and ID. Sixty-one percent (n=508) of participants were taking antipsychotic medication. Compared with those not taking antipsychotics, participants taking antipsychotics did not experience significantly higher rates of prediabetes/diabetes, dyslipidemia, or hypertension. Antipsychotic use was significantly associated with male gender (p<0.01) and having both ASD and ID (p=0.02). Participants with triple insurance coverage (Medicaid, Medicare, and private) were less likely to take an antipsychotic medication (p=0.01) than those with Medicaid alone. Metabolic monitoring rates among participants taking antipsychotics were as follows: lipids, 75%; glucose/Hemoglobin A1c (BG/HbA1c), 85%; weight, 91%; and blood pressure, 93%. Advanced age was associated with BG/HbA1c (p<0.001) and lipids (p<0.01), whereas younger age was associated with monitoring weight (p=0.01).

Conclusions: Our findings demonstrate high antipsychotic medication use among participants with neurodevelopmental disabilities in this outpatient setting. A greater likelihood of antipsychotic use was associated with male gender and the co-occurrence of ASD and ID, but not with ASD only. Overall, most participants were monitored for weight and blood pressure and the majority, for BG/HbA1c and lipids. Notably, advanced age was associated with BG/HbA1c and lipid monitoring and inversely associated with weight monitoring. Metabolic monitoring rates for participants taking antipsychotics were high in HOME, suggesting the importance of an integrated care model for patients at risk for medical complications from psychiatric medication. Further study is needed to identify factors that facilitate medical monitoring of medication in individuals with neurodevelopmental disabilities.

5 **106.005** Anxious Imagery in Children with Autism Spectrum Disorder

A. Ozsivadjian[1], M. J. Hollocks[2], M. Absoud[3], J. Southcott[4] and E. Holmes[5], (1)Guy's Hospital, London,

United Kingdom, (2)Denmark Hill, King's College London, London, United Kingdom, (3)Children's Neurosciences Centre, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom, (4)Children's Neurosciences Centre, Guy's and St Thomas' NHS foundation trust, London, United Kingdom, (5)Cognition and Brain Sciences Unit, Cambridge University, Cambridge, United Kingdom

Background:
Anxiety disorders occur in ~40% of children with ASD (van Steensel et al, 2011), compared to 2-3% in the general population. Reasons for this increased rate are currently speculative although a small body of research is emerging investigating cognitive and physiological pathways to anxiety in ASD (Hollocks et al, 2013). In the typically developing (TD) adult population, research has suggested mental imagery may play a role in the aetiology and maintenance of anxiety disorders. Images can be extremely vivid, intrusive and more emotionally-laden than verbal thoughts; despite this, the latter have tended to be the focus of most cognitive behavioural research. Given that individuals with ASD are often thought of as being 'visual thinkers' (Kunda and Goel, 2011), we sought to examine the role anxious imagery might play in the development and maintenance of anxiety in this population.
Objectives:
This is an exploratory cross sectional cohort study investigating anxious imagery in children with ASD with both high and low anxiety, compared to TD children with both high and low anxiety.
Methods:
78 participants (29 ASD high anxiety; 14 ASD low anxiety; 17 TD high anxiety; 18 TD low anxiety) aged 8-16 (69% male) matched for IQ took part in a semi-structured interview that provided both quantitative and qualitative data on the features of images experienced, and the meaning attached to them. Participants completed four questionnaires examining anxiety, depression, spontaneous use of imagery in daily life, and emotional regulation. Parents completed anxiety, depression, and the Social Communication Questionnaire. Nominal data were compared using χ^2 or Fisher's exact tests. Parametric or nonparametric tests were used for continuous measurements as appropriate given normality. For the binary logistic regression a backward elimination approach was used using predictor variables with presence of anxiety as the dependent variable.
Results:
Children with ASD and anxiety reported the highest number of anxious images, followed by children with ASD and low anxiety, TD children with anxiety, and finally TD children with low anxiety ($\chi2=22.7$; p<0.001). Children with anxiety regardless of ASD diagnosis had images that were more frequent ($\chi2=9.1$; p=0.028); more vivid (t=-2.7; p=0.012), and had more emotional valence (t=-2.8; p=0.007). Examples of anxious intrusive imagery included 'the eyes emanating from the television'; 'the nothing thing – a shadowy creature'; 'the sound of the teacher shouting at my classmate' 'standing alone at the school gates with no one to pick me up'; 'the smell of blood from my arteries popping'. Logistic regression revealed that anxiety in all groups was predicted by vividness of images(OR=3.6, p=0.011).
Conclusions:
Children with ASD and anxiety experience anxious imagery that causes them distress. These images may play a significant role in the high rates of anxiety seen in ASD. This finding also has treatment implications for the delivery of CBT in anxiety disorders in this group, which may be more effective if imagery modification/restructuring as well as verbal cognitions are addressed in therapy.

6 **106.006** Assessing ASD Symptoms and Comorbid Psychopathology in Adults with ASD: Who Should You Ask?

A. N. Heintzelman, A. M. Pearl, M. Murray and K. C. Durica, Department of Psychiatry, Penn State Hershey, Hershey, PA

Background: ASD symptoms and psychiatric comorbidities in adults with ASD are notoriously difficult to assess. Recently, self- and other-report versions of the Social Responsiveness Scale, Second Edition (SRS 2) have been normed on adults. In regards to psychopathology, there are several well-established measures to assess psychiatric symptoms in typically developing adults. To the authors' knowledge, the few assessment tools specifically designed to assess for comorbid psychiatric symptoms in individuals with ASD are still in their infancy. However, little is known about the agreement between self- and other-reports of these symptoms in adults with ASD on available assessment tools.
Objectives: To explore agreement between self- and caregiver-report of ASD symptoms and comorbid psychopathology.
Methods: Twenty-one adults diagnosed with ASD ages 18- to 35-years-old (M = 22.57, SD = 4.03) enrolled in a 16-week social skills intervention. 91% were male and 95% were Caucasian. Prior to beginning the intervention, ASD diagnosis was confirmed via the Checklist for Autism Spectrum Disorders (CASD; M = 22.67, SD = 3.17) and verbal IQ was estimated using the Kaufman Brief Intelligence Scale, Second Edition (KBIT 2; M = 93.40, SD = 18.84). Exclusionary criteria included verbal IQ below 70. Additionally, the participants and a primary caregiver completed the Adult Self-Report (ASR) or Adult Behavior Checklist (ABCL), as well as the SRS 2.
Results: Intraclass (ICCs) and Pearson correlations between raters for ASD symptoms on the SRS 2 were significant only for the Social Cognition (ICC & r = .54, p < .01) and Social Motivation (ICC & r = .51, p < .01) subscales. Inter-rater differences were examined using paired-samples t-tests. There were significant differences between self- and caregiver-report on all subscales of the SRS 2. Effect

sizes for these differences ranged from medium to large (Cohen's *d* range = .42 to .72). There were no significant differences between self- and caregiver-report on any of the subscales on the Adult Self-Report/Adult Behavior Checklist. When intraclass (ICCs) and Pearson correlations between raters for these subscales were examined the all subscales were significant correlated except for the Withdrawn Problems, Thought Problems, Rule-breaking Problems, and Avoidant Problems subscales. The Aggression and Externalizing subscales had the highest correlations suggesting that these variables are observed more consistently between young adults with ASD and their caregivers as compared to the other subscales.

Conclusions: The SRS 2 demonstrated poor inter-rater reliability between reporters. Caregivers of young adults with ASD consistently rated their children higher on the SRS 2 than individuals rated their own behavior. This suggests that importance of acquiring other-reports of ASD symptoms when assessing young adults' symptoms of ASD. The ABCL and ASR demonstrated high inter-rater reliability between reporters. These results suggest that these broadband measures of psychopathology are valuable tools for researchers and/or clinicians to screen for the presence of symptoms of internalizing and externalizing disorders in adults with ASD. The high inter-rater reliability provides more confidence for the utility of these instrument when obtaining a self-report rating.

7   **106.007** Association Between Age at Menarche and Autistic Traits in Turkish University Students

*A. Herguner[1] and **S. Herguner**[2], (1)Child and Adolescent Psychiatry Clinic, Konya Reseach and Training Hospital, Konya, Turkey, (2)Department of Child and Adolescent Psychiatry Meram Faculty of Medicine, Necmettin Erbakan University, Konya, Turkey*

Background: The androgen theory of autism suggests that masculinizing effect of fetal androgens may play a role in the expression of autism. Recent evidence also showed that prenatal androgen exposure might delay age at menarche (AAM).

Objectives: There is a limited number of studies examining the relation between autism and AAM. In a cross-sectional survey, relied on retrospective self-reports, AAM was delayed by 8 months in women with ASD when compared with age-matched controls (13 years 4 months vs. 12 years 7 months, respectively). Recently, an association between higher autistic-like symptoms and relatively later AAM was reported in a sample of typically developing girls. The aim of this study was to examine the association between AAM and autistic traits in a nonclinical sample of female university students. As prenatal androgen exposure is implied in the etiologies of both AAM and autism, we predicted that there would be a positive relation between autistic traits and menarche age.

Methods: The participants of the study were female university students, recruited from a public university in the middle part of Turkey, Konya. Because timing of menarche differs among ethnic groups, only White-Caucasian participants were included in the study. AAM was assessed using the following question: 'How old were you when you experienced your first menstrual bleeding?' Participants were asked to respond in years and months. Retrospective self reports of AAM are generally accepted as reliable and accurate in young women. Autistic traits were measured using the Autism Spectrum Quotient (AQ).

Results: A total of 436 female university students participated in the study. The mean age of the sample was 19.6 ± 1.3 years (range = 17.1 – 24.8) and the mean AAM was 13.3 ± 1.1 years (range = 9.6 – 16.5). The mean AQ Total Score was 18.6 ± 4.7 (range = 6 - 32). Spearman's correlation analysis revealed a positive relation between AQ Total score and AAM (r = .100, p = .037), indicating individuals with higher AQ Total scores had later AAM. We examined the correlations between AAM and each subscale of the AQ. Social Skills, Communication and Imagination subscales were significantly and positively correlated with AAM. We also compared the AAM between participants who scored 26 or higher on the AQ (n = 25, % 5.7) versus those who scored less than 26 (n = 411, %94.3), as 26 had been proposed as a cut-off score. Subjects with above average autistic traits (AQ ≥ 26) reported later AAM than subjects with below average autistic traits (AQ < 26) (13.8 ± 0.9 years vs. 13.3 ± 1.0 years; Z = -1.943, p = .052).

Conclusions: We found a positive relation between autistic traits and AAM in nonclinical university students. These findings are consistent with the androgen theory of autism suggesting that delayed menarche and autistic traits may share a common developmental mechanism, exposure to high levels of prenatal androgens.

8   **106.008** Association Between Pubertal Stage and Behavioral Profile Across Neurodevelopmental Disorders

M. Penner[1], A. Dupuis[2] and E. Anagnostou[3], (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Clinical Research Services, The Hospital for Sick Children, Toronto, ON, Canada, (3)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

Background: Puberty is a time period associated with tremendous biological, social and behavioral change. Youth with neurodevelopmental disorders (NDDs), including autism spectrum disorder (ASD), are not immune to these changes, and small case series have reported they may be at additional risk for behavioral deterioration at the time of puberty. To date, no research has evaluated the behavioral response to puberty across NDDs.

Objectives: The objective of this study was to determine the association between Tanner stage of

puberty and behavioral profile across NDDs.

Methods: This was a cross-sectional study using data collected through the Ontario Brain Institute Province of Ontario Neurodevelopmental Disorders (OBI-POND) network. OBI-POND enrolls children with NDDs, including ASD, attention deficit hyperactivity disorder (ADHD), obsessive compulsive disorder (OCD), and intellectual disability (ID). All participants had caregivers complete the Child Behaviour Checklist (CBCL). Participants aged 6 years or older (or their caregivers) completed a Tanner Staging Form, where penile/breast growth and pubic hair development are both reported compared to reference pictures. Spearman correlation coefficients were used to determine the bivariate association between Tanner stages of growth and pubic hair development and between Tanner stages and CBCL T-scores. We then assessed the influence of Tanner stage on CBCL scores using multivariate linear regression controlling for age, gender, and diagnosis.

Results: Three-hundred twenty participants were included in the analysis. Seventy-four percent of the sample was male (n=237). The mean age at enrollment was eleven years (standard error = 2.9 years). The distribution of NDDs was: ASD: 152 participants (48%); ADHD: 99 participants (31%); OCD 64 participants (20%); and ID 5 participants (2%). Participants were distributed through all Tanner stages (growth/pubic hair, respectively): Stage 1: 114/145; Stage 2: 67/55; Stage 3: 55/27; Stage 4: 52/51; and Stage 5: 28/39. The correlation coefficient between self-reported Tanner stages of growth and pubic hair was 0.88 (p<0.0001). There were no significant associations between CBCL internalizing behaviour scores with Tanner stage or any independent variable. Spearman correlations were significant between Tanner stage of puberty and externalizing behavior (r= -0.19, p=0.0006; and r= -0.24, p<0.0001 for growth and pubic hair, respectively) and in univariate regression models, diagnosis and age were also significantly associated with CBCL externalizing scores (p<0.0001). After controlling for diagnosis or age, the association between Tanner stage and externalizing behaviour scores was no longer significant.

Conclusions: Unadjusted associations between Tanner stage and externalizing behavior showed a trend toward decreasing externalizing behavior with increasing Tanner stage; however, this relationship was not significant when controlling for diagnosis and particularly, age. Future longitudinal studies of the effects of puberty in NDDs should focus on consecutive behavioral measures at successive Tanner stages.

9   **106.009** Associations Between ASD Symptoms, Internalizing Symptoms, Empathy, and Social Loneliness in Young Adults with ASD

A. M. Pearl, K. C. Durica, M. Murray and A. N. Heintzelman, *Department of Psychiatry, Penn State Hershey, Hershey, PA*

Background: Autism Spectrum Disorder (ASD) is a persistent and debilitating condition which is frequently accompanied by comorbid psychopathology. Problems with comorbid psychopathology are well-documented in children and adolescents with ASD, specifically in regards to anxiety and social loneliness (Mazurek & Kanne, 2009; White & Roberson-Nay, 2009), as well as impaired empathy in adults with ASD (Baron-Cohen & Wheelwright, 2004). More specifically, researchers have found high-functioning individuals with ASD report higher levels of anxiety, more loneliness than typically developing individuals (White & Roberson-Nay, 2009). However, little is known about these specific associations in young adults with ASD.

Objectives: The authors sought to examine associations between self- and caregiver-report of ASD impairment and internalizing symptoms, as well as self-reported empathy and social loneliness in young adults with ASD.

Methods: Twenty-one adults diagnosed with ASD ages 18- to 35-years-old (M = 22.57, SD = 4.03) were enrolled in a 16-week social skills intervention. 91% were male and 95% were Caucasian. Prior to beginning the intervention, ASD diagnosis was confirmed via the Checklist for Autism Spectrum Disorders (CASD, M = 22.67, SD = 3.17) and verbal intelligence was estimated through administration of the Kaufman Brief Intelligence Scale, Second Edition (KBIT 2; M = 93.40, SD = 18.84). Additionally, the participants and a primary caregiver completed the Achenbach Adult Self-Report (ASR) or Adult Behavior Checklist (ABCL), as well as the Social Responsiveness Scale, Second Edition (SRS 2). Participants completed the Social and Emotional Loneliness Scale for Adults (SELSA), Empathy Quotient (EQ), and the Social Phobia Inventory (SPIN).

Results: Bivariate correlations were completed to identify significant associations between the variables of interest. Higher self- and other-reported ASD symptoms were associated with higher self-reported internalizing symptoms [r = .62 (self), .64 (other), $p < .01$] and higher self-reported social anxiety symptoms [r = .67 (self), .41 (other), $p < .01$]. Additionally, higher other-reported internalizing symptoms were associated with higher empathy (r = .45, $p < .05$). Finally, in regards to social loneliness, higher social loneliness was associated with older age (r = .56, $p < .01$), ASD symptoms (r = .57, $p < .01$) and lower empathy (r = .57, $p < .01$). Higher family emotional loneliness was associated with higher impairment in ASD symptoms (r = .47, $p < .01$).

Conclusions: Findings contribute to the ASD literature supporting a significant association between level of ASD impairment and internalizing symptoms, including social anxiety in young adults. However, it was found that higher internalizing symptoms are also associated with more empathy in young adults with ASD. In regards to social loneliness, it was found that this was associated with older age, more ASD impairment, and less empathy. More specifically, young adults with more impairing ASD reported higher family emotional loneliness.

10   **106.010**   Autism Spectrum and Psychosis Risk in the 22q11.2 Deletion Syndrome; Findings from a Prospective Longitudinal Study

*A. M. Fiksinski[1], T. Opacak[1], E. J. Breetvelt[1], S. N. Duijff[1] and **J. A. Vorstman**[2], (1)Psychiatry, Brain Center Rudolf Magnus UMC Utrecht, Utrecht, Netherlands, (2)UMC Utrecht, Utrecht, Netherlands*

Background: Individuals with the 22q11.2 deletion syndrome (22q11DS) have a 25-fold increased risk for developing psychotic disorders, in particular schizophrenia. Interestingly, several studies in children with 22q11DS have reported that the rate of Autism Spectrum Disorders (ASDs) is also increased in this population. However, it has been postulated that the social and communicative deficits observed in a subgroup of children with 22q11DS are in fact the prodromal signs of schizophrenia, rather than symptoms of another disorder (i.e. ASD). If this proposition is true, one would expect that the diagnosis of ASD in childhood predicts the emergence of psychosis later in life in individuals with 22q11DS.
Objectives: To test the hypothesis that children with 22q11DS with a diagnosis of ASD are more likely to develop a psychosis compared to children with 22q11DS without ASD.
Methods: 66 children with 22q11DS were assessed twice in a prospective longitudinal study; the average age ($\pm$SD) at first measurement was 14.3 ± 2.0 yrs, and at the second measurement 19.2 ± 2.9 yrs. Both measurements were performed by the same research team using standardized clinical interviews including the Autism Diagnostic Interview (ADI-R) and the Schedule for Affective Disorders and Schizophrenia for School-Age Children-Present and Lifetime Version (Kiddie-SADS). Diagnosis of ASD and/or psychotic disorders were made in accordance to the DSM-IV criteria. The rate of individuals with psychotic disorders (including Schizophrenia and psychotic disorder NOS) and the rate of individuals who reported persistent positive psychotic symptoms (hallucinations and or delusional thoughts) were compared with those who had and those who had not been diagnosed with of ASD at first measurement.
Results: A total of 30.8% of children developed psychotic symptoms while 24.2% fulfilled criteria of a psychotic disorder during follow-up. The proportion of children with ASD who were diagnosed with a psychotic disorder at a follow-up assessment was 14,6 % versus 40.0% of children without ASD ($p=0.020$). The proportion of children who developed psychotic symptoms during follow-up followed a similar pattern (psychotic symptoms were observed in 25.0% of those with ASD versus in 40.0% of those without ASD ($p=0.20$)).
Conclusions: The findings of this study indicate that a diagnosis of ASD early in life is not associated with an increased risk for the subsequent development of psychotic disorders. If any, our data suggest that those with ASD may be less likely to develop psychotic disorders later in life. These results replicate a previously reported retrospective study in an independent cohort of adult individuals with 22q11DS. Our results indicate that early developmental deficits in social and communicative abilities in a subgroup of patients with 22q11DS can not be considered as prodromal symptoms of schizophrenia.

11   **106.011**   Body Mass Index (BMI) Is Negatively Correlated with Adaptive Functioning in a Population of Children with Neurodevelopmental Disorders

__L. Capano__[1] and E. Anagnostou[2], (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, University of Toronto, Toronto, ON, Canada, (2)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Childhood obesity is a global epidemic that leads to both significant physical health problems, such as, diabetes and cardiovascular disease, as well as mental health and behavioral problems. Both young children and adults with obesity have increased rates of internalizing and externalizing behaviors, and in children, the association seems to increase with age. Children with neurodevelopmental conditions have at least a similar if not greater risk of obesity compared to the normal pediatric population. Maladaptive behavior is a key feature of most neurodevelopmental disorders. Identifying alternative factors external to the disorder itself that may compound this problem is worthwhile, especially given the limited management options. Such behaviors greatly impact overall functioning, independence and quality of life.
Objectives: To determine if body mass index (BMI) is associated with internalizing behavior, externalizing behavior, or adaptive skills.
Methods: Data was drawn from the Province of Ontario Neurodevelopmental Disabilities (POND) Network, a large cohort of children with neurodevelopmental disabilities including autism spectrum disorder (ASD), attention deficit/hyperactivity disorder (ADHD), intellectual disability and obsessive compulsive disorder. Internalizing and externalizing behavior was measured using the Child Behavior Checklist (CBCL). Adaptive skills were measured using the Vineland Adaptive Behavior Scales (VABS). The Pearson correlation was used to determine the correlation between BMI, internalizing behavior, externalizing behavior and adaptive functioning.
Results: Complete data was available for 405 children with BMI values and externalizing and internalizing behavior scores. Children with BMI and VABS data were 263. The Pearson correlation demonstrated a significant negative correlation with the VABS Sum of Scores score (-0.381, $p < 0.01$) and total score (-0.244, $p < 0.01$). There was no significant correlation between BMI and internalizing or externalizing behavior.
Conclusions: Elevated BMI is a risk factor for physical and mental health issues, and is already an

important target in child health. Our data demonstrate an association of increasing BMI with worse adaptive skills. Further research is needed to more carefully explore this relationship. However, adaptive skills may represent an important target to help reduce BMI, and subsequently obesity in this population. Alternatively, reducing BMI may improve adaptive skills and overall independence.

12   **106.012** Burden of Psychiatric Symptoms in ASD: Understanding the Full Range from Inpatients to Outpatients and Across IQ

M. D. Lerner[1], C. A. Mazefsky[2], M. Siegel[3], R. Gabriels[4], D. L. Williams[5], J. Pierri[6], C. Peura[7] and K. D. Gadow[8], (1)Psychology, Stony Brook University, Stony Brook, NY, (2)Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (3)Tufts School of Medicine - Spring Harbor Hospital, Westbrook, ME, (4)Children's Hospital Colorado, Aurora, CO, (5)Speech-Language Pathology, Duquesne University, Pittsburgh, PA, (6)University of Pittsburgh Medical Center, Pittsburgh, PA, (7)Developmental Disorders Program, Spring Harbor Hospital, Westbrook, ME, (8)Psychiatry, Stony Brook University, Stony Brook, NY

Background: Children with autism spectrum disorder (ASD) have high rates of impairing comorbid psychiatric symptoms (Kaat, Gadow, & Lecavalier, 2013). However, there is a gap in our understanding of the symptom profiles of children with ASD who require psychiatric hospitalization as well as those with the most limited verbal and intellectual abilities.
Objectives: The overall project goal is to further elucidate the phenomenology of psychiatric symptoms in ASD. This is the initial comparison of two large cohorts of children with ASD with the full spectrum of intellectual and verbal ability levels who were treated at either a psychiatric inpatient unit or outpatient developmental disorders clinic.
Methods: Participants were children with an ADOS-2-confirmed ASD who were either inpatients on specialized psychiatric units (Autism Inpatient Collection, AIC; n = 78) or seen in an outpatient clinic (Cody Center for Autism and Developmental Disabilities; n = 283). Parent report of child psychiatric symptoms using the Child and Adolescent Symptom Inventory (CASI-4R and -5) was collected. The IQ range was similar in both samples (standard scores ~30 - ~140), but the AIC had a significantly lower ($p < .0001$) mean IQ (M = 68.51, SD = 29.39) than the Cody sample (M = 85.81, SD = 23.50), and more AIC participants (57%) were minimally-verbal than Cody participants (21%). Analyses focused on symptom count cut-off scores that reflect whether the required number of symptoms for a DSM-5 diagnosis are present and continuous symptom severity scores in five common ASD comorbidity domains (attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), generalized anxiety disorder (GAD), depression, mania).
Results: Parents endorsed a high rate of symptoms across both samples, with 99% of the AIC sample and 82% of the Cody sample exceeding at least one CASI cut-off (see Figure 1 for cut-offs by disorder). The AIC sample had significantly higher symptom severity scores ($p < .0001$) with large effect sizes across domains (Cohen's d's from .65-.90), except for depression. Higher IQ was related to more severe symptoms of ODD, GAD, and depression in the AIC sample, but was not related to either ADHD or mania symptoms (Figure 2). Magnitude of correlations between IQ and psychiatric symptom severity between the AIC and Cody samples only significantly differed for MDD (p=.005).
Conclusions: Psychiatric inpatients with ASD generally had more severe symptoms across common psychiatric domains than outpatients with ASD. These findings highlight the importance of psychiatric symptom severity as a key correlate of the most severe ASD presentations. Depression patterns were notably unique, with similar severity ratings across samples and a strong association with higher IQ only in the AIC. IQ was related to psychiatric symptom severity in several domains, which highlights the need to study comorbidity in fully representative samples. Future item-level analyses will help clarify whether IQ effects stem from reporting differences for symptoms that are more difficult to detect among those with less verbal ability. This work will help identify indicators of psychiatric hospitalization risk and inform our understanding of the structure of psychiatric symptoms in ASD.

13   **106.013** Chronic Sleep Reduction and Psychopathology Symptoms in Adults with High-Functioning Autism Spectrum Disorder

E. K. Baker[1] and A. L. Richdale[2], (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Cooperative Research Centre for Living with Autism Spectrum Disorders (Autism CRC), Brisbane, Australia

Background: Insomnias are common co-morbidities reported by individuals with ASD, with resultant reduced total sleep time. Individuals with ASD are also reported to have a higher prevalence of anxiety and depressive disorders. However, the relationship between sleep, chronic sleep reduction, and psychopathology in adults with ASD has not yet been investigated.
Objectives: To investigate the relationships between sleep, chronic sleep reduction and psychopathology symptoms in adults with a diagnosis of autism spectrum disorder (ASD) and no comorbid intellectual impairment compared to age-, sex-, and IQ-matched neuro-typical (NT) adults.
Methods: Participants completed a questionnaire battery including the Chronic Sleep Reduction Questionnaire (CSRQ), the Patient Health Questionnaire, the State Trait Anxiety Inventory, and the Sleep Anticipatory Anxiety Questionnaire. Participants also completed a 14 day sleep/wake diary and 14-day actigraphy.
Results: Thirty-six adults with ASD and no comorbid intellectual impairment and 57 NT adults

completed the study. Currently data from 28 ASD and 28 NT participants has been analysed. These preliminary results showed that adults with ASD had significantly higher scores on all psychopathology measures; effect sizes were moderate to large. Adults with ASD also had significantly higher total scores on the CSRQ as well as on the shortness of sleep, irritability, and loss of energy sub-scales; effect sizes were also moderate to large. CSRQ scores were significantly and strongly correlated with all psychopathology variables in both groups. In assessing, psychopathology variables with sleep diary and actigraphy variables in the NT group, state anxiety was significantly correlated with total sleep time (TST; r = -.397) measured by both the diary and actigraphy. In addition, wake after sleep onset (WASO) duration measured by the diary was significantly associated with physiological sleep anxiety (r = .327), cognitive sleep anxiety (r = .363), and depression (r = .372). While in the ASD group only actigraphy variables were correlated with psychopathology measures. Specifically, state anxiety was significantly correlated with sleep onset latency (SoL; r = .356), WASO duration (r = .396), and sleep efficiency (r = -.433). Physiological sleep anxiety was associated with SoL (r = .340), and sleep efficiency (r = -.345), and depression was associated with WASO duration (r = .382), and sleep efficiency (r = -.346).

Conclusions: The CSRQ measures symptoms of chronic sleep reduction and thus the impact of sleep debt. The strong correlations between chronic sleep reduction and psychopathology variables confirms the impact poor sleep can have on general wellbeing in both groups; however the relationship between psychopathology symptoms and sleep appears to differ between the two groups. Subjective feelings of poor sleep are associated with increased symptoms of psychopathology in NT adults; however objective poor sleep is related to increased symptoms of psychopathology in ASD adults. It may be that NT adults are more inclined to under-report their sleep while ASD adults with increased psychopathology symptoms may not perceive their sleep to be as problematic. Data for the full sample of participants will be available at the time of presentation.

14   **106.014** Close but No Cigar: Factor Structure of the ADHD Rating Scale in Children with Autism Spectrum Disorder

B. E. Yerys[1,2], *J. Nissley-Tsiopinis*[3], *A. de Marchena*[1], *L. Antezana*[1], *T. J. Power*[2,3] *and R. T. Schultz*[1,4], *(1)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Psychiatry, University of Pennsylvania, Philadelphia, PA, (3)Center for the Management of ADHD, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)Departments of Pediatrics and Psychiatry, University of Pennsylvania, Philadelphia, PA*

Background: DSM-5 allows comorbid diagnosis of autism spectrum disorder (ASD) and attention deficit/hyperactivity disorder (ADHD). This comorbidity was not allowed under DSM-IV, thus there is a paucity of research that examines whether parent and teacher rating scales used to identify significant ADHD symptoms are appropriate for use in youth with ASD. Many core symptoms of ADHD occur in a social context (e.g., talks excessively, doesn't listen when spoken to directly, interrupts or intrudes others, difficulty awaiting turn), and it is possible that elevated scores in children with ASD may be capturing social impairments rather than inattention and hyperactivity/impulsivity impairments. The ADHD Rating Scale is a commonly used measure in clinics and research as a screen for ADHD, because it maps directly to DSM symptoms. In a normative sample, the original factor analysis of the ADHD-IV rating scale found the best fit to be a two-factor solution (inattention and hyperactivity/impulsivity) consistent with the DSM-IV and DSM-5 ADHD subtypes. There are no published studies that examine the ADHD Rating Scale's factor structure in school-age youths with ASD.

Objectives: To characterize the factor structure of parent and teacher ratings ADHD rating scale in a large sample of youth with ASD and to probe commonly observed relationships between ADHD symptoms and youth characteristics.

Methods: Parents and teachers of 208 youths with an ASD diagnosis (192 males; Age M=10.45 (Range: 6-18 years)); General Conceptual Ability M=100 (Range: 67-158), completed this study. ASD was diagnosed using DSM-IV criteria and confirmed with ADI-R/ADOS. Confirmatory factor analysis (CFA) was used with polychoric correlations using one-, two- (Inattention, Hyperactivity/Impulsivity), and three-factor (Inattention, Hyperactivity, Impulsivity) models, with a robust weighted least squares estimation. We also conducted Pearson correlations with age, executive function, and adaptive behaviors.

Results: According to parents, 57% did not meet clinical cut-off; 16% were Predominantly Inattentive, 6% Predominantly Hyperactivity/Impulsivity, and 21% Combined type. According to teachers, 73% did not meet clinical cut-off; 14% Predominantly Inattentive, 4% Predominantly Hyperactivity/Impulsivity, and 9% Combined type. Correlations revealed significant, but modest, negative relationships for age with parent and teacher ratings of hyperactivity/impulsivity (rs=-.26 and -.29), and teacher ratings of inattention (r=-.22). Partial correlations between parent ADHD symptoms and parent BRIEF scales while controlling for age revealed moderate-to-large effects (r's>.46). Correlations between parent ADHD symptoms and parent adaptive behavior ratings revealed significant but modest negative correlations (Socialization r=-.23 and Communication r=-.29).

The CFA did not meet Goodness-of-Fit criteria for the 1-factor (Parent: CFI=.907, TLI=.894, RMSEA=.127; Teacher: CFI=.873, TLI=.857, RMSEA=.144) or 2-factor models (Parent: CFI=.946, TLI=.938, RMSEA=.097; Teacher: CFI=.946, TLI=.938, RMSEA=.095), but the 3-factor met partially (Parent: CFI=.952*, TLI=.944, RMSEA=.093; Teacher: CFI=.958*, TLI=.951*, RMSEA=.084). Modification indices suggest items 5, 10, and 15 reduced the 3-factor model fit.

Conclusions: Prevalence rates and relationships with youth characteristics converge with prior studies, but the factor structure observed in community youth did not fit for youth with ASD. Three items require modification to distinguish ADHD from social interaction deficits or more general ASD deficits. This study has significant clinical and research implications for screening/diagnosing ADHD in ASD.

15 **106.015** Correlates of Cross-Sectional and Longitudinal Health-Related Quality of Life Among Children with Autism Spectrum Disorders

K. Kuhlthau[1], E. McDonnell[2], N. Payakachat[3], D. L. Coury[4], J. Delahaye[5] and E. Macklin[5], (1)Department of Pediatrics, Massachusetts General Hospital, Boston, MA, (2)Biostatistics, Massachusetts General Hospital, Boston, MA, (3)Pharmacy Practice, University of Arkansas for Medical Sciences, Little Rock, AR, (4)Nationwide Children's Hospital, Columbus, OH, (5)Massachusetts General Hospital, Boston, MA

Background:
Studies of the health-related quality of life (HRQoL) of children with Autism spectrum disorders (ASD) have not examined the association of health conditions with HRQoL.
Objectives:
We examine the associations of ASD-related characteristics, behavioral characteristics, and health conditions with baseline and longitudinal change in HRQoL.
Methods:
We examined HRQoL using the Pediatric Quality of Life Inventory (PedsQL) total scores for children enrolled in the Autism Speaks – Autism Treatment Network (AS-ATN) Registry. Children in the AS-ATN Registry were enrolled from 2008 through 2013 from 19 sites with a confirmed ASD diagnosis. We used linear regression to identify associations between baseline behavioral and health characteristics and baseline HRQoL and longitudinal structural mean models to test for baseline characteristics predictive of change in HRQoL over time. We examined the following characteristics: Age, race, gender, insurance status, household income, caregiver education, IQ, ASD diagnosis characteristics including the DSM-IV and the calibrated ADOS severity score, Child Behavior Checklist (CBCL) internalizing and externalizing scores, Children's Sleep Habits Questionnaire (CSHQ) total scores, parent reported gastrointestinal (GI) symptoms (by type), and history of seizures and specific mental health problems. Longitudinal models were adjusted for potentially informative loss to follow-up using inverse-probability weights estimated from the same predictors.
Results:
Our sample of 5,624 children was 6.3±3.5 years old at baseline (range 2 to 18 years), 84% male, 77% Caucasian, 53% covered by private insurance, and 59% with an income of $50,000 or higher. Baseline analyses omitted 843 children who lacked PedsQL assessments completed within 60 days of their baseline visit. Children were followed for an average of 0.8 years (range 0 to 4 years).
Mean PedsQL score at baseline was 65.1 (range of 11.8 to 100). All but ADOS and caregiver education independently predicted baseline PedsQL in bivariate analyses. In a multivariate model using stepwise selection considering all baseline characteristics, older age (beta=-1.40, p<.01), having any insurance (beta=-8.17, p<.01), higher CBCL externalizing and internalizing scores (beta=-.23, p<.01; beta=-.53, p<.01), higher CSHQ scores (beta=-.27, p<.01), caregiver education of at least some college (beta=-2.53, p<.01), having seizures (beta=-3.45, p<.05), having stomach pain (beta=-2.87, p<.01), and having stomach reflux (p=-2.01, p<.05) were associated with lower baseline PedsQL total scores.
Baseline mean PedsQL total scores did not significantly improve or decline over time. Age, DSM-IV diagnosis, IQ, CBCL internalizing and externalizing scores, having anxiety, having depression, and having OCD were significant unadjusted predictors of PedsQL trajectory. In a multivariate longitudinal model, using stepwise selection considering all baseline characteristics, older age predicted slower decline in PedsQL (interaction beta=.49, p<.01) while having public insurance and history of seizures predicted faster decline (beta =-2.04, p<.05; beta=-4.13, p<.01, respectively).
Conclusions:
Similar to previous work, both behavioral issues and sleep problems are associated with lower baseline HRQoL. This study additionally found that physical characteristics including GI symptoms and seizures were associated with HRQoL. These results strongly suggest that paying attention to physical health is important for children with ASD.

16 **106.016** Dietary Influences on BMI in Children with Autism Spectrum Disorders

S. R. Straka[1], S. L. Hyman[2], B. L. Schmidt[2], K. Evans[3] and P. A. Stewart[2], (1)Developmenal and Behavioral Pediatrics, Golisano Children's Hospital University of Rochester Medical Center, Rochester, NY, (2)Department of Pediatrics and Clinical and Translational Science Institute, University of Rochester School of Medicine, Rochester, NY, (3)University of Rochester Medical Center, Rochester, NY

Background: The prevalence of childhood obesity has increased over the past two decades in the United States. Children with autism spectrum disorders (ASD) may have a similar or greater prevalence of obesity due to selective eating and mealtime behaviors which may alter risk factors
Objectives: Known dietary risk factors (points of intervention) for overweight/obesity in the general population will be analyzed for children with ASD. Children with ASD with and without

overweight/obesity will be compared on the following factors: 1) food categories contributing the most calorie per day 2) caloric intake from sugar sweetened beverages (SSB); 3) servings of fruits and vegetables consumed 4) number of eating occasions/day; and 5) breakfast consumption.

Methods: Children (n=292) with ASD (2-11 years) from five Autism Speaks Autism Treatment Network (AS ATN) sites (Rochester, Pittsburgh, Cincinnati, Little Rock, Denver) participated in an AIRP study of dietary intake (2010-11). They were characterized per the AS ATN registry protocol for diagnosis and demographics. Prospective three day diet diaries were collected and analyzed using Nutrition Database Research Studies software. BMI (Body Mass Index) was calculated. In addition to the above, data analysis includes food category comparison to the National Health and Nutrition Examination Survey (NHANES 2005-06 for ages 2-13 years), descriptive statistics, t-test and chi square.

Results: The mean age of respondents was 5.2 years, 84% were male. Only the 4-8 year old age group in both the ASD and NHANES groups were similar in the top ten food categories relative to calorie intake: grain based desserts, yeast breads, pizza, pasta and pasta dishes and reduced fat milk. The top foods that contributed to caloric intake were different in children (2-3, 8-11 years) with ASD compared to the NHANES sample. SSB contributed fewer calories (% kcal/day) for children with ASD compared to the NHANES sample (2-3 years: 0.7% v.s. 1.5%; 4-8 years: 1.8% v.s 2.8%, 9-11 ASD: 1.8% v.s 9-13 NHANES: 2.8%). Within the top ten calorie contributing food categories, 100% fruit juice (not orange or grapefruit) (2-3 years 5.3%; 4-8years 3.2%) and fried white potatoes (3.0%) were the only fruit or vegetable that were ranked. Children with ASD had eating occasions on average of 18/3 days (5.9 SD). More than 95% of children with ASD consumed breakfast on all three days across BMI groups. Relationships of these feeding behaviors with BMI will be further examined.

Conclusions: As in the general population, addressing eating behaviors is an important behavioral target for overweight/obesity prevention and management in children with ASD. Targeting SSB and breakfast consumption may have less impact on obesity management. Additional modifications to the current approach of promoting healthy weight may be necessary for children with ASD.

17   **106.017** Dispositional Mindfulness Predicts Anxiety in Adults Diagnosed with Autism Spectrum Disorder

M. E. Maisel[1], K. Stephenson[1], J. C. Cox[2] and M. South[3], (1)Department of Psychology, Brigham Young University, Provo, UT, (2)Counseling and Psychological Services, Brigham Young University, Provo, UT, (3)Psychology and Neuroscience, Brigham Young University, Provo, UT

Background: Converging findings show that individuals diagnosed with autism spectrum disorders (ASD) often experience severe comorbid anxiety. Other research suggests that mindfulness skills (paying attention to the present moment in a non-judgmental way), are associated in neurotypical people with less anxiety and stress. A few recent studies have shown benefits of mindfulness-based interventions on anxiety in ASD. However, no studies to date have examined how trait mindfulness and trait anxiety are associated in everyday function in ASD.

Objectives: This study aimed to examine the role that dispositional mindfulness plays in predicting anxiety in adults diagnosed with ASD, compared to age- and IQ matched typical controls. We hypothesized that ASD adults would report decreased mindfulness overall compared to controls but that mindfulness would significantly predict anxiety levels in both ASD and control groups. Finally, we explored whether the separate factors of mindfulness captured by the Five Facet Mindfulness Questionnaire (FFMQ) might vary across groups in their predictive value for anxiety.

Methods: Participants included 21 young adults (ages 18-30) who have been diagnosed with ASD and a control group (CON group) consisting of 20 college students who reported no history of psychological diagnoses. Participants completed a brief intelligence test (WASI-II) and several self-report measures including the Five Facet Mindfulness Questionnaire, the State Trait Anxiety Inventory (a measure of everyday anxiety symptoms), and the Social Responsiveness Scale-2nd Edition (as a measure of dimensional autism symptoms).

Results: As expected, the ASD group reported significantly less mindfulness than controls. However, mindfulness was shown to affect the two groups differently. Multiple regression demonstrated that increased anxiety for ASD group is predicted by decreased levels of the mindfulness facets of *observe*—which measures attention to sensations and emotions; and *non-reactivity*—the ability to let emotions come and go without getting stuck on them. In contrast, anxiety in the CON group was significantly predicted by the facet of *non-judging*, meaning the ability to experience negatively-valenced feelings without condemning them.

Conclusions: These findings support other recent research in our lab that anxiety in ASD may arise from limited awareness of internal emotional states. We hypothesize that this limited awareness leads to feelings of uncertainty about how to respond to any given situation, and subsequent worry about whether one is responding appropriately. This may underlie a tendency to get "stuck" on particular feelings and situations. These findings also confirm that incorporating mindfulness in psychological interventions can be helpful for ASD populations. However, because mindfulness may moderate anxiety differently in ASD than neurotypical adults, interventions should be tailored specifically for the types of comorbidity seen in ASD populations.

18   **106.018** EEG Endophenotypes in Autism Spectrum Disorder

ABSTRACT WITHDRAWN

Background: The association between autism and epilepsy has been consistently reported.   EEG abnormalities have been reported in patients with autism spectrum disorder (ASD) without a history of seizures. However, little is known about the relationship between EEG abnormalities and the core features of autism, particularly relating to deficits in communication, cognition and behavior.
Objectives: The purpose of the study was to identify the presence of epilepsy and EEG abnormalities among youth with well-characterized ASD in order to determine the relationship between epileptiform discharges and specific disease-associated impairments in ASD.
Methods: Data was collected from medical records of patients at Cincinnati Children's Hospital Medical Center, ages 2 years to 6 years, with well-characterized ASD. These patients were sub-divided into four groups: ASD/abnormal EEG, ASD/normal EEG, ASD/no EEG, and ASD/epilepsy. Phenotypic data was collected, including cognitive and behavioral measures (Mullen Scales of Infant Development, Stanford-Binet, Vineland Adaptive Behavior Scales, Child Behavior Checklist), language testing (Preschool Language Scales), ADOS scores, birth and developmental history, medications, and medical comorbidities. EEG data was abstracted from reports and included presence, characterization, and localization of abnormalities.
Results: We now report on data from an initial group of 534 consecutively treated patients with ASD drawn from a larger 3,800 subject data set. From this initial group, analysis was carried out on 168 patients with ASD who had an EEG. Thirty-seven (24.5%) had an abnormal EEG and no history of seizures. Of these, 17 (46%) were epileptiform. Patients with epilepsy exhibited higher scores on the Anxious/Depressed subscale of the CBCL compared to the other patient groups, which reached statistical significance when compared to patients with abnormal EEGs (p=0.01). Patients with abnormal EEGs exhibited NVIQ scores 14 points lower than patients with normal EEGs on the Stanford-Binet. Although differences were not statistically significant, significance may be attained with larger sample size. For these two groups, a sample size of 45 in each group will have 80% power to detect a difference in means of 15.0 in NVIQ with a standard deviation of 25.0 using a two group t-test with a 0.050 two-sided significance level, yielding an effect size of 0.4. Patients with epilepsy performed worse on all IQ measures on the Stanford-Binet compared to the abnormal EEG group. Though the differences were not statistically significant, significance may be attained with larger sample size. For these two groups, a sample size of 26 in each group will have 80% power to detect a difference in means of 19.3 with a standard deviation of 24.0 using a two group t-test with a 0.05 two-sided significance level, yielding an effect size of 0.8. Based on our identified sample size, we are confident that we will have the power to detect a significant difference between groups.
Conclusions: Preliminary analysis suggests that the presence of an abnormal EEG or epilepsy in the setting of ASD confers worse cognitive and behavioral outcomes. Further analysis will further help to clarify these associations and may offer insight into treatment for this sub-population.

19 **106.019** Eating Problems Are Associated with Autism Severity in Toddlers with Autism Spectrum Disorder

O. E. Stolar[1], D. A. Zachor[2], D. Eitan[3] and E. Ben Itzchak[4], (1)Pediatric, The Autism Center, Assaf Harofeh Medical Center, Ra'anana, Israel, (2)Assaf Harofeh Medical Center, Tel Aviv University, Zerifin, Israel, (3)ALUT the Israeli National Organization for children with ASD, Zerifin, Israel, (4)Ariel University/ Assaf Harofeh Medical Center, Givat Shmuel, Israel

Background:
The prevalence of feeding problems in typical toddlers is estimated to be 25% and 46-89% for children with autism spectrum disorder (ASD). Most of the problems in feeding toddlers with ASD are behavioral in nature and includes food selectivity or picky eating. The selective diet which in some cases doesn't meet the nutrition needs for optimal growth may lead to adverse long term medical and developmental outcomes. There are only few studies on the relationship between eating problems and severity of the ASD core symptoms.
Objectives: The aim of the current study was to explore the frequency and type of eating disorder in toddlers with ASD and to examine the association between selective eating disorder and the severity of autism symptoms.
Methods:
The study included 117 toddlers aged 19-39 months (M=29.2; SD=4.3), 93 boys and 24 girls diagnosed with ASD that were enrolled in 8 center-based early intervention programs (EIP) for toddlers with ASD. The assessment included evaluation of autism severity using the Social Communication Questionnaires (SCQ), filled by the caretakers and the EIP professional team at the entrance to EIP. Information on eating profile was obtained by a questionnaire developed by the researchers. The questionnaire included information on the variety of foods accepted by the participant, the eating habits, dietary intake and selectivity based on colors, textures and shapes.
Results:
Based on the results of the eating profile questionnaire 5 subgroups were defined: 38% had no eating problems, (adequate variety and appropriate for age eating habits); 30% had extreme selectivity in food intake (eating < 16 types of food, not meeting the food pyramid requirements); 16% had mild selectivity in food intake (accept at least 16 types of food including at least 4 types of fruit and vegetables, 3 different types of protein rich food and 3 different types of carbohydrates); not meeting the food pyramid requirements); 4% ate only ground food or formula; 1% refused food (eating small amount of food, 1-2 times a day, fulfilled the criteria for failure to thrive). To assess the

association between selective eaters and autism severity, the group without eating problems (n=40) was compared in autism severity to a group with selective eating consisted of participants from the subgroups 2, 3 and 5 (n=51). The professional team SCQ scores revealed that the group with selective eating had significantly more severe autism symptoms than the group without eating disorder (p<0.001). Specifically, higher reciprocal-social interaction and communication domains scores were noted for the selective eating group (p<0.05).

Conclusions:
Toddlers with ASD present high prevalence of eating problems specifically extreme selective eating. The selective eating profile is associated with higher severity of ASD symptoms, specifically in social and communication domains. These findings emphasize the importance of evaluating the eating problems of young children with ASD. Specific intervention for the eating abnormalities to ensure an adequate diet for proper growth and development should be part of the treatment plan. It is suggested that improving core ASD symptoms might reduce the selective eating problems.

20 **106.020** Eating Problems in Men and Women with ASD and Average Intelligence

A. A. Spek, *Autisme Kenniscentrum, Utrecht, Netherlands*

Background:
Research shows that eating problems are common in children with ASD. However, we know little about eating problems and eating disorders in adults with ASD with normal or high intelligence. Furthermore, information is lacking about differences in eating problems between men and women with ASD.

Objectives:
To examine eating problems in men and women with ASD and average or high intelligence.

Methods:
19 men and 21 women with ASD and full scale IQ > 85 were examined using the Dutch translation of the SWEA (SWeadish Eating Assessment for Autism). Results were compared with 30 neurotypical men and 32 neurotypical women. The ASD and non-ASD groups were matched on level of education and age. Diagnoses of the participants with ASD were based on the ADI-R and an interview based on the DSM-5 criteria of ASD.

Results:
Results showed that the men with ASD reported significantly more preferences for certain foods, more sensitivity for food surrounding and less sensitivity for signals of hunger and thirst than the neurotypical men. The women with ASD reported similar problems as the men with ASD. The women with ASD also reported significantly more sensory sensitivity regarding foods, problems in motor control, difficulty with social aspects of eating situations and symptoms of formal eating disorders than neurotypical women.

Conclusions:
Our results seem to indicate that men and especially women with ASD experience various eating problems. In women, there was also evidence for symptoms of eating disorders. Further research is necessary, especially regarding the diagnostics and treatment of eating problems and eating disorders in men and women with ASD.

21 **106.021** Elevated Prevalence of Overweight and Obesity Among Children with Autism Spectrum Disorders

A. P. Hill[1], K. E. Zuckerman[2] and E. J. Fombonne[1], (1)Oregon Health & Science University, Portland, OR, (2)Pediatrics, Oregon Health & Science University, Portland, OR

Background:
Pediatric overweight and obesity are a significant public health concern. Although many of the risk factors for unhealthy weight are likely the same among children with ASD as in the general population, children with ASD may be vulnerable to additional risk factors including atypical eating patterns, food selectivity, and limited opportunities for social/physical activity. The presence of these additional risk factors raises the question of whether children with ASD are more likely to be overweight or obese compared to children without ASD.

Objectives:
To determine if the prevalence of unhealthy weight overall and obesity specifically is significantly higher in individuals with ASD (available through the Autism Speaks Autism Treatment Network [ATN]) versus those from a general population sample (available through the National Health and Nutrition Examination Survey [NHANES]).

Methods:
Children with ASD (n = 5053; ages 2-17) enrolled in the ATN were compared to children in an age-matched sample available through NHANES (n = 8844). In both samples, weight and height were measured during a standardized physical exam and were used to calculate BMI percentiles; classifications of overweight (OWT; 85th percentile ≤ BMI < 95th percentile) and obesity (OBY; BMI ≥ 95th percentile) were according to CDC guidelines for BMI for sex and age. Children in the ATN sample had confirmed ASD diagnoses according to DSM-IV-TR (American Psychiatric Association, 2000) criteria and supported by administration of the ADOS (Lord et al., 2000). Following NHANES analysis guidelines, prevalence estimates were calculated after applying the mobile examination center 6-year

sample weights to take into account the complex sampling design. Estimates were compared using two-proportion z-tests across all ages (2-17) as well as by age group (2-5, 6-11, 12-17) for unhealthy weight status (OWT or OBY) as well as only obese weight status (OBY). Further analyses were conducted for boys and girls separately, as well as by the following racial/ethnic groups: Non-Hispanic white, Non-Hispanic black, Hispanic.

Results:
In this study, 33.6% of children with ASD (2-17 years) were an unhealthy weight and 18% were obese. Compared to the NHANES general population sample, prevalence estimates for unhealthy weight overall and for obesity only were significantly higher among children with ASD than in the general population for those ages 2-5 and 12-17, regardless of gender.

Conclusions:
Our results indicate that the prevalence of unhealthy weight status is significantly greater among children with ASD compared to the general population, which is consistent with several recent reports based on measured height and weight values in individuals with confirmed ASD diagnoses (Broder-Fingert, Brazauskas, Lindgren, Iannuzzi, & Van Cleave, 2014; Egan, Dreyer, Odar, & Beckwith, 2013). We also found that these differences are present as early as ages 2-5. Since obesity is more prevalent among older children in the general population (Ogden, Carroll, Kit, & Flegal, 2014), these findings raise the question of whether there are different trajectories of weight gain among children with ASD, possibly beginning at a very early age.

22   **106.022**   Ethnic Differences in Comorbid Impairments in Attention and Hyperactivity Among Youth with Autism Spectrum Disorder

A. B. Ratto[1], L. G. Anthony[2], L. Kenworthy[3], K. M. Dudley[4], A. C. Armour[2] and B. J. Anthony[5], (1)Children's National Health System, Silver Spring, MD, (2)Center for Autism Spectrum Disorders, Children's National Medical Center, Rockville, MD, (3)Children's Research Institute, Children's National Medical Center, Washington, DC, (4)Children's National Medical Center, Rockville, MD, (5)Center for Child and Human Development, Georgetown University, Washington, DC

Background: Under the DSM-5, a diagnosis of autism spectrum disorder (ASD) no longer excludes a diagnosis of Attention-Deficit/Hyperactivity Disorder (ADHD). Given the high rates of problems with attention and impulse control in ASD, it is likely that many children with ASD will qualify for a comorbid diagnosis of ADHD (Leyfer et al., 2006). Prior research has found that in the general population, African American (AA) children tend to have higher rates of problems with attention, hyperactivity, and impulsivity than White children, but are less likely to be diagnosed with ADHD (Miller, Nigg, & Miller, 2009). AA children are also less likely to be diagnosed with ASD (CDC, 2014). Thus, AA children with ASD may be at particular risk for under-diagnosis of comorbid ADHD.

Objectives: The aim of the present study was to investigate rates of comorbid symptoms of ADHD and ADHD diagnoses in AA versus White children with ASD. Based on prior research, it was hypothesized that rates of ADHD diagnosis would be lower in AA children than White children, but that symptom rates would be higher.

Methods: Participants included treatment-seeking youth with a confirmed diagnosis of ASD, ages 5-19 years with an IQ>70, recruited as part of a larger research study and through clinical evaluation. From the initial sample of 966 participants, a final sample of 35 White and 35 AA participants was generated, matched on gender and full-scale IQ (within 5 points). Groups did not differ significantly based on age or highest level of parental education. Parent report on the ADHD Rating Scale (DuPaul, Power, Anastopoulos, & Reid, 1998), and select subscales of the Behavior Rating Inventory of Executive Function (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000) and the Child Behavior Checklist (CBCL; Achenbach, 2001), was compared across the AA and White groups. Rates of clinical ADHD diagnosis and use of stimulant and non-stimulant medication for ADHD symptom treatment, obtained by medical record review, were also compared.

Results: Independent samples t-tests were used to assess differences in ADHD symptoms across ethnic groups. Chi-square analysis was used to assess differences in diagnostic rates. Significant differences were found on both the Inhibit (t=3.04, p<.003) and the Working Memory (t=2.95 p<.004) subscales of the BRIEF, with White children rated as having significantly more problems than AA children. White children were also rated as having significantly more problems on the Attention Problems subscale of the CBCL (t=3.04, p<.003) and the Inattention subscale of the ADHD Rating scales (t=2.66, p<.01). Results of a chi-square analysis indicated that White children were significantly more likely to be diagnosed with ADHD (χ^2=5.57, p<.02). However, rates of medication use did not differ significantly by ethnicity.

Conclusions: Contrary to findings in the general population, AA children with ASD were rated as having fewer symptoms of ADHD than their White peers. AA children with ASD may have lower rates of comorbid ADHD. Differences in parent perceptions may also have affected the present findings.

23   **106.023**   Features of Pathological Demand Avoidance Identified Using the Diagnostic Interview for Social and Communication Disorders ('DISCO')

E. O'Nions[1], J. Gould[2], C. Gillberg[3], P. Christie[4] and F. Happe[5], (1)Division of Psychology and Language Sciences, University College London, London, United Kingdom, (2)National Autistic Society, London, United Kingdom, (3)Gillberg Neuropsychiatry Centre, Gothenburg, Sweden, (4)Nottingham Regional Society for Adults and Children with Autism (NORSACA), Nottingham, United Kingdom, (5)Institute of

Background:

Pathological demand avoidance (PDA) is a term coined by Elizabeth Newson to describe children within the autism spectrum who exhibited an unusual pattern of behaviour. The key characteristics of this group included (1) an obsessive resistance to complying with everyday demands; (2) an apparent ability to use behaviour strategically to subvert requests, such as distracting or using socially shocking behaviour; (3) an obsessive need for control, including domineering behaviour towards peers and adults; (5) a tendency to perceive themselves as having adult status; (6) a tendency to adopt others' roles when interacting; and (7) obsessive behaviour, often towards targeted at particular people, who may be loved or hated (or both). Intriguingly, Newson reported an equal gender ratio, and also noted that those with PDA responded to different educational and management approaches than most individuals with autism – in particular surprise, humour and flexibility. Identifying PDA features in individuals with ASD may have an important clinical function in providing more tailored educational and support strategies.

Objectives:

Whilst interest in PDA is increasing apace in the UK, as yet, no validated clinician-rated instrument has been used to systematically quantify PDA features. The primary objective was to identify items that tap PDA features from within the Diagnostic Interview for Social and Communication Disorders (DISCO) (Wing & Gould, 2002). In particular, we were looking for items that are relatively low frequency across an autism spectrum sample per se, but commonly endorsed in PDA. The second objective was to examine the behavioural profile across a high scoring subset on PDA indicators in a sample assessed using the DISCO (N=153).

Methods:

We identified items relevant to PDA from the DISCO on the basis of previous data on a sample reported to have been identified as having PDA (O'Nions et al., 2014), and by examining which items were endorsed as 'marked' in less than 30% of the sample for whom DISCO data was available (N=153). We then identified cut-offs for the purposes of these analyses, and compared our high scoring subset to the rest of the sample on other DISCO indicators.

Results:

The behavioural profile of the high scoring group resembled Newson's descriptions. The group was characterised by high levels of lack of cooperation, use of socially manipulative behaviour, socially shocking behaviour with deliberate intent, difficulties with others, and sudden changes from loving to aggressive behaviour in particular. Anxiety was reported at very high rates in the high scoring subset. Additional features, including physical aggression, laughing at others' distress, lack of awareness of psychological barriers, difficult or objectionable personal habits, needing constant supervision and demanding attention from caregivers were also seen more frequently in the high scoring PDA subset than the rest of the sample. All but one of the high scoring PDA group met criteria for ASD.

Conclusions:

This study provides an important step towards deriving a clinician rated measure to tap PDA features. Differences in the behavioural profile highlight the need for further investigations of the neurocognitive and etiological basis of this profile.

24 **106.024** Fractal Analysis of Autonomic Nervous System Function in ASD

H. Saghir[1,2], T. Chau[2,3] and A. Kushki[2,4], (1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada, (3)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Emerging evidence suggests that autism spectrum disorder (ASD) may be associated with dysfunction of the autonomic nervous system (ANS). However, it remains unclear how the observed atypicalities are related to atypicalities in individual branches of the ANS (sympathetic versus parasympathetic). The interplay between these two branches is particularly challenging to investigate as the nonlinear relationship between the activity of the two branches of the autonomic nervous system challenges the reliability of commonly used linear tools (e.g., HRV spectrum analysis). In this paper, we employ fractal analysis of cardiac interbeat intervals to investigate this issue. In typical populations, fractal analysis have revealed the presence of long-range, power-law correlations in this time series which are altered with disease and aging. Fractal analysis of cardiac signals in ASD have not been reported to date. This new approach to analysis ANS function may provide further insight on the nature of these atypicalities.

Objectives: To investigate ASD-related alterations in the fractal structure of interbeat intervals during baseline and response to an anxiogenic stimulus.

Methods: A sample of typically-developing children (n=33, age: 12.5 +/-2.9 years, full-scale IQ: 112.9 +/- 14.1, 19 male), and those with a diagnosis of ASD (n=40, age: 12.0 +/- 2.9 years, full-scale IQ: 92.9 +/- 20.6, 33 male) completed an anxiogenic task (Stroop test), preceded and followed by a 15-minute and 5-minute baseline task (movie watching), respectively. Throughout the experimental session, electrocardiogram (ECG) was measured and used to extract inter-beat interval time-series. Deterended fluctuation analysis (DFA) was used to obtain the scaling exponent, an index of complexity in the signal. Repeated measures multiple regression analysis was performed to examine

the effect of group and group x time interaction on the scaling exponent while controlling for age, gender, and full-scale IQ.

Results: Multiple regression analysis revealed a significant group x time interaction for the scaling exponent (p=0.04) (Figure 1), suggesting atypical fractal dynamics in the ASD group.

Conclusions: Our results suggest that ASD may be associated with atypical fractal structure in the cardiac interbeat sequences. Specifically, the results point to altered, and possibility decreased, flexibility and adaptability of the autonomic response in ASD. This study adds to the body of evidence supporting atypical ANS function in ASD. Future studies with longer time-series are needed to further characterize the nature of nonlinear atypicalities in this domain.

25   **106.025** Gastrointestinal Issues in Children with Autism Spectrum Disorders Compared to Children with Developmental Delays and a Population Based Sample in the Study to Explore Early Development (SEED)

A. M. Reynolds[1], G. N. Soke[1], L. A. Croen[2], J. Daniels[3], M. D. Fallin[4], T. V. Kral[5], L. C. Lee[6], C. J. Newschaffer[7], J. A. Pinto-Martin[8], L. A. Schieve[9], A. Sims[10] and S. E. Levy[11], (1)University of Colorado Denver, Aurora, CO, (2)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (3)UNC Gillings School of Public Health, Chapel Hill, NC, (4)Johns Hopkins School of Medicine, Baltimore, MD, (5)University of Pennsylvania School of Nursing, Philadelphia, PA, (6)Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (7)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (8)Biobehavioral Health Sciences, University of Pennsylvania, Philadelphia, PA, (9)National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA, (10)Biomedical Research and Informatics Core, Michigan State University, East Lansing, MI, (11)Developmental & Behavioral Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA

Background: Gastrointestinal (GI) problems are commonly reported in children with autism spectrum disorders (ASD), with prevalence ranging from 9 to 70%. However, many studies do not include comparison groups; thus, it has been difficult to assess whether GI problems in children with ASD differ in frequency from children with developmental delays (DD) or children with typical development.

Objectives: Determine the prevalence of parent-reported GI problems and the use of treatments for constipation in children with ASD compared to children with DD recruited from community sources serving children with developmental concerns and children recruited from the general population (POP) in the Study to Explore Early Development (SEED).

Methods: SEED is a multi-site, case-control study designed to thoroughly characterize phenotypes of ASD in children ages 2 to 5 years and to examine potential genetic and environmental risk factors for ASD. The cohort includes children born between the years 2003 and 2006. Children classified as ASD (n=672), DD (n=994), and POP (n=911), whose parent completed a GI questionnaire were included in this analysis (80.5% of the total sample). These analyses are limited to questions related to current GI issues (occurring greater than 2 times per month) such as vomiting, diarrhea, constipation, abdominal pain and gas; treatment for constipation in the previous 30 days with stool softeners, laxatives, or fiber supplements; and GI problems that were present in the past but were not present at the time of the survey. Chi-square tests were used to assess overall group differences. Between group differences were explored through univariable logistic regression.

Results: Parents reported current GI problems in 35% of children with ASD, 22% of children with DD, and 12% of POP children (p<0.0001). Children with ASD were more likely to have current GI problems than POP children (OR= 4.01, 95% CI= 3.10, 5.21) or children with DD (OR=1.96, 95% CI= 1.56, 2.44). Parents reported past GI problems in 28% of children with ASD, 19% of children with DD, and 14% of POP children (p<0.0001). Children with ASD were more likely to have past GI problems than POP children (OR= 4.51, 95%CI= 1.95, 3.26) or children with DD (OR=1.68, 95% CI 1.32, 2.12). Parents reported use of treatment for constipation in 16% of children with ASD, 13% of children with DD, and 8% of children in the POP group (p<0.0001). Children with ASD were more likely to use treatments for constipation than POP children (OR=2.24; 95% CI 1.63, 3.09). However, the use of treatments for constipation was not significantly different between the ASD and the DD groups (OR= 1.27; 0.96, 1.68).

Conclusions: Based on parent report, children with ASD had a higher frequency of current and past GI problems than children with DD and children from the POP group. Children with ASD and DD had greater use of treatments for constipation compared with the POP group. These findings have implications for clinical management. The findings are also informative for understanding phenotypic subtypes in future genetic analyses of risk for ASD.

26   **106.026** Gastrointestinal Symptoms and Associated Clinical Features in Preschoolers with Autism Spectrum Disorders

*F. Fulceri[1], M. Morelli[2], E. Santocchi[3], A. Narzisi[3], **S. Calderoni**[4] and F. Muratori[5], (1)Calambrone Pisa, IRCCS STELLA MARIS FOUNDATION, Pisa, Italy, (2)Stella Maris Foundation, Pisa, Italy, (3)University of Pisa – Stella Maris Scientific Institute, Pisa, Italy, (4)Magnetic Resonance Laboratory, Division of Child Neurology and Psychiatry University of Pisa; Stella Maris Scientific Institute, Pisa, PI, Italy, (5)Stella Maris Scientific Institute, Calambrone (Pisa), Italy*

Background:
Parents of children with autism spectrum disorder (ASD) frequently report gastrointestinal (GI) symptoms in their child with a higher prevalence than in typically developing peers (TD). Moreover, literature suggests that children with ASD and GI disorder(s) (ASD/GI+) may be at high risk for problem behaviors.
Objectives:
To investigate the clinical features of ASD/GI+ preschoolers compared to ASD children without GI symptoms (ASD/GI-) and to TD using the Child Behavior Checklist for ages 1.5 to 5 years (CBCL 1.5-5), a parent-report questionnaire for evaluating the child's functioning during the last two months.
Methods:
A total of 230 preschoolers were included in this study. The ASD group consisted of 115 subjects (95 male and 20 female; mean [SD] age =3.8 [1.1] years; age range =1,8-5,9 years) with a clinical diagnosis of Pervasive Developmental Disorders (PDD) based on the DSM-IV-TR criteria. The control group consisted of 115 TD children (95 male and 20 female; mean [SD] age =3.9 [1.0] years; age range =1,8-5,9 years) with a CBCL 1.5- 5 Total Problems T score below the clinical range and without a CBCL profile suggestive of ASD (Muratori et al., 2011). Parents of children filled out the CBCL 1.5 -5. Items responses are recorded on a Likert scale: 0 = Not True, 1 = Somewhat/Sometimes True, 2 = Very True/Often True. A Total Problem Score, the Internalizing and Externalizing Problems scores, six different syndromes scores (Emotionally Reactive, Anxious/Depressed, Withdrawn, Sleep Problems, Attention Problems, and Aggressive Behavior) and five DSM-oriented Problems scales scores (Affective, Anxiety, Pervasive Developmental, Attention Deficit/Hyperactivity, Oppositional) were evaluated. GI symptoms were identified in seven CBCL items (Costipated, Diarrea, Nausea, Noteat, PainfulBM, Stomachaches, Vomiting).
Results:
At least one GI symptom was reported by parents of 69,6% of ASD children versus 53,9% of TD peers (p<0.05). When more stringent criteria to define subjects suffering GI symptoms (at least one GI symptoms scored as "2") were used, the prevalence of GI problems were still significantly higher in ASD (37,4%) than in TD individuals (15,7%) (p =0.0003). Specifically, "Not eat" and "Costipated" were the items more frequently reported both in ASD/GI+ and in TD with GI symptoms (TD/GI+) children, but with a significantly higher prevalence in ASD than in TD (respectively p<0.01; p<0.01).
Within the ASD group, ASD/GI+ showed a higher percentage of borderline/clinical scores in Aggressive (p<0.01), Internalizing (p<0.01) and Total Problems than ASD/GI-(p<0.001) scores whereas within the TD group, TD/GI+ exhibited a higher percentage of borderline/clinical scores in Internalizing (p <0.01) and Affective Problems (p<0.05) scores than TD/GI-.
Conclusions:
Preschoolers with ASD had higher prevalence of at least one GI symptom than TD peers. GI symptoms were related to behavioral problems both in ASD and in TD subjects, but aggressive behaviors appeared specific to ASD/GI+ children. The observed association suggests that GI symptomatology should be systematically checked and treated in ASD patients, in order to potentially reduce not only GI symptoms, but also the emotional and behavioral associated features.

27 **106.027** Gastrointestinal Symptoms, Whole Blood Serotonin Levels, and Behavioral Symptoms in Children and Adolescents with Autism Spectrum Disorder

S. Marler[1], E. B. Lee[2], G. M. Anderson[3], B. Ferguson[4], E. McDonnell[5], D. Q. Beversdorf[6] and J. Veenstra-Vander Weele[7], (1)Psychiatry, Vanderbilt University, Nashville, TN, (2)Pediatrics, Vanderbilt University, Nashville, TN, (3)Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Radiology, University of Missouri, Columbia, MO, (5)Biostatistics Center, Massachusetts General Hospital, Boston, MA, (6)Radiology, Neurology, Psychological Sciences, University of Missouri, Columbia, MO, (7)Psychiatry, Columbia University / New York State Psychiatric Institute, New York, NY

Background: Autism spectrum disorder (ASD) is characterized by social communication deficits and repetitive behavior, but several co-occurring medical disorders are also increased in ASD. Constipation appears to be particularly common, occurring in 32% of children in the Autism Speaks Autism Treatment Network (Peters et al., 2014). In parallel, elevated whole blood serotonin, or hyperserotonemia, is a well-replicated, heritable biomarker occurring in a subgroup of approximately 28% of children with ASD (Gabriele et al., 2014). In the periphery, serotonin (5-hydroxytryptamine, 5-HT) is synthesized in gut enterochromaffin cells that release it into the blood, where >99% of whole blood 5-HT is found stored in platelets. Within the gastrointestinal (GI) system, 5-HT regulates multiple processes, including motility and inflammation (Gershon, 2014). To our knowledge, no previous study has examined the relationship between gastrointestinal symptoms and whole blood 5-HT levels in ASD. Previous studies have separately examined behavioral correlates in these ASD subgroups, with some but not all studies finding elevated rates of self-injury, repetitive behavior, sensory processing difficulties, and heightened stress reactivity associated with either GI symptoms or elevated blood 5-HT levels.
Objectives: Our primary aim was to investigate the relationship between gut symptoms, particularly functional constipation, and whole blood 5-HT levels in children and adolescents with ASD. We also aimed to assess the relationship between functional constipation, whole blood 5-HT levels, and previously reported behavioral correlates.
Methods: This multicenter study involved a sample of 81 children with ASD, ages 6-18, with and without GI symptoms. The Questionnaire on Pediatric Gastrointestinal Symptoms—Rome III Version

(QPGS-RIII) was used to assess GI disorders. Whole blood serotonin was measured by high-performance liquid chromatography. Sensory symptoms, repetitive behavior, and anxiety were assessed using caregiver reported measures. Stress reactivity was assessed by heart rate variability during two stress-inducing tasks.

Results: Functional constipation (FC) was the most common Rome III diagnosis, occurring in 42% (34/81) of the sample. Participants with functional constipation did not differ from those with no GI diagnosis on age, sex, race, ethnicity, or IQ. Comparing to previous norms (McBride et al., 1998), 23% (19/81) of the participants had 5-HT levels two standard deviations above the mean for their age, sex, and race. Whole blood 5-HT levels, corrected for age and sex, were not significantly different in the functional constipation group in comparison to those with no GI diagnosis ($p = 0.18$). Behavioral measures and stress reactivity were not different in the hyperserotonemic or in the functional constipation subgroups in comparison to the rest of the sample.

Conclusions: No association between functional constipation and whole blood serotonin was observed in this population of children with ASD. These are preliminary analyses, with further analysis ongoing to include measurement of inflammatory markers.

---

28   **106.028** History of Tympanosotomy Tube Placement in Children Referred to a Tertiary Autism Diagnostic Center

S. Monteiro[1], L. Berry[2], J. B. Swanson[3], E. Smith[4], R. Rodrigues[4], A. Spinks-Franklin[3] and R. G. Voigt[3], (1)Baylor College of Medicine/Texas Childrens Hospital, Houston, TX, (2)Suite 180, Baylor College of Medicine, Houston, TX, (3)Pediatrics, Baylor College of Medicine, Houston, TX, (4)Pediatrics, Baylor College of Medicine/Texas Children's Hospital, Houston, TX

Background: Tympanostomy tube placement (TTP) is the most common outpatient pediatric surgery performed in the United States, with nearly 1 in 15 children having tubes by the age of 3 years. Despite a lack of evidence to support TTP in improving developmental outcomes in previous studies that have excluded children with neurodevelopmental disorders, clinical guidelines have been published recommending tubes be offered to children with neurodevelopmental disorders, including speech/language disorders, global developmental delay, and autism spectrum disorder (ASD). However, the prevalence of TTP in children prior to receipt of a formal ASD diagnosis has not been previously reported.

Objectives: To determine the prevalence of prior TTP in children referred for d

Methods: The electronic medical records of all children ≤ 5 years of age evaluated at a single regional ASD diagnostic center between September 2012 and June 2014 were reviewed. History of TTP, clinical diagnoses, and demographic information was abstracted for each patient.

Results: 561 children (80% [N=450] male; 20% [N=111] female) with mean age of 44 months (SD 10 months) completed a diagnostic autism evaluation. Of those evaluated, 95 (17%) had a history of TTP. Of those patients with tubes, 61% (N=58) received an ASD diagnosis and 33% (N=31) were diagnosed with another neurodevelopmental disorder (speech/language disorder [N=11]; global developmental delay [N=20]).

Conclusions: Our data indicate that 1 in 6 children presenting for diagnostic evaluation at a regional autism center have a history of prior TTP. Despite recently published guidelines advocating for TTP in children with neurodevelopmental disorders, given concerns about the potential negative neurodevelopmental impact of exposure to anesthesia/surgery further investigation into whether neurodevelopmental outcomes are improved in children with neurodevelopmental disorders who undergo TTP is needed, as previous studies on the impact of TTP have excluded this population of children.

---

29   **106.029** Impact of Feeding Disorders in Parental Stress in Children with Autism Spectrum Disorder and with Other Developmental Disabilities

M. D. Valicenti-McDermott[1,2], K. F. Hottinger[3], K. Lawson[3], R. M. Seijo[1,2], L. H. Shulman[1,2], M. Schechtman[3] and S. Shinnar[4], (1)Pediatrics/CERC, Albert Einstein College of Medicine, Bronx, NY, (2)Children's Hospital at Montefiore, Bronx, NY, (3)Albert Einstein College of Medicine, Bronx, NY, (4)Neurology, Pediatrics and Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY

Background: Feeding difficulties, in particular food selectivity, have been reported in children with autism spectrum disorder (ASD) and eating problems are typically part of the repertoire of symptoms for a child with ASD. There are few comparisons with children with other developmental disabilities (DD) and the impact of such problems in the family dynamics.

Objectives: To compare feeding disorders in children with ASD vs. those with other DD, and to assess the relationship of feeding problems to parental stress.

Methods: Cross sectional study with structured interview for 50 children with ASD and 50 children with other DD, matched by age/gender. DDs included intellectual disability/global delay and cerebral palsy. Interview included: Feeding Questionnaire, Aberrant Behavior Checklist (ABC) and Parental Stress Index, Short Form. Statistical analysis included McNemar, chi-square, t test and logistic regression.

Results: Mean age 8±3 yr; 15% White, 44% Hispanic and 24% African/American. Food selectivity was

reported in 74% of the ASD group and 62% of the DD group (p=1). Both groups reported selectivity to textures (ASD=36% vs. DD=32% p=.8) and to color (ASD=20% vs. DD=10% p=.2) but children with ASD were more likely to present smell selectivity (36% vs. 14% p=.02), brand selectivity (30% vs. 6% p=.008), inability to mix the food (36% vs. 8% p=.003) and pica (24% vs. 2% p=.003). Both groups reported food allergies (14% vs. 14% p=1). Children with ASD were more irritable (54% vs. 20% p=.001) and parents reported more stress (46% vs. 22% p=.05). There was no association between irritability or parental stress with overall food selectivity in either group, but in the ASD group children with selectivity to textures were more irritable (83% vs. 35% p=.03) and parents reported more stress (77% vs. 26% p=.001). The association between food selectivity (textures) and parental stress persisted after adjusting for demographics, developmental diagnosis and irritability (OR 2.7 95% CI 1.01-7.5).

Conclusions: Both children with ASD and other DD presented with different types of food selectivity. In families of children with ASD, selectivity to textures was associated with parental stress. Feeding programs that ameliorate food selectivity in children with ASD may decrease parental stress.

---

30   **106.030** Internalizing Symptoms in Adults with ASD: Relation to ASD Symptomatology

J. L. Mussey[1], M. R. Klinger[2], S. P. Thomas[2], P. S. Powell[3] and L. G. Klinger[1], (1)TEACCH Autism Program; Department of Psychiatry, University of North Carolina, Chapel Hill, NC, (2)Allied Health Sciences, University of North Carolina, Chapel Hill, NC, (3)University of North Carolina, Chapel Hill, NC

Background: Studies of internalizing symptoms in autism spectrum disorder (ASD) estimate that approximately 40-45% of individuals with ASD have significant levels of anxiety and depression (Sterling et al., 2007; White et al., 2009). To assess internalizing symptoms, measures used in the general population or those being used with individuals with intellectual disability (ID) are being adapted or considered for use in ASD. However, given overlap of symptoms, it can be difficult to differentiate ASD and internalizing symptoms, raising the possibility of diagnostic overshadowing and challenging differential diagnosis. The wide range of functioning in ASD complicates measurement and screening of internalizing symptoms.

Objectives: The purpose of this study was to examine caregiver reported internalizing symptoms and how these symptoms relate to severity of ASD. This study assessed a variety of internalizing problems in adults with ASD across a wide range of intellectual functioning and ASD symptom severity.

Methods: Caregivers completed surveys about adults with ASD as part of a study on the long-term outcome and needs of individuals with ASD in mid-adulthood served as children by the University of North Carolina TEACCH Autism Program. Thus far, 81 caregivers have completed surveys. Adults with ASD had an average age of 33 years (range 20-64 years). The Social Responsiveness Scale, Second Edition (SRS-2; Constantino & Gruber, 2012) Adult (Relative/Other Report) and Waisman Activities of Daily Living Scale (W-ADL; Maenner et al., 2013) were completed in addition to a screening instrument for internalizing symptoms developed for use among individuals with ID, the Anxiety, Depression, and Mood Scale (ADAMS; Esbensen et al., 2003).

Results: The SRS-2 total score was significantly positively correlated with all factors of the ADAMS although the strength of the correlation varied across factors. General Anxiety was significantly positively correlated with SRS-2 total, $r = .35$, $p = .002$, as was Depressed Mood, $r = .23$, $p < .04$, Social Avoidance, $r = .62$, $p < .001$, Compulsive Behavior, $r = .49$, $p < .001$, and Hyper/Manic Behavior, $r = .51$, $p < .001$. Better adaptive skills were significantly related to fewer internalizing symptoms and fewer ASD symptoms. When adaptive skills were controlled for, SRS-2 total and ADAMS factors of Social Avoidance, Compulsive Behavior, and Hyper/Manic Behavior remained significant; Generalized Anxiety and Depression were no longer related to SRS-2 total.

Conclusions: Generally, internalizing symptoms on the ADAMS were related to increased ASD symptoms and fewer adaptive skills. However, these results do not necessarily suggest that those with more ASD symptomatology are at higher risk for comorbidity. Instead, some internalizing factors may be measuring symptoms of ASD. For instance, ASD symptoms were most highly correlated with Social Avoidance and Compulsive Behavior, which overlap with symptoms of ASD. However, Generalized Anxiety and Depression scores were weakly correlated with ASD symptoms and may be more indicative of comorbidity on this screener. These results suggest that increased focus on appropriate screening and measurement of comorbidity in adults with ASD deserves significant attention as it has important implications for treatment, community service needs, and quality of life.

---

31   **106.031** Investigating Sympathetic over-Arousal in ASD

S. Panju[1], J. A. Brian[2], A. Dupuis[3], E. Anagnostou[4] and A. Kushki[1,5,6], (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital/ U of Toronto, Toronto, ON, Canada, (3)The Hospital for Sick Children, Toronto, ON, Canada, (4)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (6)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada

Background: There is emerging evidence to suggest that ASD is associated with atypicalities in the autonomic nervous system (ANS), the branch of the peripheral nervous system responsible for regulating visceral body functions. The findings to date, however, have been disparate with regards

to which branch of the ANS is affected in ASD, and point to large heterogeneity in individual responses. Characterizing autonomic functioning and variables contributing to heterogeneity in this domain are important steps towards understanding the neurobiology in ASD.

Objectives: The objectives of this study were to 1) characterize the functional profile of the sympathetic branch of the ANS in a sample of children with ASD using electrodermal activity measurement, and 2) examine the effect of anxiety symptoms on ANS profiles in this population as a potential variable contributing to response heterogeneity in this domain.
Methods: A sample of typically developing (TD) children (n=29, age:12.7+2.8, FSIQ: 112.2+ 13.6, 16 male) and children with ASD (n=36, age: 12.4+ 2.8, FSIQ: 94.6+20.7, 30 male) were recruited for this study. Participants performed tasks eliciting anxiety, attention, working memory, response inhibition, and social cognition. During the performance of these tasks, electrodermal activity (EDA) signals were recorded for each participant using a wearable sensor from Shimmer Research. Mean tonic EDA and number of electrodermal responses produced during each task were computed for each participant. Anxiety symptoms were characterized using the Child Behaviour Checklist (CBCL). Participants in the ASD group were divided into high and low anxiety groups using a cut-off of 65 on the CBCL Anxiety/Depressed domain.
Results: The ASD group had significantly lower tonic EDA than the TD group (p=0.03). There was a significant effect of anxiety group on the electrodermal response, with the high anxiety ASD group having significantly decreased tonic electrodermal activity compared to the TD group (p=0.03). The difference between the low anxiety group and the TD and high anxiety group did not reach significance, although this may be due to insufficient statistical power.
Conclusions: The results of this study suggest hyperarousal of the sympathetic branch of the ANS in children with ASD, and suggest anxiety as a potential variable for stratification of participants in studies of ANS in ASD.

32   **106.032** Longitudinal Changes in the Presence and Severity of Self-Injurious Behaviors, and Predictors of Change, in Children with Autism Spectrum Disorders

G. N. Soke[1], C. DiGuiseppi[2], T. Fingerlin[3], C. Robinson[4], S. A. Rosenberg[5], R. F. Hamman[6] and A. M. Reynolds[1], (1)University of Colorado Denver, Aurora, CO, (2)Epidemiology/Colorado School of Public Health, University of Colorado - Denver, Aurora, CO, (3)National Jewish Health, Denver, CO, (4)Pediatrics and Psychiatry, University of Colorado School of Medicine, Aurora, CO, (5)Department of Psychiatry, University of Colorado School of Medicine, Aurroa, CO, (6)Epidemiology, Colorado School of Pubic Health, Aurora, CO

Background: Self-injurious behaviors (SIB) are common in children with autism spectrum disorders (ASD). Understanding the natural history of SIB in ASD can inform studies examining the efficacy of interventions. Furthermore, identification of characteristics that predict changes in SIB over time may help target interventions.
Objectives: To assess parent-reported changes in the presence and severity of SIB in children with ASD over one year and explore baseline characteristics that predict changes.
Methods: Parent-reported current presence (yes/no) and current severity (mild, moderate, severe) of SIB at both baseline and follow-up visit were examined among children with ASD aged 2-17 years enrolled in the Autism Treatment Network registry. Participants were categorized into: SIB present at both visits, SIB absent at both visits, SIB present at baseline but not follow-up (improvement), and SIB absent at baseline but present at follow-up (new occurrence). Subjects who improved were compared to those with SIB at both visits. Subjects with new occurrence were compared to those without SIB at both visits. The four severity groups were: mild at both visits, moderate-severe at both visits, moderate-severe at baseline and mild at follow-up (improvement), and mild at baseline and moderate-severe at follow-up (deterioration). Subjects who improved were compared to those who remained moderate-severe, and subjects who deteriorated were compared to those who remained mild. McNemar's test was used to evaluate all differences in proportions and logistic regression was used to assess effects of baseline demographic, developmental, behavioral, and somatic characteristics on all changes.
Results: Among 1575 participants with data on presence of SIB at both visits, SIB was present in 34.2% at baseline and 28.0% at follow-up. SIB improvement was more common at follow-up (14.7%) than was new occurrence (8.5%, p<0.0001). Improvement was associated with higher baseline adaptive behaviors scores (adjusted OR=1.02; 95% CI: 1.00, 1.04). Improvement was less likely in children with developmental regression (aOR=0.64; 0.43, 0.95) and low maternal education (aOR=0.66; 0.44, 0.98) at baseline. New SIB occurrence was associated with aggression (aOR=2.09; 1.43, 3.06) and low maternal education (aOR= 1.81; 1.18, 2.78). New occurrence was less likely with higher baseline adaptive behaviors scores (aOR=0.97; 0.95, 0.99). Only 277 participants had severity data at both visits due to changes in data collection, but had similar characteristics to those without follow-up data. Among these 277 children, 54.3% had mild SIB and 45.7% had moderate-severe SIB at baseline, while 60.1% had mild SIB and 39.9% had moderate-severe SIB at follow-up. More parents reported change from moderate-severe to mild (19.5%), compared to the reverse (11.5%; p=0.02). Higher IQ at baseline predicted improvement (aOR=1.02; 1.00, 1.04), while having public insurance (aOR=3.02; 1.16, 7.90) and low maternal education (aOR=3.46; 1.28, 9.40) at baseline predicted deterioration.
Conclusions: At baseline, parents reported SIB in 34.2% of children. More parents reported resolution than development of new SIB. Further, SIB severity was more likely to improve over time than to

worsen. Maternal education, public insurance, IQ scores, developmental regression, and adaptive behaviors scores at baseline predicted changes in SIB and may be useful for targeting SIB prevention and interventions.

33 **106.033** Loxapine Substitution for Reversal of Antipsychotic-Induced Metabolic Disturbances: A Retrospective Chart Review

J. A. Hellings[1], S. Jain[2] and R. Andridge[3], (1)Psychiatry, The Ohio State University Nisonger Center McCampbell Hall, Columbus, OH, (2)The Ohio State University College of Medicine, Columbus, OH, (3)Biostatistics, The Ohio State University, College of Public Health, Columbus, OH

Background:
Atypical antipsychotics are widely used to treat irritability and aggression in Autism Spectrum Disorders (ASD), despite side effects of significant weight gain and associated metabolic disturbances. Our findings regarding low-dose loxapine, a typical antipsychotic with atypical properties, warrant further study in reversal of metabolic illness associated with atypical antipsychotic treatment in ASD.
Objectives:
To examine a naturalistic outpatient clinic sample of adolescents and adults with ASD who received loxapine for weight and metabolic indicator outcomes. We hypothesized that substitution of loxapine for atypical antipsychotics or chlorpromazine would have beneficial effects on weight and metabolic indicators as well as behavioral outcomes.
Methods:
We performed a retrospective chart review of consecutive adolescents and adults with DSM-IV-TR ASD presenting on an atypical antipsychotic (n=14) or chlorpromazine (n=1), together with at least one form of metabolic disturbance before low dose loxapine substitution.
Results:
Subjects were 12 males and 3 females. Mean age was 31.7 years (range 16-61 years). Mean loxapine treatment duration at the time of chart review was 11.5 months (range 3-20 months). Final loxapine dose for 12 subjects was 5 mg/day and 10 mg/day for 3 subjects. 14 of 15 subjects tolerated addition of loxapine and tapering or discontinuation of their presenting antipsychotic. At the time of chart review, 14 of 15 subjects had a Clinical Global Impressions Scale- Improvement (CGI-I) of 2 (Much Improved) or 1 (Very Much Improved). In addition, 13 of 15 subjects had a CGI-I of 2 or 1 at $\geq$ 50% of their visits during loxapine treatment. Mean weight loss was significant at -6.65 kg (SD 10.07; median -3.22 kg). Mean BMI reduction was significant at -2.47 (SD 3.3; median -1.67). Mild extrapyramidal symptoms were noted in 3 subjects. No significant change in blood pressure or pulse was noted. Detailed metabolic indicator data, including fasting lipids, fasting glucose, and HbA1c, will be elaborated on.
Conclusions:
Our findings suggest that loxapine may safely enable tapering of an atypical antipsychotic in order to reverse drug-induced weight gain in patients with ASD.

34 **106.034** Medical and Psychiatric Comorbidities in a Cohort of Adults with Autism Spectrum Disorder

N. Brondino[1], L. Fusar-Poli[1], U. Provenzani[1], M. Rocchetti[1], C. Panisi[1], R. Keller[2], F. Barale[1] and P. Politi[1], (1)Department of Brain and Behavioral Sciences, University of Pavia, Pavia, Italy, (2)ADULT AUTISM CENTER, ASL TO2, TURIN, ITALY, Turin, Italy

Background: it is well known that children with autism spectrum disorder (ASD) usually present a wide range of medical comorbidities. Some of these medical conditions, such as epilepsy, gastrointestinal disorders, asthma, autoimmune diseases or sleep disorders, are usually more frequent in this patient group compared to the general population. Unfortunately, to date there is a paucity of data regarding medical and psychiatric co-occurring symptoms in adults with ASD.
Objectives: the aim of the present study is to investigate the presence of medical and psychiatric comorbidities in a cohort of adults with ASD.
Methods: one hundred and fifty subjects were recruited. All participants were screened by a senior psychiatrist who diagnosed ASD and evaluate the current presence of other psychiatric or neurological symptoms. Medical status was evaluated by a physician specialized in internal medicine. Medical charts were thoroughly reviewed in order to obtain information about previous medical problems.
Results: in the entire sample, we observed numerous medical comorbidities such as epilepsy, tuberous sclerosis, celiac disease or gluten sensitivity, systemic lupus erythematosus, etc. We observed a discrepancy according to QI value: ASD patients with intellectual disabilities present more medical comorbidities then patients with higher QI values (p<0.05). The more frequent psychiatric diagnoses were major depression and anxiety disorder.
Conclusions: These preliminary results support the hypothesis of a specific medical risk associated with ASD, with a different pattern according to the presence of intellectual disability. These data will possibly enable physicians to carry on appropriate examinations and to provide prompt care and treatment.

106.035 Medical and Psychiatric Comorbidity Among US Adolescents with Autism Spectrum Disorder from the NCSA

B. Sheppard[1], T. Lateef[2], J. P. He[2], M. D. Fallin[3] and K. R. Merikangas[2], (1)Johns Hopkins School of Public Health, Baltimore, MD, (2)National Institute of Mental Health, Bethesda, MD, (3)Mental Health & Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Background: Autism spectrum disorder (ASD) is a heterogeneous disorder with high prevalence of comorbid learning disability (LD), another neurodevelopmental disorder. ASD is associated with increased risk for a wide range of medical and psychiatric conditions affecting multiple bodily systems, including gastrointestinal (GI), autoimmune/inflammatory, and neurological disorders as well as anxiety and conduct disorders. These comorbid conditions have been shown to cluster differentially within ASD samples.

Objectives: This study evaluates parent-reported ASD and other comorbid disorders in a nationally representative sample of U.S. adolescents to estimate and compare the prevalence and risk of medical and psychiatric comorbidity among ASD youth with and without comorbid LD compared to their typically developing peers.

Methods: The sample included adolescents aged 13-18 who participated in the National Comorbidity Survey – Adolescent supplement (NCS-A) whose parents answered a self-administered questionnaire concerning their child's lifetime health and development, including ASD and LD status (N=6,295). The NCS-A is a nationally representative household survey of adolescent mental health in the US. Participants were recruited between 2001 and 2004. ASD, LD, and status of 9 medical conditions were evaluated by parent report. Psychiatric disorder status was derived from both adolescent interview and parent report and grouped into six categories. Adjusted odds ratios (aOR) were estimated using multivariate logistic regression adjusted for age, sex, race/ethnicity, and household income. All estimates were weighted to represent the national population of adolescents at the time of recruitment and were evaluated at a 95% confidence level.

Results: The overall prevalence of ASD and LD was 0.7% (SE: 0.1) and 14.3%, (SE: 0.7) respectively. Approximately 70% (SE: 8.0) of ASD adolescents also had LD, while 3.6% (SE: 0.9) of adolescents with LD had ASD. There was increased risk for GI (ASD without LD: aOR= 8.83, p= 0.04; ASD with LD: aOR=4.52, p=0.003; LD without ASD: aOR= 1.70, p=0.03) and epilepsy/seizures (ASD without LD: aOR= 16.30, p= 0.005; ASD with LD: aOR=7.60, p=0.003; LD without ASD: aOR= 2.82, p=0.001) across all neurodevelopmentally-affected subgroups compared to typically developing peers. Only ASD without LD adolescents had higher odds of having heart problems (aOR=8.03, p=0.04). ASD with LD was significantly associated with allergy (aOR= 3.41, p=0.02), while ASD without LD approached significance (aOR=3.44, p=0.06).

Conclusions: Overall prevalence and comorbidity between ASD and LD in the NCS-A is similar to other population-based estimates, with a majority of ASD adolescents also having LD. ASD subgroups with and without LD reveal distinct patterns of comorbidity, possibly indicating different biological underpinnings as well as health and social service needs. Increased risk for allergy was specific to ASD. However, increased risk for GI and seizures, two medical conditions thought to be etiologically related to ASD, spanned all affected subgroups, suggesting an overarching neurodevelopmental component to this risk not specific to ASD. These findings highlight the importance of comprehensive multidisciplinary evaluation of youth with ASD.

36 **106.036** Methodological and Reporting Issues in Child Weight Research in ASD

S. N. Grondhuis, The Ohio State University, Jackson, MS

Background: Researchers have been increasingly interested in studying weight in particular groups, such as those with autism spectrum disorder (ASD). They are specifically attempting to identify risk factors and correlates of abnormal weight, possibly for use in prevention or intervention programs, as well as to increase understanding of how prescribing medications could have long-term effects on body mass. While there is literature available that can offer insight, often times the methodology or reporting practices are inconsistent, which can lead to confusion and prevent future results from being compared to existing data. Part of this confusion in weight reporting may stem from authors choosing to report p values and specific results (e.g., odds rations or F tests) in the absence of reporting the amount of variance for which these risk factors were able to account.

Objectives: Identify the amount of variances different studies are able to account for and compare that to the results that are reported in their publications. Evaluate whether the way current data are presented is useful for general consumption, and if not, construct recommendations that will further understanding and allow comparisons to be drawn between studies.

Methods: Search for weight literature using keyterms such as "child," "children," "weight," "overweight," "obese," and "obesity" that were published no earlier than the year 2000. All abstracts were evaluated to see if the paper included (a) original research, (b) identification of a risk factor or correlate of weight, and (c) included statistical outcomes that could be manipulated into amount of variance accounted if it was not explicated stated. If a paper appeared to include these criteria, it was evaluated further. Special attention was given to papers directly including children with ASD.

Results: Preliminary results at the time of abstract submission identified 23 articles that met the criteria mentioned above. Four of the articles related to children with ASD and an additional four related to children with intellectual or developmental disabilities. Although it was expected that

multiple statistical techniques would be used to evaluate weight (multiple regression, logistic regression, etc.), the results produced highly variable outcomes, with amount of variance ranging from .01%-41%.

Conclusions: Most studies where investigators reported statistic that were able to be converted into amount of variance accounted for produced relatively small amounts of variance (less than 8%). If studies accounted for substantially greater amounts of variance, they normally used BMI that was unadjusted for age, which is not recommended for children. Eleven studies out of the 23 preliminarily included were not able to be converted, as they did not include all needed necessary output (e.g., explicit degrees of freedom). Future researchers should be mindful that accounting for considerable variance is difficult, and possibly unlikely in weight studies, and that small numbers should be reported so it is common knowledge. The ASD field is investigating abnormal weight issues with increasing frequency, and as such, it is in our interest to quantify specific results (especially variance) for increased clarity by reporting more than significant p values.

37   **106.037**   New Directions and Research Opportunities for Investigators: Longitudinal Outcomes in the Autism Speaks Autism Treatment Network (AS ATN)

D. S. Murray[1], A. M. Shui[2], K. Kuhlthau[3], D. L. Coury[4] and P. Wang[5], (1)Autism Speaks, Boston, MA, (2)02114, Massachusetts General Hospital, Boston, MA, (3)MGH, Boston, MA, (4)Nationwide Children's Hospital, Columbus, OH, (5)Science Department, Autism Speaks, New York, NY

Background:
The Autism Speaks Autism Treatment Network (AS ATN) Registry, which began enrollment in December 2007, is a multi-center clinical registry that includes both retrospective and prospective data on children ages 2-17 years with ASD. The ATN Registry is unique in containing data on medical co-morbidity, as well as diagnostic, behavioral, and functional assessments. As of December 2013, there were 6854 children enrolled in the AS ATN Registry. While cross-sectional data are valuable, there is a critical need to track children over time in order to better examine the trajectory of medical co-morbidities in ASD and their impact on neurodevelopmental outcomes. A subset of children in the current registry have longitudinal data (medical follow-up visits in year 1, 2, and 3). The AS ATN has made a focused effort over the last 12 months to increase the longitudinal data in the registry to provide researchers with more opportunities to examine medical and clinical changes in children with ASD over time. One of the goals of the AS ATN is to provide opportunities to develop collaborations and partnerships with clinicians and researchers who are external to its current ATN centers.
Objectives:
To make IMFAR attendees aware of the type of longitudinal data available in the AS ATN Registry.
Methods:
Baseline measures including autism assessment, cognitive, behavioral, quality of life, and medications were described. Frequencies for categorical variables were tabulated, and descriptive statistics (number of observations, mean, and standard deviation) were generated for continuous variables. Counts were provided for the number of children with longitudinal data available for each measure.
Results:
The majority of the children in the registry are male (83.9%), Caucasian (80.0%), non-Hispanic (89.8%), have an ASD diagnosis of autism (72.3%), have primary caregiver education level of at least some college (78.8%), and have a mean age at enrollment of 6 years (6.2 ± 3.4). Medication use had the most longitudinal data available. Information on medication use, including ADHD meds, alpha agonists, anticonvulsants, SSRIs, atypical antipsychotics, and melatonin, is available for 2770 children at baseline and first follow-up, for 1242 children at baseline, first, and second follow-up, and for 583 children at baseline, first, second, and third follow-up. Similar counts are provided for the ABC irritability subscale, PedsQL total scale, CGS-severity of autism, CGI-level of autism, Stanford-Binet abbreviated IQ standard score, Vineland adaptive behavior composite standard scores, and several parent form questions.
Conclusions:
Over 6800 children with ASD have been enrolled in the AS ATN Registry, and the ATN continues to enroll and collect longitudinal data on measures such as autism assessment, cognitive, behavioral, quality of life, and medications. Investigators may explore the registry data using the online query tool (*ASATN.org/asatn-query*) and may propose research analyses by submitting a Request for Data (RFD) to the AS ATN. For more information on the RFD please visit *ASATN.org/request/data*.

38   **106.038**   Parental Co-Regulation and Expressed Emotion As Predictors of Psychopathology in Children with ASD

V. Ting, A. Maughan, C. S. Albaum and J. A. Weiss, Psychology, York University, Toronto, ON, Canada

Background: Individuals with an Autism Spectrum Disorder (ASD) often have comorbid mental health problems (Ooi, Tan, Lim, Goh, & Sung, 2011; Totsika, Hastings, Emerson, Lancaster, & Berridge, 2011). Parental co-regulation (i.e. motivational or emotional scaffolding, and using strategies to help their child regulate emotions) has been associated with fewer internalizing and externalizing problems in typically-developing children and those with ASD, 3 to 6 years of age (Hooven, Gottman, & Katz, 1995; Wilson et al., 2013). Indications of low parental negative expressed emotion have also been linked with fewer mental health problems in adolescents and adults with ASD (Smith, Greenberg,

Seltzer, & Hong, 2008). However, expressed emotion and co-regulation have not been studied together, or examined in relation to psychopathology in older children with ASD.

Objectives: To investigate whether parental co-regulation and expressed emotion were related to externalizing and internalizing problems in children with ASD, 8 to 12 years of age.

Methods: Twenty-nine children with ASD (86.2% male) and their caregivers (75.9% female) have participated in a larger ongoing treatment trial to improve emotion regulation, which is expected to increase to 40 participants by April 2015. Children were 8 to 12 years of age ($M = 9.79$, $SD = 1.26$), with average IQ ($M = 102.90$, $SD = 11.91$, Range: 80-125). Parental co-regulation skills (i.e. scaffolding) were measured using a behavioural coding scheme (Gulsrud, Jahromi, & Kasari, 1995), applied to parent behaviours during a standardized *Emotion Discussion Task*. Expressed emotion was measured using the *Autism-Specific Five-Minute Speech Sample* (Benson, Daley, Karlof, & Robinson, 2011). Externalizing and internalizing problems were measured via parent report on the *Behavior Assessment System for Children, Second Edition – Parent Rating Scales* (Reynolds & Kamphaus, 2004). Clinically significant mental health problems were measured by the *Anxiety Disorders Interview Schedule for DSM-IV* (ADIS; Silverman & Albano, 1996).

Results: The following results are based on 20 participants with coded expressed emotion and co-regulation data, and data collection and analysis is ongoing. Pearson correlations were conducted to identify relationships among child characteristics (i.e. age, IQ), parent scaffolding and expressed emotion, and child internalizing and externalizing problems. Level of internalizing symptoms was negatively correlated with parent scaffolding ($r = -.45$, $p = .046$) and positively correlated with overall ADIS severity score ($r = .52$, $p = .006$) and child age ($r = .46$, $p = .016$). Level of externalizing symptoms was negatively correlated with parent scaffolding ($r = -.45$, $p = .047$) and positively correlated with overall expressed emotion ($r = .47$, $p = .037$) and ratio of critical to positive comments ($r = .57$, $p = .009$). With the increased power expected with the larger sample of 40 participants, the poster will also report on multiple regressions to further predict child psychopathology.

Conclusions: Findings will be discussed in relation to supporting parents of children with ASD who are experiencing emotional problems, such as anxiety or aggression. Findings can help inform clinicians on how to best include parents in treatment.

39 **106.039** Parental Eating Disorders and Broad Autism Phenotype Traits: Is There a Link?

J. M. Lee[1], *B. A. Barrionuevo*[2], *N. D. Dueker*[1], *J. R. Gilbert*[1], *M. A. Pericak-Vance*[1] and *M. L. Cuccaro*[2], (1)John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, (2)University of Miami Miller School of Medicine, Miami, FL

Background: Family members of individuals with ASD demonstrate increased social-communicative problems and multiple neuropsychiatric impairments. One class of neuropsychiatric disorders, eating disorders (ED), has not been well-studied in ASD relatives. However, several studies have shown that women with ED, especially anorexia nervosa, display clinically significant scores on measures of ASD symptoms. This study is the first to systematically evaluate the relationship between ED and the broad autism phenotype (BAP) in first-degree relatives.

Objectives: This study will: (1) compare autism trait measures for parents of individuals with ASD who have ED to those without ED; and (2) compare clinical outcomes for the offspring of these two groups.

Methods: Our dataset consisted of 2623 families from the Simons Simplex Collection (SSC), a collection of families containing one individual with ASD and no other first-third degree relatives with an ASD diagnosis.

As part of SSC ascertainment procedures, family histories and multiple measures of ASD traits were collected. Family history interviews included questions about the presence of ED in parents and their relatives. The Broad Autism Phenotype Questionnaire (BAP-Q) and Social Responsiveness Scale: Adult Research Version (SRS:ARV) measured ASD traits.

Descriptive analyses compared ED and non-ED groups on BAP-Q total and subscale scores (Aloof, Pragmatic Language, and Rigidity), and SRS total and subscale scores (Awareness, Motivations, Mannerisms, Cognition, and Communication). The proportion of individuals with clinically significant BAP-Q scores in both groups was also compared. Finally, clinical outcomes in offspring as a function of parental ED were examined.

Results: In total (N=2623), no fathers and 57 (2.2%) mothers had a positive history of ED. Comparison of BAP-Q scores showed that mothers with ED had significantly higher BAP-Q Total ($p=6.6^{10-5}$) and subdomain (Aloof p=0.003; Pragmatic p=1.4^{10-4}; Rigid p=0.013) scores. In contrast, mean SRS total and subdomain scores did not differ between the ED and non-ED mothers.

Among mothers with an ED, there was a significantly higher proportion with an elevated BAP-Q Total score (and elevated subdomain scores). The most significant differences were noted for the BAP-Q Total score [22.8% of those with an ED were positive for the BAP versus only 8.8% without an ED (p=0.0003)] and the BAP-Q Rigid subdomain score [21.1% of those with an ED were positive for this trait vs. 5.6% without an ED (p=1^{10-6})]. Comparisons of offspring of mothers with ED vs. those without ED showed no significant differences in sex, adaptive functioning, or behavior problems.

Conclusions: Our results show that ED were restricted to mothers and lower than population estimates. For mothers with an ED, BAP-Q scores were significantly higher than mothers without an ED and were more likely to meet criteria for the presence of the BAP trait. By contrast, the groups did not differ on any SRS variables.

These results converge with findings of increased ASD features among women with ED. The overlap of ED and elevated BAP-Q scores merits further study to determine if there is also biologic overlap (i.e., common genes or pathways) and which BAP features may heighten risk for ED in select individuals.

40   **106.040** Physiological Arousal Is Related to Parent-and Self-Report of Anxiety in Youth with ASD: Preliminary Evidence for the Concurrent Validity of Anxiety Symptoms

L. Sterling[1,2], J. J. Wood[3] and P. Renno[4], (1)Psychology, Claremont McKenna College, Claremont, CA, (2)Psychiatry, UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (3)Departments of Education and Psychiatry, University of California Los Angeles, Los Angeles, CA, (4)Department of Education, UCLA, Los Angeles, CA

Background: High rates of anxiety have been reported among youth with autism spectrum disorders (ASD). Coexisting symptoms of anxiety have the potential to cause substantial clinical impairment for youth with ASD. However, the diagnostic interview schedules used to assess anxiety in youth with ASD have not been validated in the autism spectrum population, and it is unclear whether the high rates of comorbid anxiety disorders generated by these assessment instruments actually reflect clinical anxiety, or if they reflect a false positive result. Physiological measurement has the potential to serve as an 'objective' index of anxiety given the robust relationship between physiological arousal and manifest anxiety in non-ASD populations.
Objectives: The current study aimed to investigate the concurrent validity of anxiety in ASD by examining the correspondence between physiological response and parent- and self-report of anxiety symptoms. If youth with ASD are actually experiencing clinical anxiety, physiological arousal should theoretically correspond with reported symptoms of anxiety.
Methods: Thirty-two youth with ASD (ages 7-14 years) participated in a startle response paradigm to measure physiological indices of fear conditioning. Skin conductance response (SCR) was collected during the first 3 minutes of baseline, prior to presentation of the first stimulus. The final minute of baseline was used for the current analyses. Youth and their parents also completed the Multidimensional Anxiety Scale for Children (MASC; parent and child versions) and the Child and Adolescent Symptom Inventory-4R (CASI). Results from questionnaires were compared to SCR to investigate whether physiological response paralleled patterns of parent- and child-report of anxiety symptoms.
Results: Correlational analyses revealed strong relationships between baseline SCR and the following subscales of the MASC: Parent Somatic/Autonomic ($r = .356$, $p = .05$), Child Anxious Coping ($r = .644$, $p < .01$), Child Harm Avoidance ($r = .545$, $p < .01$), Child Separation/Panic ($r = .459$, $p < .05$), and Child Total score ($r = .423$, $p < .035$). Additionally, SCR baseline scores were related to the CASI Separation Anxiety Disorder subscale ($r = .439$, $p < .05$).
Conclusions: Results indicate that there is a correspondence between child- and parent-report of anxiety symptoms and physiological measurement of arousal. This provides preliminary evidence for the validation of anxiety symptoms in youth with ASD. Additional physiological data, including heart rate measurements, will be added to the model to further investigate the concurrent validity of anxiety symptoms in this sample. Results from this study have the potential to provide objective evidence that a proportion of youth with ASD actually experience clinical anxiety, which will in turn aid in proper identification of comorbid symptoms and provision of appropriate treatment for youth on the autism spectrum.

41   **106.041** Precision Grip Control with and without Visual Feedback in Autism Spectrum Disorder

S. Mohanty[1], K. A. Neely[2], L. M. Schmitt[1], Z. Wang[1], D. E. Vaillancourt[3], J. A. Sweeney[1] and M. W. Mosconi[1], (1)Center for Autism and Developmental Disabilities, UT Southwestern Medical Center, Dallas, TX, (2)Department of Kinesiology, Penn State University, State College, PA, (3)University of Florida, Gainesville, FL

Background: Sensorimotor abnormalities are common in individuals with autism spectrum disorder (ASD). The ability to grasp objects has been shown to be disrupted in ASD and likely interferes with many activities of daily living such as writing and feeding. During grasping, precise control of force output is regulated by visual, somatosensory and proprioceptive feedback mechanisms as well as motor memory systems. The mechanisms contributing to grasping abnormalities in ASD remain unclear.
Objectives: To examine precision grip in ASD with and without visual feedback.
Methods: Seventeen individuals with ASD and 20 healthy control subjects matched on age, nonverbal IQ and handedness completed a test of precision grip. Participants pressed on opposing load cells with their thumb and index finger (Figure 1A). They viewed a horizontal white *force* bar that moved upwards with increased force and downwards with decreased force and a static *target* bar (Figures 1B & C). They were instructed to press on the load cells so that the *force* bar reached the same vertical level as the *target* bar, and then to maintain that level of force for the duration of 20 sec trials. During *vision* trials, the *force* bar remained visible for the whole trial. During *no-vision* trials, the *force*bar was removed for the last 12 seconds of the trial and participants were instructed to continue producing force at the target level until the trial ended. The target force level was set to 50% of each individual's maximum force for each of six trials (two vision and four no-vision trials). The accuracy (mean force: target force) and slope of the mean force were calculated for the last 12

seconds of each trial.

Results: During the vision condition, there was no difference in force accuracy between individuals with ASD and healthy controls ($p > 0.05$). During the no-vision condition, force accuracy was reduced across participants relative to the vision condition ($p < .001$). Reductions in force accuracy following removal of visual feedback were more severe in ASD compared to controls (group x condition interaction: $p= 0.03$). Participants' force showed a negative slope during the no-vision condition (Figure 2; main effect of condition: $p < .001$), and this slope was more negative for individuals with ASD compared to controls (group x condition interaction: $p=.04$).

Conclusions: Our findings indicate that individuals with ASD and controls show similar levels of precision grip force accuracy when visual feedback is provided, but force accuracy deteriorates more rapidly in ASD when visual feedback is not available. Vision plays a dominant role in guiding motor output. However, other sensory feedback mechanisms including somatosensory and proprioceptive control processes as well as motor memory systems play important roles in regulating precision grip forces. Thus, deficits in somatosensory and proprioceptive feedback control processes and motor memory mechanisms appear to contribute to impairments in precision grasping in ASD and may underlie the commonly seen abnormalities in handwriting and feeding behaviors in this disorder.

42   **106.042** Psychiatric Follow up of Children and Adolescent with Past History of Autism

N. M. Mukaddes[1], T. Mutluer[2], B. Pasabeyoglu[3] and A. Umut[4], (1)Istanbul Institute of Child and Adolescent Psychiatry, Istanbul, Turkey, (2)Child Psychiatry Clinic, Van Education and Research Hospital, Van, Turkey, (3)Department of Child and Adolescent Psychiatry, Bakirkoy Professor Mazhar Osman Mental Health and Disorders Hospital, Istanbul, Turkey, (4)Istanbul Institute of Child &Adolescent Psychiatry, ISTANBUL, Turkey

Background: Autism spectrum disorders (ASDs) were once considered lifelong disorders, but recent studies show that some children with diagnosis of ASD no longer meet the criteria for ASD. These children are considered to have achieved optimal outcome (OO)(Fein 2013 ,Orienstein 2014,Mukaddes 2014). Despite the presence of a few studies reporting optimal outcome in this group, there is lack of follow up studies in this group.

Objectives: The present study aims to assess the psychiatric disorders in individuals who lost the diagnosis of autism.

Methods: Twenty six individuals (21 male, 5 female) were included in this study with the age range: 6-16 years old (mean age: 9,1923 +/- 2,87081). They all lost the diagnosis of autism at least two years before follow up examination.The participants were recruited from a group of individuals with past history of autism who were diagnosed and assessed previously by the first author. The characteristics of this group has been described in another study from the same group (Mukaddes et al 2014). From 39 individuals who lost the diagnosis of autism and were reported earlier, individuals who achieved optimal outcome at least two years before were included.All individuals were assessed by a team of child psychiatrists and a clinical psychologist.The follow up clinical assessment was done 2 to 8 years   after losing the diagnosis of autism. Assessment and Measurements included:a)Systematic psychiatric interview with both children and parents based on Schedule for Affective Disorders and Schizophrenia for School-Age Children Present and Lifetime Version (K-SADS -PL) ,b) Intelligence quotient (IQ.) assessed using the Wechsler Intelligence Scale for Children—revised version(WISC-R) ,c) Autistic features were assessed using Social Comunication questionnaire (SCQ)(current).All data were organized in Microsoft Excel 2010, and all statistical tests were conducted in Excel. Relationships between parametric values were assessed using the Pearson correlation coefficient in the Statistical Package for Social Sciences (SPSS) 18.0, SPSS Inc., Chicago, Illinois, USA.

Results: According to K-SADS -Lifetime, 92.3 % of individuals (n:24) had at least one psychiatric disorder. ADHD (% 69.2 , n:18), specific phobia (% 46.2 , n:12) and OCD (% 38.5 ,n:10) were the most common life time disorders in this group.K-SADS -P revealed the presence of psychiatric disorders in 76.9 % of the group (n:20) . ADHD (% 53.8 , n:14), Specific Phobia (% 46.2 , n:12) and OCD (%19.2 , n:5) were the most common psychiatric disorders in K-SADS -P.Based on WISC-R test, all the participants showed performance in non- retarded range. Their Full IQs were between 73-148.Their SCQ revealed the total score between 1 -13 (cutoff score>15 is necessary for ASD).

Conclusions: The present study shows that although some children lose the diagnosis of autism, they are prone to develop other psychiatric disorders later in life. Therefore, long term psychiatric follow up of this group seems necessary even after achieving optimal outcome.

43   **106.043** Psychophysiological Predictors of Gastrointestinal Symptomatology in Autism Spectrum Disorder

B. Ferguson[1], S. Marler[2], E. B. Lee[3], J. E. Akers[4], M. O. Mazurek[5], K. Sohl[6], A. McLaughlin[5], B. Kille[5], K. Hartnett[5], E. A. Macklin[7], E. McDonnell[8], L. Alstein[9], J. Veenstra-Vander Weele[10] and D. Q. Beversdorf[11], (1)University of Missouri-Columbia, Columbia, MO, (2)Psychiatry, Vanderbilt University, Nashville, TN, (3)Pediatrics, Vanderbilt University, Nashville, TN, (4)Research Core, Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO, (5)University of Missouri, Columbia, MO, (6)Child Health, University of Missouri - Thompson Center, Columbia, MO, (7)Biostatistics Center, Massachusetts General Hospital and Harvard Medical School, Boston, MA, (8)Biostatistics,

Massachusetts General Hospital, Boston, MA, (9)Massachusetts General Hospital, Boston, MA, (10)Psychiatry, Columbia University / New York State Psychiatric Institute, New York, NY, (11)Radiology, Neurology, Psychological Sciences, University of Missouri, Columbia, MO

Background: Research suggests that individuals with Autism Spectrum Disorder (ASD) tend to suffer from a high rate of gastrointestinal (GI) disorders, but the underlying biology and etiology of GI disorders in ASD is not clearly understood. In the general population, there is a strong relationship between stress and GI symptomatology, and evidence suggests an augmented stress response in ASD. Taken together, it is possible that GI symptoms in those with ASD may vary as a function of stress reactivity. Determining the cause of GI disorders in ASD is important given their associations with sensory over-responsivity and stress, which can exacerbate problem behaviors. Understanding of the relationships among GI symptoms, stress, and behavior will be critical in planning future studies and better individualizing treatment.

Objectives: The present investigation examined the relationship between GI symptomatology and heart rate variability (HRV), a measure of stress reactivity, in those with ASD. Given the relationship between stress and GI symptoms, we hypothesized that a negative relationship would exist between HRV and GI symptomatology.

Methods: Children and adolescents from Missouri and Vanderbilt ATN sites (n = 101, Mean Age =12.2, SD =3.8, Range = 6-18) with an ASD diagnosis were outfitted with a 2-lead ECG apparatus. Initial baseline reactivity to the testing environment was taken for a period of 3 minutes. Next, to examine stress reactivity, participants engaged in independent trials of unilateral cold pressor and vibrotactile stimulation to the hands for 30 seconds in a counterbalanced fashion. After artifacts in the data were removed, the R-R interval data (average pulse interval) were processed, and the percentage of normal R-R intervals during each trial were calculated for each stimulus condition, and for each hand. Baseline and cold pressor stress reactivity are reported here. To assess GI symptomatology over the past 2 months, the participant's caretaker completed the QPGS Rome-III, and a continuous severity score was calculated with higher scores indicating greater GI severity.

Results: Results indicate that a significant positive correlation was found between lower GI symptomatology and baseline heart rate variability (Pearson correlation r = 0.23, p=0.024). Furthermore, a significant negative correlation was found between lower GI symptomatology and the change in heart rate variability from baseline under cold pressor stimulation (Pearson correlation r = -0.32, p=0.002). Similar but slightly weaker associations were observed with upper GI symptomatology (baseline: r = 0.18, p=0.08; cold pressor change: r = -0.26, p=0.01).

Conclusions: These findings suggest that altered autonomic function and reactivity may co-occur with lower GI symptoms in ASD. From these correlational data, it is unclear whether stress and stress reactivity may trigger GI symptoms, whether GI symptoms could exacerbate stress or stress reactivity, or whether abnormalities in both domains might reflect a common underlying pathophysiology that spans these systems in ASD. Future treatment work may be necessary to understand the directionality of this association.

44 **106.044** Relationships Between ASD/ADHD Symptoms and Abnormal Eating Behaviors in Children

M. Hamada[1], H. Ito[2], Y. Murayama[3], M. Katagiri[4], A. Uemiya[4] and M. Tsujii[5], (1)Osaka-Hamamatsu Joint Center for Child Development, Hamamatsu University School of Medicine, Hamamatsu-city, Japan, (2)Hamamatsu University School of Medicine, Nagakute, Aichi, Japan, (3)Hamamatsu University School of Medicine, Hamamatsu-shi, Japan, (4)Hamamatsu University School of Medicine, Hamamatsu-city, Japan, (5)Chukyo Univesity, Toyota, Japan

Background: Some people with autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD) symptoms also have eating disorders. An increasing number of studies have dealt with comorbidity of eating and developmental disorders. Anorexia nervosa overlaps with ASD (Iwasaki et al., 2014; Oldershaw et al., 2011), while binge eating behaviors are associated with ADHD (Nazar et al., 2014). It is important to recognize people with ASD and ADHD symptoms who have abnormal eating behaviors. Despite the correlation between ASD and ADHD, little previous research has investigated their connection to eating disorders at the same time. Therefore, it is necessary to consider ADHD symptoms as covariant. Furthermore, most previous studies investigated clinical groups. Thus, there is little research examining the relationship of ASD and ADHD symptoms with eating behaviors in the general population in Japan.

Objectives: The present study investigated whether ASD and ADHD symptoms are related to abnormal eating behaviors in elementary and junior high school students in Japan.

Methods: Participants were 4584 children from 4th to 9th grade students enrolled in all elementary and junior high schools of a single city. 2314 were boys and 2270 were girls. The children completed an eating behavior inventory that measured propensity of anorexia and bulimia (Ito et al., submitted). Their parents or caregivers completed two questionnaires: the Autism Spectrum Screening Questionnaire (ASSQ; Ehlers, Gillberg, & Wing, 1999) for ASD symptoms and the ADHD Rating Scale (ADHD-RS; Dupaul, Power, Anastopoulos, & Reid, 1998) for inattention/hyperactivity. To investigate the effect of ASD and ADHD symptoms on the propensity of anorexia and bulimia, polynominal regression analysis was conducted.

Results: The analysis found that the linear effect of ASSQ (β=.062, p=.011) and ADHD-RS (β=.086, p<.001) were significant regarding propensity of anorexia. In terms of propensity of bulimia, the liner and nonlinear (quadratic) effect of ASSQ (liner; β=.062, p=.017, nonlinear; β=-.057, p=.018) and the

liner effect of ADHD-RS (β=.140, p<.001) were significant. (Fig.1) The other was not significant. Conclusions: First, both propensity of anorexia and bulimia are affected by ASD and ADHD symptoms. This relationship is supported by previous research, which refers to similar results in clinical cases. Second, propensity of bulimia is affected more by ADHD symptoms than by ASD symptoms. It is thought that aspects of ASD symptoms associated with poor social skills and those of ADHD symptoms associated with impulsivity may be associated with abnormal eating behaviors. These findings suggest that investigation of ASD and ADHD symptoms may lead to more appropriate treatment for people exhibiting abnormal eating behavior.

45 **106.045** Sensory Feedback Mechanisms Underlying Postural Control Abnormalities in Individuals with Autism Spectrum Disorder (ASD): A Preliminary Study

Z. Wang[1], R. Hallac[2], K. Conroy[1], R. Greene[3], S. P. White[3], J. A. Sweeney[1] and M. W. Mosconi[4], (1)Center for Autism and Developmental Disabilities, UT Southwestern Medical Center, Dallas, TX, (2)Analytical imaging and modeling center, Children's Health, Dallas, TX, (3)Center for Autism and Developmental Disabilities, University of Texas Southwestern Medical Center, Dallas, TX, (4)Psychiatry and Pediatrics, Center for Autism and Developmental Disabilities, UT Southwestern Medical Center, Dallas, TX

Background: Postural control abnormalities have been demonstrated in some but not all studies of autism spectrum disorder (ASD). These prior studies have quantified the amount of sway during standing, but stability also depends on each individual's postural limitation boundary, or the maximum extent to which they may sway in each direction without losing their balance. In the present study, we examined postural sway relative to each individual's postural limitation boundary (virtual time to contact; VTC) in individuals with ASD and healthy controls (Fig.1A).
Objectives: To examine the range of center of pressure (COP) fluctuations as well as spatial and temporal VTC complexity for individuals with ASD and healthy controls during both static and dynamic standing postures.
Methods: Six children with ASD (ages 11-16 yrs) and 6 healthy controls matched on age, sex and non-verbal IQ completed tests of static and dynamic stances. Prior to testing, participants were instructed to stand side-by-side with their feet shoulder width apart on a force platform. Their foot position was traced on the platform so that their starting position at the beginning of each trial was consistent. Participants' postural limitation boundary was determined by having them leaning their body in each of four different directions (anterior, posterior, left and right) as far as they could without fallingand then fitting an ellipse to the COP maxima for each direction (Fig. 1B). COP measurements were derived from the force platform output.
During *static* stance trials, participants were instructed to stand as still as possible. During dynamic stance trials, participants were instructed to continuously sway their body either anterior-posteriorly (AP) or medial-laterally (ML) at a comfortable speed. Participants completed three 30-sec trials for each stance. Each participant's VTC was derived by comparing the spatial and temporal relation between their postural limitation boundary and their COP collected during each trial. To examine participants' ability to dynamically adjust their postural sway over time in response to sensory feedback, the spatial and temporal complexity of each participant's VTC also were compared.
Results: During static stance, individuals with ASD showed **increased** COP range of motion in both AP and ML directions (p <0.05) and decreased spatial and temporal VTC complexity (p<0.05). During dynamic stances, patients showed **reduced** COP range of motion in each postural sway condition (p<0.05), but again they showed decreased VTC complexity in both spatial and temporal domains (p<0.05).
Conclusions: Our findings suggest that individuals with ASD show reduced postural stability relative to controls, but the quality of this deficit varies across different types of postural conditions. While traditional measures of postural stability highlight both increases and decreases in sway during static and dynamic stances, respectively, we find that the spatial and temporal complexity of patients' sway is reduced in ASD across stances. Thus, patients demonstrate deficits in their ability to dynamically adjust their balance across different postural conditions reflecting a reduced ability to integrate sensory feedback to maintain postural stability.

46 **106.046** Sleep Disturbance and Aggression in Children with Autism Spectrum Disorder : An Autism Speaks Autism Treatment Network Analysis

G. P. Cejas[1], E. Anbalagan[2], G. Singh[1], R. Brown[1] and K. Sohl[3], (1)University of Missouri, Columbia, MO, (2)University of California at San Diego, San Diego, CA, (3)Child Health, University of Missouri - Thompson Center, Columbia, MO

Background: Autism Spectrum Disorders are defined by impairments in behavior, communication, and social skills that initially appear in childhood. Children and Youth with Autism Spectrum Disorders (CYASD) frequently experience sleep disturbances, with bedtime resistance being especially problematic. Recent studies show that children with autism and sleep disturbances have worse adaptive skill development and greater behavior difficulties than children with autism without sleep difficulties. In addition, children with autism with more severe core symptoms were more likely to have increased sleep problems.
Objectives: **1)** Examine the prevalence of sleep problems and aggression in CYASD. **2)** Examine

relationship link between sleep disturbances and behavior problems in CYASD.

Methods: Data was analyzed from 100 CYASD diagnosed with autism during the calendar year 2012-2013. All patients analyzed received diagnosis and care at an Autism Speaks Autism Treatment Network Center of Excellence, affiliated with an academic medical center. Demographic information and specific variables were analyzed including mood lability, sleep quality, aggression, communication skills and IQ. Behavioral and mood items were measured via parent/legal guardian reporting.

Results: Sleep disturbances were reported in 56% of patients; of these, 64.3% experienced symptoms of aggression, and 98.2% experienced mood lability. Of the 44% of patients who did not experience sleep disturbances, only 31.8% of patients had aggression and 90.9% experienced mood lability. The mean difference in IQ between those with and without sleep disturbances was only 4.3 points.

Conclusions: CYASD have a high prevalence of sleep disturbance, yet the behavioral manifestations of sleep disturbance are not well elucidated. This study supports previous findings of mood lability in CYASD and further delineates marked aggression in this subset of CYASD. Currently, sleep disturbances are an underrecognized co-occurring condition in CYASD. Care for CYASD is multifaceted and complex including social, emotional, behavioral and medical treatments. Findings from this study support the need for increased awareness and assessment of sleep concerns in CYASD to maximize understanding of behaviors and inform treatment planning. Larger studies looking at the correlation between sleep and aggressive behaviors will be an important next step.

47 **106.047** Sleep Problems in Autism Spectrum Disorders: The Influence of Anxiety, Restricted and Repetitive Behaviours and Intolerance of Uncertainty

E. K. Baker[1], A. L. Richdale[2] and D. Soliman[3], (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Cooperative Research Centre for Living with Autism Spectrum Disorders (Autism CRC), Brisbane, Australia, (3)School of Psychological Science, La Trobe University, Olga Tennison Autism Research Centre, Bundoora, Australia

Background: Sleep problems are one of the most common comorbidities experienced by individuals with ASD. While sleep problems have been well characterized in children with ASD less is known about the types of sleep disturbances experienced by adults with ASD. Further, the aetiology of the sleep disturbances is relatively unknown. It has been suggested that the inherent anxiety experienced by those with ASD may predispose them to experience sleep problems. In addition, core behaviours associated with ASD such as restricted and repetitive behaviours and an intolerance for uncertainty may also lead to delayed sleep onset and reduced total sleep time.

Objectives: The aim of this study was to investigate the relationships between sleep disturbance and symptoms of anxiety, restricted and repetitive behaviours (RRBs), and intolerance of uncertainty in adults with ASD and no intellectual impairment compared to age-, sex-, and IQ-matched NT adults.

Methods: Thirty adults with ASD and 30 NT adults participated in the study. Participants completed an online questionnaire battery that contained the Autism Quotient, the Pittsburgh Sleep Quality Index (PSQI), the State Trait Anxiety Inventory (STAI), the Restricted Behaviour Questionnaire-2 Adult (RBQ-2A), and the Intolerance of Uncertainty Scale (IUS).

Results: Adults with ASD had higher total PSQI scores as well as higher scores on the sleep quality, sleep latency, sleep disturbance, and daytime dysfunction due to sleepiness subscales of the PSQI; effect sizes were moderate to large. Adults with ASD had significantly higher total and subscale scores on the STAI, RRB-2A, and IUS; all effect sizes were large. In assessing the relationship between sleep and the other variables, PSQI total scores were significantly correlated with both state ($r = .63$) and trait ($r = .52$) anxiety and the rigidity/adherence to routine subscale of the RBQ-2A and the uncertainty paralysis ($r = .46$) of the IUS. There were no significant correlations between PSQI scores and any of the other variables in the NT group. Hierarchical regression was used to determine predictors of PSQI scores in the ASD group; state anxiety, rigidity/adherence to routine and uncertainty paralysis were entered into the regression. The model accounted for 37.5% of the variance in PSQI scores, with only state anxiety being a unique predictor.

Conclusions: This is one of the first studies to assess the relationship between sleep, anxiety, RRBs, and intolerance of uncertainty in adults with ASD. As expected adults with ASD had higher scores on all questionnaire measures and subscales, confirming that atypical sleep persists from childhood into adulthood in ASD. While RRBs and intolerance of uncertainty were related to sleep problems in the ASD group, only state anxiety was a unique predictor of PSQI scores. Treatments that aim to target anxiety, particularly around the onset of sleep, may improve sleep. Further, this may have a direct effect on RRBs and the experience of intolerance of uncertainty.

48 **106.048** Sleep Problems in Children with Autism Spectrum Disorder: Examining the Role of Anxiety and Sensory over-Responsivity

M. O. Mazurek[1] and G. Petroski[2], (1)Department of Health Psychology, University of Missouri, Columbia, MO, (2)Department of Health Management and Informatics, University of Missouri, Columbia, MO

Background:

Sleep problems are common among children with autism spectrum disorder (ASD), and can have significant detrimental effects on daytime functioning. Hyperarousal is often associated with insomnia in the general population and may also underlie sleep difficulties for children with ASD, particularly

given their increased risk for arousal-related symptoms. Emerging evidence from previous studies suggests that specific arousal-related symptoms, sensory problems and anxiety, may be related to the development and maintenance of sleep problems in children with ASD. However, research has yet to explore the associations between these symptoms.

Objectives:

The goal of the current study was to examine the bivariate and multivariate relationships among anxiety, sensory over-responsivity, and specific sleep problems in a large well-characterized sample of children and adolescents with ASD.

Methods:

Participants included 1348 children and adolescents (ages 2-18) enrolled in the Autism Speaks Autism Treatment Network (AS ATN) registry database. Primary measures included the Children's Sleep Habits Questionnaire (CSHQ), Child Behavior Checklist (CBCL), and Short Sensory Profile (SSP).

Results:

In bivariate correlations and multivariate path analyses, anxiety was associated with each type of sleep problem examined (i.e., bedtime resistance, sleep onset delay, sleep duration, sleep anxiety, and night awakenings; ranging from $p < .01$ to $p < .001$; small to medium effect sizes). Sensory over-responsivity (SOR) was correlated with all sleep problems in bivariate analyses (ranging from $p < .01$ to $p < .001$; small effect sizes). In the multivariate path model for older children (ages 6-18), SOR was significantly associated with all sleep problems except night awakenings. In contrast, in the path model for younger children (ages 2-5), SOR was significantly associated with sleep onset delay, night awakenings, and sleep duration, but not bedtime resistance or sleep anxiety.

Conclusions:

The purpose of this study was to examine the relationships among three common co-occurring problems for children with ASD: sleep problems, sensory problems, and anxiety. Despite evidence to suggest that these three conditions may be highly related, this was the first study to examine their interrelations in children with ASD. Consistent with our predictions, the results indicate that children with ASD who have anxiety and SOR may be particularly predisposed to sleep problems. These data provide support for the idea that sleep problems in many children with ASD may be due to arousal dysregulation, and that hyperarousal may represent a shared underlying mechanism. Future research using physiological measures of arousal and objective measures of sleep are needed. Longitudinal studies would also be helpful to identify patterns of sleep, anxiety, and sensory problems over time.

49   **106.049** Suicidal Ideation in Korean Children at-Risk for Autistic Spectrum Disorder (ASD)

V. Hus Bal[1], B. Leventhal[1], G. Carter[2], G. Yim[1], P. S. Hong[1] and Y. S. Kim[1], (1)Dept of Psychiatry, University of California San Francisco, San Francisco, CA, (2)University of Newcastle, NSW, Australia

Background: High rates of suicidal behaviors have been reported in individuals with ASD (e.g., Cassidy et al., 2014). Reported risk factors for suicidal behavior in ASD are male gender, comorbid psychiatric diagnosis and peer victimization (see Segers & Rawana, 2014). Studies have been in clinic- or community-based samples of ASD participants; no studies of prevalence or risk factors have drawn from representative, population-based samples.

Objectives: 1) Examine prevalence of current suicidal ideation (SI) in population-based samples of 7-12 year olds diagnosed with ASD or classified as high- or low-risk for ASD. 2) Determine whether having ASD is a risk factor for SI in addition to previously reported risk factors for SI. 3) Within the ASD group, explore differences between children with and without SI.

Methods: A retrospective cohort design was used in three population-based samples (Korean Prevalence=13,561, Sooncheon=4,837, CHEER=3,702). In the Korean Prevalence sample, 94 children had ASD diagnoses confirmed by comprehensive diagnostic assessment and were compared to 13,467 children with ASSQ scores <14 (low-risk). In the Sooncheon and CHEER cohorts, children were classified as high-risk for ASD based upon a score of >14 on the Autism Spectrum Symptom Questionnaire (ASSQ). Current SI was determined by items from the parent-rated Behavior Assessment for Children, 2nd Edition (BASC).

Differences in proportions (prevalence) were tested with Chi Square. Logistic regressions were used to determine whether ASD diagnosis/ASD risk status was a significant predictor of SI in addition to previously reported risk factors (gender, BASC scales reflecting emotional/behavior problems and items suggesting negative social experiences). Analyses were repeated for each of the samples. Independent Sample T-tests were used to compare ASD+SI vs. ASD+NoSI on age and BASC scales to inform understanding of factors that may relate to increased risk for SI within individuals with ASD.

Results: For the Korean prevalence study, SI was significantly more common in children with confirmed ASD (14.9%) than children at low-risk for ASD (5.4%; OR=3.09, CI95% 1.75-5.49). Logistic regression models showed that ASD diagnosis was a significant predictor of SI (OR=2.13, CI95% 1.15-3.92). Being teased (OR=1.96, CI95% 1.66-2.33) and chosen last for games (OR=1.84, CI95%=1.56-2.17), and scores from BASC scales of depression, hyperactivity, aggression, conduct problems, anxiety, and attention problems were also significant predictors of SI. Gender was not associated with SI. Children

with ASD+SI had more anxiety symptoms than children with ASD+NoSI (p<.01); groups did not differ on age or other BASC scales.

Children at high-risk for ASD had greater prevalence of SI than children with low ASD risk in the Sooncheon (16.6% vs. 3.4%; OR=5.59) and CHEER cohorts (27.4% vs. 6.9%; OR=5.08). Patterns of predictors of SI were similar to the Korean Prevalence sample.

Conclusions: Children with ASD or suspected high-risk for ASD had increased prevalence of current SI in all three Korean samples. Clinical implications for assessment and monitoring of SI in children with ASD will be discussed. Interventions in ASD aimed at reducing exposure to modifiable risk factors should focus on emotional and behavior problems, as well as negative social experiences.

50 **106.050** Suicidality in Children with Autism Spectrum Disorders

A. C. Armour[1], Y. Granader[1], A. B. Ratto[1], C. E. Pugliese[1], J. L. Martucci[2], L. Mohamed[3], L. Kenworthy[4] and J. F. Strang[5], (1)Center for Autism Spectrum Disorders, Children's National Medical Center, Rockville, MD, (2)Children's National Medical Center, Rockville, MD, (3)Children's National Health System, Rockville, MD, (4)Children's Research Institute, Children's National Medical Center, Washington, DC, (5)Center for Autism Spectrum Disorders, Silver Spring, MD

Background: Studies indicate that children with Autism Spectrum Disorders (ASD) have increased rates of suicide ideation and attempts (SI/SA). The available literature indicates demographic characteristics (age 10+, male, African American, Hispanic, low SES) and psychological characteristics (depression, teasing/bullying, aggression, impulsivity and anxiety) as risk factors for SI/SA.

Objectives: Based on studies of SI/SA, as well as depression in ASD, we hypothesize that AD/HD diagnosis, impulsivity, executive dysfunction (especially inflexibility), and weak adaptive skills are related to increased SI/SA , while lower IQ and greater autism symptoms (poorer insight/self-awareness) are related to reduced SI/SA.

Methods: Parents of 199 youth with ASD (female=32), age 7-13.83 (M=10.15, SD=1.72), who met CPEA criteria for 'broad ASD' on the ADI-R and/or ADOS, completed clinical reports on their children. SI/SA were measured with item-level data from the Child Behavior Checklist and the Child and Adolescent Symptom Inventory parent-report measures of emotional and behavioral functioning. Independent samples t-tests and chi-square analyses were used to compare youth with and without SI/SA with ADHD diagnosis, Behavior Rating Inventory of Executive Function (BRIEF) scores, Vineland Adaptive Behavior Scales, and ADOS ratings.

Results: 16.1% of youth with ASD had parent reported SI/SA. SI/SA and non-SI/SA groups did not differ in their sex or age. Problems with inhibition (p<.01), shifting (p<.01), and emotional control (p<.01) were greater in those with SI/SA (see Figure 1). The comparison of those with SI/SA and greater ADHD symptoms approached significance, as did adaptive behavior weaknesses. There were no significant differences between the groups in IQ or ASD symptoms.

Conclusions: Youth with ASD who consider or attempt suicide had poorer inhibition and flexibility skills. Greater ADHD symptoms and poor adaptive behavior approached significance. Findings indicate the importance of considering ADHD, executive function (i.e., flexibility), and adaptive behavior as risk factors when assessing for SI/SA.

51 **106.051** The Relationship of ASD Symptoms with the Occurrence of Self-Injury Behaviors Among Middle School Students

Y. Murayama[1], H. Ito[2] and M. Tsujii[3], (1)Hamamatsu University School of Medicine, Hamamatsu-shi, Japan, (2)Hamamatsu University School of Medicine, Nagakute, Aichi, Japan, (3)Chukyo Univesity, Toyota, Japan

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder involving significant phenotypic variability, and is characterized by social and communication deficits in addition to restricted and repetitive behaviors (American Psychiatric Association, 2000). Children with ASD often exhibit comorbidity with behavioral problems as well as psychiatric symptoms (e.g. Lecavalier, 2006). One of the most serious problems is self-injury behavior (SIB). It has been reported that up to 52% of ASD children show more than one type of SIB (Poustka & Lisch, 1993). Because SIB is a risk factor for increased suicidal ideation and probability of suicidal attempts (Glenn & Klonsky, 2009), it is crucial to provide appropriate, sufficient supports with children and adolescents with ASD. It is not specific to children and adolescents with ASD, but it is common among school-aged children (Camelot Foundation & Mental Health Foundation, 2006). However, there are few studies to investigate the relationship between ASD symptoms and SIB among school aged children. We have little known about whether ASD symptoms have any effects on the occurrence of SIB.

Objectives: The present study examined the effects of ASD symptoms on the occurrence of SIB among students from seventh through ninth grades in Japan.

Methods: The participants were students (N =2,181) attending all junior high schools in a city, along with their parents. The students completed a questionnaire to assess the occurrence of two types of SIB, hitting and cutting. Their parents answered the Autism Spectrum Screening Questionnaire (Ehlers, Gillberg, & Wing, 1999) and the Attention Deficit Hyperactivity Disorder (ADHD) Rating Scale-IV (Du Paul et al., 1998), to assess the ASD and ADHD symptoms that the students exhibited. Multivariate logistic regression analysis was performed to study the effect of ASD symptoms on SIB

over and above the effects of age, grades, and ADHD symptoms
Results: Multivariate logistic regression analysis indicated that after controlling for age, grade, and ADHD symptoms, ASD symptoms had an effect on the occurrence of both types of SIB that we assessed. Specifically, students with more severe ASD symptoms were more likely to engage in both hitting and cutting SBI (hitting SIB: $OR = 1.404$, $p < .001$; cutting SIB: $OR = 1.371$, $p = .001$). Age and ADHD symptoms also had a significant influence on the occurrence of SIB. Female students were more likely to engage in both types of SIB, and students with severe ADHD symptoms had a higher probability of the hitting SBI.
Conclusions: The current study indicated that even after controlling for sex, grade, and the severity of ADHD symptoms, ASD symptoms had a significantly influence on the occurrence of SIB, which suggests that ASD symptoms are a risk factor for SBI. In addition to the result of the current study, previous studies have reported that children and adolescents with ASD show higher levels of depression, which increases the probability of SIB (e.g., Kim et al., 2000). Therefore, we should provide children and adolescents with ASD, even those who have not official diagnosis, with sufficient psychosocial support to prevent them from engaging in SIB.

52   **106.052** The Role of Verbal Ability in the Co-Occurrence of Problem Behaviours and Gastrointestinal Symptoms in Autism Spectrum Disorders

C. Horlin[1] and E. Anagnostou[2], (1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: Autism Spectrum Disorders (ASD) is frequently associated with behavioural, neurological, and medical comorbidities. Maladaptive and problem behaviors are often observed in individuals with ASD and largely considered to be part of its constellation of neurological abnormalities (Horvath, Papadimitriou, Rabsztyn, Drachenberg, & Tildon, 1999). However recent studies have linked problem behaviors, anxiety and irritability with gastrointestinal (GI) symptoms, another common comorbidity for children with ASD.
The co-occurrence of maladaptive problem behaviors and GI symptoms in individuals with ASD has been examined within the literature (Gorrindo et al., 2012; Maenner et al., 2012; Mazefsky, Schreiber, Olino, & Minshew, 2013; Mazurek et al., 2013; Nikolov et al., 2009). However, although the potential contributory role of expressive language deficits has been mentioned (Gorrindo et al., 2012), it is yet to be formerly examined. In a group of disorders characterized by socio-communicative and language difficulties, it is possible that gastrointestinal pain or discomfort improperly expressed emerge as irritability, aggression, or atypical physical or self-injurious behavior (Bauman, 2010; Buie et al., 2010; Horvath et al., 1999)
Objectives: To examine the relationship between the presence of GI symptoms in children with ASD and manifest behavioral and affective problems, and investigate the possible mediating role of expressive language ability.
Methods: Children and adolescents with ASD were examined in regards to expressive language ability, GI symptomatology and maladaptive behaviors.
Results: Children with concurrent GI symptoms exhibited significantly more problem behaviors on the CBCL compared to children without GI symptoms. No significant relationship was found between problem behaviors and expressive language and as such the mediational hypothesis was not supported. Contrary to expectations, children with GI symptoms exhibited significantly higher expressive language.
Conclusions: In accordance with previous literature, children with ASD and comorbid GI symptoms were reported to exhibit more problem behaviours. In this instance, impairments in expressive language were not found to contribute to the relationship between the presence of GI symptoms and behavioral and affective problems.

53   **106.053** Variability in Autism Symptom Severity: The Role of Diurnal Cortisol and Daily Stress in Youth with Autism Spectrum Disorder

P. Renno[1], L. Sterling[2], J. T. McCracken[3], K. S. Mallya[4] and J. J. Wood[5], (1)Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, (2)Claremont McKenna College, Los Angeles, CA, (3)Psychiatry and Biobehavioral Sciences, UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (4)Department of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (5)Departments of Education and Psychiatry, University of California Los Angeles, Los Angeles, CA

Background: The literature indicates increased rates of anxiety disorders in children with autism spectrum disorder (ASD); however, little research has investigated the determinants and consequences, physiologic and functional, of anxiety in ASD. Wood and Gadow (2010) have proposed a model in which daily stressors contribute to increased mood dysregulation and anxiety, which then exacerbates clinically impairing ASD symptoms.
Objectives: The current study aimed to investigate the relation between diurnal cortisol levels and parent-report of ASD-related stressors in youth with ASD. Secondly, it aimed to examine the relations among daily stressors, anxiety, and ASD symptom severity by testing Wood and Gadow's (2010) hypothetical mediational model.

Methods: Participants were 43 youth, aged 7-14, with ASD. Cortisol levels were collected at four time points throughout the day for three days. Parent, child and diagnostician reports of daily stressors (e.g., Stress Schedule Survey), anxiety symptoms (e.g., Pediatric Anxiety Rating Scale), and ASD symptom severity (e.g., Social Responsiveness Scale) were collected.

Results: Results from multilevel modeling suggest diurnal cortisol samples in youth with ASD follow a similar daily pattern established in the typically developing population, and that increased daily cortisol is related to greater ASD-related daily stressors ($t = 2.34$, $p < .05$). Additionally, results from path analysis suggest anxiety partially mediates the relation between ASD-related stressors and ASD-symptom severity.

Conclusions: Findings from this study establish a relation between physiological response and subjective reports of stressors and anxiety in youth with ASD and suggest that increased stressors contribute to greater anxiety and ASD symptom severity. These results suggest that treatments aimed at reducing anxiety and stressors in youth with ASD may also affect core ASD symptom severity and impairment. Future research should continue to investigate these potential relations, other related factors, and response to treatments for increased anxiety and ASD symptom severity in youth with ASD.

54 **106.054** Who Are You Afraid of?: Stress Response to Performance Evaluation in Young Adults Diagnosed with ASD

C. Nielson[1], M. E. Maisel[2], C. Kindt[1], S. Shahan[2], T. Homewood[1], A. Grow[2], A. Ashton[2] and M. South[3], (1)Neuroscience Center, Brigham Young University, Provo, UT, (2)Department of Psychology, Brigham Young University, Provo, UT, (3)Psychology and Neuroscience, Brigham Young University, Provo, UT

Background: Epidemiological studies have found high co-morbidity of ASD and social anxiety disorder (SAD) (White, Oswald, Ollendick and Scahill; 2009). Some theories propose that the social anxiety exhibited in ASD has a similar biopsychological basis as SAD, and that individuals with ASD have a difficulty with social interaction because they are hyperaware of their lack of social skills (Monk et al., 2010). Others claim that the social ineptitude of individuals with ASD stems from a lack of awareness and motivation to act in socially acceptable ways (Dawson, 2005). In this study, we used psychophysiological measures of arousal to characterize reactivity in ASD during socially stressful (i.e. explicit performance evaluation) task trials compared to unevaluated trials.

Objectives: We aimed to understand how anxiety in people with ASD is mediated by fear of negative social evaluation. In light of previous work in our lab on non-social stress, we hypothesized that ASD group would show elevated stress to both types of threat while the control group (CON) would be more affected by social evaluation than non-social (evaluative) contexts.

Methods: Twenty adults aged 18-29 diagnosed with ASD were compared to age- and IQ-matched healthy controls on modified Stroop and Multi-Sensory Integration tasks developed by Gianaros and colleagues (Sheu, Jennings and Gianaros, 2012). We measured stress response with impedance cardiography and skin conductance response. Participants completed the computerized task in one room, while research assistants in another room communicated via speakers. Participants were instructed at the beginning of each alternating block, whether they would or would not be evaluated for that block, by the research assistant watching through cameras and by the computer recording their responses. We examined within subjects differences over evaluated and unevaluated trials, as well as between subjects with ASD and CON groups.

Results: We found that adults with ASD had higher overall autonomic physiological responses, relative to controls, during stress conditions. Parasympathetic activity during recovery periods was likewise reduced in the ASD group. There were significant group x evaluation condition interactions, with the evaluated trials adding substantially more to the stress response in the CON but not the ASD group, which was already near ceiling. Response to social evaluation was significantly correlated with scores on the Fear of Negative Evaluation and the Social Anxiety Questionnaire in both groups.

Conclusions: This is the first study we know of to use measures of impedance cardiography in an autism sample. Findings of increased sympathetic activity during stress and decreased parasympathetic activity during rest confirm suggestions from other recent studies that ASD adults are out-of-sync with fear versus safety contexts, which may underlie a great deal of everyday anxiety. This elevated overall stress level may mitigate any extra stress that performance evaluation brings. Interventions for anxiety in ASD should focus on helping individuals to recognize physiological responses to stress and develop specific coping skills for such situations.

55 **106.055** "Typical Teen" or "Typical ASD"?: Changes in Self- and Parent-Report of Co-Occurring Conditions for Adolescents with ASD Following a Social Skills Intervention

S. M. Minnick, A. M. Pearl, K. C. Durica, A. N. Heintzelman and M. Murray, Department of Psychiatry, Penn State Hershey, Hershey, PA

Background: Discrepancies between adolescent and caregiver reports of symptoms and impact in a wide range of behavioral and physical health concerns is well documented. It is not well understood whether discrepancies also exist for adolescent and caregiver report of co-occurring conditions associated with Autism Spectrum Disorder (ASD). Observed discrepancies could illuminate challenges faced by families and adolescents with ASD during a developmental stage marked by shifting roles.

Objectives: This study examined agreement between self and caregiver assessment of co-occurring

conditions for adolescents with ASD participating in a social skills intervention. Additionally, changes in agreement patterns over time were examined to determine the impact of active intervention on self and caregiver assessment of needs.

Methods: Thirty-six adolescents with a confirmed diagnosis of ASD between the ages of 13- and 18-years-old (M = 14.61, SD = 1.36) completed a 12-week social skills intervention. 81% were male and 97% were Caucasian. Verbal IQ was estimated using the Kaufman Brief Intelligence Scale, Second Edition (KBIT 2; M = 104.33, SD = 18.85). Exclusionary criteria included verbal IQ below 70. Participants and caregivers completed the Strengths and Difficulties Questionnaire (SDQ) to assess for comorbidities at pre- and post-intervention, as well as at three-month follow-up.

Results: Paired-sample t-tests were completed to compare self- and parent-report of comorbidities at the three assessment points. Self- and caregiver-report of the adolescent's level of anxiety was not significantly different at pre-, post-intervention, or at three-month follow-up. At pre- and post-intervention, self- and caregiver-report of the adolescent's behavioral difficulties also did not differ. However, at the three-month follow up, caregivers reported significantly less behavioral difficulties (t = -2.81, p < .01). In regards to symptoms of hyperactivity/impulsivity, caregivers rated the adolescent's symptoms as significantly higher at pre-intervention (t = 3.58, p < .01); at post-intervention and at three-month follow-up, ratings did not significantly differ. In terms of peer difficulties, at every time point caregiver report rated the adolescents' behavior as significant higher than self-report (t = 4.78, p < .001; t = 2.65, p < .05; t = 5.20, p < .001). Finally, in the area of total difficulties, adolescents and their caregivers did not differ in their report of symptoms at pre-intervention and post-intervention; at three-month follow-up adolescents reported having significantly less total difficulties as compared to caregivers (t = 2.89, p < .01).

Conclusions: Consistency between self and caregiver report was noted at post intervention and follow-up for anxiety and hyperactivity/impulsivity reflecting good agreement between assessment of internal and external symptoms. The most significant and consistent discrepancies between self- and caregiver-report were observed for relationship and social interaction challenges, most notably with peer difficulties. Adolescents and their caregivers also had significant discrepancies on assessment of behavior and total problems at the three-month follow-up. Further investigation is warranted to determine whether these discrepancies are reflective of self-assessment challenges faced by adolescents with ASD or are more indicative of perceptual differences in the adolescent-caregiver relationship.

Poster Session
107 - Service Delivery/Systems of Care
11:30 AM - 1:30 PM - Imperial Ballroom

---

56   **107.056** A Pilot Study of a Screening Model to Triage Toddlers Referred for Autism Spectrum Disorder (ASD) to a Tertiary Care Center (TRC) Using a New Level 2 ASD Screening Test

R. Choueiri[1], J. F. Lemay[2] and S. Wagner[3], (1)Pediatrics, University of Massachusetts Memorial Children's Medical Center, Worcester, MA, (2)Developmental and Behavioral Pediatrics, Alberta Children's HOspital, Calgary, AB, Canada, (3)Behavioral, Developmental and Educational Services (BDES), New Bedford, MA

Background:
Toddlers referred for concerns of ASD to be evaluated by ASD experts, wait an average of 6 months before being evaluated delaying diagnosis in those with true ASD and treatment.

Objectives:
To evaluate a screening model to expedite autism evaluations in toddlers in a TRC by trained speech pathologists and a developmental pediatrician (SP-DP)

Methods:
The *Rapid Interactive screening Test for Autism in Toddlers* (RITA-T) is a new Level 2 ASD screening test in toddlers. It includes 9 activities that evaluate social communication skills in toddlers in less than 10 minutes. We have established its scoring algorithm, manual, developed a training protocol and demonstrated its discriminative properties in specifically identifying toddlers with ASD. Over five weeks, toddlers under 39 months of age waiting to be evaluated, were administered first the MCHAT and the RITA-T by the SP-DP. They were then assigned to 3 different risk groups based on their respective scores. Another team of clinicians administered the following tests and provided diagnoses of ASD or Non-ASD accordingly: Low Risk: DSM 5 checklist and the Vineland Adaptive Behavior Scales (VABS); Medium Risk: DSM 5, VABS and the ADOS; High Risk: DSM 5 and a developmental evaluation.

Results:
Twenty-two toddlers (82% boys) were evaluated. Mean age was 29.8 months (17-39 months). 18% were low risk, 41% were in each medium and high risk groups. ASD diagnoses were 0%, 67% and 100% in the 3 groups respectively. In total, 15 (68%) had a diagnosis of ASD. The RITA-T total score, DSM-5 criteria checked, and the MCHAT critical items failed were significantly different between the ASD and Non-ASD groups (ANOVA, p<0.01) and between the 3 risk groups (ANOVA, p<0.01). There were no significant differences on the VABS. The RITA-T was significantly correlated with the DSM & MCHAT measures (Pearson corr=0.49, p<0.01).

Conclusions:
The RITA-T is useful in a screening protocol in expediting autism evaluations of toddlers in a TRC. Testing of the RITA-T and of this paradigm continues.

57   **107.057** ASD Database Development within the Uk's National Health Service, for Service Evaluation/Research Purposes

D. Wimpory[1] and B. Nicholas[2], (1)Penrallt Road, Bangor University & BCU Health Board, Bangor, United Kingdom, (2)Gwynedd LL57 2AS, Bangor University, Bangor, Wales, United Kingdom

Background:
We report on the development and use of an ASD database module as an enhancement to the UK National Health Service's (NHS) Community Child Health database (CCH). The ASD database module was established at the end of 2011 specifically for adults and children who have received NHS diagnoses in childhood in North Wales (total child population 145,000). Previous NHS analysis of data such as numbers of ASD diagnoses, age at diagnosis, diagnostic instruments employed, waiting times and types of professions contributing to diagnoses was only available via time-consuming inter-departmental audits requiring dedicated staffing. Parental consent to electronic record keeping is given as part of each child's birth record on the CCH and the database maintains an ongoing record of children's developmental milestones, routine vaccinations and significant conditions. The purpose of the ASD module and its supporting administrative process is to improve efficiency in reporting ASD in North Wales; the quality of data collected; and, appropriate access for ASD practitioners to derive improved delivery of assessment/care. University research ethical permission is granted for this project so that prevalence of fragile X syndrome and other ASD co-morbidities can be determined.
Objectives:
Evaluate and research the data to quantify changes in diagnostic practice and depth of data collection by monitoring the contents of the ASD records and their annual rate of addition to the CCH.
Methods:
A count, cross check and collation of CCH ASD database module records were made for the years 2012 and 2013 (2014 in progress). The data was compared with standards for ASD prevalence and the prevalence of ASD genetic comorbidities.
Results:
The original electronic database (without enhancements) recorded an ASD diagnosis rate of ~1/month. For 2012 the recorded rate rose to ~15/month and this rate was maintained in 2013. ASD prevalence increased from 0.4% immediately before the implementation of the ASD Database Module, to over 0.6% by the end of 2013. For 2012/13: The average age at diagnosis was ~8 years. ADOS was the most frequently employed instrument, and children waited 11 months, on average, between ASD referral and diagnosis. Clinical Psychologists were the most frequent contributors to the diagnoses. ASD genetic comorbidity records were lower than expected due partly to an unexpectedly low number of counts for ASD genetic comorbidities in the CCH compared to the standard prevalence for these disorders.
Conclusions:
The ASD database module initiative has prompted an increase in the rates of diagnosis that is closing the gap between the CCH reported prevalence of ASD and the generally accepted ~1% prevalence for the disorder. The rather high average age at diagnosis (~8 years) for 2012 and 2013 reflects a catch-up on previously undiagnosed ASD in the system. This status is anticipated to remain until the current improved rate of recording overwhelms the historical under-recording. The lower than expected number of reports of genetic disorders that carry increased risk of ASD as a comorbidity indicates there is scope for improvements in the availability of genetic testing in North Wales.

58   **107.058** Adults on the Spectrum Sharing Success: A Model

E. Francis[1], B. V. Parsons[2], R. J. Wuebker[3], K. J. Cottle[4], A. R. Asman[5], J. Viskochil[4] and W. M. McMahon[4], (1)University of Utah, Salt Lake City, UT, (2)Psychiatry Adjunct, University of Utah, Salt Lake City, UT, (3)Management, University of Utah, Salt Lake City, UT, (4)Psychiatry, University of Utah, Salt Lake City, UT, (5)Department of Psychiatry, University of Utah, Salt Lake City, UT

Background: Currently, online networks, blogs, Facebook pages and organizations connect individuals with Autism Spectrum Disorders (ASD). Many of these gifted adults have overcome their developmental challenges to achieve remarkable levels of occupational, social and personal success. Published autobiographies by such gifted individuals have documented their personal triumphs and ongoing struggles of adult life, as well as the altruistic desire to share their stories with others who might benefit. Building upon existing methods of personal narrative, we have developed a live workshop model for interactive sharing of stories of success that we call *Self-Optimization on The Spectrum*. This report summarizes our experience piloting this model through two workshops involving 57 participants.
Objectives: Our objective is to enhance autonomy and self-advocacy by supporting adults who identify as on the autism spectrum. The workshops are designed to:
1. Describe avenues of success.
2. Share messages of hope.
3. Encourage dialogue regarding challenges in social, educational, and occupational domains.

4. Provide a forum for community building.

Methods: A key element of our model is that it is designed collaboratively by and for adults with ASD. Workshop speakers are all residents on the Spectrum who are able to provide peer-mentoring, successful methods navigating challenges and tips on self-advocacy. They develop formal presentations based on their life experiences, professional skills and interactions with an individual psychotherapist who serves as a coach prior to the workshop. The University of Utah Department of Psychiatry provides organizational support, advertising, registration, space, and other supports (Cambia Health Foundation). Data are collected from satisfaction surveys and a needs assessment.

Results: Attendees registered in response to media advertising for participants over age 22 years who identified themselves as on the autism spectrum. The first workshop was held on a Friday evening and all day Saturday. The second workshop was held on a Saturday for 7 hours. The number of attendees, demographics, and satisfaction survey results are depicted in Table 1.

Conclusions: Feedback from the satisfaction surveys was consistently positive, as was anecdotal responses from participants and their family members.

---

59   **107.059** Are We Failing the M-CHAT? Self-Assessment in a Diverse Community Sample

C. B. Nadler[1,2], C. Low-Kapalu[1], L. Pham[1] and S. S. Nyp[1,2], (1)Developmental and Behavioral Sciences, Children's Mercy Kansas City, Kansas City, MO, (2)University of Missouri - Kansas City School of Medicine, Kansas City, MO

Background: The American Academy of Pediatrics (AAP) recommends standardized screening for autism at 18 and 24/30 months, but this standard is met inconsistently. Moreover, when practitioners (and researchers) implement evidence-based screenings, little attention is paid to the fidelity of implementation. In the case of the M-CHAT/F and M-CHAT-R/F, an evidence-based scoring algorithm prompts providers to conduct a structured follow-up interview and/or refer positive screens for evaluation and early intervention. Without the follow-up interview, psychometric value (i.e., sensitivity) of the measure is lost. No quality assurance procedures are available to quantify the degree to which autism screening in practice or research contexts adheres to validated implementation standards.

Objectives: To investigate the implementation fidelity of autism screening via the M-CHAT/F (and/or M-CHAT-R/F) conducted in the primary care clinics of a large urban hospital.

Methods: Electronic health records for 18 and 24/30 month pediatric well child visits during a one-month study period were manually reviewed to extract autism screening implementation parameters.

Results: The review yielded a sample of 281 eligible clinic visits serving children who were majority male (60.9%) and diverse (42.7% African American, 31.7% Hispanic, 10.3% White). Primary care providers documented that 4.3% of visits included a positive screen based on the M-CHAT; in contrast, re-scoring of parent-completed M-CHATs yielded 13.7% of visits with a positive screen (based on both critical item and total score approaches). No visit documented use of the structured M-CHAT follow-up interview, or any components of the M-CHAT-R/F. Providers' sensitivity with the M-CHAT was 0.214 (identifying 6 of 28 positive screens). Providers documented a referral for early intervention or evaluation services in 50% of cases (6 of 12) when a positive screen was identified in clinic; of children who screened positive based on rescoring of the parent M-CHAT, only 14.3% (4 of 28) were referred.

Conclusions: Manual chart review allowed for direct evaluation of the clinical implementation and interpretation of the M-CHAT in a large urban hospital. Despite routine administration of the M-CHAT at 18 and 24/30 months, providers failed to identify over 75% of children who screened positive on the measure. Pediatrician surveillance (i.e., clinical judgment without the aid of standardized tools) is well known to identify only 20-30% of children with developmental delays, and employing a standardized tool incorrectly does not appear to add incremental value in clinical practice. This pilot project demonstrates the viability of quantifying implementation and interpretation fidelity for autism screening. Efforts are underway to use this methodology to monitor quality improvement activities focused on provider education and training, as well as systems-level changes to facilitate standardized autism screening. Future studies are necessary to determine the extent to which other hospitals who use measures like the M-CHAT fail to monitor implementation fidelity, as well as how monitoring improves functional adherence to AAP guidelines. Research with developmental screening tools may also need to routinely include implementation fidelity data to better characterize results in community samples, given consistent (and even explicit) omission of the structured follow-up in recent publications.

---

60   **107.060** Autism Research: Contribution from the Arab WORLD

F. Alnemary[1], Y. Alamri[2] and F. Alnemary[1], (1)University of California, Los Angeles, Los Angeles, CA, (2)University of Otago, New Zealand, Los Angeles, CA

Background: Autism/autistic spectrum disorder (ASD) represents one of the more common neuro-developmental disorders. The true prevalence of ASD is still obscure given the lack of rigorous epidemiological studies in the Arab world as a whole. Reported prevalence rates from smaller studies in individual countries vary considerably (1.4-33.3 per 10,000)1. Research is one way to mitigate the limited servcies for these children and their families in the Arab world. However, autism research in that region is yet to be scrutinised.

Objectives: We aimed to comparatively review all published autism research originating from the Arab

world in peer-reviewed English journals.

Methods: Studies where the sample and/or the afflition of one of the authors was from any of the 22 Arab countries was searched in Medline through PudMed, Web of Science and EMBASE databases from 1946, 1947 and 1991, respectively, to January 2014.

Sutdies were coded for several variables including:1) country, 2) research area (i.e., based on the seven areas of research plan of the Autism Inteagency Coordinating Committee report, 2011), 3) methodology and desgin , 4) impact factor and 5) the number of authors per publication. The interrater reliability was 95%, which was calculated for 10 % of the studies using a point-by-point method.

Results: Saudi Arabia and Egypt were the two most active countries, respectively producing 36% and 32% of autism research. The remainder of autism research originated from Oman (8%), UAE (6%), Kuwait (4%), Jordan (4%), Lebanon (3%), Bahrain, Libya, Morocco and Qatar (1% each). With respect the resreach area, 30 % , 21%, 14%, and 12% of the published studies were related to biology, dignostic and screenings, risk factors, and treatmetn and interventions, respectively. The mean impact factor of journals accepting contributions from the Arab world was 2.28 (SD=2.97) ranging from 0-31. With respect to the design, most of the studies were observational, 10 % or the studies were interventional in nature emplying randomised controlled trial desgin.

Conclusions: These findings indicate the urgent need to encourage higher-quality research in this area, as well as raise the awareness of local policy-makers in the Arab world to fund and publicise evidence-based information about autism and its management.

Taha, G. R., & Hussien, H. (2014). Autism Spectrum Disorders in Developing Countries: Lessons from the Arab World. In Patel., V.,B., Preedy V. R., & Martin, C. R. (Eds.), Comprehensive Guide to Autism (pp. 2509-2531). New York, NY, Springer.

61   **107.061** Barriers to Early Diagnosis in Children with Autism Spectrum Disorder: Preliminary Results

S. N. Brasher and J. Elder, College of Nursing University of Florida, Gainesville, FL

Background:

Autism Spectrum Disorder (ASD) is a complex neurodevelopmental disorder with no conclusive cause or cure. ASD is the fastest growing developmental disability in the United States, currently affecting 1 in 68 children (Autism Speaks, 2014). Researchers have established that early recognition and intervention are critical in the long-term outcomes of children with ASD. However, many children do not receive these services in a timely way. Therefore, the purpose of this descriptive study is to elucidate perceived barriers to early diagnosis in children with ASD.

Objectives:

The objective of this study is to identify healthcare professionals' perceptions of barriers to early diagnosis in children with ASD.

Methods:

The investigators developed an Internet survey comprised of open-ended and closed-ended questions. Initial survey questions were constructed based on an extensive literature review. After IRB approval, questions were presented to an interdisciplinary Community Advisory Board (CAB) consisting of nine ASD professionals to obtain feedback. The final survey was constructed online using REDcap (Research Electronic Data Capture) and disseminated to healthcare professionals throughout the state of Florida. Statistical outcomes were calculated in REDcap.

Results:

To date, thirty-four responses have been obtained and more are expected prior to the IMFAR conference. All but two respondents (5.9%) identified barriers to accurate, timely diagnoses in children with ASD. The barriers identified included socioeconomic factors (67.6%), medical insurance constraints (67.6%), geographical location (32.4%), limited transportation (35.3%), limited parental education (85.3%), not knowing where to seek help (85.3%), culture (58.8%), time constraints (23.5%), language (38.2%), uneducated providers (67.6%), lack of family acceptance (70.6%), and provider hesitancy (55.9%).

Conclusions:

These preliminary findings help to validate the clinical impression that barriers to receiving an early diagnosis in children with ASD exist and indicate a need for further research. Furthermore, these findings allow us to understand the types of barriers encountered by families of children with ASD from the perspectives of healthcare professionals. Additionally, these findings inform healthcare professionals about potential barriers to early diagnosis of ASD in children and have the ability to reduce these barriers through an improved understanding.

62   **107.062** Bridging the Gap: Primary Care Physician Self-Efficacy in Assessing and Treating Sleep Problems in Children with ASD

K. S. Kwedar[1], C. R. Engelhardt[1], N. C. Cheak-Zamora[1], M. O. Mazurek[1] and K. Sohl[2], (1)University of Missouri, Columbia, MO, (2)Child Health, University of Missouri - Thompson Center, Columbia, MO

Background: Children with autism spectrum disorder (ASD) are at increased risk for sleep disturbances compared to children with typical development (TD). Sleep disturbances in children with ASD have traditionally been treated by sleep specialists. However, given that sleep specialists are limited in number and that the reported prevalence of ASD has risen in recent years, an increasing number of children with ASD must receive treatment for sleep problems from primary care physicians

(PCPs). Insofar as recent evidence suggests that PCPs feel generally less efficacious in treating children with ASD compared to children with TD, it stands to reason that PCPs might also feel ill equipped to treat sleep disturbances in children with ASD.

Objectives: **1)** To examine differences in PCP self-efficacy in addressing and treating sleep disturbances in children with ASD compared to children with TD. **2)**To examine whether low perceived knowledge among PCPs is associated with reduced comfort in treating sleep problems in children with ASD.

Methods: General pediatricians (n = 52) and family physicians (n = 23) across Missouri completed an online questionnaire assessing: 1) knowledge and comfort in managing sleep concerns among individuals with ASD and TD, 2) factors affecting ability to address sleep concerns, 3) knowledge of specific sleep interventions, 4) educational topics useful for practice, and 5) preferences for sleep education. Comfort composite scores were determined using a scale from 1 [Not Comfortable] to 4 [Very Comfortable].

Results: PCPs feel markedly less comfortable in treating sleep problems in children with ASD ($M = 2.40$; $SD = 0.83$) compared to TD children ($M = 3.22$; $SD = 0.61$), $d = 1.10$, with 95% confidence interval [0.82, 1.41]. A lack of perceived knowledge about treating and assessing sleep problems in children with ASD was associated with less comfort in treating sleep problems in this group ($r = .76$ [.67, .85]). A majority of PCPs want to increase their knowledge of disordered sleep (93%) and medical conditions in children with ASD (91%).

Conclusions: Although PCPs want to address sleep disturbances in children with ASD, a lack of knowledge in this domain limits their comfort in effectively doing so. In a time of subspecialty shortage to diagnosis and treat ASD, it is imperative that PCPs bridge the gap between their desire to help and their expertise. This study supports increasing outreach efforts to PCPs to build capacity for community-based care.

63   **107.063** Characterizing Parent Influence in the Diagnosis of ASD

P. Colatat[1], Y. Qian[2], M. L. Massolo[2] and L. A. Croen[2], (1)Olin Business School, Washington University in St Louis, St Louis, MO, (2)Division of Research, Kaiser Permanente Northern California, Oakland, CA

Background:
It is commonly understood that increased rates of ASD diagnoses over time may be partially explained by increased awareness of ASD. Scholars – in particular sociologists - have attempted to explain the recent rise in autism diagnoses by examining the diffusion of information about ASD across the social networks of parents.   The argument has been that parents share information about autism with one another in parks, playgrounds and other local public spaces. This information in turn encourages parents to seek out the diagnosis and pursue medical, school and state therapy resources for their children.

On one hand, this finding might be interpreted as concerned and knowledgeable parents being more likely to raise their concerns to their pediatricians and other medical professionals, who might have otherwise overlooked symptoms of ASD. On the other hand, this finding might be interpreted as parents having greater ability to manipulate – either sincerely or cynically - the health care system to obtain supports and services for their child. Further unpacking the mechanisms of patient influence is immensely important for crafting appropriate health care policy.

Objectives:
This research aims to better understand how parents might affect the ASD diagnostic process of health care providers and health care organizations.

Methods:
First, data from the California Department of Developmental Services were used to replicate the discrete-time event history analysis of previous research and demonstrate the same correlation between measures of parent social interaction and rates of ASD diagnosis. Next, a subset of these data were merged with detailed electronic medical records from a large HMO in California (2000-2007 birth cohorts, n = 276,395). Using the HMO data and employing text-mining methods, we disaggregated the diagnostic process into two conceptually-distinct phases: (1) *initial suspicion* of ASD - an extended period of diagnostic uncertainty as signs and symptoms of a medical condition are initially identified (typically by a generalist), and (2) *formal diagnosis* - a diagnosis that resolves this uncertainty (typically by a specialist). To see whether parent social interaction has an impact on who is suspected and/or who is diagnosed (conditional on suspicion), we repeated the discrete-time event history analysis at each phase.

Results:
Consistent with previous research, we find that parent social interaction was positively associated with likelihood of being diagnosed with ASD (OR = 1.156, p < 0.001). However, when the diagnostic process was disaggregated, we found that parent social interaction was positively associated with initial suspicion of ASD (OR = 1.15, p < 0.001), but not associated with a formal diagnosis of ASD (OR = 0.83, p < 0.001).

Conclusions:
Our research provides the first evidence of how and where parents may influence the ASD diagnostic process.   Further examination of the specific social processes at play is critical to understanding patterns of diagnosis and informing health care policy.

64 **107.064** Community General Pediatricians' Barriers to Providing Autism Spectrum Disorder Diagnoses: A Qualitative Study

*G. King[1], **M. Penner**[2], E. Anagnostou[3], M. Shouldice[4] and C. Moore Hepburn[5], (1)Bloorview Research Institute, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Hospital for Sick Children, Toronot, ON, Canada, (5)Division of Paediatric Medicine, Hospital for Sick Children, Toronto, ON, Canada*

Background: Wait times for diagnosis of autism spectrum disorders (ASD) may negatively impact outcomes by delaying access to early interventions. Community general pediatricians (CGPs) are often consulted in cases of suspected ASD, and may play a role in increasing ASD diagnostic capacity in the community setting.
Objectives: The objective of this study was to explore the perspectives of CGPs regarding their role in the system of ASD diagnoses using qualitative methods.
Methods: We performed a phenomenological qualitative study of CGPs' experiences with cases of suspected ASD. Two groups of CGPs were sampled to provide maximal variation in perspectives: a group that had referred patients with suspected ASD for a subspecialist assessment, and a group that regularly attended ASD educational events. Interviews began with a discussion of a case study describing a child with features of ASD. Individual in-depth interviews were recorded and transcribed. Two investigators coded each interview. Thematic saturation was reached when two successive interviews did not generate new codes. Texts were analyzed using a grounded theory approach. A preliminary theoretical framework was developed, summarized and sent to participants with a request for feedback (member checking; currently in progress). Member feedback will be incorporated into the final theoretical framework.
Results: Eleven in-depth interviews were conducted (six males, five females; mean years in practice 17.1). Participants described three elements to the process of assessment: diagnostic determination, communication of the diagnosis, and management of the diagnosis. Each element contained potential barriers to assigning a diagnosis of ASD. Diagnostic determination was affected by patient factors (severity of presentation, age, gender, comorbidities, and the amount of stimulation in the environment), family factors (how the family relays the history), and physician factors (training, practice setup, access to informal expert consultation, access to other staff's observations of the child, and interest in ASD). Family factors were essential considerations in the communication of the diagnosis. It was important that families know enough, but not too much, about ASD; families who knew too much were perceived to need an "expert" opinion. Participants felt a significant emotional burden and were very sensitive to the impact of the diagnosis. They felt ill equipped to deal with the fragmented service delivery system for ASD. Helping families to access services was time-consuming, poorly remunerated, and less satisfying than other areas of pediatric practice. A consistent theme in the interviews was the participants' negative attributions toward cases of ASD, particularly as they related to interfacing with dysfunctional health systems factors.
Conclusions: Though CGPs are frequently consulted on cases of suspected ASD, they experience many barriers to making a diagnosis, leading to increased subspecialist referrals. Efforts to improve diagnostic capacity in this group must focus not only on diagnostic determination, but also on communicating the diagnosis and efficiently connecting families to resources. Health system factors contribute to negative attributions toward ASD, potentially creating stigma and disadvantaging children with ASD from accessing care at the community level.

65 **107.065** Comparison of Adults with Autism Spectrum Disorder with and without a Guardian

***N. K. Naylor**[1], H. Coon[2], D. A. Bilder[2], L. Francis[1] and W. M. McMahon[2], (1)S.J. Quinney College of Law, University of Utah, Salt Lake City, UT, (2)Psychiatry, University of Utah, Salt Lake City, UT*

Background: Guardianship is a legal intervention used to protect adults unable to care for their health, safety, or provide self-care by providing them with a surrogate decision-maker who has the same rights and responsibilities over the protected adult that a parent has over their minor child. Legal scholars posit guardianship may not be appropriate for adults with Autism Spectrum Disorders (ASD), especially those considered high functioning.
Objectives: One previous small study examining characteristics of adults with ASD under guardianship found adults with ASD were more likely to be male and were younger than other protected adults under guardianship. We undertook a larger, more detailed comparison of adults with ASD with and without guardianship. We hypothesized that participants with a guardianship would have more severe clinical symptoms, lower IQ, and more co-morbid psychiatric and medical conditions than those without a guardian. We expected participants with a guardian to be more likely to receive a variety of social services
Methods: We studied 144 individuals ascertained 1982-1986 who met criteria for ASD (DSM-III or DSM–IV). Questionnaires and psychometric testing were completed in personal follow-up visits. Data were analyzed using analysis of variance and logistic regression.
Results: Ninety-two percent of guardians were the parent of the adult with ASD, 5% were a guardians *ad litem*, 1.3% were another relative, and 1.3% were unknown. Gender differences were not significant (p=0.27). Adults with ASD under guardianship had significantly higher scores on the Autism Diagnostic Scale (p<0.0001), significantly lower Adaptive Behavior Scale total and subscale

scores, (p<0.0001) were significantly more likely to destroy things in anger (p=0.028), and had significantly lower IQ scores (p<0.0001). Participants without a guardian were significantly more likely to receive vocational rehabilitation (p=0.004) and less like to obtain Social Security (p<0.0001), Medicaid (p>0.0001), and assistance from the Division of Services for Persons with Disabilities (p<0.0001). Contrary to expectations, the two groups did not differ regarding co-morbid psychiatric and overall number of medical disorders. However, more individuals with guardianship had seizure disorders (p=0.001).

Conclusions:
Adults with ASD with guardianship in our sample had significantly more severe autism symptoms and lower IQ scores than those without guardians. However, they did not differ in the number of comorbid medical and psychiatric conditions, suggesting that in aggregate, co-occurring conditions, not including intellectual disabilities, do not play a strong role in obtaining guardianship. Seizure disorders were significantly more common among those with guardianship, suggesting that type/severity of co-morbidity may yet be important. We confirmed our hypotheses regarding service use. While we found no overall gender differences between the two groups, this may have been due to the low number of female participants; further explorations of gender interactions are presented. We note that because the sample was originally ascertained in the 1980's, adults with high functioning ASD are not part of this cohort, so our conclusions are limited to a subset of more severe ASD. In spite of this limitation, our study is the first study to investigate multiple characteristics of adults with ASD with and without guardianship.

---

66   **107.066**   Cost-Effectiveness Evaluation for Services Provided to People with Autism: Update and Recommendations

J. M. Tilford[1] and N. Payakachat[2], (1)Dept. of Health Policy and Management, University of Arkansas for Medical Sciences, Little Rock, AR, (2)Pharmacy Practice, University of Arkansas for Medical Sciences, Little Rock, AR

Background: Cost-effectiveness analysis is a tool that can be useful for autism research and policy. For example, findings from a cost-effectiveness analysis can be used to identify clinical comparative effectiveness research that should be rapidly translated into practice. It can also inform policy about coverage for services and optimal treatment strategies. Unfortunately, there is a lack of understanding about the role and practice of cost-effectiveness that impedes its use among practitioners.

Objectives: The purpose of this paper is to describe state of the art approaches for evaluating the cost-effectiveness of services provided to people with autism specifically focusing on children.

Methods: The US Panel on Cost-Effectiveness in Health and Medicine developed guidelines for conducting cost-effectiveness analysis to create a standard approach so that findings could be compared across different studies, conditions, and population groups. Guidelines exist for other countries, especially the UK, but they differ on specific issues. This paper reviews guidelines for measuring quality adjusted life years and costs to conduct a cost-effectiveness analysis from a societal perspective. We note the special features of child health services that pertain to children with autism. In particular, children with autism are more likely to receive services in multiple settings that create difficulties in measuring costs, there are issues in measuring quality adjusted life years (QALYs) particularly in young children, and family spillover effects can play an important role in calculating the benefits of the intervention. We illustrate these issues using specific examples based on recent findings.

Results: Only one cost-effectiveness evaluation has been conducted on services for people with autism that followed either the US or UK guidelines. In that study, supported employment was found to produce a cost-effectiveness ratio of £5600 per QALY suggesting that such a practice should be adopted on a larger scale. The study lacked data on health utilities for calculating QALYs and had to extrapolate estimates from other conditions. There are no cost-effectiveness evaluations for services provided to children with autism using the cost per QALY metric, despite significant advances in utility data for measuring QALYs. Finally, there is evidence that services for children with autism produce spillover utility benefits for family members and failure to include these benefits can lead to cost-effectiveness ratios that understate the true value of the services provided.

Conclusions: Practitioners in the field of autism research can benefit from a greater understanding of cost-effectiveness evaluation to prioritize service delivery and influence policy. There are a number of exciting developments in the field of cost-effectiveness evaluation relevant to autism research, especially the measurement of QALYs in children and spillover effects of services on family outcomes.

---

67   **107.067**   Development and Preliminary Validation of a New Scale to Measure the Social Validity of Skill Building Interventions for Autism Spectrum Disorder

N. I. Berger[1] and B. Ingersoll[2], (1)Michigan State University, East Lansing, MI, (2)Psychology, Michigan State University, East Lansing, MI

Background: There is growing evidence that evidence-based interventions for ASD are often not adopted or successfully implemented in community settings. Research suggests that social validity (i.e., the social importance of treatment procedures/outcomes) may strongly influence both the adoption and implementation of treatments. Thus, it is imperative to develop a better understanding

of community stakeholders' views of different evidence-based interventions for children with ASD. While there are established scales for examining the social validity of interventions designed to decrease unwanted behaviors, there are currently no tools for assessing the social validity of skill-building interventions.

Objectives: The primary purpose of this study is to refine a newly developed scale meant to assess the social validity of skill-building interventions for individuals with ASD, and to examine the scale's psychometric properties. The secondary purpose of the study is to use the scale to examine how consumers view different evidence-based, comprehensive interventions for ASD.

Methods: A 35-item measure (Scale of Treatment Perceptions; STP) was constructed to assess the social validity of skill-building interventions for individuals with ASD. In Phase 1, 600 undergraduate students read a vignette describing a young child with ASD, and one of four different comprehensive treatment descriptions (LEAP, EIBI, TEACCH, Floortime). Responses were submitted to item analysis and exploratory factor analysis. The scale was refined to improve the structure and reduce number of items. In Phase 2, 500 parents of young children unfamiliar with ASD interventions were recruited from Amazon mTurk and subjected to the Phase 1 procedure (using the refined version of the STP). This allowed us to investigate the robustness of the psychometric structure of the STP when including individuals who are potential consumers of early intervention. In each phase of the study we also examined the relative social validity of the four interventions as measured by the STP.

Results: Results from both Phase 1 and 2 provided support for a four-factor structure of the scale (acceptability, effectiveness, family impact, and potential risks). Internal reliability was excellent. In both college students and parents, the scale successfully discriminated between treatments both in terms of overall score and across individual factors.

Conclusions: The STP appears to have adequate psychometric properties for examining the social validity of skill-building treatments for ASD. The ability of the scale to evaluate social validity across four dimensions is a considerable strength, as it allows researchers to investigate social validity at a more nuanced level. Findings indicating that well-established treatments targeting skill development in individuals with ASD differ in their overall level of social validity and across these four factors suggest that the STP can be effectively utilized to compare the social validity of existing, evidence-based, interventions. Differences in the social validity of ASD treatments has significant implications for dissemination practices.

68   **107.068** Development of the Autism Family Navigator: A Pilot Study on Barriers to Care

T. Savion-Lemieux[1], L. Girouard[2], L. Stern[3], M. Steiman[4], R. Simon[5], L. Fernandez[6] and M. Elsabbagh[7], (1)Psychiatry, McGill University, Montreal, QC, Canada, (2)2155 Guy Street, 5th Floor, McGill University Health Centre - Research Institute, Montreal, QC, Canada, (3)Montreal Children's Hospital, Montreal, QC, Canada, (4)Psychology, The Montreal Children's Hospital-McGill University Health Centre, Montreal, QC, Canada, (5)Psychology, Montreal Children's Hospital - McGill University Health Centre, Montreal, QC, Canada, (6)Montreal Children's Hospital - McGill University Health Centre, Montreal, QC, Canada, (7)McGill University, Montreal, PQ, Canada

Background: Navigation is a relatively new area of personalized health care, defined as a "proactive, intentional process of collaborating with a person and their family to provide guidance as they negotiate the maze of treatments, services, and potential barriers" as they seek health care (Fillion, 2012). Originally designed/implemented with patients diagnosed with cancer, navigation is now used for a wide range of health conditions to reduce barriers to health care outcomes (Wells et al., 2013). Multiple sources of evidence suggest the need for navigation support for families affected by Autism Spectrum Disorder (ASD). There are often long delays between parents' first concerns about ASD, diagnosis, and receipt of interventions (Steiman et al., 2008). Throughout this period and beyond, caregivers take on duties of "case managers" and experience serious challenges in navigating complex and uncoordinated systems of care (Nicholas et al., 2013), with disparities reported in access and/or utilization of services (e.g., Savion-Lemieux et al., 2014).

Objectives: The objective of the current pilot study was to identify the most common unmet needs and barriers faced by families while navigating community services. This study will help inform the development of an Autism Family Navigator model to support personalized care for ASD.

Methods: This pilot study was conducted in Montreal (Quebec), Canada where many aspects of health and social care are universal and publically (i.e., government) funded. From an overall group of 47 families routinely followed within a research program in a university hospital, 20 were identified as experiencing barriers in care access and/or coordination. Their children (5 girls; 15 boys) were diagnosed at ages 2-4 years and were 8-10 years old at the time of this study. A pilot Navigator worked with the primary caregiver to identify and address barriers to care. Each case was then reviewed by two authors (TSL, LG) to categorize the nature of concerns, barriers to care, and navigator strategies.

Results: The following categories of unmet needs were identified (including % of families affected per category): child's skills and needs assessment (50%), revisions/issues pertaining to child's diagnosis (25%), issues pertaining to child's mental health (25%), assistance required to apply for government benefits (20%), issues pertaining to caregiver's own mental health (5%). The following barriers were identified: unawareness of available community services (60%); lack of relevant public sector services (30%); long wait lists (25%); financial barriers (20%); language barriers (15%); and issues related to caregiver's health/wellbeing (5%). To reduce barriers, the Navigator used these strategies: liaison with health care agents regarding the family's unmet needs or supporting the caregiver to

communicate with these agents (90%), psychosocial support (90%), and education about services (65%).

Conclusions: The findings illustrate that, even within a universal health care system, there are serious gaps in care access and coordination for families affected by ASD. While follow up is needed to establish whether the identified strategies were successful in reducing barriers, our pilot study demonstrates that navigation should be explored as a method of expanding access to and coordination of community-based care.

69 **107.069** Developmental Trajectories Diverted: Empowering Frontline Community Childcare Providers to Support Children's Social Communication Development through a Coach-the-Coach Model

S. M. Ziegler[1], S. K. Fuhrmeister[1], E. Brooker Lozott[2], C. Payne[3], T. D. Ryan[4] and J. Stapel-Wax[5], (1)Infant and Toddler Community Outreach Program, Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (3)Marcus Austim Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (4)Marcus Autism Center,Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (5)Marcus Autism Center, Atlanta, GA

Background:
Early detection and rapid mobilization of individualized supports are critical components of ensuring that children at risk for developing ASD obtain their fullest developmental potential. The National Research Council (2001) found that early detection and 25 hours a week of active engagement promoted optimal success for young children with ASD in kindergarten. Knowledge of red flags for ASD and transactional supports to promote active engagement, for example, those derived from the SCERTS framework (Prizant et al., 2005), is vital for providers working in the early childcare setting. Translating this knowledge into practice through collaborative learning experiences with early childhood professionals (ECPs) allows front-line providers to alter disadvantaged developmental trajectories of young children at risk for ASD. Learning "how to" coaching and collaboration strategies is needed for successful collaborative learning experiences between ECPs and childcare providers (Friedman & Woods, 2012). However, there is a paucity of research on the effectiveness of coach-the-coach models with ECPs.

Objectives:
This project aimed to improve collaborative coaching proficiencies within Georgia's Bright from the Start (BFTS): Department of Early Care and Learning (DECAL) professionals via implementation of a novel, three phase coach-the-coach model focusing on increasing knowledge of normative development and detection of red flags for ASD, and using transactional supports to promote active engagement in early childcare settings.

Methods:
This study tracked the progress of 12 ECPs from BFTS: DECAL (5 Infant Toddler Specialists and 7 Inclusion Coordinators) coached to coach childcare providers using a collaborative coaching model. Through the use of coaching and collaboration strategies to promote adult learning, coaching centered on increasing active engagement in the early childcare setting using transactional supports. Coaching by Community Interventionists was conducted in person, via mobile coaching, and through video conferencing across three, 12-week phases with decreasing frequency and intensity to build independence and capacity. Effectiveness of Phase I of the coach-the-coach model was assessed by 1) rate of support and coaching provided by ECPs during video-recorded independent classroom sessions with childcare providers throughout the coaching period; and 2) number of children identified at risk for ASD.

Results:
The rate of coaching and supports provided by ECPs during Phase I significantly increased from baseline ($t_{11}=1.774$, $p=0.05$). In addition, 12 children have been identified with social communication concerns, indicating an increase in awareness of social communication milestones and red flags for ASD.

Conclusions:
These data indicate that the current coach-the-coach model results in increased support and coaching provided by ECPs and an increased awareness of red flags for ASD. Through the coaching-the-coach model, ECPs learned important aspects of coaching and collaboration, used transactional supports to promote active engagement, and increased awareness of red flags for ASD. This enabled them to improve their coaching proficiency of others, thus exponentially multiplying the number of children who receive necessary developmental supports.

70 **107.070** Early Intervention Service Providers Knowledge and Use of Intervention Practices

ABSTRACT WITHDRAWN

Background: Recent research has made significant progress in the identification and description of evidence-based practices (EBP) for working with children with Autism Spectrum Disorders (ASD) (e.g., Wong et al., 2013). However, a "research to practice gap" is widely acknowledged (e.g., Cook, Cook, & Landrum, 2013). For example, unsupported treatments (e.g., sensory integration therapy, vitamin

supplements, and elimination diets) continue to be reported to be used frequently in surveys of both parents (for a review see Carlon, Stephenson, & Carter, 2014) and professionals (e.g., Kadar et al., 2012). Little is known however, about what intervention practices are used in community-based early intervention services for children with ASD, or what factors may facilitate or hinder the uptake of EBPs in such services. This information is vital for improving outcomes for all children with ASD.

Objectives: The present study aimed to explore the level of knowledge and use of EBP and links to organisational culture, individual attitude, and demographic variables in a state-wide community-based ASD early intervention service in Australia using a questionnaire design.

Methods: Participants included 99 staff at an ASD early intervention service including professional (teachers and therapists) and paraprofessional (learning facilitators) staff across both rural/regional and metropolitan areas. Questionnaires measures included the Organisational Culture Questionnaire (Russell et al., 2010); the Evidence-based Attitudes Scales (Aarons, 2004), ratings of knowledge and use of a range of intervention practices (EBP, promising, and unsupported) drawn from the literature (e.g., Odom et al., 2010), and demographics.

Results: Participants reported a moderate level of organisational culture supporting the use of EBP in terms of available resources, culture, and supervisor support. Greater perception of a supportive organisational culture was linked to greater knowledge and greater use of EBP. Participants likewise reported a moderate level of attitudinal support towards the use of EBP in terms of willingness to use EBP if they were a requirement, appealed, and their openness to using EBP. Only openness was linked to knowledge and use. Knowledge and use of EBP were also linked to each other with greater knowledge linked to higher self-reported use. Demographic differences were found in use of EBP including that professionals reported using EBP more than paraprofessionals. Additionally, participants in the metropolitan area reported greater use than rural/regional participants.

Conclusions: This study adds to our knowledge and understanding about factors related to knowledge and use of EBPs in community settings. Results suggest a need for organisations to address staff knowledge and use of EBPs, particularly for paraprofessionals and for staff working in regional/remote areas. These results also suggest that organisational culture and individual attitudes may also affect uptake. Further research using direct observation could extend this research by investigating whether practices are implemented with fidelity and how they align with self-report. Such research would provide valuable insight into the needs of community-based paraprofessionals and professionals to better translate EBP into practice to support the use of high quality interventions with all children with ASD.

71 **107.071** Evaluation of a Parent-Response Scale to Measure the Progress of Children with ASD in State Early Intervention Programs

B. Elbaum[1], D. M. Noyes-Grosser[2], K. Siegenthaler[3], R. G. Romanczyk[4], R. N. Cavalari[5], R. L. Carter[6], J. D. Dare[7] and A. L. Barczykowski[8], (1)Department of Teaching and Learning, University of Miami, Coral Gables, FL, (2)Bureau of Early Intervention, New York State Department of Health, Albany, NY, (3)Bureau of Early Intervention, New York Department of Health, Albany, NY, (4)Department of Psychology, State University of NY at Binghamton, Binghamton, NY, (5)State University of NY at Binghamton, Binghamton, NY, (6)Department of Biostatistics, State University of New York at Buffalo, Buffalo, NY, (7)Population Health Observatory, State University of NY at Buffalo, Buffalo, NY, (8)State University of NY at Buffalo, Buffalo, NY

Background:
Under the Individuals with Disabilities Education Improvement Act of 2004, state early intervention (EI) programs, which serve children birth to age three, are required to report annually on the developmental progress made by enrolled children in three broad outcome areas: social relationships, acquisition and use of knowledge and skills, and taking action to meet their needs. A key indicator of program performance is the percentage of children with developmental delays who make substantial progress in these areas. However, states are not required to disaggregate their child outcomes data by type of developmental delay or diagnosis. Therefore, the extent to which children with a diagnosis of Autism Spectrum Disorder (ASD) are making progress in response to state EI services is unknown. This is particularly important in that children with ASD represent a growing percentage of the children served in state EI programs.

Objectives:
To evaluate the psychometric properties of a parent-report scale addressing the impact of EI services on the developmental progress of children with ASD.

Methods:
Items for the Impact on Child Scale - ASD Version (ICS-ASD) were developed through a Concept Mapping process conducted with a diverse set of EI stakeholders that included substantial representation of family members of a child with ASD. The 83 items used in this research are displayed in the attached Table; all items used the same 6-point response scale, from 1=very strongly disagree to 6=very strongly agree. The ICS-ASD items, along with other parent measures, were sent to a research sample of 204 families of a child with ASD who was diagnosed either prior to or during participation in the New York State Early Intervention Program. Responses to the ICS-ASD were received from 167 participating families around the time that their child transitioned out of the EI program. Measurement analyses were conducted through the Rasch framework using WINSTEPS (Linacre, 2003) data analysis software. Scale reliability and principal components analysis were

conducted using SPSS.

Results:

Cronbach's alpha for the 83-item ICS-ASD was .99. Point-measure correlations for the items ranged from .66 to .83. Item mean square infit statistics ranged from 0.62 to 1.67, with values for all but 10 items between 0.70 and 1.40. A principal components analysis indicated that all the items loaded substantially (.62-.92) on the first component, which explained 72% of the variance. Five other components together explained an additional 10% of the variance.

Conclusions:

Findings of this study suggest that the ICS-ASD yields reliable measures of the extent to which parents report that EI helped their child with ASD achieve key developmental outcomes. Work is currently under way to examine the validity of the ICS-ASD as a measure of the overall developmental progress of children with ASD in EI. For state accountability purposes, the ICS-ASD represents a highly cost-effective data source that can inform program improvement efforts. Its use also reinforces the importance of family members' participation in the evaluation of EI services for young children with ASD.

72   **107.072** Examining System-Level Resources in Building Employment Capacity for Adults with ASD

D. B. Nicholas[1], L. Zwaigenbaum[2], M. Clarke[3], K. P. Stoddart[4], B. Muskat[5], W. Roberts[6], M. Spoelstra[7], S. Duhaime[4], H. Emery[8], L. Ghali[9], D. Barrett[10], L. Parakin[11], C. Carroll[12], P. Mirenda[13], I. M. Smith[14] and T. Jackman[15], (1)University of Calgary, Edmonton, AB, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Pediatrics, University of Calgary, Calgary, AB, Canada, (4)The Redpath Centre, Toronto, ON, Canada, (5)Social Work, The Hospital for Sick Children, Toronto, ON, Canada, (6)Pediatrics, University of Toronto, Toronto, ON, Canada, (7)Autism Ontario, Toronto, ON, Canada, (8)University of Calgary, Calgary, AB, Canada, (9)The Ability Hub, Calgary, AB, Canada, (10)Autism Society Alberta, Edmonton, AB, Canada, (11)Autism Calgary Association, Calgary, AB, Canada, (12)Autism Nova Scotia, Halifax, NS, Canada, (13)University of British Columbia, Vancouver, BC, Canada, (14)Dalhousie University / IWK Health Centre, Halifax, NS, Canada, (15)Autism Society Canada/Autism Society Newfoundland and Labrador, St. John's, NF, Canada

Background:

Despite gains in employment supports for adults with autism spectrum disorder (ASD), substantial gaps remain. The Canadian population-based *Participation in Activity Limitation Survey* (PALS, 2006) database suggests that adult males (25-64 years) with ASD, have remarkably lower labour market participation. Only 40% of adult males in this category are employed. Less than half participate in the labour force (employed or unemployed but looking for work). These employment outcomes are approximately 10% lower than other disabled male counterparts. Given these outcomes, it is not surprising that there is a substantial reliance on social assistance and disability benefits (PALS, 2006). Vocation-related service needs for adults with ASD have thus emerged with increased urgency as a growing cohort of adolescents with ASD are aging into adulthood.

Objectives:

This study addressed employment access and support for adults with ASD. It examined the perceived quality of employment supports, and the experiences of adults with ASD, families and employment support service providers, relative to employment support.

Methods:

A mixed method study was conducted in five regionally-distinct provinces across Canada, comprising the following methods:

(A) An employment support capacity survey, and

(B)   Qualitative interviews with key stakeholders.

Results:

 (A) An employment support capacity survey was completed by n=95 senior level service providers (one per organization) across Canada. Participants ranked, based on percentages, their ASD employment support capacity (followed in parenthesis by mean capacity ranking): (i) organizational capacity to provide employment support to individuals with ASD (88.9%), (ii) organizational capacity to meet the broader needs of adults with ASD (beyond only vocational needs) (75.4%), (iii) organizational capacity for evidence-informed service planning and evaluation (62.2%), and (iii) broader community capacity of the region to meet the employment support needs of adults with ASD (57.8%). With regard to the first three domains, there was general, although mixed and incrementally decreasing, agreement among respondents that their respective agencies were variably successful in addressing the employment support needs of individuals with ASD. In the fourth domain of "community capacity", there was a decrease in terms of perceived effectiveness to meet employment support needs for adults with ASD.

(B) Qualitative interviews were conducted with n=141 stakeholders, consisting of adults with ASD (n=45), parents/caregivers (n= 60), and service providers (n=36). Interviews indicated that current services are insufficient to provide the extent and nature of support needed by persons with ASD to achieve desired engagement and success in employment and other adult life contexts.

Conclusions:

Vocational challenges for persons with ASD were compounded by a lack of access, coordination and collaboration between agencies, secondary and post-secondary schools, and government systems. Funding was repeatedly not equitably distributed across the ASD spectrum in terms of employment

support, and participants consistently conveyed that support agency/program criteria can emerge as a barrier to resource access. Heightened challenges for families with lower SES were identified. Overall, greater opportunity for employment access, retention and advancement for adults with ASD is needed, as are strategies to build employer capacity. Practice and policy implications will be offered.

73 **107.073** Examining the Overlap of School Disciplinary Action, Hospitalization, and Police Contact in Individuals with Autism Spectrum Disorder: Predictable Factors for Preventable Outcomes

P. F. Turcotte[1], L. J. Shea[1] and D. S. Mandell[2], (1)A.J. Drexel Autism Institute, Philadelphia, PA, (2)Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA

Background: Children and adolescents with autism spectrum disorder (ASD) are at a greater risk for adverse outcomes, such as psychiatric hospitalization, police contact and school disciplinary actions, than other children. Little research has examined these outcomes in the same sample. If different child characteristics predict different outcomes, it would suggest that prevention strategies should differ for these different outcomes. If these outcomes are correlated and similar child characteristics predict all of them, it would suggest potential concurrent points of prevention for several adverse outcomes.
Objectives: To examine associations among school disciplinary actions, police contacts, and psychiatric hospitalizations for children with ASD, and demographic and clinical factors associated with each and all of these adverse events.
Methods: Survey data from a statewide ASD-specific needs assessment provided data for this study. Data were included from 2,525 parent/caregivers with a child with ASD in elementary, middle, or high school. A police contact was defined as having any interaction with the police leading to disciplinary action. A school disciplinary action was defined as detention, in and out of school suspension, and expulsion. A hospitalization was defined as admittance to an emergency room or hospital or hospital-like setting for behavioral or psychiatric reasons. Frequencies describing the outcome variables and demographic variables were tested for significance using chi square analysis. Logistic regression will be used to estimate the association between these outcomes and demographic and clinical variables.
Results: In our sample, 378 individuals (15%) had a school disciplinary action, 196 (8%) experienced a hospitalization, and 199 (8%) had contact with the police. Variables that will be included in the regression analyses include parent or caregiver marital status, primary diagnosis, and age. A significant amount of individuals experienced greater than one negative outcome, 156 experienced two of the three negative outcomes, and 31 experienced all three. Early results suggest that family structure, primary diagnosis, and age may be significant predictors of these negative outcomes.
Conclusions: School disciplinary action, psychiatric hospitalizations, and police contact are traumatic for individuals with ASD and their families and costly to the systems that serve them. The results of this study suggest their significant overlap, and that experiencing one of these outcomes is a risk factor for the other two. Although the present study was cross sectional, it may be that children experiencing negative outcomes early on (most likely school disciplinary actions), are at high risk for hospitalization and police contact, and should be targeted for more intensive interventions and supports. Demographic and clinical characteristics predicting these outcomes offer important points for intervention or to identify groups at high risk.

74 **107.074** Factors Affecting Caregiver Satisfaction with a Family-Centered Evaluation for Autism Spectrum Disorder (ASD)

*E. Bernabe[1] and **L. Dewey**[2], (1)Behavioral Health, Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE, (2)Nemours/Alfred I duPont Hospital for Children, Wilmington, DE*

Background: Research consistently shows that the needs of children with ASD are complex and involve medical, educational, social, community, and family factors. These complex needs often necessitate multidisciplinary care and coordination of services from a wide range of providers (Volkmar et al., 2014). Unfortunately, studies have identified difficulties when families of children with ASD attempt to access empirically-validated services in a coordinated way, thus reducing family satisfaction and delaying initiation of services (Liptak et al., 2006). Furthermore, although ASD can be diagnosed in children as young as 12 months, delays in accessing healthcare systems often prevent diagnosis until age four (CDC, 2014). This delay in diagnosis prevents the family from accessing early, intensive behavioral interventions which have been empirically validated to significantly improve the social, communication, cognitive, and adaptive functioning of children with ASD (Wong et al., 2014). Given wait-times for ASD evaluation that exceed one year, a single-visit evaluation clinic where children are evaluated within one month was developed in a hospital setting to rapidly assess a family's needs and expedite medical diagnosis and recommendations.
Objectives: Minimal research has investigated caregiver satisfaction with a hospital-based, single-visit evaluation clinic for children with ASD. Thus, the aims of the study were to: 1) assess if pre-existing diagnosis impacts caregiver satisfaction; 2) assess if type of recommendations offered during the evaluation impacts caregiver satisfaction; and 3) assess if child's age impacts caregiver satisfaction.
Methods: Following participation in the evaluation clinic, caregivers (n = 67) completed questionnaires that assessed satisfaction with the evaluation. Caregivers were divided into groups based on pre-existing diagnosis (no diagnosis, ASD diagnosis, other mental health diagnosis) and

child age (four and under, over four). Recommendations offered during the evaluation were obtained via chart review.

Results: Overall caregiver satisfaction with the evaluation was high (M =28.58 out of 35, SD = 7.5). Caregivers of children with no pre-existing diagnosis were more satisfied [$F(2, 57) = 4.94$, $p = .011$] and reported greater stress reduction as a result of the evaluation [$F(2, 57) = 5.48$, $p = .007$]as compared with those whose children had a pre-existing diagnosis (see Figure 1). Caregivers of children four years and younger were significantly more satisfied than parents of older children [$F(1, 59) = 7.85$, $p= .007$] (See Figure 2). The recommendations provided (e.g., referred for further testing) did not impact caregiver satisfaction.

Conclusions: Preliminary data indicate that a rapid, one-visit evaluation meets family's needs for diagnosis, particularly when they lack prior diagnostic clarity or if their child is under age four. Additionally, the outcome of the appointment, such as whether further testing was recommended, did not impact satisfaction. The preliminary results of this study offer a cost-effective model for diagnosis of ASD that meets family's needs and supports access to empirically-validated interventions.

75   **107.075** Home and Community Based Services Waivers for Children with Autism Spectrum Disorder

D. L. Velott[1], E. Agbese[1], D. S. Mandell[2], B. D. Stein[3,4], A. W. Dick[3], H. Yu[3] and D. L. Leslie[1,5], (1)Public Health Sciences, Penn State Hershey College of Medicine, Hershey, PA, (2)Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA, (3)RAND, Pittsburgh, PA, (4)University of Pittsburgh School of Medicine, Pittsburgh, PA, (5)Psychiatry, Penn State Hershey College of Medicine, Hershey, PA

Background:

Autism spectrum disorder (ASD) is a complex lifelong neuro-developmental disorder associated with repetitive behaviors, restricted interests and impairments in social communication that affects one in 68 children. The disorder often co-occurs with significant behavioral and communication challenges. While the causes of autism are unclear, early diagnosis and evidence-based treatment, such as therapy delivered by trained behavior analysts for up to 40 hours per week, have been shown to enhance cognitive and adaptive functioning. Although several states have enacted policies to facilitate access to care, such as insurance mandates or mental health parity laws, many families of children with ASD experience significant barriers to obtaining needed services.

Objectives:

To describe characteristics of 1915(c) Home and Community Based Services (HCBS) waivers for children with ASD across states and over time. While increasingly popular, little is known about these Medicaid waivers. Understanding the characteristics of these programs is important to clinicians and policy makers in designing programs to meet the needs of this vulnerable population and to set the stage for evaluating changes that occur with the implementation of health care reform.

Methods:

HCBS waiver applications that included children with ASD as a target population were collected from the Centers for Medicare and Medicaid Services (CMS) website, state websites, and state administrators. A data extraction tool was used to document waiver inclusions and restrictions, estimated service provision and institutional costs, and the inclusion of four core ASD services: respite, caregiver support and training, personal care, and behavioral treatments.

Results:

Investigators identified 29 states offering 49 current or former waivers that explicitly included children with ASD in their target populations. Of these waivers, 10 were exclusively targeted to children with ASD while the others included either adults with ASD or adults and children with other developmental disabilities. Waivers differed substantially across states in the type and breadth of ASD coverage provided. Specifically, waivers varied in the (1) minimum or maximum age for inclusion (i.e., no restrictions, 0-2, <8, 0-21); (2) limits on the length of time one could be served by the waiver (no limit, 3 years); (3) individual cost limits (i.e., dollar limits that individuals were not allowed to exceed based on level of service designations or estimated institutional costs); (4) geographic exclusions; (5) limits on the amount, frequency or duration of specific services; (6) the maximum number of participants that could be served in a year (30 – 110,000); (7) state estimated cost of services ($6,295-$161,040), and (8) specific services offered to children with ASD (ABA to respite only).

Conclusions:

HCBS waivers for children with ASD are very complex and are not consistent within or across states. As states and advocacy groups continue to develop these programs to facilitate access to care for individuals with ASD, understanding and evaluating current programs is critically important. Further efforts are needed to examine the characteristics of these programs that are associated with improved access to care and clinical outcomes to maximize the benefits of these programs to individuals with ASD and their families.

76   **107.076** Identifying Interventions for Dissemination and Implementation Research Using the National Database for Autism Research (NDAR): Promises and Pitfalls

N. Payakachat[1] and J. M. Tilford[2], (1)Pharmacy Practice, University of Arkansas for Medical Sciences, Little Rock, AR, (2)Dept. of Health Policy and Management, University of Arkansas for Medical Sciences, Little Rock, AR

Background:
The National Database for Autism Research (NDAR) is an NIH-funded research data repository created with the express purpose of accelerating autism research by integrating heterogeneous datasets through data sharing agreements with the National Institute of Health.
Objectives:
This study summarizes a user-developed catalog of interventions shared in NDAR that would assist health services researchers and implementation scientists interested in autism studies that could be targeted for dissemination and implementation.
Methods:
This descriptive study was conducted through October 15, 2014 to review all shared NDAR data using the "data from labs" query. The term "intervention" refers to any treatments or services provided to children with autism to improve core impairments and other associated symptoms. Each NDAR project was reviewed using its research description in the NIH Research Portfolio Online Reporting Tools to identify if any interventions were involved. A catalog of interventions was then created in an Excel spreadsheet and shared data were downloaded for further investigation.
Results:
A total of 184 research projects have shared data with NDAR involving 108,386 subjects by age (54,053 affected subjects by age and 54,333 control subjects by age) whose ages ranged from toddlers to adults. Sixty-three projects (34%) involving interventions were identified. These projects were categorized further as observational (7), effectiveness (10), health services research (11), and efficacy (35) studies. However, 30 projects appearing in NDAR have not yet released their data and at least 20 projects are still ongoing, resulting in 11,972 subjects with information currently available. Interventions include pharmacotherapy (3), early intensive behavioral therapy (5), cognitive behavioral techniques (3), community health services (3), and others (e.g., peer-engagement, sensory integration based therapy, school integration service, language integration).
Conclusions:
The NDAR has high promises for data aggregation and secondary analyses to guide dissemination and implementation of interventions. However, missing data seems to be a prominent problem in those previously sharing data. In addition, researchers require clinical background knowledge on a large number of measures used in autism to enable data aggregation. Despite some inconvenience associated with finding needed data, downloading time, and data cleaning, NDAR provides rich data for the autism research community without charge. Future improvements to NDAR and those providing data can be expected that will greatly improve functionality for services research to extract information on treatments or interventions provided to individuals with autism.

77 **107.077** Imprinting Variation in the Diagnosis of ASD at Two Specialty Clinics

P. Colatat[1], Y. Qian[2], M. L. Massolo[2] and L. A. Croen[2], (1)Olin Business School, Washington University in St Louis, St Louis, MO, (2)Division of Research, Kaiser Permanente Northern California, Oakland, CA

Background:
A large part of the public controversy over ASD stems from the process of diagnosis. Like many other disorders presenting as mental or behavioral rather than immediately physiologic, diagnosis is made on the basis of interpretation against a set of qualitative behavioral criteria in the Diagnostic and Statistical Manual of Mental Disorders (DSM). Intellectually, health care providers must connect specific observed symptoms to abstract criteria. Because the process of inference is opaque, it is unclear whether too few, too many, or simply the wrong people are being diagnosed.
Variation in medical practice among health care providers has been well documented in a number of settings (e.g. Dartmouth Atlas). Applied to the diagnosis of ASD, it is likely that there exists substantial variation in diagnostic practice among health care providers – not only in the structure of the evaluation and the use of specific instruments such as the ADOS, but also in the way in which evidence is assessed against diagnostic criteria.
Sociologists of organizations and professions have studied how technical knowledge may diffuse across individuals or remain localized. The processes studied by sociologists may explain the distribution in diagnostic knowledge and, therefore, differences in diagnostic outcomes both temporally and spatially.
Objectives:
This research examines diagnostic 'styles' among health care providers and how these styles are shaped by factors in the health care workplace.
Methods:
We obtain data from a large HMO which operates two clinics specializing entirely in ASD diagnosis. Data include electronic medical records of eight birth cohorts (n=276,395) as well as qualitative data including: direct observation of evaluations at the clinics, 28 interviews, and internal documents describing the history of ASD diagnosis at the HMO. These qualitative data amount to over 200 pages of field-notes and interview transcripts.
Results:
We demonstrate a 30 percentage point difference in ASD diagnosis rates between the two clinics even after controlling for patient characteristics. Methodologically, we accomplish this by (1) including controls in regression models and (2) exploiting a natural experiment based on changes in clinic catchment areas. These results suggest that local organizational, cultural factors may be responsible for the observed diagnostic difference.

Organizational factors are identified and described using qualitative data. We find that the local style of diagnosis was influenced by key individuals at each clinic during the opening of each clinic. These differences in diagnostic styles persists even as these key individuals have left the HMO or have taken on different roles, and despite efforts by organizational leaders to establish a uniform diagnostic process throughout the HMO.
Conclusions:
It is commonly understood that increased diagnosis reflects an increased awareness of ASD, especially in the health care community. The implications of this are underexplored however. Namely, this suggests that variation in knowledge across health care providers and health care organizations shapes the observed patterns of ASD diagnosis. Our research is among the first to study the health care organization directly and muster substantial evidence describing how organizational processes can lead to unexpectedly large differences in diagnosis rates.

78   **107.078** Improving Early Access to Care in Underserved Communities

*A. D. Norton[1], **M. Zuniga**[2] and J. Harris[2], (1)Autism, Children's Specialized Hospital, Mountainside, NJ, (2)Children's Specialized Hospital, Mountainside, NJ*

Background: Early diagnosis of autism is associated with earlier access to intervention which increases optimal outcomes, yet research suggests that racial and income disparities exist in early detection of developmental disabilities including autism. While symptoms of autism may be noted as early as 12 months of age, the average age of diagnosis is 4-5 years and is significantly higher among African American and Hispanic children. This delay means that young children with ASD might not get the help they need. Children with low SES, racial and ethnic minorities and those with limited English proficiency are less likely to be identified with ASD despite no known prevalence differences. When identified as having ASD, those with low SES, racial or ethnic minorities are often identified at later ages. Reasons for disparities in identifying autism and developmental disabilities are varied and may include access difficulties due to insurance or transportation issues as well as lack of available local service providers.
Objectives: A model program was created to provide free community-based developmental screening within underserved communities in order to improve early access to care.
Methods: Target sites for screening clinics were located primarily in low income cities having large percentages of racial minority, Hispanic/Latino, and/or Spanish-speaking households. The free clinics were held in locations near public transportation and easily accessible such as libraries, recreation or community centers or daycare centers. Screening staff had expertise in child development and provided screenings to children ages 11-66 months in English or Spanish. The Ages and Stages Questionaire-3 (ASQ-3) was administered interactively with the child and accompanying parent/guardian. Resources to promote child development and anticipatory guidance were provided to all families and those screened as at risk were also given resources for further evaluations and information to be shared with their healthcare provider. Phone follow up for those at-risk was provided one month following screening to determine if further help was needed to access services.
Results: 715 children were screened, with 50.3% found to be at risk. The children identified as at risk had not been previously seen by a developmental specialist. At one month follow up, 59% of those at risk were able to be contacted. Those not contacted had disconnected phones or did not respond to 3 phone messages.Of those contacted, 96.3% had arranged diagnostic evaluation, early intervention, and/or school-based services.
Conclusions: A model developmental screening program was created to reduce healthcare disparities in early access to care among an underserved population. Provision of free, quick interactive bilingual screenings in easily accessible community locations eliminated access barriers such as insurance, transportation, and difficulty finding services, and resulted in identification of young children not previously identified as at risk for developmental disabilities including ASD. Of note is that the ASQ-3 allows for alternative administration methods and materials for children from different cultural backgrounds and was normed with culturally diverse populations. Cross-cultural considerations of screening programs will be discussed.

79   **107.079** Improving the Patient Experience for Families of Children with Autism Spectrum Disorder through Use of an Autism-Specific Care Plan

S. broder-Fingert[1], A. M. Shui[2], C. Ferrone[3], K. Donelan[4], A. M. Neumeyer[5] and K. Kuhlthau[6], (1)Boston University School of Medicine, Newton, MA, (2)Biostatistics Center, Massachusetts General Hospital, Boston, MA, (3)Lurie Center for Autism, Lexington, MA, (4)Mongan Institute for Health Policy, Massachusetts General Hospital, Boston, MA, (5)Pediatrics, Lurie Center for Autism Massachusetts General Hospital, Lexington, MA, (6)Department of Pediatrics, Massachusetts General Hospital, Boston, MA

Background: Hospital admissions can be difficult for patients with autism spectrum disorder (ASD) and their families. Therefore, as part of a quality improvement initiative at MassGeneral Hospital *for* Children, we created an autism-specific care plan (ACP) to be used during hospital admissions. The ACP is an electronic document completed by families or physicians which delineates a patient's ASD-specific needs related to a hospital admission (e.g. mode of communication, sensory issues, safety concerns) and is loaded into the patient's medical record.

Objectives: The objective of this pilot study was to compare the experience of care for children with ASD who used an ACP to children with ASD who did not an ACP.

Methods: In April 2014, we mailed surveys to all parents of children with ASD (ICD-9 code 299.0 or 299.8) who had a hospital admission between January 2013-December 2013 (n=143). Of these, 33 used an ACP and 109 did not. The ACP group was self-selected and response rate was 69.6% in the ACP group and 64.2% in the non-ACP group. Question domains included general experience with hospital care and experience related to the patient's ASD. We then used multivariable linear regression to assess the association of experience of care with ACP use, while adjusting for reason for hospital visit and autism severity.

Results: The ACP group was more likely to be admitted for a medical versus psychiatric diagnosis, and had more severe autism symptoms than the non-ACP group. Parents who used the ACP reported better experience of care relating to their general hospital experience (B coefficient 1.48, p<0.001) and staff attention to the child's ASD specific needs (3.06, <0.001) compared to those without an ACP.

Conclusions: Based on this pilot study, care plans may hold promise to improve the experience of care for children with ASD and their families in the hospital setting. Limitations include non-randomized study population and small sample size. More rigorously designed trials are needed to determine if these findings persist.

80   **107.080** Mapping the Diagnosis of Autism Spectrum Disorders By Age 7 in Australia: 2010 – 2012

C. A. Bent[1], C. Dissanayake[2] and J. Barbaro[3], (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Olga Tennison Autism Research Centre, Melbourne, Australia, (3)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Victoria, Australia

Background: The early diagnosis of young children with Autism Spectrum Disorder (ASD) is critical to ensure access to early intervention services. ASD can be accurately and reliably diagnosed by 24 months; however, diagnosis often does not occur until a later age.

Objectives: The frequency and age of diagnosis (AoD) of ASD in children, under 7 years, living in Australia was investigated to examine trends across states, metropolitan, regional and remote areas and the child characteristics of sex, diagnosis type, Indigenous, and cultural minority group status.

Methods: Secondary de-identified data regarding 15,096 children aged 0 – 7 years registered through the national Helping Children with Autism Package between 2010 and 2012 were utilised. ASD diagnoses consistent with the DSM-IV were confirmed by a pediatrician, psychiatrist or multidisciplinary team assessment. The number of cases by state was calculated and compared to the estimated population of children in the specified age range.

Results: On the basis of this data, 0.74% of the population of children aged 0-7 in Australia are currently diagnosed with ASD. The average age of diagnosis of ASD (by age 7 years) was 49 months, with the most frequently reported diagnostic age being 71 months. Differences were evident in the frequency of ASD and average AoD across states (see Figure 1) and between major cities, regional and remote areas. There was no difference in AoD between Indigenous and non-Indigenous Australians, but children from a culturally and linguistically diverse background were diagnosed 5 months earlier than other children.

Conclusions: The current AoD of ASD in Australia indicates a substantial gap between the age at which a reliable and accurate diagnosis is possible, and the age at which most Australian children are diagnosed with ASD. Findings suggest that the frequency of ASD in Australia has increased substantially from previous estimates.

81   **107.081** Meta-Analysis of Community-Based Early Intervention Programs for Children with Autism Spectrum Disorders

A. S. Nahmias[1,2], D. S. Mandell[3] and J. Pereira[1], (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Psychology, University of Pennsylvania, Philadelphia, PA, (3)Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA

Background:

Careful measurement of interventions delivered in community settings is an important component of developing effective and sustainable programs. Part of the rationale of measuring community-based intervention is to identify intervention characteristics that are associated with improved child outcomes. Recent results from early intervention trials suggest significant variability in the extent to which children with ASD make gains in community-based early intervention programs. For example, children in some community preschool programs make equivalent gains to children in university-developed programs (Boyd et al., 2013), while children in other programs make much smaller gains (Magiati et al., 2007). To date, however, results from community-based early intervention programs and usual practices have not been examined systematically. Estimating the variability in and predictors of outcomes from published reports of community early intervention programs offers a first step to identifying active ingredients that are potentially effective in community settings.

Objectives:

To calculate the average effects and predictors of cognitive, adaptive behavior, communication, and social outcomes among children receiving community-based early intervention.

Methods:

Studies of community-based early intervention for children with autism were identified through a systematic search of online databases (PsycInfo, Medline, Eric, and Proquest dissertation), hand-searching relevant journals, and reviewing citations from previous meta-analyses and systematic reviews. Community-based early intervention was defined either as "treatment as usual" control groups in randomized or quasi-experimental trials or in studies that explicitly examined outcome in community settings. Changes in cognitive, adaptive behavior, communication, and social functioning from pre-treatment to post-treatment were assessed using standardized mean gain scores. Effect sizes (Hedges' g) were calculated by dividing the mean change from pre to post-treatment by the pooled standard deviation of the difference score. Overall effect sizes were estimated using random effects models. The Q-statistic and the I^2 index were used to examine heterogeneity of effect sizes. Potential moderators included type of intervention, geographic location of intervention, year of intervention, sample section methods, sociodemographic characteristics of participants, and length of intervention; their effects were assessed using analysis of variance of mixed-effects models and meta-regression analyses.

Results:
Analysis, especially of moderators, is ongoing. Preliminary results based on 22 studies showed an average effect size of 0.2 (95% CI 0.1 -0.3), 0.5 (95% CI 0.3-0.8), 0.4 (95% CI 0.3 -0.6), and 0.4 (95% CI 0.2-0.5) for cognitive, adaptive behavior, communication, and social outcomes respectively.   Hedges' gs for individual studies ranged from 0.0-0.7 for cognitive outcomes, 0.1-1.3 for adaptive behavior outcomes, 0.0-1.1 for communication outcomes, 0.0-0.9 for social outcomes. Significant heterogeneity across studies was identified for adaptive behavior, communication, and social outcomes.

Conclusions:
Children receiving community-based early intervention make small to medium sized gains on average. The heterogeneity in outcomes suggests significant variation in program quality. Examination of intervention features associated with more effective community-based early intervention programs could offer insight into program features that may be important to consider in the implementation of other community-based programs.

82   **107.082** Missed Opportunities: Use of Early Services and Age of ASD Diagnosis Among African American Children

S. S. Richardson, *S. E. Barnum, T. Hamner, J. P. Berman and C. A. Saulnier, Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA*

Background:
Early identification and accurate diagnosis of ASD are critical for tailoring autism-specific early intervention services, guiding parents, and accessing resources. On average, parents visit multiple professionals, wait a year for diagnosis, and report dissatisfaction with the overall process (Goin-Kochel, Mackintosh, & Myers, 2006; Wiggins, Baio, & Rice, 2006). Interpreting research on age of diagnosis is complicated by disparities based on race and SES in access to services. African American children, on average, receive diagnoses later than Caucasian children (Mandell et al., 2009).
Objectives:
The goal of this study was to determine early service use and its relationship to age of ASD diagnosis for African-American children.
Methods:
Fifty-three children (42 males and 11 females) with a confirmed ASD diagnosis and their primary caregivers participated in the current study. An additional 30 participants are expected before May 2014. Family variables and service history were obtained via the ACE-2 EHCI: Diagnostic Odyssey Instrument (Shattuck, Mandell, & Constantino, 2013). Child functioning was ascertained using the Differential Ability Scales, Second Edition and the Autism Diagnostic Observation Schedule, Second Edition.
Results:
The average age of first diagnosis was 5 years old (SD = 33.77 months). There was no correlation between autism severity or intellectual level and age of diagnosis. Eighty-one percent of children obtained services before diagnosis, at an average age of 3 years, 1 month (SD = 20.46 months); creating a gap of 22 months between accessing services and diagnosis. There was no significant difference in age of diagnosis between children with a history of services prior to diagnosis (M = 61.74 months, SD = 29.14) as compared to those who had never received services (M= 53.60 months, SD = 34.88; $t(51)$ = 0.68, p = 0.27). Whether services were provided through public or private programs (F (3, 39) = .37, p = 0.78) (61% public, 23% private, 9% combined) and total number of services (F (2, 40) = 1.41, p = 0.26) were not related to age of diagnosis. Parent education (r = 0.33, p = 0.03) was related to number of services received, though neither education nor family income were associated with age of diagnosis. Of children receiving prior services, 59% received speech, 32% occupational therapy, 10% behavioral intervention, and 10% special education. Service type was unrelated to age of diagnosis with the exception of occupational therapy (t (41) = -0.83, p= 0.01). Children receiving OT received an earlier diagnosis (M = 56.74) than children without OT (M = 65.71).
Conclusions:
Despite recognition of the need for services, children experienced delays in diagnosis. Accurate

diagnosis is needed to educate parents and professionals, ensure access to appropriate intensive services, and refer for additional medical work-up and sibling monitoring. While most participants received services, they did not receive early, intensive Autism-specific services. In this almost two year gap, children missed opportunities for maximizing outcomes (e.g., public education services). When concerned, pediatricians should immediately refer children (especially African Americans) for both services and diagnostic evaluation. Service providers should also be empowered to refer for evaluation.

83   **107.083** Patterns of Psychiatric Comorbidity in a Sample of School-Aged Children with Autism Spectrum Disorder Receiving Community and School Based Mental Health Services

N. Stadnick[1], C. Chlebowski[1], M. Baker-Ericzen[2], M. Dyson[1] and L. Brookman-Frazee[1], (1)Psychiatry, University of California, San Diego, San Diego, CA, (2)Child and Adolescent Services Research Center, Rady Children's Hospital, San Diego, San Diego, CA

Background: Psychiatric comorbidity in children with autism spectrum disorder (ASD) is common with rates reported at greater than 70% (Leyfer et al, 2006; Simonoff et al., 2008). Given these high rates, publicly-funded community and school-based mental health (MH) programs play a significant role in treating youth with ASD. Understanding common patterns of psychiatric comorbidity in children with ASD served in publicly-funded MH programs is important to implement appropriately tailored interventions.
Objectives: To identify child sociodemographic and clinical characteristics associated with psychiatric comorbidity for children served in publicly-funded MH services.
Methods: Preliminary data are drawn from baseline assessments from an ongoing randomized community effectiveness trial of AIM HI ("An Individualized Mental Health Intervention for ASD") conducted in publicly-funded community and school-based MH services. AIM HI is a clinical intervention and training model that targets challenging behaviors in children with ASD and designed to be delivered by community MH providers. The current sample includes 103 children (86% boys) ages 5-14 (M = 8.83 years; SD= 2.51) with existing ASD diagnoses (validated by the ADOS-2) and their primary caregivers. Children were drawn from 17 participating publicly-funded community and school-based MH programs, receiving care from 91 therapists. Non-ASD psychiatric diagnoses were assessed using the MINI-KID (Sheehan et al., 1998) that was adapted for use and conducted by six study personnel with primary caregivers. Sociodemographics were assessed via parent-report, social communication skills were assessed via parent-report on the Social Responsiveness Scale (SRS; Constantino & Gruber, 2005), child behavior problems were assessed via parent-report on the Eyberg Child Behavior Inventory Intensity Scale (ECBI; Eyberg & Pincus, 1999), and child cognitive skills were assessed using the Wechsler Abbreviated Scale of Intelligence-II (Wechsler, 2011). Multivariable logistic regression analyses were conducted to identify child sociodemographics and clinical characteristics associated with meeting criteria for a non-ASD disorder. Data were examined by five diagnostic categories: ADHD, ODD, anxiety, mood, and a Tic Disorder. A model was calculated for each diagnostic category.
Results: Approximately 88% of children met criteria for a non-ASD disorder on the MINI-KID. Factors significantly associated with meeting criteria for an Anxiety Disorder included: less severe social communication difficulties (B = -0.14, p < .05) and higher ASD symptom severity (B = 0.23, p < .05) on the SRS. Factors significantly or marginally associated with meeting criteria for ODD included: greater behavior problems on the ECBI (B = 0.16; p < .01) and ADOS-2 classification as Autism Spectrum (vs. Autism) (B = -1.36; p = .06). No child characteristics were associated with meeting criteria for ADHD, a Mood Disorder, or a Tic Disorder. Child age, race/ethnicity, gender, or cognitive abilities were not associated with any disorder.
Conclusions: The majority of children with ASD receiving publically-funded MH care in this sample met criteria for at least one additional psychiatric condition. Child clinical characteristics were associated with meeting criteria for an Anxiety Disorder and ODD. Results suggest that child clinical correlates may facilitate differential diagnosis and inform appropriate tailoring of intervention for youth with ASD served in general child MH settings.

84   **107.084** Provider Practices Regarding the Treatment Referrals and Recommendations Made to Parents of a Child with ASD

K. Pickard[1] and B. Ingersoll[2], (1)Michigan State University, East Lansing, MI, (2)Psychology, Michigan State University, East Lansing, MI

Background: Literature in the autism spectrum disorder (ASD) field has highlighted that parents endorse individual recommendations as being critical in the choices that they make about service use for their child with ASD. However, research has yet to examine how intervention-related knowledge and referrals are provided to parents by providers in the community. The current study sought to clarify providers' experience when attempting to guide parents to the appropriate services for their child.
Objectives: The current study sought to determine: 1) the types of referrals made by community providers to parents of a child with ASD (i.e. generic referrals versus specific referrals); 2) provider-reported barriers when making referrals to ASD services in the community; and 3) the variables that predict providers' referrals to high quality, evidence-based practices (EBPs).
Methods: 82 providers working with of children with an ASD diagnosis completed an online survey that

assessed the following: 1) provider demographic information; 2) years of experience working with children with ASD; 3) professional confidence; 4) professional competence; 5) perceived barriers to making service recommendations in the community; 6) belief in evidence-based practices; 7) service referrals commonly made; and 8) strategies used to make referrals. Service referrals were broken down in order to analyze the variables that predicted providers' likelihood of making referrals to evidence-based practices (EBPs).

Results: Overall, 86.14% of the referrals that providers reported making were to EBPs. As part of preliminary data analysis, a stepwise, multiple linear regression was used to determine the variables that predicted the number of referrals that providers made to EBPs. As can be seen in Table 1, the final model explained 25% of the variance in referrals made to EBPs, with provider confidence and perceived barriers to service referrals as significant predictors of evidence-based referrals. Finally, providers noted many barriers when making referrals to services for families of a child with ASD in community settings. The most common of these barriers were a lack of availability of services, and a lack of insurance coverage for particular services, each being reported by over 65% of participating providers.

Conclusions: Research within the ASD field has already documented that parents endorse individual recommendations as being critical in the choices that they make about service use for their child with ASD. However research had yet to examine how these recommendations are made to parents by providers in the community. The current study provides perspective on providers' experience in making referrals, and provides important implications for the ways in which we disseminate EBPs into community settings.

85   **107.085**   Reducing Disparities in Timely Autism Diagnosis through Family Navigation

E. Feinberg[1,2], M. Augustyn[1], K. Devlin[2], J. Sandler[2], Y. Linhart[1] and M. Silverstein[1], (1)Department of Pediatrics, Boston University School of Medicine, Boston, MA, (2)Department of Community Health Sciences, Boston University School of Public Health, Boston, MA

Background: Emerging evidence demonstrates that Autism Spectrum Disorder (ASD) can be reliably diagnosed by age two, and that early identification, defined as diagnosis before age 3, can improve outcomes. Low-income and minority children with ASD, however, are diagnosed later than their white and more financially advantaged peers. Feasible, culturally appropriate interventions with broad scale-up potential are necessary to reduce this disparity. One promising strategy is patient navigation. Patient navigation has its origins in cancer care and has demonstrated efficacy in improving adherence to follow-up visits after a screening abnormality and decreasing the time from an abnormal screen to diagnostic resolution. We reframed the model from patient to family navigation and focused on a defined episode of care, beginning with an abnormal autism screen and ending with the completion of the diagnostic assessment.

Objectives: To assess the feasibility and acceptability of family navigation and its potential to decrease time to diagnostic resolution among of low-income and minority families of children, ages 15 months to 3 years, who have positive behavioral screens indicating a need for an ASD diagnostic assessment.

Methods: Pilot RCT of 40 children who failed the M-CHAT or whose clinicians have clinical concerns related to ASD and who receive primary care within an integrated urban healthcare network. Children with confirmed risk for ASD, based on the results of the M-CHAT Follow-up Interview, are randomized to receive either Family Navigation (FN) until diagnostic resolution or usual care (UC).We are examining the following process measures: participant recruitment and flow, delivery of navigator services, collection of follow-up data, and family satisfaction with FN. The primary outcome is time to diagnostic resolution. We will conduct an intention-to- treat analysis and compare time to diagnosis between groups by survival analysis, creating Kaplan-Meier plots and applying a Cox proportional hazards model.

Results: To date, we have screened 50 children of whom 34 met eligibility criteria and 32 were randomized. The FN and UC groups are demographically similar. Children were 59% male; mean age 26 months. Families were 77% non-white and 93% low-income. All FN families have had at least 2 visits with navigator, with an average of 4 encounters. To date, 11 of 16 FN families versus 7 of 16 UC families have completed the diagnostic assessment; 4 FN and 4 UC families remain in process, and 1 FN family versus 5 UC families have not completed the diagnostic assessment during the follow-up period. Among the 18 families who have completed the diagnostic process, 10 received an ASD diagnosis; mean time from confirmatory screening to diagnostic resolution among all completers was 77 days (SD 39).

Conclusions: Results support the intervention's feasibility and promise to increase the proportion of children who complete an ASD diagnostic assessment. They are consistent with an earlier pilot trial in which 19 of 20 FN families versus 10 of 19 UC families completed the diagnostic assessment. This model will be expanded and tested in a recently awarded NIMH R01, Early Identification and Service Linkage for Urban Children with Autism.

86   **107.086**   Relations Among School Professionals' Knowledge, Previous Experience, and Self-Efficacy for Working with Students with ASD

L. L. Corona[1], M. L. Rinaldi[1] and K. V. Christodulu[2], (1)University at Albany, SUNY, Albany, NY, (2)Center for Autism and Related Disabilities, University at Albany, SUNY, Albany, NY

Background: Teachers and other school professionals who work with students with autism spectrum disorders (ASD) face unique challenges (Busby, Ingram, Bowron, Oliver, & Lyons, 2012) and frequently report high levels of burnout (Jennett, Harris, & Mesibov, 2003). Teacher self-efficacy may buffer teachers and school professionals against stress and burnout. Teacher self-efficacy has been associated with quality of instruction, innovation in teaching methods, and more effective classroom management, among other positive outcomes (Ruble, Usher, & McGrew, 2011). Fostering self-efficacy among school professionals may therefore be a useful goal in working toward providing quality education for students with ASD, and some evidence suggests that training teachers in a given approach for working with students with ASD is positively related to feelings of self-efficacy (Jennett, Harris, & Mesibov, 2003).
Objectives: The objective of the present study was to examine the self-efficacy of school professionals working with students with ASD, focusing on the predictive ability of variables including school professionals' knowledge about ASD, previous training regarding ASD and evidence-based practices, and years working with students with ASD.
Methods: Participants in the present study were school professionals from New York State school districts participating in a series of trainings on best practices for educating students with ASD. Prior to beginning training, school professionals completed the Autism Self-Efficacy Scale for Teachers (ASSET; Ruble, Toland, Birdwhistell, McGrew & Usher, 2013) and an assessment of knowledge about ASD and evidence-based practices created specifically for the current project. School professionals also provided information about the number of years they had been working with students with ASD and previous training they had received on ASD and evidence-based programs, specifically positive behavior support (PBS). Preliminary results from the study (data collection ongoing) are based on 41 school professionals who participated in trainings during September-October, 2014.
Results: Bivariate correlations among the variables revealed that self-efficacy, knowledge about ASD, previous training on ASD, and previous training on PBS were all positively correlated (See Table 1). Number of years working with students with ASD was not correlated with any of the previously mentioned variables. Multiple regression was employed to examine the relative utility of each of the four independent variables (knowledge about ASD, previous training in ASD, previous training in PBS, and experience working with students with ASD) in predicting self-efficacy. When all four predictors were entered together, the full model accounted for 55% of the variance in school professional self-efficacy. Among the variables, previous training on positive behavior support was the best predictor of self-efficacy (β=0.495, t=3.260, p=.002).
Conclusions: The results of the present study suggest that the self-efficacy of school professionals for working with students with ASD is related to individual knowledge about ASD and previous training in ASD and evidence-based practices such as PBS. When taken together, training in PBS provided the best prediction of self-efficacy. This finding suggests that it is not merely time spent with students with ASD or training on ASD in general that has the largest impact on self-efficacy, but rather specific training on evidence-based practices.

87 **107.087** Supporting Students with ASD in the Inclusive Classroom: Teacher Perspectives

*M. Sreckovic[1], **T. Schultz**[2], H. Able[3] and T. White[4], (1)Frank Porter Graham Child Development Center, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Special Education, University of Wisconsin-Whitewater, Whitewater, WI, (3)School of Education, University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background:
While parents and education personnel agree that interventions addressing the social skill deficits of students with ASD are needed for students to attain independence and success (Brown, Odom, & Conroy, 2001), research suggests general education teachers do not feel prepared to implement such interventions. General education teachers have specifically noted concerns about their lack of knowledge and training related to ASD (Finke, McNaughton, & Drager, 2009) and some even hold misconceptions related to ASD (Segall & Campbell, 2012). Further, while educational professionals have indicated they want parents to be involved in their child's education, educators have reported difficulties establishing such collaborative relationships (Bezdek, Summers, & Turnbull, 2010).
Objectives:
The purpose of this study was to understand elementary, middle, and high school educators' perspectives of the social support needs of students with ASD educated in inclusive settings, their own needs as educators, and their perceptions of parent roles.
Methods:
Six focus groups and one interview were held over a one year period in one school district in a southeastern state. General and special education teachers (n = 34) who had experience working with students with ASD educated in inclusive classrooms from six different schools (two at each level of elementary, middle, and high school) were invited to participate in the focus groups. Focus groups were recorded and transcribed. Data were coded using a constant comparative method (Strauss & Corbin, 1998). Themes and subcategories were generated, reviewed, revised, and organized in order to group the data into discrete categories. While reviewing the data, memo writing (Charmaz, 2000) was used to identify relationships within the transcripts and help the researchers better understand the participants' perspectives regarding their students and professional development needs.
Results:

Themes emerged in three main categories. First, teachers across all grade levels noted several key characteristics of their students with ASD interfering with their successful inclusion in the school setting, and noted social support needs of students with ASD to include: (a) social-relationships, (b) social- academics, (c) self-advocacy, (d) transitioning, and (e) peer related needs. Second, based on these characteristics, teachers indicated a need for education and professional development in the following areas: (a) ASD and students' individual characteristics, (b) accommodations for students' academic and social needs within inclusive classrooms, and (c) promotion of advocacy for students with ASD. Third, teachers discussed their perceptions of parents' roles in supporting students with ASD, which included: (a) parental advocacy and (b) facilitating skill development at home.
Conclusions:
The study's results illuminated the critical need for social-related interventions for youth with ASD in inclusive classrooms, professional development for teachers related to facilitating successful inclusion of students with ASD, and promotion of greater parent-teacher collaboration. A collaborative approach is needed in which special and general education teachers as well as parents, collaboratively problem solve drawing on their own expertise to make successful inclusion truly work for all – teachers, peers, *and* students with ASD.

88   **107.088** The Effectiveness of an ABA Training Workshop for Teachers and Health Care Professionals in China

C. Wang[1], D. Yip[2], N. Dunn[3] and P. Bains[4], (1)School of Medicine, Nankai University, Tianjin, China, (2)P.L.A.I. Behaviour Consulting, HongKong, Hong Kong, (3)BCBA, Burnaby, BC, Canada, (4)BCBA, Vancouver, BC, Canada

Background: Applied behavior analysis (ABA) is a science in which the principles of the analysis of behavior are applied systematically to improve socially significant behavior, and in which experimentation is used to identify the variables responsible for change in behavior (Cooper, Heron & Heward, 1987). There is a growing need for trained clinicians to provide ABA-based treatment for children with autism. However, demand for Board Certified Behavior Analysts (BCBA) professionals greatly outstrips the current supply, which is evidenced by the case of Tianjin where the need for ABA intervention has continued to grow with the increasing prevalence of ASD in China. However there is a paucity of peer-reviewed evidence comparing the accessibility, effectiveness, and cost-effectiveness of different approaches to training.
Objectives: In the current paper, we examined the effectiveness of a group ABA training workshop for teachers and health care professionals in China.
Methods: 150 educators and health care professionals were recruited to participate in a five-day workshop in Tianjin, China, which was conducted by three BCBA's from Canada and Hong Kong. The workshop covered the following areas: Autism Spectrum Disorders (ASD), Early Intensive Behavior Intervention (EIBI), Applied Behavior Analysis (ABA), Discrete Trial Teaching (DTT), Natural Environment Teaching (NET) and Positive Behavior Support (PBS). The participants completed tests before and after the workshop, and the results of the tests were analyzed. The study used a causal design. The independent variable was the participation of the 5-day workshop. The dependent variable was the participants' understanding of the concepts taught, demonstrated by the scores of their tests.
Results: During the pre-test, the average score was 41%. Most participants got 40% correct. The maximum score was 70% and the minimum score was 10%. During the post-test, the average score rose to 61%. Most participants got 60% correct. The maximum score was 100% and the minimum score was 20%. Most participants obtained high scores in the areas of ASD, general ABA knowledge, EIBI, and milieu teaching strategies. In the area of applying evidence-based strategies to manage problem behaviors, the scores were significantly lower. Social validity was measured through a workshop evaluation. The scores for all likert scale of 1 to 5, items ranged from 4.5 to 4.9.
Conclusions: The group training was found to be an effective and acceptable method in increasing knowledge and understanding of ABA-based teaching strategies. It is suggested that large-group cross-cultural ABA training can be a cost effective way for training professionals across the globe.

89   **107.089** The Effects of Medicaid Home and Community-Based Services Waivers on Unmet Needs of Children with Autism Spectrum Disorder

D. L. Leslie[1,2], K. Iskandarani[1], A. W. Dick[3], B. D. Stein[3,4], D. L. Velott[1] and D. S. Mandell[5], (1)Public Health Sciences, Penn State Hershey College of Medicine, Hershey, PA, (2)Psychiatry, Penn State Hershey College of Medicine, Hershey, PA, (3)RAND, Pittsburgh, PA, (4)University of Pittsburgh School of Medicine, Pittsburgh, PA, (5)Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA

Background:
Traditionally, families of children with autism spectrum disorder (ASD) have had difficulty obtaining coverage for ASD services. The challenges in identifying, accessing, navigating and paying for ASD services can place a substantial burden on parents and caregivers of children with ASD. In response, several states have expanded Medicaid coverage for children with ASD through 1915(c) Home and Community-Based Services (HCBS) waivers. However, these waivers vary considerably across states, and little is known about their effectiveness in reducing family burden.
Objectives:

In this study, we use detailed information about HCBS waivers for ASD across all states, combined with national survey data, to examine the effects of the waivers on the perceived level of unmet need among families of children with ASD. Our goal was to determine which characteristics of these waivers appear to be most effective at reducing unmet need.

Methods:

We combined data from multiple waves of the National Survey of Children's Health and the National Survey of Children with Special Healthcare Needs with state-level data we assembled regarding characteristics of Medicaid HCBS waivers from 2000 through 2013, extracted from source materials that were submitted by states in their wavier applications. Unmet need was defined across surveys by combining questions that probe for difficulties in receiving needed care. Key HCBS waiver measures included (1) expected annual cost per enrollee, (2) annual cost limit per enrollee, (3) enrollment limit, and (4) whether the waiver specifically targeted ASD or broader developmental disabilities. With the exception of the ASD targeted measure, which is dichotomous, we normalized each of the policy variables to have mean=0 and standard deviation=1 within the sample to ease interpretation of results. We then used multivariable logistic regression in a difference-in-difference design that exploited differences in HCBS waivers within states over time to identify effects for children with ASD relative to children without ASD (controls) to characterize the relationship between unmet needs and waiver characteristics, controlling for other covariates. To examine robustness, we estimated the model using several different samples, including (1) all children, (2) children in families with income < 200% FPL, (3) all children in Medicaid, and (4) children in Medicaid living in families with income < 200% FPL.

Results:

We identified a total of 370,193 children, of whom 8,218 had ASD. The multivariable logistic regression results show that each of the waiver policies was associated with reductions in rates of unmet needs for children with ASD relative to children without ASD, and that the associations were stronger in samples limited by income and by Medicaid enrollment status. For example, 1 standard deviation increases in the cost limit and the enrollment limit were associated with ORs of 0.63 (p<.001) and 0.53 (p<.001), respectively, in the sample limited to Medicaid-enrolled children in families with income <200% FPL.

Conclusions:

Medicaid HCBS waivers have reduced unmet need among children with ASD. The characteristics of those waivers, however, are important. Our results will be useful to policymakers as they consider policies to improve access to care for children with ASD.

90   **107.090** Timeliness of Autism Spectrum Disorder Diagnosis and Subsequent Use of Services

K. E. Zuckerman[1], O. Lindly[1,2] and B. K. Sinche[1], (1)Pediatrics, Oregon Health & Science University, Portland, OR, (2)Public Health, Oregon State University, Corvallis, OR

Background: Little national data are available regarding how delays in autism spectrum disorder (ASD) diagnosis correlate with use of autism-related health and educational services.
Objectives: We assessed the relationship between age of ASD diagnosis and delay in ASD diagnosis with current use of psychotropic medications, intensive behavioral interventions (IBI), complementary and alternative medicine (CAM), and school-based therapy, in a nationally-representative sample of U.S. elementary school-aged children.
Methods: The Center for Disease Control's 2011 Survey of Pathways to Diagnosis and Services was used to assess age and delay in ASD diagnosis, and its relationship with health services use, among 722 children age 6-11 with autism spectrum disorder. Older age of diagnosis was defined as diagnosis at age 5 years or older. Longer delay in diagnosis was defined as 3 or more years between first parent concern and ASD diagnosis. Bivariate and multivariable logistic regression analyses were used to assess the association between age and delay and current use of psychotropic medications, IBI, CAM, and school-based therapy
Results: Nearly half (44.8%) of children were diagnosed at age 5 or older (95% confidence interval [CI] 38.5%-51.3%), and 39.6% (95% CI: 33.3%-46.3%) experienced a diagnostic delay of 3 or more years. Multivariable regression results showed younger age of diagnosis was associated with more frequent use of school-based therapy (adjusted odds ratio [AOR]: 2.21, 95% CI 1.12-4.35). Longer delay in diagnosis was associated with increased likelihood of CAM use (AOR: 2.55, 95% CI: 1.38-4.73). Use of psychotropic medications or IBI did not have any significant associations with age or delay in diagnosis on adjusted analysis.
Conclusions: Both older age of diagnosis and longer delay in diagnosis were associated with different health and educational services utilization patterns among elementary school-aged children with ASD. Results suggest that prompt and early diagnosis may be associated with increased use of conventional therapies for ASD.

91   **107.091** Trajectories of School-Based Services for Youth with ASD

C. J. Spaulding[1], J. A. Gates[1], K. D. Gadow[1] and M. D. Lerner[2], (1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY

Background: For children with autism spectrum disorder (ASD), educational systems are a central treatment source (Mandell et al., 2005), providing the most accessible route to services (White et al.,

2007). Though individuals with ASD often utilize numerous treatments simultaneously, some have been identified as uniquely applicable to ASD (speech, occupational therapy (OT) and physical therapy (PT); Goin-Kochel et al., 2007), while others target more general academic and mental health needs (e.g., resource room and mental health counseling; Wei et al., 2014; Hammill & Wiederholt, 1972; Griswold et al., 2002). Interestingly, cross-sectional studies suggest that younger children with ASD are more likely to be enrolled in ASD-specific services than older children (Goin-Kochel et al., 2007). It has also been noted that families and teachers of children with ASD seem initially more concerned with addressing core social deficits in the early years of a child's education before placing an emphasis on academics in later years (Pollard, 1998). As the relative *need* for services addressing core ASD deficits tends to remain stable or increase across development (Picci & Scherf, 2014), further understanding is needed regarding trajectories of ASD-specific and nonspecific services for students with ASD (Thomas et al., 2007).

Objectives: To explore the trajectory of school-based services for youth with ASD over time. We hypothesize that the amount of ASD-specific school-based services would decrease over time, while nonspecific services would increase.

Methods: Caregivers of seventy-one youth with DSM-IV-TR-confirmed pervasive developmental disorder (PDD) diagnoses (N=71; 59 male; M_{age}=10.17, SD=3.15, range=6-17) completed educational histories from Kindergarten to the child's current grade, including school-based services received in each grade. Presence as well as intensity (minutes/week) of ASD-specific and nonspecific services was examined. Hierarchical linear growth modeling was used to assess trends within educational service history and between participants over time.

Results: 92.4% of students received ASD-specific services and 65% received nonspecific services at some time during their academic career. Binomial hierarchical modeling of presence of services indicated that as youths progressed through school they were less likely to receive ASD-specific services (speech therapy: OR = .60, p<.001; PT: OR=.65, p<.01; OT: OR=.76, p=.05), and more likely to receive nonspecific services (counseling: OR=1.71, p<.001; resource room: OR=1.37, p=.04). In terms of intensity, total minutes per week of occupational therapy services diminished as youths continued through school (B = -5.06, p <.001). No other trends in service categories over time were observed.

Conclusions: Results of this study suggest a decrease in ASD-specific services, and increase in nonspecific services as youth progress through school. The results support the view that as children progress through the educational system, goals may shift from intervening for social and communication problems to increasing academic success. As school-based services are essential to treatment of students with ASD, and their need for such services usually does not decrease over time, these findings show an increasing gap between needed and delivered service categories across school. Further investigation into the cause of differential service trajectories is crucial to ensuring effective treatment access.

92   **107.092** Using Parents' and Children's Input to Inform a Peer-Mediated Intervention for Young School-Aged Children with Autism Spectrum Disorder

M. Kerr[1], A. Boudreau[2] and I. M. Smith[3], (1)Mount Saint Vincent University, Halifax, NS, Canada, (2)Dalhousie University, Halifax, NS, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, NS, Canada

Background: There is growing awareness of the research-to-practice gap in evidence-based interventions (EBI) for children with autism spectrum disorder (ASD) at school. The dearth of school-based EBIs targeting social skills for children with ASD is particularly concerning, as successful peer interactions are among parents' most valued outcomes for their children with ASD. Peer-mediated interventions (PMI) have shown initial efficacy for targeting social-communication impairments of children with ASD. Moreover, PMI is a practical approach for resource-limited schools. A peer-training approach based on Pivotal Response Treatment (PRT) holds high heuristic value for implementation in schools, given its emphasis on embedding learning opportunities into everyday contexts and routines. However, little is known about how acceptable this approach would be for individuals with ASD, parents of children with ASD, or parents of typically developing (TD) peers. Given families' roles in decisions regarding interventions for their children with ASD, it is imperative to seek their input to improve the feasibility and acceptability of school-based interventions. The views of individuals with ASD have only recently been elicited in the design of interventions.

Objectives: The current study aimed to fill a void in the literature by considering families' perspectives alongside the development of a peer-mediated, play-based PRT intervention for children with ASD in the first year of school. The goals of the study were to broadly inform peer-mediated and social skills interventions for children with ASD at school, and to inform the development of the specific proposed peer-mediated PRT intervention. Acceptability and feasibility of the proposed intervention in the school setting, as well as families' recommended modifications were examined.

Methods: Semi-structured interviews were conducted with 6 parents of children with ASD (5-10 years), 6 parents of TD children (5-10 years), and 10 youths with ASD (10-12 years; *N* = 22). The interviews examined respondents' perspectives of EBIs and PRT in general, and the overall acceptability and feasibility of the proposed intervention. Interview data were analyzed using descriptive content analysis.

Results: Overall, peer-mediated PRT was considered to be acceptable and feasible. Parents and youths agreed that communication and peer interaction skills (i.e., skills addressed in the proposed

intervention) are important intervention targets, and that the first year of school (i.e., age 4-6 years) is an ideal time to facilitate peer interaction skills for children with ASD (i.e., as in the proposed play-based intervention). Some specific challenges with respect to peers as intervention implementers were identified; these differed by participant group. Parents and youths also provided specific advice regarding components of PMI and social skills interventions broadly (e.g., concerning the acceptability of older TD children as intervention implementers).

Conclusions: Key findings provided important direction with regard to the implementation of the proposed peer-mediated PRT intervention within schools, including recommendations that informed how to frame the intervention to parents and their children with and without ASD. The current study contributes to the literature by considering family perspectives on a proposed intervention during its design. The result of this collaboration is the development of an intervention with a higher probability of uptake in the school context.

93 **107.093** Using a Wireless Measure of Electrodermal Activity: Comparisons to Traditional Wired Equipment

L. Stein[1], T. Chaspari[2], S. A. Cermak[1], S. Narayanan[2], A. Schell[3] and M. E. Dawson[4], (1)Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)Signal Analysis and Interpretation Lab (SAIL), University of Southern California, Los Angeles, CA, (3)Psychology, Occidental College, LA, CA, (4)Psychology, University of Southern California, Los Angeles, CA

Background: Electrodermal activity (EDA) has long been utilized as a physiological measure of arousal, stress, and anxiety. Traditional wired measures of EDA require a laboratory setting, electrodes attached to a polygraph by wires, and a stationary subject. New wireless EDA equipment can record in the real world without the obtrusiveness of traditional equipment. However, despite these advantages, the validity of such equipment has not been widely examined in pediatric or special needs populations.

Objectives: The purpose of this study was to compare the EDA data obtained from wireless equipment (Q-Sensor) to data from traditional, gold-standard equipment (BIOPAC). Our hypotheses were: (1) wired and wireless EDA measures would be moderately-to-highly correlated, and (2) wireless skin conductance level would be significantly lower than the wired signal due to electrode type and placement.

Methods: Participants were 37 children 6-12 years old (n=19 typical, n=17 autism spectrum disorder, ASD). EDA data using wired and wireless equipment were recorded from children in their home environment during a passive attention-sustaining task. Wired electrodes were place on distal phalanx of the second and third fingers of the non-dominant hand; wireless equipment was fit into a strap worn around the wrist, with electrodes touching the anterior surface of the wrist. A low-pass filter was applied to data from both wired and wireless sources to filter out noise and reduce artifacts. Correlation analyses to compare the average skin conductance level (SCL) and non-specific skin conductance response frequency (NS-SCR) across subjects were undertaken. Additionally, in order to measure the overall signal similarity (OSS) we computed a point-by-point Pearson's correlation coefficient between the wired and wireless signals from each subject.

Results: No significant correlation was found in SCL between wired and wireless equipment in either group (typical r=.03; ASD r=.29; p's≥.26). Additionally, the wireless SCL was significantly lower than wired results in both groups (p's<.001). Due to the extremely low SCL of the wireless signal, no NS-SCRs of ≥.05μS were obtained. Therefore, analyses were required to identify an appropriate smaller amplitude threshold of NS-SCRs for subsequent Q-Sensor evaluation. Starting with .05μS we decreased the amplitude threshold, testing 17 potential amplitudes until the highest correlation was found between wired and wireless NS-SCR frequency (threshold = .002μS, r=0.57). Comparing the NS-SCR frequency using the smaller amplitude threshold for wireless signals to the traditional .05μS amplitude for wired signals, large correlations of NS-SCRs between wired and wireless equipment were found in children with ASD (r=.71, p<.01) and all children combined (r=.57, p<.01), but not in the typical-only group (r=.11). Weak but significant OSS measures were found between the wired and wireless EDA waveforms in the ASD group (median correlation value r=0.28 with 100% of participants p<.05) and TD group (r=0.23, with 89% of participants p<0.05).

Conclusions: Preliminary support exists for the use of the new, wireless Q-Sensor when investigating NS-SCR frequency and OSS in children with ASD. However, further research is required in clinical and non-clinical populations to examine the ideal electrode type and placement for wireless EDA collection in ambulatory settings.

94 **107.094** Variables Associated with Coverage for Educational, Mental Health, and Medical Services in Autism Spectrum Disorder

S. J. Lee, J. W. Lee, L. Kraus and L. V. Soorya, Psychiatry, Rush University Medical Center, Chicago, IL

Background: The rising prevalence of ASD has been associated with increased healthcare expenditures in the United States and United Kingdom. Recent reports also suggest differential burden on public aid relative to private insurance companies with fewer services covered by private insurance in the U.S. In addition to systems level variables, demographic variables associated with coverage have potential to inform policy, improve access, and reduce economic burden related to

ASD. For example, literature in pediatric mental health care has identified multiple variables influencing service coverage. Contrastingly, diagnostic and demographic variables associated with service coverage in ASD are not well known.

Objectives: To explore potential demographic variables affecting service coverage and out-of-pocket expenditures in individuals with autism spectrum disorder (ASD), ASD and comorbid psychiatric conditions, and control groups.

Methods: Surveys were posted on institutional webpages and available for completion via the phone. Parents/caregivers (n=571) completed survey questions related to services sought, received, covered by insurance, and out-of-pocket expenses for dependents. Comparisons were made across four diagnostic groups: ASD (n=355), ASD/Psychiatric (n=101), non-ASD developmental disorders (DD, n= 41), and non-DD psychiatric disorders (n=94). Logistic regressions were completed to examine relationships between diagnosis, age, race, and income on healthcare coverage. Household income, age, and race were evenly distributed across diagnostic categories. Data are presented here from logistic regressions for three service categories: Educational, Mental health, and Medical/Auxiliary services.

Results: Coverage for educational services was predicted by diagnosis only. Individuals with ASD were two times more likely to receive coverage for educational services relative to control groups (odds ratio = 2.01). Mental health services were predicted by diagnosis, race, and age. For ASD, the odds ratio was 0.60, indicating dependents with ASD were 40% less likely to receive coverage for mental heath services sought. Dependents who were Caucasian were 60% more likely to receive coverage for mental health services (odds ratio = 1.60). As individuals grew older, the likelihood of receiving coverage for mental health services increased by 43% per age group (odds ratio = 1.43). Dependents in the ASD/Psychiatric diagnostic category were nearly three times as likely to receive coverage for medical/auxiliary services sought (odds ratio = 2.67).

Conclusions: Survey data indicate psychiatric comorbidity, age, and race were associated with service coverage for individuals with ASD. Caregivers of dependents with ASD reported higher rates of coverage for educational services relative to psychiatric and DD controls. Substantially higher rates of medical service coverage were associated with ASD and psychiatric comorbidity. Taken together with age-related findings on mental health coverage, data suggest potential to improve healthcare access via mental health delivery systems in pediatric ASD. Results also support well known findings of racial disparities in mental health care and a need for culturally sensitive diagnostic and educational programming in minority communities to improve awareness about psychiatric comorbidities in ASD.

95 **108.095** Changes in Parietal Cortex Response in Children with Autism Followed By a Visualizing Reading Intervention

J. O. Maximo, D. L. Murdaugh, A. R. Lemelman, S. E. O'Kelley and R. K. Kana, *Department of Psychology, University of Alabama at Birmingham, Birmingham, AL*

Background: Poor language comprehension is a major clinical feature of autism spectrum disorders (ASD). Previous studies suggest that individuals with ASD may rely on compensatory mechanisms such as increased use of visuospatial abilities, which are relatively spared or even superior in ASD, to better facilitate language comprehension. Such compensation may underlie altered brain activity and connectivity in ASD individuals while processing language tasks. The current study takes a translational neuroimaging approach to use visual spatial strength in ASD to address language comprehension difficulties through a reading intervention.

Objectives: The main objective of this study was to test the impact of an intensive visual imagery-based reading intervention in improving language comprehension and in changing the brain circuitry underlying language in children with ASD.

Methods: Functional MRI data were used from 20 high-functioning children with ASD and 13 typically developing (TD) control participants. The ASD participants were randomly assigned to a Wait-list control group (ASD-WLC; n = 10) and an Experimental group (ASD-EXP; n = 10). The TD group was scanned once and both the ASD-WLC and ASD-EXP groups were scanned pre- and post-intervention, with only the ASD-EXP group receiving the intervention before their second scan. Participants went through an established reading intervention program (visualizing and verbalizing for language comprehension and thinking; 10-week, 200 hours of face-to-face instruction) created by the Lindamood-Bell Learning Processes. In the fMRI scanner, the participants read a series of sentences and made judgments as to whether the sentences made sense or not (e.g., *When I want to play baseball, I grab a swimsuit and go to the pool*). fMRI data were analyzed using AFNI and SPM8 softwares.

Results: The main results are: 1) before intervention, the ASD participants, relative to TD, showed significantly reduced activation ($p < .05$, corr.) in frontal (medial prefrontal cortex, right superior frontal gyrus), ventral temporal (left parahippocampal area, right fusiform gyrus), and occipital regions (bilateral middle occipital, right cuneus) and increased activation in left inferior parietal lobule

while processing absurd and control sentences; II) the ASD-EXP group showed an increase in brain activation in occipital regions (bilateral middle/superior occipital and calcarine sulcus) compared to the ASD-WLC group post-intervention; III) intervention-related changes in brain activation were observed in the ASD-EXP group post-intervention in right precuneus, calcarine, and superior parietal lobule; and IV) multiple regression analysis, while controlling for verbal IQ, showed that changes (pre-post) in Gray Oral Reading Test (GORT) scores significantly predicted post-intervention activation in the ASD-EXP group in regions such as precuneus, middle occipital, and right IFG.

Conclusions: The findings of this study revealed that reading intervention increased the brain activity in ASD-EXP children in parietal areas associated with visual imagery. It should be noted that the increase in activation was accompanied by improvement in language comprehension in these participants. This study provides novel evidence of improvement in brain functioning in autism in the context of an innovative and rigorous imagery-based reading intervention that is designed to use nonverbal sensory input, an area relatively spared in individuals with ASD.

96 **108.096** Abnormal Induced Neural Oscillations in 16p11.2 Deletions and Duplications

S. S. Nagarajan[1], L. B. Hinkley[2], C. L. Dale[3], A. Findlay[1], T. Luks[1], P. Bukshpun[1], T. Thieu[4], N. Pojman[5], E. Marco[6], S. Khan[7], K. Heiken[8], S. Qasmieh[8], W. Chung[9], P. Mukherjee[1], R. L. Buckner[10], T. P. Roberts[11] and E. H. Sherr[6], (1)UCSF, San Francisco, CA, (2)UCSF Autism & Neurodevelopment Program, San Francisco, CA, (3)Radiology and Biomedical Imaging, UCSF, San Francisco, CA, (4)Neurology, UCSF, San Francisco, CA, (5)Neurology, Radiology, UCSF, San Francisco, CA, (6)University of California, San Francisco, San Francisco, CA, (7)CHOP, Philadelphia, PA, (8)Radiology, Children's Hospital of Philadelphia, Philadelphia, PA, (9)Pediatrics, Columbia University, New York, NY, (10)Harvard University, Cambridge, MA, (11)Children's Hospital of Philadelphia, Philadelphia, PA

Background: Rare genetic copy number variations (CNVs), specifically the recurrent ≈600 kb (BP4-BP5) 16p11.2 deletion and duplication, are known to contribute to a range of neurodevelopmental disorders, including autism spectrum disorders, language delay, and intellectual disability. Here, we examined changes in oscillatory activity derived from magnetoencephalographic imaging (MEG-I) in a large cohort of individuals recruited as part of the Simons VIP project (Simons VIP Consortium, Neuron 2013 73:1063-1067).

Objectives: We hypothesized that gene dosage in this interval is critical for the development of abnormal neural oscillatory networks in the brain that in turn are associated with behavioral phenotypes.

Methods: Data were acquired using 275-channel whole-head biomagnetometers (CTF; Vancouver, BC) installed at UCSF and CHOP. During MEG recording, participants engaged three tasks: 1) an auditory discrimination task of spoken words into semantic categories - living or non-living ; 2) a visual discrimination task differentiating between faces and patterns; 3) a picture naming task in which the subject responded by overtly naming the object on a picture. Tomographic reconstructions of oscillatory activity across the alpha, beta, gamma and high-gamma frequency bands were stimulus and response-locked and generated using an adaptive spatial filtering technique implemented in Nutmeg (nutmeg.berkeley.edu). For the picture naming task, we also compute laterality index (LI) from oscillatory activity in the left and right frontal and temporal hemispheres to evaluate language dominance.

Results: Induced high gamma activity was reduced bilaterally in auditory cortex for 16p11.2 deletion child participants only relative to their control group, in response to auditory stimuli occurring at ~100 ms post-stimulus onset. Induced high gamma activity was also reduced in the right fusiform cortex in 16p11.2 child deletion participants, in response to faces. In the picture naming task, while typically developing adults (mean age = 32.6) and children (mean age = 11.3) exhibited left-hemisphere dominance (LI>0.1 in 70% adults and 69% children), 54% of 16p11.2 child deletion carriers exhibited right-hemispheric or bilateral patterns of activity. LI was significantly lower in the 16p11.2 deletion group (p=0.0035) when compared to matched controls. Importantly, LI (or the degree of leftward laterality) in deletion carriers was positively correlated with non-word repetition (CTOPP) scores (r=0.53) – a test of phonological processing. Interestingly, in 16p11.2 adult duplication carriers, only 20% were right-hemispheric dominant, and laterality patterns were comparable to controls.

Conclusions: These results suggest pervasive abnormalities in induced neural oscillations across multiple sensory cortices in participants with 16p11.2 deletions. These findings also indicate that one versus two copies of gene(s) at 16p11.2 alter hemispheric specialization of language.

97 **108.097** Searching for Neuroimaging Targets for Interventions in ASD

K. Pelphrey, D. Yang, D. G. Sukhodolsky, M. J. Crowley, D. Oosting, H. E. Friedman, C. M. Keifer and P. Ventola, Child Study Center, Yale University, New Haven, CT

Background: As humans, we are constantly engaging in social cognition, using cues from facial expressions, gaze shifts, and body movements to infer the intentions of others, predict their actions, and plan our own actions accordingly. Considerable advances have been made in the past 20 years in the fields of cognitive, social, and affective neuroscience in identifying neural-circuit-level mechanisms of dysfunction in ASD.

Objectives: In this talk, I will describe my laboratory's research using neuroimaging techniques

including functional magnetic resonance imaging (fMRI), electrophysiology (EEG), and functional near infrared spectroscopy (fNIRS) to chart the development of brain mechanisms for social cognition in typically developing children and adolescents.

Methods: Our work has served to characterize the functional properties and development, from infancy to adulthood of a set network of interacting, distributed neuroanatomical structures dedicated to processing social meaning. In particular, I will focus on our work describing the identification of neuroimaging biomarkers for emotion regulation and the perception of biological motion.

Results: With this understanding of the typical development of the neural basis of social cognition as a backdrop, I will describe our efforts to utilize these candidate biomarkers in a developmental experimental therapeutics approach to using social neuroscience findings in the developmental and evaluation of behavioral and pharmacological treatments for autism and related neurodevelopmental disorders.

Conclusions: Availability of well-studied neuroimaging tasks that reliably engage neural circuitry of social functioning in typically developing children and in children with ASD is a prerequisite for deploying experimental-therapeutics approaches aimed at discovering novel interventions for ASD .

98   **108.098**   Thalamo-Cortical Underconnectivity during Sensory Stimulation in Youth with ASD

S. A. Green[1], L. M. Hernandez[2], S. Y. Bookheimer[1] and M. Dapretto[3], (1)Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (2)Interdepartmental Neuroscience Program, UCLA, Los Angeles, CA, (3)Ahmanson-Lovelace Brain Mapping Center, UCLA, Los Angeles, CA

Background:
Children with autism spectrum disorders (ASD) often exhibit sensory over-responsivity (SOR), which may cause them to react negatively to sensory stimuli such as noisy environments or scratchy clothing (Liss et al., 2006). Rates of SOR are over five times higher in children with ASD than in typically developing (TD) children (e.g., Baranek et al., 2006; Ben-Sasson et al., 2007) and SOR is associated with increased functional impairment (e.g., Liss et al., 2006; Pfeiffer et al., 2005). Previously, we found that individuals with ASD and SOR have hyperactivation in the amygdala and sensory cortices in response to mildly aversive sensory stimuli. Further, SOR was related to decreased neural habituation in these areas (Green et al., 2014; Green et al., under review). The present study extends these findings by examining thalamo-cortical connectivity in response to tactile and auditory stimuli in youth with and without ASD. The thalamus is considered the "hub" of the brain's sensory systems, and furthermore there is evidence for reduced thalamo-cortical structural connectivity in individuals with Sensory Processing Disorder (Owen et al., 2013). We focused on the pulvinar specifically because this thalamic nucleus is thought to aid in interpretation and integration of sensory information (e.g., Sherman & Guillery, 1996).

Objectives: To compare functional connectivity within the brain's sensory networks in youth with and without ASD during exposure to sensory stimuli.

Methods: Participants were 19 children and adolescents with ASD and 19 TD matched controls, between 9-17 years of age. During fMRI, participants were presented with mildly aversive auditory stimuli (noisy traffic sounds) and tactile stimuli (scratchy sweater rubbed from wrist to elbow). The block design paradigm included 4, 15-sec trials of each stimulus type: the auditory stimulus, tactile stimulus, or both. A psychophysiological interaction (PPI) analysis was conducted to examine functional connectivity during exposure to both sensory stimuli with the pulvinar area of the thalamus as a seed region. The pulvinar seed was functionally defined by first masking a 5mm sphere around the peak coordinate of activation in each group during the Joint condition and then adding the two masks. Within- and between-group-level analysis were thresholded at $Z > 1.7$ and corrected for multiple comparisons at $p < .05$. Both positive and negative connectivity were examined.

Results: Results are illustrated in figure below. The TD group demonstrated widespread task-based thalamo-cortical connectivity, including negative connectivity between pulvinar and primary and secondary somatosensory cortex, as well as positive connectivity between pulvinar and additional frontal and temporal cortical regions. In contrast, the ASD group had no significant task-based thalamo-cortical connectivity. Furthermore, a small volume analysis focused on the amygdala demonstrated that the ASD, but not TD group showed positive connectivity between pulvinar and amygdala.

Conclusions: In one of the first fMRI studies of sensory over-responsivity in children with ASD, we show task-related underconnectivity in ASD. Results suggest decreased cortical-thalamic inhibition, and an exaggeration of stimulus salience in ASD. These findings could help explain sensory integration deficits in ASD as well as reduced somatosensory cortical habituation to tactile stimuli.

99   **108.099**   Self-Related Processing and Its Reflections in Memory: An fMRI Study of Youth with and without ASD

R. S. Brezis[1], L. S. McKay[2], T. Galili[3], T. Wong[4] and J. Piggot[5], (1)School of Psychology, Interdisciplinary Center, Herzliya, Herzliya, Israel, (2)University of Dundee, Dundee, United Kingdom, (3)Department of Statistics and Operations Research, Tel Aviv University, Tel Aviv, Israel, (4)Department of Radiology, University of Washington, Seattle, WA, (5)Department of Psychiatry, University of Dundee, Dundee, United Kingdom

Background:
Previous studies of memory in Autism Spectrum Disorder (ASD) have pointed to specific difficulties in autobiographical memory in ASD (Lind, 2010). Furthermore, several fMRI studies have shown abnormalities in brain activation during self-processing in persons with ASD (Lombardo et al., 2009; Kennedy and Courschesne; 2008; Pfeifer et al., 2013). Yet little is known about the neurobiological correlates of autobiographical memory in ASD. To our knowledge, this is the first study to examine the functional neurobiological correlates of self-related memory, in both ASD and Typically Developing (TD) youth.

Objectives:
To determine the brain activation associated with self-related words, and their subsequent memory, in ASD and TD youth.

Methods:
Participants: Twelve youths with ASD and 15 TD youths, matched for age (range: 8-18; mean=13.3±2.9), gender (70% male) and IQ (FSIQ range: 81-141; mean=115±15) participated in the study. ASD diagnosis was confirmed using ADOS and ADI-R.

Experimental Task: While in the scanner, subjects were presented with 60 trait-words, which participants evaluated as self-descriptive or not (Self Condition); and the same words with jumbled letters, which participants evaluated for presence of the letter 'e'. Thirty minutes later, outside the scanner, subjects were presented with a recognition task including the 60 trait-words they had seen and 60 distracters.

Data analysis: BOLD activation was compared using a 2 x 2 random effects ANCOVAs, with age and VIQ entered as covariates. Two levels of thresholding were used: strict (False Discovery Rate correction with a q=0.005 and Cluster Size Threshold Estimation (CSTE) at $p<0.05$); and lenient ($p<0.005$, CSTE threshold of $p < 0.05$).

Results:
Behavioral: There were no significant group differences in self-endorsement nor in memory recognition rates.

Brain activation:
Self-processing: During Self (>Orthographic) processing, both ASD and TD participants significantly activated the left Superior Frontal Gyrus (SFG), the left Inferior Frontal Gyrus (IFG), Middle Frontal Gyrus (MFG) and the Middle Temporal Gyrus (MTG). During Orthographic (>Self) processing, participants significantly activated their precuneus bilaterally. No group differences were found at the stricter threshold, but at the more lenient threshold the left Precuneus was significantly more active in the TD than ASD participants.

Memory: The left Anterior Cingulate and Lingual Gyrus were significantly more active for Forgotten than Remembered words at the more lenient threshold; and no group differences nor interaction effects were found at either threshold.

Conclusions:
The regions activated by both ASD and TD participants during self-related orthographic and memory processes are in line with previous fMRI studies of self-related (e.g., Lombardo et al., 2009; Kennedy and Courschesne; 2008; Pfeifer et al., 2013), orthographic (e.g., Bolger et al., 2008); and memory processes (Kim, 2010) suggesting that our results are robust. Further, while it is possible that ASD individuals may be impaired on other, more complex, personal memory tasks, the fact that no group differences were found at the strict threshold for self-processing, and at either threshold for memory-related processing (and that no behavioral differences were found for this task), suggests that ASD and TD participants engage similar brain regions when processing, and remembering, self-related trait-words.

---

100 **108.100** A Pilot Neuroimaging Study of Phelan Mcdermid Syndrome

A. T. Wang[1,2,3], *T. Lim*[1,2], *J. M. Jamison*[1], *L. A. Bush*[1], *L. V. Soorya*[4], *A. Kolevzon*[1,2,5] *and J. D. Buxbaum*[1,2,3,6]*, (1)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (3)Fishberg Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Psychiatry, Rush University Medical Center, Chicago, IL, (5)Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY, (6)Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: Deletions and mutations of the *SHANK3* gene, located at 22q13.3, are one of the more common monogenic causes of autism spectrum disorders (ASD). Loss of one copy of *SHANK3* results in Phelan McDermid Syndrome (PMS), characterized by global developmental delay, hypotonia, delayed or absent speech, and ASD features. While the association between PMS and ASD is well documented at the behavioral level, there is a striking paucity of data on the underlying abnormal neural systems. Qualitative clinical profiling suggests above average rates of neuropathology in PMS, but no studies so far have included comparison data.

Objectives: The goal of this study is to investigate the effect of *SHANK3* deficiency on brain structure and function and contribute to parsing the heterogeneity in ASD. Individuals with PMS are compared with individuals with idiopathic autism (iASD). Here we present data from diffusion tensor imaging (DTI) and functional MRI.

Methods: In this preliminary study, 11 children with PMS and 9 comparison children with idiopathic autism underwent MRI under light sedation. All PMS participants met ADOS and ADI criteria for ASD;

severity of autism symptoms and developmental quotient did not differ significantly between groups. The fMRI paradigm was a passive auditory task, developed by Pelphrey and colleagues, which presented communicative (e.g., speech, vocalizations of agreement, disgust) and non-communicative sounds (e.g, sneezing, walking, water).

Results: Tract-based spatial statistics revealed significantly reduced fractional anisotropy (FA) bilaterally in the PMS group relative to the iASD group in numerous association, commissural, and projection tracts. All major long-range tracts were more impaired in the PMS than iASD group, which is striking given that ASD has been associated with significant reductions in FA in long-range tracts relative to typically developing controls.

With respect to fMRI, previous research has shown that the superior temporal gyrus/sulcus (STG/STS) is sensitive to communicative versus non-communicative sounds. Here, selective STG activity was detected in the PMS group during communicative relative to non-communicative sounds, but not in the iASD group. Moreover, better orienting toward social sounds was positively correlated with activity in the STG and medial prefrontal cortex (MPFC), relevant for theory of mind, in the PMS group. Interestingly, activity in STG and MPFC was inversely related to ASD symptom severity in both groups, but in different domains - the social affect domain for the PMS group and the repetitive behavior domain for the iASD group.

Conclusions: These initial findings suggest that long-range structural connectvity may be more compromised in PMS than in iASD. In contrast, selective functional activity in the STG appeared to be sensitive to communicative versus non-communicative sounds in the PMS group despite severe receptive and expressive language impairment. While caution is warranted given the small sample size, these data represent a first step in characterizing the neural phenotype of PMS and identifying common and distinct neurobiological substrates with ASD more broadly.

Poster Session
109 - Cognition: Attention, Learning, Memory
11:30 AM - 1:30 PM - Imperial Ballroom

101   **109.101** A Child-Friendly Eye-Tracking Paradigm Reveals Impaired Implicit Repetition Learning in Adults and Children with ASD

S. B. Gaigg[1], E. Jones[2], A. Roestorf[1], D. M. Bowler[1] and C. T. Derwent[1], (1)Autism Research Group, City University London, London, United Kingdom, (2)Birkbeck College, University of London, London, United Kingdom

Background: In the domain of memory adults with ASD tend to experience difficulties in repeating back sequences of stimuli in their order of presentation (Poirier et al., 2011; Gaigg et al., 2014). When tasks require participants to respond as quickly as possible to repeating sequences of stimuli children with ASD sometimes demonstrate typical learning rates (Barnes et al., 2008; Brown et al., 2010; Travers et al., 2010) and sometimes not (Motofsky et al., 2000; Gordon & Stark, 2007). This pattern is of considerable interest because explicit and implicit serial order memory processes play a critical role in children's language development (e.g., Ullman, 2004). It is therefore possible that individual differences in this domain contribute to the heterogeneity in language development in ASD. To examine this issue fully it is necessary to device methods that can be used to study serial order memory in children of any age and ability level.

Objectives: Our primary objective was to develop a novel eye-tracking paradigm that is suitable for examining serial order memory processes in children and adults of any age and ability level.

Methods: Two experiments are reported that involved 38 adults (19 ASD; 19 TD) and 54 children (31 ASD; 23 TD) respectively. The adults in experiment 1 all had IQs within the typical range whereas experiment 2 included children with and without substantial learning difficulties. In both experiments participants were asked simply to 'watch out for' a rabbit that appeared in a repeating sequence of 5 (out of a possible 8) rabbit holes on a screen. A Tobii eye-tracker was used to monitor gaze latencies to the rabbit and to quantify the number of times participants anticipated the rabbit in a particular location.

Results: In both experiments gaze latencies to the rabbit and anticipatory fixations indicated significantly reduced implicit repetition learning in the ASD groups. Importantly, and in line with observations from explicit serial order memory tasks, both groups appeared to learn in which of the 8 locations the rabbit was likely to appear. In other words, both groups anticipated the rabbit progressively more frequently in one of the 5 locations that formed part of the sequence, even if they did not anticipate it in the correct location at the correct time. Moreover, both groups also demonstrated reliable primacy effects, whereby gaze latencies to the first rabbit in the sequence decreased significantly more over successive trials than gaze latencies to the other rabbits in the sequence.

Conclusions: Both experiments extend the findings from explicit serial order memory tasks (e.g., Poirier et al., 2011) in showing that adults and children with ASD experience relatively specific difficulties in learning about the order of events. Moreover, the observations suggest that eye-tracking paradigms such as these will proof fruitful for examining the developmental trajectory of serial order memory processes in ASD in the future.

109.102 A Meta-Analysis of the Wisconsin Card Sort Task in Autism

O. Landry[1] and S. Al-Taie[2], (1)La Trobe University, Bendigo, Australia, (2)McMaster University, Hamilton, ON, Canada

Background: Despite 30 years of research, there remain inconsistencies in reports of the nature of the executive dysfunction of autism. One of the most widely used tests of executive function is the Wisconsin Card Sort Task. There are numerous conflicting reports of the nature and magnitude of purported impaired facets of performance, as well as presumed facets of intact performance. Executive function is a broad concept, and a more refined understanding of executive dysfunction in autism will inform both intervention programs and neurodevelopmental theory.

Objectives: We conducted a meta-analysis of Wisconsin Card Sort Task performance in participants with autism to consolidate and clarify the inconsistencies in the literature, and examine potential explanatory factors such as participant sample characteristics and experimenter versus computerized administration.

Methods: We were able to retrieve 31 studies reporting on a total of 793 participants with autism, published over a 30-year span. We also obtained five raw data sets, with a combined 191 participants with autism. We calculated Cohen's *d* effect sizes for four measures of performance: sets completed, perseveration, failure-to-maintain-set, and non-perseverative errors. We examined effect sizes as a function of participant sample characteristics, year of publication and diagnostic criteria, and manual versus computerized administration. We also analysed relationships among participant age, verbal and performance IQ, and ADI scores with performance within the combined raw data sets.

Results: We found the average weighted effect size ranged from 0.30 (failure to maintain set) to 0.82 (perseveration) for each measure, all of which were statistically greater than 0. As study authors more often than not concluded that failure to maintain set and non-perseverative errors, the failure to detect these small to medium effect sizes is likely due to small sample sizes. We also found a decrease in the magnitude of perseveration impairment in samples diagnosed under DSM-IV criteria relative to older criteria. We did not find any evidence for systematic variation as a function of mode of administration (experimenter versus computer). In the raw data, we found that age and IQ appear to influence overall performance via unique influences on perseverative and non-perseverative error rates. Age, ADI, and perseveration were associated with one-another. Performance and Verbal IQ were associated with non-perseverative errors and number of sets completed. We did not find any associations with failure to maintain set.

Conclusions:
We conclude that failure-to-maintain-set and non-perseverative errors represent facets of impaired task performance in autism often overlooked due to small sample sizes and that the impairment is less pronounced than perseveration. We further conclude that perseveration decreases with age in autism, a relationship somehow tied also to symptomology, while non-perseverative errors are driven by cognitive abilities reflected in both verbal and performance IQ, independent of age and symptomology.

109.103 Absent Optimism Bias in Updating Beliefs about Future Life Events in Adults with High-Functioning Autism

ABSTRACT WITHDRAWN

Background:
People update their beliefs about their own future outcomes in an optimistically biased way because they tend to neglect undesirable new information. Theoretical explanations of this bias assume that motivational mechanisms related to the pleasure of having positive future outlooks interact with and guide cognitive mechanisms such as egocentric and confirmatory thinking. In adults with high functioning autism (HFA), however, the motivational-affective influences on decision making are diminished as evident in their rule-based reasoning in response to social cues, as well as in response to emotional framings of risky gambling options.

Objectives:
Is this enhanced logical consistency in HFA also present in updating beliefs about future outcomes?

Methods:
Adults with HFA (n = 20, 4 females, mean age 41.5 years; F84.0 and F48.5 with an at least average IQ) and typically developing controls (n = 20; 2 females, mean age 38.9 years) matched on age, gender, years of education and IQ were recruited. Diagnoses were established within a systematic assessment in a specialized outpatient clinic by two independent psychiatrists and in consideration of an extensive neuropsychological profile of the person concerned.

In the update experiment, participants estimated the probability of an adverse future event to occur in the lifetime. Next, they were presented with the official base rate of the respective event and were then given the opportunity to make a second estimation and to adjust their first estimate to this new information. Estimations were made for 44 different adverse events, concerned either oneself or a similar other, and were confronted with either desirable (i.e., lower than the first estimate) or undesirable (i.e., higher than the first estimate) base rates. Unbeknownst to participants, presented base rates were manipulated in order to control for the size of estimation errors calling for belief updates across the four experimental conditions (self_desirable base rates, self_undesirable base rates, other_desirable base rates, other_undesirable base rates).

Results:

The optimism bias was replicated in the control group as *updates* (differences between the first and the second estimate) *after undesirable base rates* were significantly *smaller*than updates after desirable base rates, and this effect was present exclusively in self-related judgments. However, in the HFA group, there were no significant differences in update sizes dependent on the desirability of the new information, neither in self- nor in other-related judgments.
Conclusions:
In contrast to typically developing controls, adults with HFA did not show an optimistically biased updating of beliefs about their own or others' future. This indicates an increased logical consistency in HFA in general prospective thinking which may be explained by diminished motivational-affective influences on decision making. Future research would need to investigate the benefits and disadvantages of the increased logical consistency in HFA for different domains such as professional and private decision making and affective state.

104 **109.104** Accuracy, Response Time and Visual Search Strategies of Adolescents with and without Autism Spectrum Disorder during a Disembedding Task

T. Falkmer, Curtin University, Perth, WA, Australia

Background: The Weak Central Coherence Theory (WCC) and Enhanced Perceptual Functioning (EPF) are two main theories which described the differences in visuo-spatial processing among individuals with Autism Spectrum Disorders (ASD). It was purported that individuals with ASD process sensory information in a way that deviates from a top down manner and shows preference to local information. Disembeding tasks, or tasks that require the locating of hidden figure is one assessment to examine the presence of possible local processing in ASD. When comparing with typically developing (TD) counterparts, previous research found that children with ASD process information differently in visuo-spatial tasks. However, the performance and visual search strategies of adolescents with in disembedding figure tasks remain unknown.
Objectives: The aim of the current study was to examine performance and visual search strategies of adolescents with and without ASD to provide insights in to the theories of WCC and EPF.
Methods: An established experimental protocol was employed including a standardized assessment of visual perceptual skills, the Test of Visual Perceptual Skills 3rd Edition to investigate disembedding performance of 27 adolescents with ASD and 30 matched peers. The accuracy and time required to respond was measured. A remote eye tracker device was used to record the visual search strategies, i.e, number of fixations and duration of fixations of the participants.
Results: There were no differences in terms of accuracy in disembedding tasks among adolescents with and without ASD. However, adolescents with ASD were slower at completing the disembedding task. There were no differences in visual search strategies with the exception of an increased number of fixations and the duration of first fixations to the irrelevant white space.
Conclusions: These results provide limited evidence for the notion of a local preference in ASD and contradict the WCC and EPF theoretical viewpoints that a local preference contributes to superior performance in disembedding tasks.

105 **109.105** An Eye-Tracking Study of Visual Attention to Human Faces and Nonhuman Graphics in Children with Autism Spectrum Disorders

C. Wang[1] and H. Zheng[2], (1)School of Medicine, Nankai University, Tianjin, China, (2)Department of Social psychology, Nankai University, Tianjin, China

Background: It was reported that typically developing children show preferential attention to social rather than inanimate stimuli, and they also prefer to focus on the more socially revealing features of the face, such as the eyes rather than the mouth; in contrast, individuals with autism seem to lack these early social predispositions.
Objectives: This study explored the visual fixation patterns of ASD children when viewing human faces and inanimate stimuli by an eye-tracking study.
Methods: Fourteen children with ASD (male vs. female=12:2, Mage=5.60, SD=1.63) aged from four to seven and thirteen age-matched TD children (male vs. female=7:6, Mage=5.63, SD=0.55) participated study one in which 30 black and white photographs showing human faces with neutral facial expressions were displayed in sequence interval, and each one was displayed 3s with 1s interval. And then they participated the experiment again a week later. Their gaze behaviours were measured via an integrated Tobii TX300. In study two, sixteen videos of graphic movements and transformations were displayed in sequence interval, and each one was displayed 5s with 1s interval. Eighteen children with ASD (male vs. female=15:3, Mage=8.03, SD=3.05) aged from four to seven and twenty-two age-matched TD children (male vs. female=10:12, Mage=5.87, SD=1.42) participated study two. The proportion of total Fixation time to the region of interest (ROI), such as, left eye, right eye, nose, mouth, the main part of face, the whole face and body were investigated.
Results: In study one, children with ASD fixed significantly less on the main regions of face than TD group. No differences were found on the fixations of ASD between the first and second week, which showed that memory did not affect their attention, but TD children showed less fixation on the left eye and left face region in the first week than in the second week. In study two, ASD children fixation significantly less on the movements and transformation of inanimate graphics than TD group, which is different from the reported findings that ASD had no impairment on their cognition to

inanimate/nonhuman information.
Conclusions: In summary, ASD showed impairments on social information cognition and graphics cognition.

106 **109.106** Assessing Tactile Perceptual Inference and Learning in Autism Spectrum Disorders

L. A. Sapey-Triomphe[1], G. Sanchez[2], S. Sonié[1], M. A. Henaff[1], C. Schmitz[1] and J. Mattout[1], (1)Lyon Neuroscience Research Center, Lyon, France, (2)University of Trento, Center for Mind/Brain Sciences, Rovereto, Italy

Background:
Recently, some Bayesian theories were suggested to explain how our perception of the world emerges and how it could be altered in Autism Spectrum Disorders (ASD)[1,2]. In these theories, the representation of a stimulus would be influenced by both the precision of the encoding of the stimulus and the *priors* we have on incoming sensations. *Priors* correspond to our internal references that are dynamically adjusted through implicit or explicit learning. Thanks to *priors*, we are quickly able to identify a stimulus as being part of a category. Nonetheless, *priors* also bias our perception: the information received will be perceived as closer to the *prior*than it is.
In ASD, the perception of the world might be less biased than in neurotypical (NT) individuals. This perception, which one could refer to as "too close to reality" would explain subsequent impairments such as failures in generalizing and making suitable predictions. Two hypotheses were suggested to explain this particular perception in ASD: 1-*Hypo-prior hypothesis*: *priors* would be too blurred and would poorly influence perception[1]; 2-*Sensory accuracy hypothesis:* sensory information would be encoded very precisely and would have an important weight[2], resulting in a too acute representation of the inputs.
Objectives:
Our current project aims to better understand *prior* construction and their influence on perception in ASD, and to test whether the *hypo-prior* hypothesis prevails in ASD.
Methods:
We investigated tactile frequency discrimination and the influence of the global perceptual context on behavioral performance, with NT (n=20) and ASD participants (n=16). At each trial, participants received two successive non-painful electrical finger stimulations to be compared. Given the range of delivered frequencies, they were able to build-up a *prior*on the forthcoming frequency of stimulation, centered on the mean value of the already perceived frequencies. In NT subjects, such a design results in a perceptual bias: the first stimulation (to be memorized) is underestimated when it is larger than the average of the delivered frequencies; and overestimated when smaller. This task reflects how subjects learn about the global range of stimulations and how this strongly influences their perceptual decisions.
Results:
As expected, NT participants showed a perceptual bias, also known as a time-order effect (Figure 1-a). However and surprisingly, ASD participants showed an even stronger effect (Figure 1-b). Our preliminary interpretation is that in ASD, the stability of the learning context would favor the construction of "hyper *priors*".
Conclusions:
This study contributes to elucidate the mechanisms underlying perceptual learning in ASD. We hypothesize that in ASD, the influence of the *priors* can either be too strong ("hyper *prior*") in a stable learning context, or too weak ("hypo *prior*")[1] in a changing learning context. Neuroimaging studies will be performed to test these hypotheses and to explore the neural correlates of *prior* construction.

107 **109.107** Assessing the Use of Eye-Blinking As a Measure of an Individual's Engagement with Ongoing Visual Content

C. Ranti[1], W. Jones[1], G. J. Ramsay[1], A. Klin[1] and S. Shultz[2], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Department of Pediatrics, Marcus Autism Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA

Background: Reduced social engagement is a pervasive, early-emerging feature of Autism Spectrum Disorder (ASD). Yet research in this area has been neglected, largely due to the absence of measures capturing an individual's subjective perception of stimulus salience. This study provides a methodological solution, building upon an approach that quantifies engagement by analyzing patterns of eye-blinking among groups of viewers. Given that blinking results in a loss of visual information, viewers unconsciously modulate blink-timing: they are *least likely* to blink during moments perceived as *most* salient. While this provides insight into what is engaging to a *group*, quantifying what an *individual*perceives as engaging presents challenges. For instance, individuals blink relatively infrequently – thus, moments of engagement (indexed by statistically significant blink inhibition) are

more readily quantified within a group. Overcoming this challenge is critical: individual metrics of engagement can provide much-needed insight into the subjective experience of a child with ASD. Objectives: Determine whether meaningful information can be recovered from an individual's eye-blinking, by examining: 1) the conditions under which eye-blinking can be used to classify individuals by experimental group during a highly-controlled pilot task; 2) whether patterns of eye-blinking can be used to classify individuals by diagnostic group (TD or ASD) during a free-viewing task. Methods: *Pilot:* Eye-tracking data were collected while 21 typical adults watched videos alternating between scenes of water animals and scenes of land animals. The categories of content were differentially engaging to viewers: half of the participants were instructed to count the number of water animals, and the other half, land animals. *Natural Viewing:*Eye-tracking data were collected while school-age TD children (n=48) and children with ASD (n=48) watched scenes of social interactions. Results: *Pilot*: An SVM classifier correctly labeled 95% of participants by experimental group, using eye-blink timing (Figure 1). Classification was robust over varying scene durations and over viewers with very low or high blink rates. *Natural Viewing*: To determine when TD and ASD viewers were most engaged, we identified moments of blink inhibition for a subset of each diagnostic group ("training groups"), using permutation testing. We then calculated blink rates of the remaining TD and ASD viewers ("test groups") during moments perceived as highly engaging by the training groups. As predicted, TD test viewers blinked *less* during moments perceived as engaging by the TD training group than during moments that ASD viewers perceived as engaging. ASD test viewers showed the opposite pattern (Figure 2). However, *individuals*within the test groups did not show this pattern. Conclusions: Pilot task analyses demonstrate that individual patterns of eye-blinking can be used to classify participants according to the timing of their engagement. In the naturalistic paradigm, different moments were identified as engaging to the TD and ASD training groups. Critically, two independent samples of TD viewers (TD train and TD test) showed similar patterns of eye-blinking, as did the independent samples of ASD viewers. Future analyses will explore the conditions under which individual patterns of eye-blinking during naturalistic viewing can be used as a diagnostic classifier.

108 **109.108** Attention Biases in Anxious Youth with Co-Occurring ASD Symptoms

R. J. Mercado[1], C. M. Kerns[2] and P. C. Kendall[1], (1)Temple University, Philadelphia, PA, (2)Drexel University, Philadelphia, PA

Background: Children with anxiety disorders typically show numerous processing biases that favor negative or threatening information and these processes are believed to be responsible for the etiology and/or maintenance of these disorders. Children with autism spectrum disorders (ASD) frequently show elevated levels of anxiety, and examining the cognitive mechanisms in children with ASD symptoms and co-occuring anxiety may prove useful in better understanding the co-occurrence of these disorders.

Objectives: We explored if children with elevated ASD traits demonstrate an attentional bias towards threat similar to that of typically developing, low-ASD children. We used a standard dot-probe task that assessed attentional biases towards emotional (threatening or happy) vs neutral faces.

Methods: Fifty-nine typically developing children with a primary anxiety disorder diagnosis (mean age = 11.52) completed a dot-probe task (500 ms presentation). ASD symptoms were assessed with the Social Responsiveness Scale-Parent Version (SRS-P). Anxiety disorders were diagnosed using the Anxiety Disorders Interview Schedule for Children, a semi-structured interview for diagnosing anxiety and other disorders. Continuous measures of anxiety were assessed using the Multidimensional Anxiety Scale for Children, administered to parents and children.

Results: Of the 59 participants, 29 had elevated ASD symptoms (as determined by cut-off scores of 60 or higher, indicating moderate to severe symptom severity). Children in the elevated ASD group were found to have higher parent-reported anxiety $t(57) = -2.76$, $p = .01$ and child-reported anxiety, $t(57) = -3.05$, $p = .00$. Children in the elevated ASD group had more cases of a primary diagnosis of social phobia, χ^2 (1, N=59) = 9.05, and this was included as a control factor in regression analyses. At the group level, neither group (low or elevated ASD) showed a significant bias towards threatening or happy faces. However, regression analyses using parent-reported anxiety, ASD symptoms, and their interaction significantly predicted bias scores for happy faces, R^2=.22, $F(4,55)$=3.61 $p<.01$. Both SRS-P scores (β= .86, $p < .05$) and the interaction between SRS-P scores and parent-reported anxiety (β=-1.90, $p< .05$) significantly predicted biases towards happy faces. Specifically, those with elevated SRS-P symptoms and high parent-reported anxiety showed an attention bias toward happy faces. In contrast, those with high ASD symptoms and low parent-reported anxiety showed an attention bias away from happy faces.

Conclusions: In the present sample, no overall differences were found in the attentional biases of children with and without elevated ASD symptoms. However, a significant interaction between parent-reported anxiety and SRS-P symptoms was observed, such that children with high ASD symptoms and high anxiety were more likely to attend to happy faces than children with low SRS scores or low anxiety. Considering the majority of studies examining children and adults does not find biases towards happy faces, these results suggest that happy faces were particularly favored in attentional processing, perhaps due to being perceived as threatening, due to the difficulties in social processing seen in children with elevated ASD symptoms. These results suggest that ASD symptoms play a role in the relationship between attentional biases and anxiety.

109 **109.109** Attention Does Not Modulate the Imitation of Biological Motion Kinematics in Autism Spectrum Disorders

S. J. Hayes[1], M. Andrew[1], D. Elliott[1,2] and S. J. Bennett[1], (1)Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom, (2)Department of Kinesiology, McMaster University, Hamilton, ON, Canada

Background: Interpersonal contexts require imitation of biological motion. Such imitation is impaired in autism spectrum disorders (*autism*) due to top-down processes associated with social modulation and attention orientation, and lower-level visuomotor control processes. This is based on examining biological motion during automatic imitation, or using voluntary imitation and manipulating movement speed. Here, we examined voluntary imitation using a novel methodology that displayed models with the same movement time, but different biological motion. A non-human agent model was used to control social modulation. To investigate the effects of attention we examined imitation under general attention, and selective attention to the biological motion during observation.
Objectives: (1) examine imitation of biological motion kinematics; (2) examine whether the imitation of biological motion is influenced by attentional control.
Methods: Eleven adults with autism, diagnosed by a clinical assessment and ADOS, plus eleven adults (control) participated in a four-phase study, which was approved by the local ethics committee. In a General-Attention phase, participants were instructed to "observe and copy the dot". In a Selective-Attention phase, participants were instructed to "observe and copy exactly how the dot moves". There were two biological motion models: atypical and typical velocity. All participants then performed a multiple object tracking task and a biological-motion-perception-task.
Results: Planned comparisons indicated that although the groups did not differ in the imitation of typical velocity ($p > 0.05$), the *control* group imitated atypical velocity more accurately than the *autism* group ($p < 0.001$). When attention was directed to the model, the *control* group more accurately imitated the typical velocity compared to general-attention phase. Imitation by the *autism* group remained the same for *atypical* and *typical velocity* irrespective of attentional instruction. The multiple object tracking task showed the *control* group (96% accurate) was more successful ($p = 0.02$) at tracking objects than the *autism* group (84% accurate). The biological-motion-perception-task indicated the *autism* group (74% accurate) and *control* group (70% accurate) were similarly successful in judging differences between biological motion models.
Conclusions: Compared to the control group, we showed imitation of biological motion was impaired in *autism.* When instruction directed attention to the model, imitation performance was not improved in the *autism* group. It is therefore unlikely that low-fidelity imitation of biological motion in the *autism* group can be explained by participants not observing the kinematics presented by the model. Moreover, although there was a group difference in general attention ability as evidenced by the multiple-object tracking task, the *autism* group still performed successfully (84% accurate). Also, the *autism* group was equally successful as the *control* group in perceiving and judging differences between two single-point-light dots presenting different forms of atypical velocity. Taking into consideration the effects for attention and perception of kinematics, in a situation where we controlled for social modulation, these findings suggest the deficit in imitating biological motion kinematics in autism is most likely related to the sensory-motor integration and representation of biological motion.

110 **109.110** Attentional Sensitivity to Features of Angry Faces and Domain-General Cognitive Characteristics

T. Isomura[1], S. Ogawa[2] and N. Masataka[3], (1)Primate Research Institute, Inuyama, Aichi, Japan, (2)Kyoto University, Graduate School of Medicine, Kyoto, Japan, (3)Kyoto University, Primate Research Institute, Inuyama, Aichi, Japan

Background:
An atypical face and emotion processing in ASD have received wide attention in the research of ASD. It is, however, still not clear whether/ how their processing is different from typical people. In the current study, to assess their basic feature regarding emotional responses, we focused on the "anger superiority effect (ASE)". ASE refers to a phenomenon where an angry face is detected more quickly than a happy or neutral face in a crowd of distracters (i.e., face-in-the-crowd task). This is believed to stem from the attention-getting properties in such threatening stimuli. Previous studies have reported that ASE is also observed in individuals with ASD (Ashwin et al., 2006; Krysko & Rutherford, 2009; Isomura et al., 2014), but the underlying mechanisms may be different from those in TD. Although ASE is known to require the configuration of features in faces (Fox et al., 2000; Tipples et al., 2002; Weymer et al., 2011), for some individuals such as individuals with ASD who have local-biased cognitive characteristics, single isolated facial features may be sufficient to activate the systems of quick attention allocation to anger. Furthermore, the mechanisms for that may be attributed to more domain-general cognitive mechanisms depending on each individual's characteristics.
Objectives:
In this study, we examined whether ASD and TD children would show feature-based anger superiority effect, and explored the association with their domain-general cognitive characteristics, by focusing on global/local perceptual attentional bias.

Methods:
Sixteen children with ASD and 16 TD children aged 7- to 13-year-old participated in this study. First they were given the face-in-the-crowd task that included three types of face-conditions: whole, eyebrows, and mouth conditions. In the eyebrows and mouth conditions, stimuli involved only the respective features with a facial contour. Global/local attentional bias was assessed by a Navon task, in which a bigger letter composed of smaller elements were identified at the global or local level. The size of individual global/local interference (namely, the Navon index) was calculated using individuals' response times based on a previous study (Zhu et al., 2010), and was used for a correlation analysis with their performance on the face-in-the-crowd tasks.
Results:
The quicker detection of angry faces over happy faces (i.e., Anger Superiority Effect) was observed both for TD and ASD children in the whole and eyebrows conditions. By contrast, in the mouth condition, only the ASD group showed the quicker detection of downward mouth over upward mouth. The results of the correlation analysis revealed that, in ASD, individuals who showed stronger local-biased perceptual characteristics tended to show the stronger single feature-based Anger Superiority Effect. In TD, by contrast, such relationships were not observed.
Conclusions:
The findings suggested that, for ASD individuals, who have local-biased perceptual characteristics, emotion-related facial features may work as emotion-evoking stimuli. Extracting local features and perceiving emotions may be a foundation of quick attention allocating to angry faces in individuals with ASD

111   **109.111** Atypical Binocular Rivalry Dynamics of Simple and Complex Stimuli in Autism

J. Freyberg[1], C. Robertson[2] and S. Baron-Cohen[3], (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (2)Harvard University, Cambridge, MA, (3)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom

Background: Binocular rivalry occurs when conflicting images are presented to the same retinal location of each eye. The two percepts compete for perceptual dominance, and conscious perception alternates between the two. The dynamics of binocular rivalry are proposed to index the balance of excitatory and inhibitory connections in the brain, and have therefore been proposed as markers of an imbalance in excitatory/inhibitory transmission that may characterize autistic neurobiology. Two studies have compared rivalry dynamics in individuals with and without Autism Spectrum Conditions (ASC), each using stimuli of different levels of visual complexity. While both found results in the expected direction, only one found significant differences in rivalry dynamics between the two groups.
Objectives: First, we hoped to replicate our previous finding of a slower rate of rivalry with longer mixed percepts in ASC in a new, expanded sample of participants. Second, we tested whether this finding was selective for stimuli of a particular level of visual complexity.
Methods: 53 participants (26 with ASC) completed twelve 40s trials of binocular rivalry (6 with object stimuli, 6 with grating stimuli) and 24 control trials. Participants continuously reported either dominant or mixed percepts throughout the trial. We analysed the rate of perceptual transitions and average percept durations as well as ratios of percept durations.
Results: We tested rivalry dynamics with Stimulus Type as between-subject factor and ASC Diagnosis as within-subject factor in repeated measures ANOVA. ASC subjects perceived a lower rate of switches ($F(1, 51) = 4.3$, $p < 0.043$) with longer mixed percepts ($F(1, 51) = 14.7$, $p < 0.001$). The differences in average mixed percepts and proportion of mixed percepts were confirmed with non-parametric comparisons of means to be significant in both stimulus conditions, while the difference in switch rate was significant only in the grating condition.
Conclusions: We replicate our previous findings of a slower rate of binocular rivalry with increased mixed percepts in ASC, and show that these effects are present at low levels of stimulus complexity. These results are predicted by an increased ratio of excitatory/inhibitory synaptic transmission in autism, and suggest that this imbalance may manifest as early as V1.

112   **109.112** Behavioral Differences in Reward Salience but Not Motivation in Toddlers with ASD: Results from a Visual Search Task

C. McCormick[1], G. S. Young[2], J. Bernstein[3] and S. J. Rogers[4], (1)Brown University, Providence, RI, (2)MIND Institute, University California Davis, Sacramento, CA, (3)MIND Institute, University of California, Davis, Sacramento, CA, (4)University of California at Davis, Sacramento, CA

Background: Visual search is consistently documented as an area of superior skill in adults and adolescents with ASD (Kaldy et al., 2013); however, few studies have been conducted in younger samples or samples with a broad range of functioning. It has been hypothesized that children with ASD find social stimuli less rewarding than do people with typical development (Dawson et al., 2004; Dawson et al., 2005). Based on current evidence, it is unclear whether differences in reward processing are specific to social stimuli. Questions also remain about what aspects of reward processing are different in ASD.
Objectives: There were three main goals of this study: (1) to develop a visual search task for very young children with ASD that could be completed without any verbal instructions by using gaze-contingent eye-tracking; (2) to test differences between children with ASD and typical development in

the motivation for and saliency of social and nonsocial rewards; and (3) to examine the effect of social and nonsocial reward on learning.

Methods: Two groups of two year olds participated in this study: ASD (N =21) and typically developing (TD = 23). During the visual search task, participants were rewarded with either a social or nonsocial video when they fixated on the target shape among a circular array of distractor shapes. Key dependent eye-tracking variables were reaction time (RT) to finding the target and looking time (LT) at the reward video when it played.

Results: Two sets of multilevel models were examined with RT and LT as the dependent measures, group (ASD vs. TD) as a main effect, condition (social vs. object) as a repeated measure, and block of trials as the time variable. Three models were tested: no growth, linear, quadratic. In the best fitting model of RT the ASD group demonstrated faster RT. There was no significant interaction between group and reward condition, indicating no difference in motivation based on reward type. Both groups demonstrated learning on the task as indicated by a significant decrease in RT across the task. The group by time interaction was not significant. Learning did not vary in either group depending on reward condition (i.e., there was no group by time by condition interaction). In the best fitting model of LT, a significant group by condition interaction was found, where children in the ASD group looked less at the social videos than nonsocial videos; whereas, the TD group had the opposite pattern of visual attention.

Conclusions: Results replicate findings of superior visual search in children with ASD compared to TD children (Kadly et al., 2011). These results also add support to previous reports of lower saliency of social stimuli for toddlers with ASD compared to TD controls (Shic et al., 2011). Although there was a group difference in saliency, there were no differences in motivation or learning based on reward type for either group. According to these results, children with ASD may work to obtain social rewards to the same degree as TD children, but engage more with nonsocial stimuli.

113   **109.113** Bootstrapping the Hippocampus? Atypical Learning Characterizes Adolescents with Autism Spectrum Disorders

J. McCauley[1], T. A. Lesh[2], T. A. Niendam[2], J. S. Beck[2], C. S. Carter[2,3], J. D. Ragland[2,3] and M. Solomon[2], (1)Department of Human Development, University of California-Davis, Davis, CA, (2)Department of Psychiatry & Behavioral Sciences, University of California-Davis, Sacramento, CA, Sacramento, CA, (3)Center for Neuroscience, University of California-Davis, Davis, CA, Davis, CA

Background:
Individuals with ASD are thought to exhibit intact semantic memory for facts, details, and routines, but manifest deficits in episodic memory and generalizing learning. The underlying neurobiology of this pattern, which may include impairments in the medial temporal lobe (MTL) and the prefrontal cortex (PFC), remains unclear. We have argued that young adults with ASD are more reliant on the hippocampus (HC) than on the PFC, given their cognitive control deficits.

Objectives:
We investigate this contention in adolescents with ASD, using behavioral measurements that assess MTL, HC, and PFC contributions to encoding, retrieval, and generalization.

Methods:
Participants included 27 12-18 year olds with ASD (mean age = 14.8) and 25 age, gender, and IQ-matched participants with typical development (TYP) (mean age = 14.8). To assess MTL and HC contributions to learning and memory, we administered the Relational and Item-Specific Encoding task (RISE; Ragland et al., 2012), which requires respondents to make item-specific and relational judgments, and to provide response confidence estimates. Performance measures include accuracy rates and d'. Familiarity and recollection also were analyzed using ROC curves. To assess PFC contributions to learning and memory, participants completed California Verbal Learning Test-Children's Version (CVLT-C; Delis, Kramer, Kaplan, & Ober, 1994). ANOVAs and t tests were performed using SPSS 22.

Results:
On the RISE, ASD versus TYP showed poorer item-specific accuracy (t(49) = 2.2, p = .0.03) and d' (t(49) = 2.7, p = .009), but comparable relational encoding accuracy and d'. ASD also showed a reduced contribution of familiarity when making relational judgments (t(49) = 2.3, p = .025). This may suggest that ASD benefitted disproportionately from the deeper spatially-oriented encoding involved in the relational condition because they possess a relatively intact HC and/or other MTL regions that support recollection. On the CVLT-C, ASD versus TYP showed poorer list learning (t(52) = 2.2, p = .032) and free and cued recall at short [free recall: t(52) = 3.345, p = .002; and cued recall: t(52) = 3.32, p = .002] and long delays [free recall: t(52) = 4.74, p < .001; and cued recall: t(52) = 3.23, p = .002]. ASD also exhibited lower recall consistency (t(52) = 3.82, p < .001) with more perseverations (t(52) = 2.17, p = .034), suggesting they have PFC deficits which impede the deep encoding of semantic materials that supports generalization (Shohamy & Wagner, 2008). Both groups relied comparably on semantic and serial clustering strategies thought to require the HC.

Conclusions:
Findings are inconsistent with the view that ASD exhibit intact lower-level learning and memory and impaired higher level learning and memory. Instead, they suggest that ASD actually may be relatively worse at lower-level learning of items that is prefrontally-mediated or that involves areas of the anterior temporal system (Ranganath & Ritchey, 2012) including the lateral and orbito-fronal cortices, and the perirhinal cortex, and relatively better at relational versus item-specific encoding under

conditions involving spatial processing, that is sub-served by a relatively more intact posterior medial system including the HC and the parahippocampal cortex.

114 **109.114** Brain Organization Underlying Superior Math Problem Solving Abilities in Children with Autism

T. Iuculano, K. Supekar and V. Menon, *Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA*

Background: In addition to social, communicative and sensorimotor processing deficits, it has been reported that individuals with autism spectrum disorder (ASD) can exhibit remarkable strengths, such as the ability to rapidly absorb and precisely remember tremendous amounts of details, or a particular interest towards regular sets with repeatable rules (i.e. "hyper-systemizing"). A synergistic interplay of these cognitive processes seem to have a role in predisposing to special abilities of savant sort. Mathematics represents the most concrete instantiation of these processes, as it is built upon systematic axiomatic procedures, and therefore represents an ideal domain to experimentally measure the cognitive and neural bases of superior-like abilities — and their heterogeneity — in ASD. Critically, the cognitive and brain mechanisms that might support such interplay — and thus foster proficiency in math — remain elusive. An emerging theoretical account of ASD has proposed that superior abilities in analytical and procedural thinking are attributable to greater engagement of primary sensory visual areas.
Objectives: We investigated: (i) whether greater engagement of primary sensory visual areas or their patterns of neural activity could explain better math abilities in children with ASD; and (ii) whether functional connectivity between these higher-order visual areas and medial temporal lobe systems implicated in procedural memory processes could support better math abilities in ASD.
Methods: We tested a group of 7-12 year old children with ASD, and a group of age-, gender-, and IQ-matched neuro-typical peers. Cognitive measures included standardized tests of calculation and problem solving, as well as strategy assessments. Brain measures included task-based functional magnetic resonance imaging (fMRI) during math problem solving.
Results: Behaviorally, we show that, on average, children with ASD showed superior math problem solving skills and relied on sophisticated analytical strategies more frequently than neuro-typical peers. Yet, not all individuals with ASD displayed proficient skills in math problem solving. Neurobiologically, we report differences between children with ASD and their neuro-typical peers in patterns of activity related to arithmetic problem complexity in the ventral temporal-occipital, parietal, and temporal cortices that support visuo-spatial, numerical, and mnemonic processes. Activation levels as well as multivariate activation patterns in ventral-temporal occipital cortex predicted individual differences in math problem solving abilities in ASD, but not in neuro-typical children. Remarkably, task-based multivariate connectivity analyses revealed that the interactions between regions of the ventral-temporal cortex, and the medial temporal lobe significantly and uniquely modulated individual math abilities in ASD.
Conclusions: Our results suggest that superior math abilities in children with ASD are engendered through a unique pattern of brain organization characterized by differential recruitment of posterior regions of the ventral stream and their functional coupling with memory systems. This is consistent with the hypothesis that analytical thinking is attributable to different engagement of posterior visual areas in ASD. Critically, our data extend this model to incorporate mnemonic systems residing in the medial temporal lobe as a locus for enhanced procedural thinking in ASD. More generally, these circuits can provide candidate biomarkers for explaining individual differences of superior cognitive skills in ASD.

115 **109.115** Building a Percept: Early Influences on Mid and Higher-Level Visual Abilities in Autism Spectrum Disorder

J. Guy[1,2], L. Mottron[3], C. Berthiaume[3] and A. Bertone[1,3,4], *(1)Perceptual Neuroscience Laboratory for Autism and Development (PNLab), Montreal, QC, Canada, (2)Integrated Program in Neuroscience, McGill University, Montreal, QC, Canada, (3)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montreal, QC, Canada, (4)School/Applied Child Psychology, Educational and Counseling Psychology, McGill University, Montreal, QC, Canada*

Background: Individuals with Autism Spectrum Disorder (ASD) present a perceptual profile that is defined by atypical performance on tasks mediated by lower- (primary visual areas), mid- (extra-striate areas) and higher-level (large-scale neural mechanisms) visual analysis (Simmons et al., 2009). These differences characterize the distinct visuo-perceptual phenotype in ASD, broadly described as strengths in detailed, local processing (mediated by lower-level analysis) with or without concurrent difficulty in global or integrative processing (mediated by mid- and higher-level analysis). The visuo-perceptual phenotype in ASD has been based largely on isolated levels of processing, providing little information with respect to how performance within the same individual varies with increasing task complexity. Alterations occurring in earlier stages of visual analysis arguably affect those occurring at higher levels (Bertone et al., 2010). It is therefore important to elucidate the relationship between perceptual abilities mediated by different levels of analysis to understand how alterations in the building blocks of perception affect higher-order cognitive and social functions in ASD.
Objectives: The present work systematically investigated whether enhanced local processing in

lower-levels of visual analysis influenced higher-level perception in the same group of children and adolescents with and without ASD. Specifically, we examined whether enhanced local perception at earlier stages of processing affected higher level perception by asking the following questions:
1) Does enhanced local processing in low-level visual analysis predict greater local interference in mid-level visual analysis?
2) Does greater local interference in mid-level visual analysis predict a decreased global performance in higher-level visual analysis?
Methods: A total of 27 and 48 respective children and adolescents with and without ASD performed three tasks, each soliciting a progressively complex visual analysis: (i) low-level perception was assessed by measuring contrast sensitivity to vertically oriented, sine-wave luminance- defined gratings of different spatial frequencies; (ii) mid-level perception was assessed by measuring local and global reaction times for consistent and inconsistent stimuli in a Navon task (Navon, 1977); and (iii) higher-level perception was assessed by measuring thresholds in a face-identity discrimination task.
Results: Simultaneous multiple regression analyses revealed no significant relationship between low- and mid-level processing in either the TD or ASD groups; specifically, enhanced local processing on the low-level task, reflected by an increased sensitivity at high spatial frequencies, did not predict slower performance on the mid-level task when local information conflicted with the identification of global information (i.e. increased local interference). The effect of mid- on high-level perception, however, revealed that an increased local interference on the mid-level task predicted a decreased performance on the higher-level, face identity discrimination task in the ASD group alone. These results suggest that an increased effect of local processing for mid-level perception in ASD impacts higher-level perception, typically requiring a global analysis.
Conclusions: Our findings establish a significant association between mid- and higher-level mechanisms in ASD. Such a relationship suggests that alterations in the "building blocks" of early perception are responsible for differences in higher-order visual processes in ASD, and possibly, functions in the domains of socialization and communication.

116 **109.116** Cognitive Control of Visual Attention in ASD in Response to Social and Non-Social Stimuli

A. S. DiCriscio[1,2], S. Miller[3], M. L. Kovac[4], E. Hanna[5] and G. S. Dichter[6], (1)University of North Carolina-Chapel Hill, Chapel Hill, NC, (2)Geisinger-ADMI, Lewisburg, PA, (3)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Carrboro, NC, (4)Carolina Institute for Developmental Disabilities- UNC Chapel Hill, Chapel Hill, NC, (5)Duke University, Durham, NC, (6)University of North Carolina, Chapel Hill, NC

Background: Narrowed interests, perseverative patterns of attention and reduced visual exploration have been linked to restricted, repetitive behaviors (RRBs) in Autism Spectrum Disorder (ASD). Circumscribed interests (CIs) in ASD, are unusually intense interests in a narrow range of subject areas, and these activities (i.e., collecting, manipulating, reading, conversing about their interest) often lead to functional impairments. Eye-tracking research investigating responses to categories of images reflecting CI that capture attention during passive viewing tasks has found that children and adults with ASD display an attentional bias towards certain categories of nonsocial images (e.g. train, automobiles, electronic devices, computers). This bias has been conceptualized to reflect increased visual salience of nonsocial images relative to social images (e.g. faces) and other, commonplace, nonsocial information (e.g. furniture, clothing, dishes).
Objectives: This eyetracking study aimed to extend findings regarding atypical patterns of attention in children with ASD by investigating the cognitive control over visual attention in response to social and non-social images.
Methods:
40 individuals ranging in age from 9-18 years old participated. Of those, 19 individuals had a diagnosis of ASD (mean age(stdev)= 13.92(±3.05), 16 male) and 21 were typically developing controls (mean age (stdev)= 14.06(±2.79), 19 male). Participants completed a visual saccade paradigm where, on each trial, first a central crosshair was presented followed by a social or nonsocial image to the left or right side of center. The task included both a prosaccade condition ("look towards a peripheral target when it appears") and an antisaccade condition ("look to the opposite side of the screen when a peripheral target appears"). Stimuli varied between social images (smiling faces) and non-social images previously shown to be related to CI's in ASD ("high interest" images) and commonplace, everyday objects ("low interest" images).
Results: The primary dependent measure was the difference between antisaccade and prosaccade errors, reflecting the influence of cognitive control over visual attention. Children and adolescents with ASD demonstrated an increased overall rate of error relative to typically developing controls, t(38)=2.21, p<.03. A repeated measures analysis of variance did not reveal stimulus or a group x stimulus interaction was revealed (p's>0.20). Between groups t-tests were carried out to investigate group differences in saccade errors in response to each of the 3 stimulus categories. Relative to typically developing controls, the ASD group made an increased number of errors in response to both non-social stimulus categories- "high interest" (t(38)=2.23, p<.03) and "low interest" images (t(38)=2.64, p<.01). Groups did not differ in saccade errors in response to faces (t(38)=1.09, p<.28). Within the ASD group, error rate was significantly related to social-communication impairments and restricted and repetitive behaviors calculated from the ADOS-2. Exploratory comparisons across children with ASD and a small cohort with another development disorder

characterized by repetitive behaviors (pediatric OCD; n=9, mean age(stdev)=15.43(±1.01)), will also be presented.
Conclusions:
Impairments in cognitive control of visual information appear to be domain general and a powerful predictor of ASD symptom severity. This study provides support for the use of visual attention and oculomotor behavior to quantify impairments in ASD.

117   **109.117** Colour Perception in Autism and Williams Syndrome

M. B. Cranwell[1], *D. M. Riby*[2], *A. S. Le Couteur*[3] *and A. C. Hurlbert*[1], *(1)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom, (2)Department of Psychology, Durham University, Durham, United Kingdom, (3)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom*

Background: Recent studies report a varied visual function profile in Autism Spectrum Disorders (ASD; Simmons et al., 2009), with relative strengths and weaknesses found in dorsal and ventral stream functions. The genetic disorder Williams Syndrome (WS) has been described as illustrating a contrasting social profile to ASD, but socio-communicative deficits overlap in the two conditions (Klein-Tasman et al., 2009) as do sensory processing difficulties, with profound deficits in dorsal stream visuo-spatial processing in WS. Given the increasing importance of understanding sensory processing difficulties and sensory reactivities in both conditions, there is a need to better differentiate between the two sensory profiles. The ventral stream primarily processes visual properties which underlie key aspects of socio-communicative ability (e.g. face/object recognition). Colour perception (a key function of the ventral stream) is relatively understudied in ASD and WS. Despite this, there is an increasing use of colour in behavioural interventions for ASD (e.g. sensory rooms, coloured overlays; Ludlow et al., 2006).
Objectives: To assess colour perception as a measure of ventral stream visual function in ASD and WS, relative to typically developing children (TD), at different levels including chromatic-discrimination (sensory level) and colour preference (cognitive/affective level).
Methods: 15 individuals with ASD (7-18y), 26 with WS (7-20y), matched individually on the Ravens Coloured Progressive Matrices to TD (4-8y), took part in the study. Two tasks were used to examine different aspects of colour perception. First, a chromatic-discrimination task measured chromatic-discrimination thresholds along three colour directions, the cone-opponent ("red-green", "blue-yellow") and luminance colour axes. The task required participants to identify the direction of a briefly flashed arrow of variable contrast against a grey background (staircase procedure). To measure colour preference, a two-alternative-forced choice task was used in which participants chose the preferred colour from each of all possible pairs of nineteen colours varying systematically in hue, lightness and saturation.
Results: Performance patterns differed between ASD and WS groups relative to the TD group. On the chromatic-discrimination task, significant interaction between colour axis and group was found between ASD and TD (p<0.01), with ASD "Blue-Yellow" axis performance significantly worse relative to TD (p<0.01). No significant differences were found between the WS and TD groups (p=0.39). For colour preference,   patterns differed between groups. TD and ASD groups show similar preference patterns across hues, but whereas the TD group show increased preference for lighter-vs-darker colours, the ASD group do not (p<0.01). The WS group displayed greater inter-individual variation.
Conclusions: These findings provide evidence for atypical colour perception in both ASD and WS but with condition-specific patterns. Relative to mental-age TD controls, in ASD "low-level" chromatic-discrimination is impaired, and colour preference depends on hue but lacks dependence on lightness. In WS, chromatic-discrimination is unimpaired, but colour preference shows high inter-individual variation. These results suggest that in behavioural interventions for ASD, it is more important to consider affective responses to hue than to lightness of colours, whereas in WS, colours should be tailored to the individual. Future research will further inform better use of colour in behavioural interventions.

118   **109.118** Concurrent and Longitudinal Predictors of Theory of Mind in TD Children and Children with ASD

T. D'souza[1], *C. Navarro-Torres*[2], *D. A. Fein*[1] *and L. Naigles*[1], *(1)University of Connecticut, Storrs, CT, (2)Pennsylvania State University, University Park, PA*

Background: Delayed or deficient theory of mind (TOM) development in children with ASD has been attributed as a root cause of many other patterns of social and cognitive impairment in autism. Indeed, school-age children with ASD usually perform significantly more poorly on TOM tasks than age-matched TD children (2, 3). Both linguistic and social measures have been shown to correlate with concurrent TOM performance (1, 4, 5); however, the longitudinal predictors/precursors of TOM are still not established. Moreover, it is still unclear whether the same longitudinal predictors will be found for TD children and children with ASD. We address these gaps with data from a longitudinal study in which both linguistic and social developmental precursors of TOM are collected.
Objectives: We investigate both social and linguistic predictors of TOM, both concurrently and longitudinally, in 5-to 6-year-old children with TD or ASD.
Methods: The participants were 27 TD children ($MA_{\text{visit 1}}$=1.7 years) and 17 children with ASD (MA_{visit}

$_1$=2.71 years). The TD and ASD groups were matched on Mullen expressive language at Visit1; however, by Visit 3, when the TOM tasks were administered (TD$_{MA}$=5.58 years, ASD$_{MA}$=6.54 years), the TD group had higher language scores (ps<0.05). The Vineland Adaptive Behavior Scales, and the Mullen Scales of Early Learning were administered at Visits 1 and 2 (TD$_{MA}$=3.33 years; ASD$_{MA}$=4.5 years); the Test of Auditory Comprehension of Language-3 (TACL) was administered at V3. Two TOM tasks were administered: an unexpected contents task and an unexpected change in location task. Scores were averaged for an overall percent correct.

Results: As expected, the TD group (Mpercent correct=89%, SD=16.69) had higher scores than the ASD group (M=43%, SD=40.43). Figure 1 shows 2 subgroups in the ASD sample; one subgroup scored in the TD range. Bivariate correlations revealed that the TACL-Q and Mullen-RL at V1 correlated positively with TOM scores in both groups (rs>.361, ps<.05). The TACL-Elaborated Sentences also correlated with TOM only in the TD group (r=.431,p<.05); the Vineland Communication at V1, MullenRL at V2, and TACL-morphology correlated with TOM only in the ASD group (rs>.663,ps<.05). Regressions revealed that for the ASD group the only significant predictors of TOM were the Vineland Communication at V1 (DR^2=.546, p=.002) and Mullen-RL at V2 (DR^2=.109, p=.075). For the TD group, the only significant predictor of TOM was TACL-Elaborated Sentences at V3 (DR^2=.172, p = .034). Conclusions: A subset of children with ASD appears to reach TD levels of TOM; however, their concurrent and longitudinal predictors differed from the TD group. As predicted, complex syntax was the strongest predictor of TOM in the TD group (1, 4). In contrast, both social and more general linguistic measures were the strongest predictors of TOM in the ASD group. Thus, TOM may develop from different roots in children with ASD compared with TD children.

119 **109.119** Contextual Influences on Eccentric Viewing in Young Children with ASD

G. S. Doneddu[1], *S. Congiu*[1], *D. Corda*[2], *G. Baldus*[2], *L. Ferretti*[1], *G. Saba*[1], *D. Serra*[1] and *R. Fadda*[3], *(1)Center for Autism Spectrum Disorder, Azienda Ospedaliera Brotzu, Cagliari, Italy, (2)BalCor s.n.c., San Sperate, Italy, (3)Department of Pedagogy, Psychology, Philosophy, University of Cagliari, Cagliari, Italy*

Background: Children with Autism Spectrum Disorder (ASD) show atypical visual behaviors either during object exploration (Mottron et al. 2007; Ozonoff et al. 2008; Hellendoorn et al. 2014) and social interactions (Noris et al. 2012). In general, they tend to produce eccentric gazes (EG), which seem mainly to serve the function to filter details during visual exploration of objects. A subtype of EG, downcast gaze (DG), are probably functional to shift attention away from over-arousing visual stimuli (Noris et al. 2012; Bogdashina 2003). However, despite the relevance of contextual factors as possible triggers of EG (namely the presence of objects or over-arousing stimuli), previous studies observed children in a single context, not comparing the frequencies of EG under different contextual conditions.

Objectives: This study aimed to investigate whether contextual factors might influence the frequency of EG in young children with ASD, and specifically the occurrence of DG.

Methods: 20 preschoolers with ASD mean age 4,8 years (3,7 to 6,4 years, SD= 10 months), mean non verbal IQ 106 (Leiter-VR range 87-131, SD= 12.86) were included in the study. All the children were diagnosed by expert clinicians according to DSM-IV criteria for ASD and standardized diagnostic instruments (ADOS and ADI-R). We observed the children in two video-recorded conditions: COND-1 (free play with toys); COND-2 (structured social interaction and free play with toys). Frequency of EG performed by the children towards 8 possible directions (up, up-left, up-right, lateral-left, lateral-right, down, down-left, down-right) were coded from the videos. The mean frequency of DG and of EG per minute in each condition were considered in the analysis.

Results: The results indicated that, in general, the mean frequency of EG performed by the children in COND-2 was significantly lower than in COND-1 (COND-1=6.33 [SD=3.66]; COND-2=9.12 [SD=4.11]; t=3.77, df=19, p=0.001). Specifically, DG were more frequent in COND-2 than in COND-1 (COND-1=0.98 [SD=0.90]; COND-2=2.47 [SD=1.34]; t=5.1, df=19, p<0.001).

Conclusions: The results indicated a significant effect of the context on the mean frequency of EG. In general, EG were significantly more frequent in the most stimulating condition, in which the children were playing with toys and interacting with the experimenter. Specifically, such a difference was mainly accounted by a higher frequency of DG, which were rare when the children were only playing with toys. These findings seem to confirm the possible function of DG in reducing sensory overload.

120 **109.120** Decreased Habituation to Naturalistic Stimuli in Autism

A. L. Cardinaux[1], *H. Nejati*[2], *C. K. Rogers*[3], *K. Tsourides*[2], *T. K. Gandhi*[4], *M. M. Kjelgaard*[5] and *P. Sinha*[2], *(1)Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA, (2)Brain and Cognitive Sciences, MIT, Cambridge, MA, (3)Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA, (4)Defence Institute of Physiology and Allied Sciences, New Delhi, India, (5)MGH Institute of Health Professions, Boston, MA*

Background: Habituation plays a fundamental role in dynamically changing saliencies of environmental stimuli. Reduced habituation reduces stimulus suppression and immerses an individual in an unrelentingly salient, and hence potentially overwhelming, world. It would also compromise the ability to 'detach' attention from a given stimulus. Thus, an impairment in habituation can, in principle,

help account for sensory hypersensitivities as well as sustained interest in a limited set of stimuli, two prominent correlates of autism.

Objectives: In work that we presented last year, we showed that habituation to low-level sensory stimuli (metronomic auditory sequences) is reduced in autistic participants compared with neurotypical controls. This study aims to extend our previous work to more naturalistic stimuli.

Methods: We investigated the habituation response to repeated presentations of naturalistic video stimuli, using a measure of galvanic skin response (GSR). Participants were shown 1 minute of neutral baseline stimuli, followed by five repetitions of an exciting 30 second video clip. The convenience and ease of collecting GSR signals allowed us to enlist a wide range of participants on the autism spectrum, including individuals with minimal language abilities.

Results: We found consistent differences in the time-course of GSR signals from ASD participants compared with age-matched neurotypical controls. For the ASD group, the slopes of GSR signals over time showed a flat or increasing trend, indicating compromised habituation to the repeated video stimuli. Conversely, for neurotypical participants, GSR signals over time consistently showed a decreasing trend, indicating habituation to the stimuli. Further computational analysis of these results, using a machine learning classifier, showed differentiation between the neurotypical and ASD groups, based on the slope of the line of best-fit to the GSR signal over time. The classifier successfully differentiated between these two groups with ~75% accuracy.

Conclusions: These results can help to explain several commonly observed features associated with individuals with ASD: restricted and repetitive interests, and associated behaviors such as repetitive intake of media such as videos and music. Furthermore, these results provide support for a broader hypothesis of reduced predictive abilities in autism. Given the simplicity and ease of administering the protocol, we believe that there are possible applications in the measurement of habituation profiles in infancy, which may help with early identification of autism. Furthermore, the results could inform the development of learning environments and interventions best suited to the unique sensory profiles of individuals with ASD. Importantly, we argue that these findings are not due to extraneous factors such as general arousal levels, agitation, movement, or inattention, although further study is required. Future investigations will assess the specificity of the reduced habituation profile in autism compared with other conditions, its occurrence in other sensory modalities, and with naturalistic stimuli in modalities other than vision. At this stage, however, the consistency of our results across a wide range of ages and cognitive abilities points towards reduced habituation as a possible endophenotype that may yield a better understanding of some key aspects of the autism phenotype.

121 **109.121** Distribution of Visual Attention When Comparing Paired Faces in Typically Developing Infants and Infants Later Diagnosed with Autism

K. M. Hauschild[1] and M. S. Strauss[2], (1)The University of Pittsburgh, Pittsburgh, PA, (2)University of Pittsburgh, Pittsburgh, PA

Background: Previous prospective research with infants later diagnosed with an autism spectrum disorder (ASD) has shown differences in how they scan a face (Jones & Klin, 2013). Many infant paradigms of face perception and memory require the infant to compare faces that vary on either novelty, or perceptual aspects such as emotion, gender, and attractiveness. No research exists on whether these infants also differ in how they compare or scan more than a single face.

Objectives: To study how 11-month old infants who were later diagnosed as being typically developing (TD), non-typically developing (NT) or having autism (ASD) differed in their eye tracking when presented with two faces to compare.

Methods: A prospective study design compared the distribution of visual attention of typically developing infants (n=49), infants assessed as non-typically developing (n=7) and infants diagnosed with ASD (n=7) at either 24, 36, or 48 months of age. Eye tracking data were collected at 11 months of age while all infants completed a visual paired comparison task. Stimuli were face pairs of two different females who had similar (neutral/positive) facial expressions. Infants received six different pairs of faces to compare. The infants' visual attention both within a face and across the pair of faces was determined by designating 14 areas of interest (AOIs) (see Figure 1).

Results: All three groups spent significantly (based on t-tests) more time looking at the bottom as opposed to the top half of the faces. Comparisons of the amount of looking to the left vs. right side of the face showed that the TD group looked longer to the right side of the face demonstrating a previously reported left visual field (LVF) bias (t(46)=1.98, p=.05). In contrast, this LVF bias was not seen in the other two groups. With respect to paired face comparisons, there were group differences in the proportion of congruent mouth-to-mouth saccades (F(2, 58)=6.71, p<.00). Infants with ASD made the largest number of mouth-to-mouth comparisons (M=.17, SD=.14), followed by the TD group (M=.06, SD=.09), and the NT group (M=.00, SD = .00). Group difference were also found in the proportion of scans that went from a non-internal facial feature of one pair member to a non-internal feature of the other pair member (F (2, 58) = 4.93, p = .01). Essentially, NT developing infants made more (M = .47, SD = .27) (t (52) = -2.950, p < .00) extraneous comparisons than did TD (M = .22, SD= .20) infants.

Conclusions: First, similar to previous studies of infant sibling populations (Dundas et al., 2012), only the typically developing infants displayed a LVF bias at 11 months of age. This suggests that the LVF bias observed during the viewing of singularly presented faces remains intact during the scanning of face pairs for typically developing infants. Second, differences found in visual attention distribution and saccade congruency were predictive of diagnostic outcome in early childhood. In particular, the

mouth region seems primary in discriminating typically developing, non-typically developing, and autism outcome groups.

109.122 Do Children with Autism Change Their Behaviour in Response to Volatility in the Environment?

C. Manning[1,2], E. Pellicano[2], T. Karaminis[2], L. E. Neil[2] and J. Kilner[3], (1)Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom, (2)Centre for Research in Autism and Education (CRAE), Institute of Education, London, United Kingdom, (3)University College London, Institute of Neurology, London, United Kingdom

Background:
Adults can track reward probabilities across trials to estimate the volatility (or uncertainty) of the environment and use this information to modify their learning rate (Behrens et al., 2007). For example, in a stable environment, participants take account of outcomes over many trials, whereas in a volatile environment, they weight their recent experience more strongly than their distant experience. It has been suggested that individuals with autism may make less use of prior information (Pellicano & Burr, 2012), in which case, they may not change their behaviour in response to the statistics of the reward environment.
Objectives:
We investigated whether children with autism use information about the reward environment in a similar way as typically developing children to guide their decisions. Specifically, we hypothesised that children with autism would change their behaviour in response to volatility in the environment to a lesser extent than typically developing children.
Methods:
We administered a developmentally appropriate version of Behrens et al.'s (2007) task to 35 children with autism aged between 6 and 14 years, and 36 age- and ability-matched typically developing children. Participants were shown a green and a blue pirate chest, each associated with a randomly determined reward value between 0 and 100 points, with a combined total of 100 points (Figure 1). On each trial, the reward was given for only one stimulus. Participants initially completed a training phase where they passively monitored which of the two stimuli was rewarded on each of 20 trials before being required to estimate the ratio of rewards for the different colour chests. In the test phase, participants were required to choose either the green or blue pirate chest using response pads, and were awarded points if they chose the correct stimulus (see Figure 1). Children completed this task under two conditions each consisting of 80 trials. In the *stable environment* condition, the ratio of the blue or green response being correct (and therefore yielding a reward) was fixed at 75:25. In the *volatile environment* condition, the ratio alternated between 80:20 and 20:80 every 20 trials. We estimated the learning rate for each participant by fitting a delta rule model, and compared these across conditions and groups.
Results:
Overall, children increased their learning rate in the volatile condition compared to the stable condition. Unexpectedly, however there was no effect of group and no interaction between group and condition.
Conclusions:
Children with autism use information about the volatility of the environment to guide their decisions to a similar extent as typically developing children. In decision-making, therefore, it appears that children with autism employ prior knowledge just as typically developing children do.

109.123 Do Children with Autism Show Reduced Susceptibility to Visual Illusions?

C. T. Allen[1], **C. Manning**[1,2], M. J. Morgan[3,4] and E. Pellicano[1], (1)Centre for Research in Autism and Education (CRAE), Institute of Education, London, United Kingdom, (2)Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom, (3)City University, London, United Kingdom, (4)Max Planck Institute for Neurological Research, Cologne, Germany

Background: Many theories of autistic perception propose that individuals with autism are less susceptible to perceptual biases than typically developing individuals. One class of evidence in support of this claim comes from visual illusions, with reports of reduced susceptibility in autistic individuals for a range of different illusions (Happé, 1996; Ishida et al., 2013; but see also Ropar & Mitchell, 1999, 2001). It is generally assumed that differences in responses to visual illusions reflect differences at the level of the percept. However, it is possible that group differences instead reflect differences in higher-level decision-making strategies.
Objectives: We aimed to measure the perceptual biases of children with autism and typically developing children as purely as possible, by minimising the influence of cognitive factors such as decision rules.
Methods: We used a 2-alternative-forced-choice method with a roving pedestal (Morgan, Melmoth & Solomon, 2013) to quantify internal noise and decision biases for Ebbinghaus stimuli in 20 children with autism aged 6 to 14 years and 26 typical children matched in age and non-verbal ability. Children were presented with a reference stimulus and two comparison stimuli (see Figure 1), and asked to identify which comparison stimulus had a central circle most similar in size to that of the reference stimulus. One comparison stimulus was a pedestal, which had a central circle either 5%

larger or 5% smaller than the reference stimulus. The other comparison stimulus had a central circle that was an increment larger than the pedestal. The pedestal size (+5%, -5%) was randomly interleaved throughout the task, so that children did not know which of the two comparison stimuli was the pedestal on a given trial. Children completed this task in two context conditions: once with small surrounding circles on the reference and large surrounding circles on the comparison stimuli (S-L), and once with large surrounding circles on the reference and large surrounding circles on the comparison stimuli (L-S; see Figure 1). The data were fit with a cumulative normal psychometric function using the maximum likelihood estimate technique, modelling the effect of context condition as an equivalent pedestal with no effect on internal noise. A difference score was computed between the biases in each context condition, in order to determine the extent of bias for each participant. Results: Children with autism differed from typical children neither in their levels of internal noise nor in their degree of perceptual bias.

Conclusions: Our findings suggest that children with autism are just as susceptible to the Ebbinghaus illusion as typical children when decisional and response biases are minimised. Our results are inconsistent with theories proposing reduced contextual integration in autism (e.g., Frith & Happé, 1994). Furthermore, our findings suggest that previous reports of reduced susceptibility to illusions arise from differences in response or decisional criteria. We are currently collecting data with the Muller-Lyer illusion to investigate the generalisability of this result.

124 **109.124** Do Individuals with Autism Spectrum Disorder Process Own- and Other-Race Faces Differently?

L. Yi[1], P. Quinn[2], C. Feng[3] and K. Lee[4], (1)Sun Yat-sen University, Sun Yat-sen University, Guangzhou, Guangdong, China, (2)University of Delaware, Newark, DE, (3)Sun Yat-sen University, Guangzhou, China, (4)Dr. Eric Jackman Institute of Child Study, University of Toronto, Toronto, ON, Canada

Background: It has been well documented that individuals with autism spectrum disorders (ASD) exhibit atypical eye scanning patterns when processing human faces. For example, they display reduced attention to faces and their core features (eyes, nose, mouth), especially the eye region (e.g., Klin et al., 2002; Pelphrey et al., 2002). Most of the previous studies on atypical face processing in ASD, however, have used only faces of individuals from the same racial group as the participants. A growing literature has demonstrated a robust "other-race effect" (ORE) in typically developing (TD) individuals. That is, TD observers recognize and discriminate own-race faces more accurately than faces from other racial groups. This effect reflects the role of visual experience in shaping face recognition expertise. We investigated whether individuals with ASD scan own- and other-race faces differentially using eye tracking. Considering that there is inconsistency in the evidence regarding the existence of a behavioral ORE in ASD (Chien et al., 2014; Wilson, 2011), we investigated face scanning patterns using eye tracking, to provide a different measure of processing race information from faces.

It has been shown that both adults and infants display differential scanning of own- and other-race faces. For example, Asian observers tend to focus on the central region (i.e., the nose) of Chinese faces and the eye region of Caucasian faces (Fu et al., 2012; Liu et al., 2011).

Objectives: The present study examined whether individuals with ASD would, like typical individuals, show differential patterns of visual scanning when viewing own- and other-race faces.

Methods: The study included 15- to 25-year-old Chinese adolescents and young adults with ASD, age-matched typically developing (TD) individuals, and individuals with intellectual disability (ID). Participants completed a face recognition task with both own- (Chinese) and other-race (Caucasian) faces, while their eye movements were tracked. We analyzed fixation durations within each area of interest (AOI) and compared them between groups and races.

Results: Results, as shown in Figure 1, indicated that (a) in terms of recognition, the ASD and ID groups, although not the TD group (due to a ceiling effect), displayed superior recognition of own-race faces relative to other-race faces; (b) different from TD individuals and individuals with ID, individuals with ASD showed atypical face processing patterns regardless of face race; (c) similar to TD and ID individuals, individuals with ASD scanned own- and other-race faces differentially: they fixated on the eyes of other-race faces longer than those of own-race faces, whereas they looked at the nose and mouth of own-race faces longer than those of other-race faces.

Conclusions: The results suggest that there are similar cross-race differences in the face scanning patterns of ASD and non-ASD individuals. The findings corroborate the behavioral evidence of an other-race effect in children with ASD (Wilson et al., 2011) and suggest that similar to TD individuals, individuals with ASD are sensitive to face race information: their visual scanning and recognition of faces are both influenced by asymmetrical experience with different types of faces.

125 **109.125** Does Being Bilingual Impact Executive Functions in Autism Spectrum Disorders?

A. M. Gonzalez Barrero and A. Nadig, School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada

Background: Executive functions comprise skills essential for daily life. One of these is cognitive flexibility, often measured by set-shifting tasks (Eigsti, 2011). Some studies have shown enhanced executive functioning in bilinguals relative to monolinguals (e.g., Bialystok & Martin, 2004; Bialystok & Viswanathan, 2009), ascribed to the control bilinguals need to exert over the competing activation of

their two languages (Bialystok, 2007; Green, 1998). However, this so called "bilingual advantage" has not been found consistently (e.g., Engel de Abreu, 2011; Namazi & Thordardottir, 2010).

Objectives: While many studies have examined the impact of bilingualism on executive functions (EF) in typically-developing children, few have investigated this relationship in a neurodevelopmental disorder with known EF impairments. If a bilingual advantage exists, it might mitigate executive dysfunction in such a case. Individuals with Autism Spectrum Disorders (ASD) demonstrate EF impairments, specifically, children with ASD tend to exhibit perseverative responses on set-shifting tasks (e.g., Ozonoff et al., 2004). Conversely, children with ASD show spared skills in other cognitive domains such as verbal short-term memory (e.g., Boucher et al., 2012; Zinke et al., 2010). We examine the impact of bilingualism on set-shifting abilities in ASD. We hypothesized that bilingual children with ASD would be impaired in set-shifting relative to bilingual typically-developing (TYP) children, but would be less impaired than monolinguals with ASD (biTYP> biASD> monoASD). As a control we hypothesized that short-term memory would not differ between groups.

Methods: Bilingual TYP, bilingual ASD, and monolingual ASD groups were matched on nonverbal IQ, chronological age, gender and socioeconomic status. The target sample includes 20 biTYP, 15 biASD, and 15 monoASD 5- to 9-year-olds. Participants include French, Spanish or English speakers (or speakers of any 2 of these languages). To evaluate set-shifting skills we used a computerized version of the Dimensional Change Card Sort task (DCCS; Zelazo, 2006), where the dependent variable is passing 5 of 6 post-switch trials. In addition, we obtained a parental report of executive function behaviors in daily life via the Behavior Rating Inventory of Executive Functioning (BRIEF; Gioia et al., 1996). Short-term memory was assessed by the number repetition subtest of the Clinical Evaluation of Language Fundamentals (CELF-4; Semel et al., 2003).

Results: Preliminary data is available from 10 biTYP, 6 biASD, and 12 monoASD children. Findings generally pattern in line with our predictions. On the DCCS bilingual children with ASD perform better than their monolingual counterparts, and in fact better than TYP bilinguals (percent of children passing the DCCS post-switch phase: biTYP= 60%; biASD= 83%; monoASD = 50%). Parent ratings on the BRIEF set-shift subscale also follow predictions (lower scores = higher functioning: biTYP M = 45; biASD M = 62; monoASD M = 64). In contrast, short-term memory was not significantly different across groups (number repetition standard score biTYP M = 10.1; biASD M = 9.3; monoASD M= 7.7).

Conclusions: Data collection is ongoing and will allow us to investigate in a larger sample if the set-shifting difficulty experienced by monolinguals with ASD is significantly reduced in bilinguals with ASD.

126   **109.126** Downcast Gaze and Hypersensitivity to Direct Gaze in Young Children with ASD

S. Congiu[1], R. Fadda[2], D. Corda[3], G. Baldus[3], D. Serra[1], **L. Ferretti**[1], G. Saba[1] and G. S. Doneddu[1], (1)Center for Autism Spectrum Disorder, Azienda Ospedaliera Brotzu, Cagliari, Italy, (2)Department of Pedagogy, Psychology, Philosophy, University of Cagliari, Cagliari, Italy, (3)BalCor s.n.c., San Sperate, Italy

Background:
The use of eccentric viewing has been found to be common in ASD and it is likely to allow the filtering of details during visual exploration (Mottron et al., 2007; Noris et al., 2012). Specifically, a subset of eccentric glances (EG), downcast gazes (DG), is believed to occur in order to reduce sensory overload (Bogdashina, 2003; Simmons et al., 2009). In Noris et al. (2012) children with ASD during a social interaction were more likely to look downwards compared to matched TD children. These findings left open the question whether DG) are linked to the hypersensitivity to high-frequency visual information or they result from a hypersensitivity to social stimuli. Indeed some individuals with ASD are likely to show gaze aversion (Tottenham et al., 2013; Dalton et al., 2005) and atypical face scanning (Chawarska & Shic, 2009).

Objectives:
Our study involving a sample of young children with ASD investigated whether the patterns of attention to pictures of human faces with direct gaze, recorded by means of an eye-tracker, vary in relation to the frequency of EG during a social interaction episode with an experimenter.

Methods:
22 preschoolers with ASD mean age 4.8 years (3.7 to 6.4 years, SD= 10 months), mean non verbal IQ 111 (Leiter-VR range 90-133, SD = 13.5) were included in the study. Subjects were diagnosed by expert clinicians according to DSM-IV criteria for ASD and standardized diagnostic instruments (ADOS and ADI-R).

The children were shown a series of 6 images of neutral faces with direct gaze. Each image lasted 5 seconds on the screen of the eye-tracker Tobii T60, frequency and duration of fixations on eyes, mouth and the whole face were recorded and computed as a ratio to gaze-time on screen. Participants were video-recorded during an interaction with an adult administering selected items from the ESCS (Mundy et al., 2003). Mean frequency of EG per minute was coded from the videos and the median of this measure was used to divide the sample in two groups: low frequency (n=11, group LFreq), high frequency (n=11, group HFreq).

Results:
Children in the HFreq group produced a significantly higher mean frequency of DG during the ESCS interaction (HFreq=3.07 [SD=1.33]; LFreq=1.63 [SD=1.08]; t=2.765, df=20, p=0.012). Independent sample T tests revealed that children in the HFreq group showed significantly reduced attention to the eyes area of the pictures, in terms of frequency (HFreq=0.43 [SD=0.15]; LFreq=0.60 [SD=1.12]; t=2.975, df=20, p=0.007) and duration (HFreq=0.48 [SD=0.21]; LFreq=0.68 [SD=1.15]; t=2.539,

df=20, p=0.02) of fixations, while no significant difference resulted for the mouth area, or for the whole face in itself.
Conclusions:
Our results seem to suggest a relationship between DG and hypersensitivity to direct gaze. Children with ASD might look downwards in order to regulate excessive arousal caused by the direct eye gaze of a social partner.

127 **109.127** Evaluating Gender Differences in Perceptual Profiles of Individuals with Autism Spectrum Disorder

E. Marcil[1,2], J. Guy[2,3], L. Mottron, M.D.[4] and A. Bertone[2,5,6], (1)School/Applied Child Psychology, Department of Educational and Counseling Psychology, McGill University, Montreal, QC, Canada, (2)Perceptual Neuroscience Laboratory for Autism and Development (PNLab), Montreal, QC, Canada, (3)Integrated Program in Neuroscience, McGill University, Montreal, QC, Canada, (4)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montréal, QC, Canada, (5)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montreal, QC, Canada, (6)School/Applied Child Psychology, Department of Educational and Counselling Psychology, McGill University, Montreal, QC, Canada

Background: Concurrent demonstrations of superior performance on visuo-cognitive, non-social tasks (i.e., Block Design Task (BDT); Shah & Frith, 1993), and decreased performance on some social tasks (i.e., face identification and discrimination; Dawson et al., 2005) are considered as defining perceptual characteristics of Autism Spectrum Disorders (ASD). These dichotomous performances can, at least in part, be explained by a local processing bias in ASD. However, since ASD's sex ratio is as high as 16 males to 1 female for high-functioning individuals (Rivet & Matson, 2011), a strong argument can therefore be made that the central tenets of perceptual theories based on the aforementioned findings in ASD are based largely on male abilities.
Objectives: Assess whether ASD-specific perceptual profiles based on non-social and social task performance are equivalent in both males and females with ASD.
Methods: Participants. Ten females and 10 males with ASD were recruited and matched on age and Full-scale Wechsler IQ. All participants completed the same two tasks. Task 1. A non-social, computerized reversed BDT: a target block design (matrix size of 4, 9, or 16) was presented centrally on a touch-sensitive screen, with four possible probes (one matching the target) presented simultaneously around it. The perceptual coherence of the block designs was also manipulated by varying the number of 'adjacencies' of opposite-coloured edges; low-coherence (LC) designs necessitating increased local analysis to be resolved (block-by-block-processing) relative to high-coherence (HC) designs. Task 2.A social, face identity discrimination task (FID): a target face image was presented centrally, with four possible probes (one matching the target) presented simultaneously around it in same view (biasing local analysis) or viewchange (biasing global analysis) orientations. For both tasks, participants were asked to choose the probe matching the target as quickly and accurately as possible. Reaction time (RT) was measured as dependent variable for both tasks. A control, motor task was included to ensure that participants had similar motor reactivity.
Results: No gender differences were found on control motor task across conditions. Task 1: A significant main effect of Condition was found ($p < .001$), with mean RTs significantly shorter for LC trials. No significant main effect of Gender ($p = .689$), nor a Gender x Condition interaction was found ($p = .397$). Task 2: A significant main effect of Condition was found ($p < .001$), with RTs for same view trials significantly shorter than for viewchange trials. No significant Gender x Condition ($p = .454$) nor main effect of Gender was found ($p = .520$.)
Conclusions: Although non-significant, females with ASD tended to respond faster than males on the more global, view-change condition of the FID task. Although previous studies have suggested gender differences for traditional BDT performance (Koyama et al., 2009) for individuals with ASD, and correlations between autistic traits and impairment in face identity in males (but not in females) (Rhodes et al., 2013), the results of this study, at this point, suggest that perceptual profiles based on social and non-social task performance are equivalent in both males and females with ASD.

128 **109.128** Examining Attentional Bias for Facial Features Across Development and in Autism

K. A. Dalrymple[1], N. Wall[2], M. L. Spezio[3], H. C. Hazlett[4], J. Piven[5] and J. T. Elison[6], (1)Institute of Child Development, University of MInnesota, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN, (3)Psychology, Scripps College, Claremont, CA, (4)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)Institute of Child Development, University of Minnesota, Minneapolis, MN

Background: Critical behavioral and biological markers of a disorder that are present early in development may be transient or may be later masked by disease progression. Thus, one challenge for researchers investigating neurodevelopmental disorders is to design tasks that can be used across broad age ranges and developmental levels so as to identify and track these markers throughout development.
Objectives: We designed and evaluated performance in a task that provides an index of attentional bias in individuals from infancy through adulthood. Specifically, we designed a paired visual comparison (PVC) version of the "bubbles" face processing task (Gosselin & Schyns, 2001;

Humphreys et al., 2006).

Methods: The final sample included 24 school-aged children (n=12 typically developing (TYP); n=12 with autism according to CBE, ADOS, and ADI-R) and 13 typically developing infants between 6 and 14 months-of-age. Stimuli were modified "bubbles" stimuli based on Gosselin and Schyns (2001). Bubbles presented on either side of fixation revealed one of three facial areas: Eyes, Mouth, or Other Facial Parts (OFPs) such as forehead, cheek, or nose. These Areas Of Interest (AOIs) were viewed in three possible pairings: Eyes vs. Mouth, Eyes vs. OFPs, and Mouth vs. OFPs. Stimuli were presented in Tobii Studio and gaze was recorded with a Tobii X120. We computed three measures of gaze for each AOI: 1) Number of trials the AOI is fixated first, as a proportion of valid trials, 2) Time to fixate the AOI, and 3) Time spent on AOI, as a proportion of time spent on screen.

Results: There were few overall differences between TYP children and children with autism: TYP children spent a larger proportion of time on the AOIs ($p=0.015$) and were faster to reach the AOIs than children with autism ($p=0.012$). No Group x Part interactions were observed, indicating that both groups showed similar attentional biases. Overall, the children fixed the Eyes first more often than the Mouth and OFPs (ps<0.001). They also arrived at the Eyes faster than the Mouth ($p=0.012$) and OFPs ($p=0.001$). They spent an equal proportion of time on the Eyes and Mouth, but a greater proportion of time on these areas than the OFPs (ps<0.001).

Like the school-age children, the infants fixated the Eyes first more often than the Mouth and OFPs (ps<0.001). They spent a greater proportion of their looking time on the Eyes than the Mouth and OFPs (ps<0.001), and Mouth compared to OFPs ($p=0.006$). There was no significant difference between time to fixate Eyes, Mouth, or OFPs.

Conclusions: School-age children with and without autism, and infants, show similar viewing patterns on this paired visual comparison version of the "bubbles" task. All the groups show a bias toward eyes in terms of what they fixate first, how quickly they arrive there, and proportion of viewing time, but a bias for mouths over other face parts was less clear. This task appears to be useful for measuring attentional bias to facial features across a wide range of ages and developmental abilities.

129 **109.129** Exploring the Clinical and Cognitive Phenotype of Child Savants with ASD

ABSTRACT WITHDRAWN

Background: Whilst savant syndrome has traditionally been associated with intellectual disability and the negative symptoms characterizing autism spectrum disorder (ASD), recent empirical studies suggest there is very little evidence for such association.

Objectives: To isolate clinical features and cognitive abilities that distinguish savant and non-savant children with ASD. Specifically, we tested two hypotheses: (i) are unique talents in ASD explained by the degree of symptoms' severity in the disorder, or (ii) can they be explained by a specific profile of cognitive strengths and weaknesses?

Methods: We tested a group of children with ASD displaying talents in the domains of mathematics, music and art, on a range of diagnostic tests and standardized measures of intellectual ability. Test profiles were then compared with those of a group of age-and IQ-matched non-savant children with ASD.

Results: The results from our study showed that talents in ASD are positively associated with highly focused attention, superior fluid intelligence, and superior working memory. Although savants and non-savant groups did not differ on measures of social/communication deficits or on measures of obsession, savants were less impaired on measures of imagination/creativity and sensory processing than non-savants.

Conclusions: Our results highlight and characterize cognitive strengths in talented individuals with ASD, prompting us to consider interactions between these strengths and the clinical characteristics of ASD in understanding savant syndrome.

130 **109.130** Exploring the Driving Behavior of Young Novice Drivers with an Autism Spectrum Disorder: A Driver Instructor Questionnaire

V. Ross[1], *E. Jongen*[2], *M. Vanvuchelen*[3], *T. Brijs*[2], *K. Brijs*[2,4] *and G. Wets*[2], *(1)Transportation research Institute (IMOB), Hasselt University, Diepenbeek, Belgium, (2)Transportation Research Institute (IMOB), Hasselt University, Diepenbeek, Belgium, (3)Hasselt University Faculty of Medicine and Life Sciences, Diepenbeek, Belgium, (4)Faculty of Applied Engineering Sciences, Hasselt University, Diepenbeek, Belgium*

Background:
Driving allows autonomy and permits maintenance of social- and work-related contacts. Nevertheless, adolescents and young adults with an autism spectrum disorder (ASD) depend to a great extent on friends and family for their transportation needs. Although little research exists of driving ability in young novice drivers with ASD, Cox et al. (2012) surveyed parents/caregivers of adolescents and young adults, attempting, or previously attempting, to learn to drive. In comparison to relatively easier driving tasks (e.g., maintaining lane position), complex driving skills, such as merging into traffic or multi-tasking, were reported as being problematic for young novice drivers with ASD. Other reported difficulties were: interpreting the behavior of other road users, dealing with unexpected situations, and sustaining attention.

Objectives:
This study, which is part of the ongoing Yes I Drive project, extends on Cox et al. (2012) by surveying driver instructors. Driver instructors are important sources of information and might be complementary to the opinion of parents/caregivers, by more objectively reflecting the teaching process.
Methods:
A web-based link of the survey was sent to Flemish driving schools in Belgium. Several questions queried the driver instructors' advice for teaching young novice drivers with ASD how to drive, and for improving the current driving education methods to better fit the needs of young novice drivers with ASD. Furthermore, respondents were asked to indicate whether specific characteristics, often associated with ASD, have an impact on the driving ability (e.g., 'difficulties with motor planning', 'difficulties with emotional self-regulation'). Data collection is still in progress.
Results:
Preliminary results: A total of 52 driver instructors (40 males) acknowledged potential problems for teaching adolescents and young adults with ASD to drive. ASD related characteristics rated to have the highest impact on driving were 'Difficulty with concentration/attention', 'Difficulty with emotional self-regulation' and 'Difficulty with unexpected routine changes'. The least problematic (i.e., although still rated above average) ASD characteristics were 'Difficulty with motor planning' and 'Difficulty with sensory overstimulation'. Results however also showed that the relation between ASD and driving performance might not always be negative and can even be positive (e.g., a focus on details might be an asset). Advice for teaching young novice drivers with ASD to drive mainly focused on a need for structure, clarity, visual demonstration, practice and repetition. The reported diversity of young novice drivers with ASD, requiring an individualized teaching strategy, supports the current classification of autism as a "spectrum" disorder with ASD related symptoms and behaviors varying from person to person. In conclusion, and similar to Cox et al. (2012), the current results indicate that learning to drive presents a substantial challenge for young novice drivers with ASD. Confirmation based on opinions from the population of young novice drivers with ASD however is still lacking.
Conclusions:
Final results will be presented at the congress.

131 **109.131** Exploring the Role of Verbal Mediation in Executive Functioning in Children with Autism

I. Gangopadhyay[1], M. Buac[2], E. K. Haebig[2], M. M. Davidson[2], M. Kaushanskaya[2] and S. Ellis-Weismer[2], (1)Communication Sciences & Disorders, Univeristy of Wisconsin-Madison, Madison, WI, (2)Communication Sciences & Disorders, University of Wisconsin-Madison, Madison, WI

Background: Children with autism spectrum disorder (ASD) exhibit deficits in executive function (EF; Bennetto et al. 1993), including planning abilities (Hill, 2004). However, it is unclear what accounts for these deficits. One hypothesis is that language use influences EF (Zelazo et al., 1997). In typical development, EF performance is facilitated by verbal mediation (Diamond et al., 2002) and disrupted by articulatory suppression (Lidstone et al., 2010). In the autism literature, however, the link between EF and language is inconclusive (Joseph et al., 2005; Russell-Smith et al., 2014; Williams et al., 2012).
Objectives: The present study aimed: (1) to examine the role of verbal mediation in a complex EF task, the Tower of London, by comparing performance of typically developing (TD) children and children with ASD, and (2) to examine whether performance disruptions arise from suppression of verbal mediation or imposition of general dual-task demands.
Methods: Fourteen TD children and 14 children with ASD were matched on age and non-verbal IQ. The TD group had significantly better language skills than the ASD group (see Table 1). Children were administered a computerized Tower of London task under three conditions: no secondary task (NST), motor suppression task (MST), and articulatory suppression task (AST). Participants moved beads to match the model shown on the screen and were instructed to plan their moves prior to moving the first bead. Total number of moves, time to first move (planning time), and time to complete the trial after the first move (execution time) were recorded for each trial.
Results: ANOVAs (2x3) were conducted separately for each dependent variable with group (TD vs. ASD) as the between-groups variable and condition (NST vs. MST vs. AST) as the within-group variable. A main effect of condition was observed for total number of moves ($p=0.004$) and execution time ($p<0.01$), where MST and AST required significantly more moves and execution time than NST (all $p<0.05$). However, MST and AST did not differ significantly (ps>0.05), and groups did not differ significantly. For planning time, analyses revealed a main effect of condition ($p=0.04$), where MST took the longest time, and AST took the least ($p=0.03$), and a main effect of group ($p=0.04$) where children with ASD took significantly less time to plan than TD. There were no significant interaction effects.
Conclusions: The results revealed that the ASD group was impacted by verbal suppression in a planning task, similar to the TD children. This is contrary to previous work that suggested articulatory suppression does not impede EF performance in ASD (Russell-Smith et al., 2014) due to lack of verbal mediation. However, findings also indicated both groups of children were similarly disrupted by articulatory and motor suppression, suggesting that EF disruption in an articulatory suppression task is due to general dual-task processing demands, rather than verbal mediation. Although children with ASD took significantly less time to plan than the TD children, these cognitively-matched groups performed similarly in total number of moves and execution time.

132   **109.132** Extending the Characterization of Semantics in ASD to Non-Verbal Domains

K. Steinman[1,2], M. K. Askren[3], T. Ward[4], J. E. Elgin[5], J. Wenegrat[6], R. K. Earl[2], R. Bernier[2] and T. J. Grabowski[3], (1)Seattle Children's Research Institute, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Radiology, University of Washington, Seattle, WA, (4)Clinical Psychology, Seattle Pacific University, Seattle, WA, (5)Seattle Children's Autism Center, Bothell, WA, (6)University of Washington Autism Center, Seattle, WA

Background: Recent research on semantic memory – using semantic dementia, the prototypical neurologic semantic disorder, as a model – has demonstrated an amodal global semantic knowledge system that underlies both verbal (i.e., language-based) and non-verbal semantic challenges seen in this disorder. In autism spectrum disorders (ASD), verbal semantic impairments are well-recognized and common. However, the characterization of semantics in ASD has been almost exclusively limited to verbal semantics; non-verbal semantic knowledge has yet to be examined in depth.
Objectives:
(1) To characterize verbal and non-verbal semantic knowledge of 7–15-year-olds with ASD vs matched typically-developing controls (TYP).
(2) To examine the relationship between verbal and non-verbal semantic deficits in 7–15-year-olds with ASD.
Methods: Participants with ASD, functional language, and PIQ≥85 as well as age- and PIQ-matched TYP participants underwent IQ testing (WASI-II) and a computer-adapted semantic battery to assess semantic knowledge across various modalities. Response accuracy (percent incorrect) and mean response latency (for correct responses) were collected on two sets comprised of corresponding verbal and non-verbal tasks that use the same semantic stimuli: (1) Naming (of a pictured object; *Nam,* verbal), Comprehension (matching word to picture; *Comp,* verbal), and Semantic Association (matching related pictures; *SemA,* nonverbal); and (2) Word-Picture (*WP,* verbal) and Sound-Picture (*SP,* non-verbal) Matching tasks. Accuracy and (item-wise) response latency differential scores were defined for corresponding nonverbal versus verbal tasks. Two-sample *t*-tests were used to assess between-group differences in accuracy and response latencies. Differential scores were compared within and between groups with one- and two-sample *t*-tests, respectively.
Results: ASD participants (n=19) displayed lower accuracy (higher percentage of incorrect responses) than TYP participants (n=20) on all verbal tasks (*Nam* p=0.02; *Comp* p=0.04; *WP* p= 0.005) and one non-verbal task (*SemA* p=0.02), but performed no differently from TYP participants on the other non-verbal task (*SP* p=0.3). Latencies for correct responses did not differ between ASD and TYP on any verbal or non-verbal tasks (p≥0.3). Comparing accuracy on non-verbal versus corresponding verbal tasks, ASD participants exhibited the same pattern as TYP of greater accuracy on *SemA* than *Nam*, similar accuracy on *SemA* and *Comp*, and less accuracy on *SP* than *WP*. Both groups exhibited longer latencies on *SemA* than *Comp* (both p<0.001), but only TYP exhibited significantly longer latencies on *SP* than *WP*(p<0.001 vs. ASD p=0.06). No significant differences between groups were found for differential accuracy or response latencies on non-verbal versus verbal tasks.
Conclusions: As anticipated, ASD participants exhibited lower accuracy on verbal semantic tasks than TYP participants. ASD participants also demonstrated impairments on a non-verbal picture matching task, but not a non-verbal auditory-picture matching task. This profile suggests an intact underlying global semantic knowledge system in ASD, with differential impairments in various verbal and non-verbal semantic tasks resulting from modality-specific abnormalities (e.g., language) in the semantic network. Future multivariable regression analysis will investigate semantic task performance differences adjusting for age, PIQ, and standardized verbal semantic tasks to yield a better understanding of the relationship between verbal and non-verbal semantic task impairments and deficits in different non-verbal semantic domains.

133   **109.133** Familiarity and Affect in Adolescents with Autism Spectrum Disorder

J. H. Filliter[1], M. Kerr[2] and S. A. Johnson[3], (1)IWK Health Centre, Halifax, NS, Canada, (2)Dalhousie University, Halifax, NS, Canada, (3)Department of Psychology and Neuroscience, Dalhousie University, Halifax, NS, Canada

Background: In typically developing (TD) individuals, increased familiarity with stimuli generally results in greater affinity toward them. This phenomenon, called the mere repeated exposure (MRE) effect, is robust and pervasive. It has also been found to influence real-world behaviours; specifically, individuals are more likely to approach and less likely to avoid stimuli that have become familiar through MRE. We hypothesized that an abnormal MRE effect would be observed in Autism Spectrum Disorder (ASD) for several reasons, including evidence of: 1) a preference for the familiar in those with ASD, 2) slowed stimulus habituation in individuals with ASD, and 3) atypicalities in the neural reward circuitry of those with ASD, relative to TD comparison participants.
Objectives: The main goal of the current project was to test the hypothesis that the MRE effect would be atypical in individuals with ASD. We also sought to examine the influence of stimulus type (i.e., social vs. non-social) on the MRE effect, as well as the association between the MRE effect and several individual difference variables (i.e., anxiety, intolerance of uncertainty, and restricted and repetitive behaviours).
Methods: We administered a standard MRE task to 28 12- to 17-year-olds with ASD and 28 age, sex,

and IQ-matched TD comparison participants, all with estimated IQs of at least 80. In an exposure phase, participants were shown a series of unfamiliar neutral visual stimuli drawn from three categories at a range of exposure frequencies. In a subsequent rating phase, they were asked to assign liking ratings to both previously-exposed and novel stimuli. Several characterization measures (the Screen for Child Anxiety Related Emotional Disorders, the Intolerance of Uncertainty Scale for Children, and the Repetitive Behaviour Scale - Revised Edition) were also administered.

Results: A 2 (Diagnostic Group) x 3 (Stimulus Category) x 4 (Exposure Frequency) repeated measures ANOVA revealed a Diagnostic Group x Exposure Frequency interaction [$F(3, 52) = 3.07$, $p = .04$; $\eta_p^2 = .15$]. Specifically, while TD adolescents displayed a MRE effect, the liking ratings of participants with ASD did not increase across stimulus presentations, even at the highest exposure frequency. The pattern of liking ratings across exposure frequencies was similar across stimulus categories for both the TD and ASD groups. Few relationships between MRE findings and individual difference variables were observed.

Conclusions: The results of the current study suggest that the relationship between familiarity and affect is disrupted in adolescents with ASD. That is, we observed that TD participants demonstrated rising and then falling liking ratings across a range of stimulus exposure frequencies (i.e., the expected MRE effect), but youth with ASD did not. This pattern of results was similar across three categories of visual stimuli. Additional research will be required in order to clarify whether our findings reflect the protraction or absence of the MRE effect in ASD. These findings provide important insight into one of the processes that may contribute to familiarity preference and novelty aversion in ASD (i.e., a disrupted MRE effect).

134 **109.134** Habituation Speed and Novelty Preference to Faces in Preschoolers with ASD

S. Ghods[1], C. Healy[2], B. L. Zappone[3], S. Corrigan[4], E. Jones[5], K. Toth[3] and S. J. Webb[6], (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Child, Health Behavior and Development, Seatle Children's Research Institute, Seattle, WA, (3)Seattle Children's Research Institute, Seattle, WA, (4)Child Health, Behavior, and Development, Seattle Children's Research Institute, Seattle, WA, (5)Centre for Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (6)Psychiatry and behavioral sciences, University of Washington, Seattle, WA

Background:
Impairments in face processing and recognition may be apparent in the early development of ASD, with toddlers aged 18 to 30 months with severe symptoms of ASD needing more time to habituate to faces than comparison groups (Webb, Jones et al. , 2010). Differentiation of familiar vs. unfamiliar faces is also delayed in ASD at this age, with the delay related to the degree of social adaptive delay (Webb et al., 2011).

Objectives:
To assess the influence of facial familiarity on behavioral measures of face processing and memory impairment in preschoolers aged 24 to 48 months with ASD symptoms.

Methods:
Two groups were tested: preschool aged children with ASD (N=61) and preschool aged children with typical development (N=61). In addition to diagnostic and developmental testing, each child took part in four habituation experiments, in a two stimulus (Face, Object) by two stimulus set (Set A, Set B) design across 2 visits. Children viewed a picture of a face or a toy until they met a habituation criterion; after a delay, children viewed the familiar picture and a novel picture. Variables included time to habituate, number of looks during habituation, and novelty preference. Faces were rated for similarity to the mother's face. As two different face sets were used (A / B), we compared habituation variables when the face set was similar vs. dissimilar to mother's face.

Results:
Total time, mean look, first look and total number of looks for habituation to faces was similar in both the ASD and TYP groups (Fs<.49, ps>.4). The look to the novel face was shorter for the ASD than TYP group (F=3.8, p=.05) although both groups (F=.385, p=.53) demonstrated a novelty preference (ts>27, ps< .01). There was no difference between habituation variables and Visit Order (F<1.9, ps>.17) nor Face Set (Fs<.13, ps>.26). Preliminary modeling of familiarity (based on hair style/color match) suggests that match to mom's face may influence total time to habituation and length of first look differentialy in the ASD group vs TYP group (Group x Similarity interaction: Fs<2.9, ps<.09) in our set of faces that had long hair (Set A).

Conclusions:
Habitation patterns may provide important information about early attention skills in children with ASD. We have suggest that attention, particularly social attention, is critical in supporting more complex social learning. Thus, altered learning about faces may be an important target of early interventions. Our preliminary analyses suggest that the overall pattern of attention to faces is normative between 2 and 4 years of age but that attention to the novel face after habituation and the influence of facial similiarity/familiarity may alter attention patterns by group.

135 **109.135** Hazard Perception Abilities of Young Novice Drivers with an Autism Spectrum Disorder: A Driving Simulator Study

V. Ross[1], E. Jongen[2], M. Vanvuchelen[3], T. Brijs[2], K. Brijs[4] and G. Wets[2], (1)Transportation research

Institute (IMOB), Hasselt University, Diepenbeek, Belgium, (2)Transportation Research Institute (IMOB), Hasselt University, Diepenbeek, Belgium, (3)Hasselt University Faculty of Medicine and Life Sciences, Diepenbeek, Belgium, (4)Faculty of Applied Engineering Sciences, Hasselt University, Diepenbeek, Belgium

Background:
Driving is a complicated, goal-directed task. Some ASD characteristics, for instance difficulties with executive functioning and interpreting the behavior of others, might interfere negatively with driving. Although little research exists on the relation between ASD and driving, Sheppard et al. (2010) investigated hazard perception in adult males with ASD. Hazard perception refers to the ability to recognize and respond to hazards that (might) develop on the road (e.g., when a school bus stops children may cross the road from behind the bus). The results indicated slower overall response times to road hazards, and increasingly slower response times to social (e.g., a pedestrian) versus non-social hazards (e.g., a vehicle). Hazard perception was studied through the evaluation of video material. Although dynamic, this does not equal the act of driving, and it is not clear therefore to what degree these results generalize to the driving task. Furthermore, Sheppard et al. (2010) only included non-drivers with ASD. Hazard perception however improves greatly with increased driving experience and is therefore especially problematic for young novice drivers.
Objectives:
Our study, which is part of the ongoing Yes I Drive project, aims to investigate hazard perception, and the underlying mechanisms (i.e., executive functioning and action observation), in young novice drivers diagnosed with ASD, using a driving simulator, an eye tracker, and computer tasks (e.g., a computerized stop signal task assesses response inhibition).
Methods:
Driving abilities of 50 young novice drivers with ASD (i.e., aged 17-25, maximum 2 years of driving experience) will be compared to a matched control group of healthy young novice drivers. The research consists of two segments: 1) A driving simulator scenario; 2) A computer task battery. The driving scenario contains several driving environments in which the driver encounters 24 road hazards (i.e., social and non-social). Standard driving measures will be collected throughout the drive (e.g., speed). Eye tracking measures (e.g., time of first fixation) will be calculated to assess hazard perception. Finally, computer tasks will measure: attention, response inhibition, working memory, and action observation.
Results:
Data collection is still in progress at the moment, and data analyses are planned for spring 2015.
Conclusions:
Results will be presented at the congress.

---

136   **109.136** How Genetically Induced Enhanced Synaptic Plasticity and Regional Cortical Rededications Account for Autistic Superior Performances: The Trigger-Threshold-Target-Neglect Model for Autism

L. Mottron[1], P. Duret[2], O. Collignon[2], L. Xiong[2] and F. Samson[2], (1)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montreal, QC, Canada, (2)Psychiatry, Clinique spécialisée de l'autisme, Montréal, QC, Canada

Background: Autism is characterized by enhanced synaptic as well as enhanced regional plasticity. This phenomenon seem to be the result of genetic mutations involved in the disorder which mostly up-regulate early synaptic development. This cascade of genetic as well as biological events seem to account for the pattern of enhanced regional activity in visual associative cortex that systematically occurs during perceptual processing tasks in individuals with autism. Yet, not all individuals with autism present enhanced perceptual functioning, and there is tremendous heterogeneity across the spectrum. This leads to examine the hypothesis of a causal link between increased synaptic and regional plasticity, and the effect of variability in perceptual activity on different subgroups within the autism spectrum.
Objectives: We here aim at investigating how enhanced synaptic and regional plasticity are responsible for opposite patterns of cognitive enhancements across subgroups within the autism spectrum.
Methods: We use two complimentary theoretical accounts of functional plasticity in autism: (i) *microstructural plasticity* wherein synaptic plasticity is the byproduct of the genetic mutations involved in autism, and (ii) *regional plasticity* wherein differences in functional and structural patterns of brain activity and grey matter integrity trigger heterogeneity in brain activity during perceptual tasks. Specifically, the latter account examines the overlap between regions of structural differences between autistic and control individuals, enhanced activation during visual and auditory perceptual processing, and regions identified as extremely plastic in rededicating functions within the context of cross modal plasticity models following congenital sensory impairment.
Results: (i) the main cognitive domains enhanced in autism are sub-served by the most plastic cortical brain region, the multimodal associative cortex; (ii) autistic cognitive enhancements and cortical rededications are overlapping with those involved in cross modal plasticity following sensory impairment; (iii) autism is associated with enhanced topographical variability of task-related activation in perceptual and motor associative regions, suggesting enhanced regional plasticity in functional allocation; (iv) regions of enhanced activity during perceptual auditory tasks differ in autistics individuals with and without speech onset delay.

Conclusions: According to the Trigger-Threshold-Target-Neglect (TTTN) model, autism is the result of a plastic reaction triggered by heterogeneous alterations, largely genetic in nature. These genetic mutations are responsible for setting a lower threshold of brain reorganization targeting ''sensitive'' cerebral territories. Within this account, the plastic reaction would be the only consequence of the genetic alteration in non-syndromic (or primary) autism, whereas syndromic (or secondary) autism would occur when the mutation alters typical plasticity mechanisms, resulting in intellectual disability and dysmorphism. Differences in the regional target (perceptual vs. linguistic) of brain reorganization might account for the widespread heterogeneity characterizing the autistic spectrum phenotype. As a result, functions that are not targeted within and by this reorganization would be responsible for autistic deficits or lack of expertise. The TTTN model accounts for pairs of specific strengths and deficits in the phenotype of autism, such as the coupling between speech delay and perceptual strengths in classical autism, as well as the coupling between precocious speech strengths and motor clumsiness in Asperger syndrome.

137   **109.137**   Individual Cognitive Strengths and Weaknesses in Autism Spectrum Disorders: Diversity Is the Rule

D. H. Skuse[1], W. Mandy[1] and M. Murin[2], (1)Behavioural and Brain Sciences Unit, UCL Institute of Child Health, London, United Kingdom, (2)Great Ormond Street Hospital, London, United Kingdom

Background: The extant cognitive literature reveals little about whether individuals with ASD have a consistent cognitive profile and, if so, what it is. Logically, a range of possibilities exists, from a situation where all people with ASD have a similar pattern of cognitive strengths and difficulties to perfect heterogeneity, with no consistent cognitive profiles. Yet the comparison of group averages does not, and cannot, reveal evidence for or against these alternate hypotheses. Claims that people with ASD in general have stronger non-verbal than verbal skills have not been adequately tested in 'high-functioning' samples. We aimed to use a multiple single case study approach to investigate the nature and range of cognitive diversity within individuals with ASD, most of whom had normal-range intelligence.

Objectives: Our objective was to seek evidence for one or more characteristic ASD profiles based on standard cognitive tests, which could serve as means to supporting diagnosis and as a step towards the elucidation of ASD biomarkers. The discovery of sub-groups defined by their cognitive profile would have profound implications for understanding distinct etiologies, treatment needs and prognoses.

Methods: Participants comprised 104 children (81% male; mean age = 11.4 years, SD=2.96, range = 6.2 to 16.9), diagnosed with ASD by a team of expert clinicians on the basis of ADI-R and ADOS scores. IQ was measured using the Wechsler Intelligence Scale for Children – Fourth UK Edition (WISC-IV). All participants had fluent language and were in mainstream education; 82% had a full-scale IQ >70.

Results: Previous literature indicated relatively strong Picture Concepts, Similarities and Matrix Reasoning characterize a 'typical' WISC-IV profile, in combination with relatively weak Comprehension and Symbol Search. We searched for children with this profile, defined according to Flanagan-Kaufman criteria (a standardized measure of discrepancy within WISC profiles). Just 1/104 participants had this 'typical' WISC-IV profile. Diverse patterns of relative strengths and difficulties were common. Only 14 children (13%) had neither strengths nor difficulties; 76 (73%) had both at least one strength and at least one difficulty. Greatest diversity was seen in verbal similarities, comprehension and coding (proportions with strengths and weaknesses differed at p<0.001). Block design, often cited as a relative strength in ASD, was not discriminating; 14 (13%) had a weakness and just 18 (17%) had a relative strength in this task.

Conclusions: Unevenness of WISC-IV subscale scores is the norm in children with ASD. Using cognitive profiles as potential endophenotypes for distinctive biomarkers, such as characteristic patterns of neural activity, is unlikely to be productive. A typically 'autistic' WISC-IV profile is rare even among high-functioning children. There is no consistent strength in any verbal or non-verbal subtest. Cognitive testing has no predictive value in the evaluation of ASD in diagnostic terms.

138   **109.138**   Integration of Visual and Proprioceptive Perception of Movement Kinematics in Children with and without Autism Spectrum Disorder

N. Salowitz[1], A. V. Van Hecke[2] and R. A. Scheidt[1], (1)Biomedical Engineering, Marquette University, Milwaukee, WI, (2)Marquette University, Milwaukee, WI

Background: Children with autism spectrum disorder (ASD) often exhibit deficits in sensory information processing, yet the nature and consequence of these deficits is unclear. An important goal of sensory information processing is the integration of information from multiple sensory modalities for perception of body and limb movements in space. Vision and proprioception are usually the two most informative modalities serving this purpose. According to current models of sensorimotor integration, if uncertainty increases in one modality (e.g. vision), the contribution of the other (proprioception) should increase.

Objectives: We used robotic technology and psychometric modeling to test the hypotheses that children with ASD exhibit deficits in multimodal sensory integration for motion perception relative to typically developing (TD) children (i.e. that children with ASD favor proprioception over vision to a

greater extent than TD controls).

Methods: Ten high-functioning children with ASD and ten TD children performed a two-interval, forced choice, hand path curvature discrimination task. Seated participants grasped the handle of a robotic device that moved in the horizontal plane and / or watched a cursor representing the hand move on the screen (Figure 1a). Task instructions were presented on the screen (Figure 1b). We characterized the ability to discriminate between hand and / or visual cursor paths (both called endpoint paths) of differing curvature (Figure 1c) and to characterize the relative importance of vision vs. proprioception in the perception of endpoint motion. Children performed the task under single-modality (visual or proprioceptive stimuli) or bimodal conditions (simultaneous visual and proprioceptive stimuli). We additionally investigated how uncertainty in the visual stimuli might influence perception by varying the width of the cursor's Gaussian spatial distribution on different trials (Figure 1d). We estimated two psychometric variables from standard cumulative Gaussian functions fitted to the task response data: the standard deviation of the underlying psychometric model (also called discrimination threshold) and the point of subjective equality (PSE). We used these variables to estimate the contributions of vision and proprioception to the perception of endpoint motion. The discrimination threshold is inversely related to the precision in which participants discriminate between curvatures.

Results: Children with ASD were more variable in their discrimination (i.e. they exhibited increased discrimination thresholds) during the bimodal condition as compared to TD children, and as compared to discrimination during the single-modality experiments (Figure 2a). By contrast, both groups of children exhibited systematic re-distribution of sensory weights such that visual dominance over proprioception decreased as the amount of visual uncertainty increased (Figure 2b).

Conclusions: We identified deficits in the precision in which children with ASD discriminate hand path curvatures when provided simultaneous visual and proprioceptive information. Contrary to our original hypothesis, we found no evidence for ASD-related deficits in the re-weighting of visual and proprioceptive information for perception of hand-path kinematics. Our findings suggest that the neural mechanisms underlying multisensory re-weighting remain intact in high-functioning children with ASD, whereas mechanisms underlying multisensory perception of movement kinematics are compromised.

139 **109.139** Intolerance of Uncertainty, but Not Anxiety, Predicts Sensory Sensitivities in Autism

L. E. Neil[1], N. Choque Olsson[2] and E. Pellicano[1], (1)Centre for Research in Autism and Education (CRAE), Institute of Education, London, United Kingdom, (2)Karolinska Institutet, Pediatric Neuropsychiatry Unit, Department of Women's and Children's Health, Stockholm, Sweden

Background:
Sensory sensitivities have risen to greater prominence with their inclusion in the recent DSM-5 criteria for autism. Yet very little is known about their underlying mechanisms. Some studies have reported significant links between sensory sensitivities and another common feature of autism, anxiety, although the causal direction of this relationship is not fully understood. Alternatively, one recent theory of autism suggests that sensory sensitivities in autism might be due to fundamental differences in the way that individuals deal with an uncertain or unpredictable environment (Pellicano & Burr, 2012).

Objectives:
Here, we investigated the relationships between children's propensity to deal with uncertainty, their sensory sensitivities and anxiety levels. The objectives of this study were threefold. First, we investigated the relationship between sensory sensitivities with the construct, 'intolerance of uncertainty', a predisposition to react negatively to uncertainty on a cognitive, behavioural and emotional level (Buhr and Dugas, 2009). Second, we examined the relationship between sensory sensitivities and anxiety symptoms. Finally, we examined whether children's anxiety levels might mediate (fully or partially) the putative relationship between intolerance of uncertainty and sensory sensitivities.

Methods:
We administered questionnaires to parents of 65 children with autism aged between 6 and 14 years, including the Short Sensory Profile (McIntosh et al., 1999) to tap children's sensory sensitivities, the Intolerance of Uncertainty Scale (Rodgers et al., 2012) and the Spence Children's Anxiety Scale (Spence, 1997). Children were administered the Wechsler Abbreviated Scales of Intelligence – 2nd Edition and the ADOS-2. We used correlation and regression analyses to examine the associations between scores on these measures.

Results:
Sensory sensitivity scores showed a clear association with scores on intolerance of uncertainty ($r = .59$, $p < .001$) and anxiety ($r = .61$, $p < .001$). Intolerance of uncertainty scores were also strongly associated with anxiety scores ($r = .78$, $p < .001$). A hierarchical regression analysis in which anxiety scores were entered in the first step and intolerance of uncertainty scores were entered in the second step showed that intolerance of uncertainty made a unique contribution to the variance in children's sensory sensitivities once the effects of anxiety were accounted for (R^2 change $= .091$, *F* change $= 8.30$, $p = .006$). In the final model, intolerance of uncertainty scores significantly predicted sensory sensitivity scores ($\beta = .44$, $p = .006$) but anxiety scores did not ($\beta = .29$, $p = .070$). Individual differences in gender, age and IQ were not associated with sensory sensitivity scores.

Conclusions:
Sensory symptoms, anxiety and intolerance of uncertainty are robustly associated with each other in

children with autism. Intolerance of uncertainty has previously been shown to predict anxiety (Boulter et al., 2014). Here, we show that it also – and uniquely – predicts sensory sensitivities. The effect of anxiety on sensory sensitivities was not upheld when both anxiety and intolerance of uncertainty were entered together as predictors in the model, suggesting that intolerance of uncertainty could potentially explain the relationship between anxiety and sensory sensitivities.

140   **109.140** Isolating Visual- and Proprioception-Based Generalization of Motor Learning in Autism Spectrum Disorder

E. Sharer[1], S. H. Mostofsky[1,2,3], L. M. Oberman[4,5] and A. Pascual-Leone[4,5], (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD, (3)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD, (4)Department of Neurology, Berenson-Allen Center for Noninvasive Brain Stimulation, Beth Israel Deaconess Medical Center, Boston, MA, (5)Harvard Medical School, Boston, MA

Background: Individuals with autism spectrum disorders (ASD) show impaired acquisition of social communication skills, a defining feature of ASD; in addition, other more basic skills are also impacted. Development of new skills requires integrating information from multiple sensory modalities. This input is then used to form internal models of action that can be accessed when both performing skilled movements, as well as understanding those actions when they are performed by others. Learning skilled gestures is particularly reliant on integration of visual and proprioceptive feedback and may provide a critical developmental building block for social communication.
Objectives: We used a modified serial reaction time task (SRTT) to decompose proprioceptive and visual generalization components and examine whether the patterns of skill learning differ in ASD participants as compared to healthy controls (HC).
Methods: Data were analyzed from 18 ASD participants (16 male, 38.72±18.362 years) and 11 healthy controls (6 male, 36.36±17.42 years) while performing a modified SRTT. Visual cues appeared in one of four positions, corresponding to one of four buttons on a response pad. To isolate different motor learning components, two separate sessions of the task were used for each participant. During both sessions participants trained using the dominant right hand. A test generalization period using the left hand followed where either the visual pattern of the sequence was kept constant (with the finger pattern mirrored) or the finger (proprioceptive) sequence was kept constant (with the visual pattern mirrored). Diagnostic differences in generalization during visual- and proprioceptive-based sessions were assessed using a repeated measures two-way ANOVA on learning scores.
Results: Analysis revealed a significant effect of generalization domain on reaction time learning scores (p=0.025) with greater generalization in the visual domain as compared to the proprioceptive domain. There was no main effect of diagnosis (p=0.284). However, there was a significant interaction between generalization domain and diagnosis on learning score (p=0.003). During the visual component, healthy controls showed greater improvement than ASD participants (p=0.010). Single sample t-tests revealed that only the control group showed significant visual generalization (HC: p=0.001; ASD: p=0.799). The two groups did not significantly differ in proprioceptive generalization (p=0.483), with neither group showing any significant learning effect (HC: p=0.637; ASD: p=0.618).
Conclusions: Findings revealed significant group differences when visual feedback was required for generalization of the learned motor sequence: healthy controls showed robust visual generalization whereas ASD participants demonstrated little generalization. In contrast, no group differences were observed when proprioceptive feedback was required for generalization, with both groups showing limited generalization. The findings suggest that when learning a motor sequence, individuals with ASD tend to rely less on visual feedback than do healthy controls. Visuomotor representations underlie imitative learning and action understanding and are thereby thought to be crucial to development of social skills and social cognition. It follows that anomalous patterns of procedural learning, with a tendency to discount visual feedback, may be an important contributor in the development of the core social communication deficits that characterize ASD.

141   **109.141** Item-Memory for Words, Pictures, Abstract Shapes and Nonsense-Words in Adults with Autism Spectrum Disorder

M. Ring, S. B. Gaigg and D. M. Bowler, Autism Research Group, City University London, London, United Kingdom

Background: Memory in ASD is characterised by a specific pattern of strength and difficulties (Boucher & Bowler, 2008) that include impairments in episodic memory whilst semantic memory is relatively preserved (Tulving, 2002). Memory in ASD is usually tested by asking individuals to memorise a list of words or a set of pictures of daily objects. Since ASD is associated with varying degrees of language and social-communication impairments (APA, 2013; Bennett et al., 2008), it is possible that memory difficulties in relation to such materials reflect language difficulties to some extent. This could be related to difficulties of ASD individuals to use categorical information to support their memory (Gaigg et al., 2008). Therefore it is unclear if findings generalise to non-verbal materials.
Objectives: The aim was to replicate prior findings of difficulties with episodic but not semantic memory in ASD with a larger sample. We were also interested to see if findings for words and pictures

can be generalised to non-meaningful pictorial and verbal materials. Finally, it was of interest to examine which materials would be remembered best by both groups.

Methods: Sixty-four (32 TD, 32 ASD) adults (age-range: 22-65 years) matched on intelligence, age and gender were asked to study a sequence of blocks of words, pictures, nonsense-words and abstract shapes with 10 items each. Their memory was tested after all blocks using a 'yes-no' followed by the 'Remember-Know' (RK) recognition memory procedure (Tulving, 2002). Participants were also asked to justify any R responses by describing what they remembered. After the task they were given a questionnaire enquiring about the strategy they used for remembering the materials (e.g. I looked at the item, I imagined the word as a picture in my head, I told myself a story about the item). In three follow-up tasks participants were asked to assign names to the pictures or form associations for nonsense-words and shapes to measure participants' ability of establishing meaning for the materials.

Results: Preliminary data (25 TD, 19 ASD) suggest that pictures were remembered better than all other materials by both groups. Both groups showed significantly higher R compared to K responses. In addition the TD group presented significantly higher R responses compared to the ASD group. The TD groups' recognition performance was overall better than the ASD groups' recognition. There was no difference in the quality of R responses between groups. Recognition differences between groups seem to be related to differences in strategy use and differences in establishing meaning for the materials to support memory. The TD group used more elaborate associative strategies compared to the ASD group and showed better performance in establishing meaning for the non-meaningful materials.

Conclusions: Results extend and replicate prior findings on memory in ASD. Memory difficulties in ASD might be related to difficulties to establish meaning for material to support memory and strategy use might play a role in task performance. Results will be discussed in relation to broader theories about memory functioning in ASD and speculations will be made about underlying cognitive processes.

142   **109.142** Joint Action Coordination in Children with Autism Spectrum Disorder

F. Fulceri[1], A. Tonacci[2], F. Apicella[3], A. Narzisi[4], L. Billeci[5], F. Muratori[6] and A. Contaldo[6], (1)Stella Maris Foundation, Pisa, Italy, Pisa, Italy, (2)Clinical Physiology Institute, CNR, Pisa, Italy, (3)"Fondazione Stella Maris" Scientific Institute, Pisa, Italy, (4)University of Pisa – Stella Maris Scientific Institute, Pisa, PI, Italy, (5)National Research Council of Italy (CNR), Pisa, Italy, (6)Stella Maris Scientific Institute, Calambrone (Pisa), Italy

Background: Impaired motor skills are seen in a large majority of children with Autism Spectrum Disorder (ASD) and are considered a possible origin of the social and communicative deficit characterizing the disorder. The different views on the origin of motor deficit in ASD range from the impairment in action planning to predictive mechanisms supporting action execution. A specific deficit in anticipating the perceptual consequences of their own and others movements may lead ASD children to experience difficulties in interpersonal interactions that include joint-actions, namely those motor interactions whereby two people coordinate their actions to achieve a change in the environment. Studying the movement during motor interaction tasks could help in elucidating the motor control mechanisms possibly altered in ASD, providing cues for novel intervention strategies.

Objectives: To analyze, in TD and ASD children, the reach-to-grasp movements in a joint-action task, and elucidate the influence of action context on movement performance and kinematics.

Methods: Five high-functioning ASD children (mean [SD] age = 94 [10.8] months) and five TD children (mean [SD] age = 92.5 [8.9] months, SD) participated in a joint-action task with the experimenter. Children were required to execute the same action - reaching and grasping little objects - in two contexts (cooperative CP vs. competitive CM). Each session was video recorded, and a magneto-inertial sensor was fixed through a support on both children and experimenter wrists. Five measures were obtained: (a) reaction time (RT); (b) movement time (MT); (c) peak acceleration (peak Acc); (d) time of peak acceleration (peak Acc Time); and (e) time at which each child started reaching as a function of the experimenter movement (ExMT%). Each variable was analyzed using RM ANOVAs to test group differences and the effect of the social context. Significance was setted at $p<0.05$.

Results: Analysis of RTs and ExMT% showed a significant interaction between group (ASD, TD) and social context (CP, CM). Both groups showed faster RTs ($p<0.001$) and lower ExMT% ($p<0.001$) in CM than in CP context. However, RTs and ExMT% in CM were respectively slower ($p = 0.04$) and higher ($p<0.001$) in ASD with respect to TD group. A main effect of social context ($p<0.001$) reflecting faster MTs in CM than CP context was found. MTs were slower in the ASD than the TD group ($p=0.005$). Analysis of Peak Acc and Peak Acc Time revealed a main effect of Group ($p<0.001$), reflecting lower and more delayed peak acceleration for the ASD than the TD group.

Conclusions: Our results support the view that motor execution is impaired in ASD. MTs, indeed, were strongly delayed, and peak acceleration was lower and more delayed compared to TD children. ASD children were partially able to modulate their movements according to the context of the action. In the competitive task, however, in which greater predictive abilities were required, their movements did not show the same differences with respect to the cooperative task as in typical children.

143   **109.143** Joint Attention and Information Processing in Higher Functioning ASD

P. C. Mundy, 2825 50Th Street, UC Davis, Sacramento, CA

Background: Research indicate the experience of initiating joint attention deepen stimulus encoding to a greater extent than the experience of following the attention of others (Bayless et al. 2013; Boothby et al. 2014; Kim & Mundy, 2012). Theory also suggests that children with ASD may not display the typical pattern of cognitive benefits from the experience of joint attention (Mundy & Kim, 2010).

Objectives: The goal of this study was to test the hypothesis that the experience of initiating joint attention would have different impact on the visual stimulus encoding of higher functioning children with ASD (HFASD) than typical peers or children with other clinical conditions, such as ADHD.

Methods: Thirty-two 9 to 13 year-olds with HFASD (IQ = 105, SD = 14.9) and age and IQ matched samples of 27 children with ADHD (IQ = 101, SD = 15.1) and 23 children with typical development (TD, IQ = 112, SD = 14.1) were presented with a virtual reality paradigm developed by Kim & Mundy (2012). They studied pictures in one condition where an avatar followed their attention to the pictures (IJA analogue). In another condition children followed the gaze of the avatar to pictures on study trials (RJA analogue). The dependent measure was the number of pictures correctly recognized in conjunction with each condition corrected for rates of false positive recognition. ASD symptom presentation was confirmed with parent report on the Social Communication Questionnaire (Means = 21, 4.9, 2.3 for the ASD, ADHD, & TD groups) and the Autism Spectrum Symptom Questionnaire (Means = 18, 7.5, 1.8 respectively). ADHD symptoms were confirmed with parent report on the Conner-3.

Results: A mixed ANOVA with IQ as a covariate revealed a significant groups by condition interaction, $F (2, 82) = 6.25$, $p < .003$, $eta^2 = .13$. Children in the comparison groups displayed significantly better picture recognition in the IJA rather than RJA condition. There was no evidence of this effect in the ASD group (See Fig. 1). The ASD group displayed worse recognition memory in the IJA condition than the other two groups ($p < .01$), but there was no evidence of recognition memory differences in the RJA condition (See Fig, 1). IQ was positively correlated with IJA recognition ($r = .37$, $p < .03$) in the ASD group but RJA recognition ($r = .05$) was not. The former was significant different than the respective correlations in the ADHD ($r = -.11$) and TD samples ($r = .16$), $F (1.82) = 4.67$, $p < .03$.

Conclusions: These results are consistent with research adults but indicate that children also display information processing benefits from the experience of IJA. However, children with HFASD do not display this benefit. Joint attention disturbance may be difficult to observe in children with HFASD, but may be evident in the information processing benefits related to joint attention. Also, ASD children with higher IQs are more likely to experience IJA information processing benefits, *or* ASD children who experience these benefits are more likely to have higher IQs.

144 **109.144** Longitudinal Changes from 11 to 16 Months in Visual Attention to Dynamic Social Scene Among Infants at High and Low Genetic Risk for Autism

L. Sperle and M. S. Strauss, University of Pittsburgh, Pittsburgh, PA

Background: To understand the origins and emergence of autism symptomatology, research has investigated infants who have an older sibling with autism spectrum disorder (ASD) and are at heightened genetic risk for the disorder. Findings by the Baby Siblings Research Consortium suggest that several developmental pathways to ASD are present from 18 to 36 months of age (Chawarska et al., 2014). This study focused on early visual attention profiles that emerge from 11 to 16 months of age to further our understanding of developmental pathways that are indicative of genetic risk and/or ASD.

Objectives: The study examined developmental changes from 11 to 16 months in visual attention to a dynamic social scene among infants with (high-risk; HR) and without (low-risk; LR) an older sibling with ASD. It was expected that HR infants would demonstrate less visual attention to the upper half of the face at 16 months than 11 months of age. It was also expected that differences in visual attention would not emerge until 16 months, with HR 16-month-olds demonstrating less visual attention to the upper half of the face compared to LR 16-month-olds.

Methods: A prospective, longitudinal design was used to compare visual attention of HR infants (n=21) with LR infants (n=19) across early development (from 11 to 16 months). Eye-tracking data were collected while infants viewed a dynamic social scene of an adult speaking and showing toys. Regions of interest were drawn to quantify infants' attention to scene elements (e.g., upper/lower facial regions, objects). Infants participated at both 11 and 16 months. These infants will be assessed at 24, 36, and/or 48 months and provided an outcome designation as typical, non-typical or ASD based on assessment tools including the Autism Diagnostic Observation Schedule-Generic (Lord et al., 1999). Assessments are ongoing.

Results: Analyses indicate that when attending to the face, LR and HR infants demonstrated similar proportions of looking time to the upper half of the face at 11 months (M=.27, SD=.31; M=.26, SD=.29). However, from 11 to 16 months, HR infants displayed a decrease in the proportion of looking time to the upper half of the face (M=.06, SD=.09), whereas LR infants remained consistent between the two age points (M=.30, SD=.28). This is shown by the significant interaction (risk X age) in Figure 1 (F(1,32)=4.05, p=.05).

Conclusions: A significant interaction between risk and age was found regarding infants' distribution of attention within the face. Importantly, HR infants demonstrated a decrease in the proportion of looking time to the upper half of the face from 11 to 16 months while LR infants' attention remained stable. This suggests that a decline in visual attention to the upper half of the face may be an early developmental pathway of the broader autism phenotype or ASD. It broadly

highlights the importance of identifying visual attention profiles of HR infants across early development since deficits may emerge after the first year of life. Further analyses may elucidate the early developmental trajectories of HR infants' visual attention based on later diagnostic outcome (ASD, non-typical).

145 **109.145** Mental Rotation: A High-Level Perceptual Strength of Young ASD Children

Y. Yoshimura[1], L. Mottron[2,3], N. Takesaki[4], T. Takahashi[5], T. Hirosawa[4], N. Furutani[4], H. Hiraishi[5], C. Hasegawa[5], S. Kitagawa[5], Y. Minabe[5] and M. Kikuchi[5], (1)Kanazawa University, Kanazawa, Ishikawa, Japan, (2)University of Montreal Center of Excellence for Pervasive Developmental Disorders (CETEDUM), Montreal, QC, Canada, (3)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montreal, QC, Canada, (4)Department of Psychiatry and Neurobiology, Kanazawa University, Kanazawa, Japan, (5)Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan

Background: Some individuals with autism spectrum disorder (ASD) perform more proficiently in particular low- (e.g. discrimination) and mid-level (e.g. visual search) visual tasks than may be predicted by their general cognitive performance. How these low- and mid-level visual abilities relate to performance in high-level tasks such as pattern manipulation is poorly understood.
Objectives: We sought to determine whether young ASD children of typical intelligence perform better in a pattern manipulation task, mental rotation, than typically developing children.
Methods: Mental rotation was measured with the first 10 questions of the "Rotations" part of the modified Purdue Spatial Visualization Test (PSVT:R; Guay, 1977). This test measures an individual's ability to determine by mental rotation whether three-dimensional shapes, rotated around a particular axis, are identical or different representations of the same object. All participants were recruited from public nursery schools in Kanazawacity (Japan), Kanazawa University Hospital and prefectural hospitals in Toyama (Japan). Eighteen ASD children were included (age: 83.9 months [59 – 111], mean IQ 105 [77 – 145]).They were diagnosed with childhood autism (n = 13), atypical autism (n = 4) or Asperger's syndrome (n = 1) according to the Diagnostic Interview for Social and Communication (DISCO) criteria. Cognitive skills were assessed with the Japanese adaptation of the Kaufman Assessment Battery for Children (K-ABC). Exclusion criteria were an IQ below 70 (i.e., two standard deviations below the mean), hearing loss, or an identified neurological condition other than autism. Eighteen typically developing children (TD; age: 85.9 months [54 - 122], mean IQ 103 [69 - 134]) matched in age, gender and general cognitive ability were included as controls.Written informed consent was obtained prior to enrolment in the study. The Ethics Committee of Kanazawa University Hospital approved themethods and procedures, all of which were in accordance with the Declaration of Helsinki.
Results: ASD children performed the task with a meanspeed of 11.4 s (4.9 – 18.0) whereas TD children of equivalent intelligence performed the task with a mean speed of 14.8 s (9.0 – 30.3). ASD children performed the task significantly faster than TD children (t = 2.11 P = 0.042). The number of correct responses was similar between the two groups (mean proportion of correct answers: 0.26 [0 - 0.60] in ASD children and 0.27 [0.1 – 0.7] in TD children).
Conclusions: These findings replicate and extend those of Soulières et al (2011). ASD children perform mental rotation tasks faster than may be predicted by their general cognitive performances, showing that enhanced perceptual functionning extends beyond pattern detection, to the manipulation of visual patterns.

146 **109.146** Negative Emotionality Disrupts Pattern Separation in Adults Diagnosed with Autism Spectrum Disorders

E. Anderberg[1], C. Nielson[2], K. Stephenson[1], S. Atwood[2], M. South[3] and C. B. Kirwan[3], (1)Department of Psychology, Brigham Young University, Provo, UT, (2)Neuroscience Center, Brigham Young University, Provo, UT, (3)Psychology and Neuroscience, Brigham Young University, Provo, UT

Background: Cognitive function is frequently and broadly disrupted in autism spectrum disorder (ASD) in areas of cognitive control, attention, and memory. However, many questions of specificity remain: which cognitive functions are disrupted for which individuals in which dimensions of function. Growing evidence indicates that significant levels of anxiety in ASD may be associated with difficulties in cognitive decision making in a circuit involving amygdala, hippocampus, and medial frontal lobes.
Objectives: This study aims to discover how pattern separation memory—the ability to keep sets of similar memories distinct from each other--is affected by emotion regulation in ASD.
Methods: Participants for the memory task included 70 adults ages 17 to 36, including 25 adults diagnosed with an ASD and 45, age- and IQ-matched college student controls. There were no significant between-group differences in age or Full Scale IQ. Participants viewed digital images of everyday objects appearing one at a time. Three categories of images appeared in random order: One group of images (foils) only appeared once during the experiment. A second group of images (repeats) appeared twice throughout the study. The final group (lures) consisted of paired images that were visually and conceptually similar but not identical to previously-shown images. For each image, participants were asked to determine if the image was *new*, *old*, or *similar*. 42 participants (24 ASD and 18 Control) completed an additional battery of emotion symptom questionnaires.
Results: On the memory task, the ASD and control groups performed similarly when responding to

novel "foil" stimuli. However, when responding to "repeat" stimuli, the ASD group chose "new" and "similar" (incorrect answers) significantly more often than controls. The ASD group also chose "new" more often than controls for the "lure" stimuli. Analysis of these errors in relation to the survey data showed significant associations between the *repeat-as-new* and *lure-as-new* choices with cognitive worry, state and trait anxiety, depression, and BAS activation arousal score. The control group had no such correlations between memory scores and emotion regulation measures.

Conclusions: The ASD group's increased tendency to identify as "new" many stimuli that were either identical or very similar to ones seen before seems to indicate particular problems with memory. Some of this trouble may reflect distraction due to emotion regulation difficulties in the ASD group. We have previously suggested that decision making in autism reflects a risk-avoidance strategy that may be in play here, in that the ASD group tries to avoid being tricked by new stimuli and thus oversamples from that choice. This unique association between negative emotionality and everyday cognitive memory skills suggests the need for further exploration of memory substrates in ASD but also for intervention tailored to a risk-avoidance style.

147 **109.147** Neural Correlates of Goal-Directed Reaching Movements in Children with Autism Spectrum Disorder

N. Salowitz[1], A. V. Van Hecke[2], N. L. Johnson[3] and R. A. Scheidt[1,4], (1)Biomedical Engineering, Marquette University, Milwaukee, WI, (2)Psychology, Marquette University, Milwaukee, WI, (3)College of Nursing, Marquette University, Milwaukee, WI, (4)Neurology, Medical College of Wisconsin, Milwaukee, WI

Background:
Children with Autism Spectrum Disorder (ASD) exhibit restricted interests and repetitive behaviors that may represent aversion to environmental uncertainty and an attempt to prevent or minimize change (Gomot and Wicker, 2012). When environmental change does occur, challenging behaviors can ensue. Thus, brains with ASD appear to respond differently to environmental uncertainty than do typically developing brains.

Objectives:
We used a novel robot and functional magnetic resonance imaging (FMRI) to measure blood oxygenation-dependent (BOLD) signals related to fast, goal-directed wrist movements (reaches) made against predictable and unpredictable robotic loads. We compared movement kinematics and BOLD signal changes produced by high-functioning children with ASD and by typically developing (TD) children. We evaluated two competing hypotheses: (1) Children with ASD and TD children solve the predictable motion task using similar feedforward control strategies that recruit similar neuronal networks, but that these patterns are fragile in ASD and susceptible to disruption in the presence of environmental uncertainty; (2) children with ASD and TD children solve the sensorimotor task using neural control strategies that differ in recruitment of feedforward and feedback mechanisms.

Methods:
Nine high-functioning children with ASD and eleven TD children reclined in a magnetic resonance imaging (MRI) scanner and held the handle of a plastic robot. They made 250 wrist flexion movements (one per trial) against spring-like loads that either remained constant (trials 1-50) or varied unpredictably across trials (trials 51-250). Subjects were to capture targets on a video screen using a cursor controlled via by the robot handle. We analyzed movement kinematics to obtain a model of each participant's trial-by-trial prediction of upcoming load. The technique quantifies the extent to which sensorimotor memories from past performances influence future movements. We analyzed functional MR images to compare the neural control networks recruited by the two groups of children exposed to the constant and variable loads.

Results:
Both groups used memories of prior performances to adjust aim on subsequent trials. Both groups undershot the target, although children with ASD moved ~10% less than TD children. Movement errors were more variable in ASD. We included the mean and standard deviation of movement error as co-factors in the image analysis to control for possible group-wise bias. Neuroimages from constant load trials revealed widespread BOLD signal activations in the TD group in regions previously implicated in feedforward or feedback control. By contrast, activation volume in the ASD group was ~17% of TD volume and was represented more heavily in the feedback control network; Within select feedback control regions, BOLD impulse responses were markedly larger in ASD vs. TD. For both groups, we found no difference in BOLD signal changes across load conditions.

Conclusions:
Our findings support the hypothesis that children with ASD and TD children solve the target capture task using neural control strategies that differ in their recruitment of feedforward and feedback control mechanisms. The strategy used by the children with ASD appeared to favor feedback control regardless of load condition, even though this strategy resulted in movements that were less accurate and more variable.

148 **109.148** Pitch Direction Perception Predicts the Ability to Detect Local Pitch Structure in Autism and Typical Development

N. E. Foster[1], M. Sharda[1], E. Germain[1], R. Chowdhury[1], A. Tryfon[1,2], T. Ouimet[1,2], K. A. R. Doyle-Thomas[3], E. Anagnostou[3], K. L. Hyde[1,2] and .. NeuroDevNet ASD Imaging Group[4], (1)International

Laboratory for Brain Music and Sound Research (brams.org), Université de Montréal, Montreal, QC, Canada, (2)Faculty of Medicine, McGill University, Montreal, QC, Canada, (3)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)http://www.neurodevnet.ca/research/asd, Vancouver, BC, Canada

Background: Most individuals with Autism Spectrum Disorders (ASD) have atypical sensory perception, particularly in the auditory domain. Some studies have reported enhanced low-level pitch discrimination (Bonnel, 2010) and higher-level processing of local pitch structure on global-local tasks (Heaton, 2005). However, auditory perception in ASD is understudied and results are inconsistent. It is unclear how low and higher-levels of auditory perception are related in ASD or typical development (TD), nor how these skills may change with development.

Objectives: The aims of this research were to test: 1) for performance differences between children with ASD and TD controls on both low-level pitch processing (pitch direction) and higher-level pitch processing (global-local pitch) tasks, 2) the relationship between low and higher-level auditory perception, and 3) the effect of age on task performance.

Methods: Participants were 17 children with high-functioning ASD and 19 TD children who had no neurological or psychiatric history. Participants were recruited from the NeuroDevNet ASD Project (Zwaigenbaum et al, 2011) and groups were matched on age (mean age 13.3 years, range 9-18 years) and IQ (mean IQ 113.5, SD 13.6). In the low-level pitch direction task (Foster et al., 2014), participants heard two tones of different frequencies on each trial and judged whether the pitch rose or fell. In a higher-level global-local task (Ouimet et al., 2012), stimuli consisted of 9-tone melodies, each containing three triplet (3-tone) sequences. Participants discriminated between ascending and descending pitch direction at the global (across triplets) and/or local (within triplets) level. The relationship between performance (percent accuracy) on these two tasks and the effect of age was assessed using linear regression.

Results: There were no significant group differences between ASD and TD in terms of overall performance accuracy on either of the pitch tasks. Overall accuracy on the low-level pitch discrimination task predicted overall accuracy on the higher-level global-local pitch task across all participants (P<0.001), but was particularly driven by performance on local pitch judgements (P<0.001; see Figure 1). The TD and ASD groups both showed a similar positive relationship between performance profiles on the low versus high-level pitch tasks. However, a trend suggests that there is a tighter coupling between low and high-level pitch task performance in ASD versus TD. There was also a trend toward a positive main effect of age on the pitch direction task performance only (and not the global-local task) across all participants.

Conclusions: The present findings suggest that: 1) low-level pitch direction ability strongly predicts performance of higher-level global-local pitch perception in general, but most prominently for local pitch judgments in ASD compared to TD, 2) pitch direction ability improves with age similarly in TD and ASD, but global-local perception is constant, and 3) superior abilities in ASD in low and high-level pitch tasks may be specific to particular task paradigms, or subgroups within the autism spectrum. The study of auditory perception in ASD serves as a complementary lens to more symptom-based studies, to better understand individual differences and to refine ASD endophenotypes.

149 **109.149** Pitch Perception in Adults with Autism Spectrum Disorder Speaking a Tone Language

G. Y. H. Lam[1], C. K. S. To[2], S. T. T. Cheng[2] and L. S. Iao[3], (1)Department of Educational and Psychological Studies, University of South Florida, Tampa, FL, (2)Division of Speech and Hearing Sciences, University of Hong Kong, Hong Kong, Hong Kong, (3)Division of Psychology, School of Social Sciences, Nottingham Trent University, Nottingham, United Kingdom

Background:
Some individuals with Autism Spectrum Disorders (ASD) possess enhanced auditory perception ability when compared to neurotypical individuals. There is higher incidence of superior auditory processing and perfect pitch in individuals with ASD than the general population. These phenomena have been explained by theories of Weak Central Coherence and Enhanced Perceptual Functioning. Emerging evidence also showed that variations in the stimuli context (e.g., pure tone, speech, music) have differential effects on their performance in auditory perception tasks.

Cantonese Chinese is a tone-language which makes use of pitch differences to encode lexical meaning. Given the heavy functional load of pitch in the language, much evidence attested that tone-language speakers demonstrate superior ability in pitch processing tasks. It would be interesting to investigate if superior auditory perception in individuals with ASD would also be observed in population speaking tone languages.

Objectives:
To compare pitch perception performance of Cantonese-speaking adults with and without high-functioning ASD.

Methods:
Participants were all native Cantonese speakers with average intellectual functioning. They included 20 adults with ASD and 20 matched neurotypical (NT) controls. The matching parameters included gender, age, education background, and experience of formal musical training. Participants received a series of pitch discrimination tasks with auditory stimuli including monosyllabic real words, nonsense words, and non-speech analogues. The stimuli were paired according to different levels of pitch differences. Participants had to determine whether the stimuli in a pair were the same or different.

Results:
There was no significant difference between ASD and control groups in discriminating the pitch differences in all the three stimulus types. Across both groups, participants made significantly more errors in speech conditions (real word and nonsense word stimuli) than non-speech condition. Regardless of group membership, individuals with formal musical training showed better performance in detecting small differences in pairs in all three stimulus types.
Conclusions:
Cantonese-speaking individuals with ASD did not show superior pitch perception ability when compared to NT controls with real word, nonsense word, and non-speech stimuli. It may be possible that the native use of tone enhances pitch perception ability in speakers in general population, diluting the effect of enhanced performance in the ASD group. This claim may also be supported by the significant effect of musical training in both ASD and NT individuals. Future research may investigate pitch perception in Cantonese population in broader contexts, such as detecting pitch differences in speech intonation and musical melody.

150 **109.150** Playing Games with Your Eyes: An at-Home Video Gaming System for Training Attention Orienting in ASD

L. Chukoskie[1], M. Westerfield[1] and J. Townsend[2], (1)Institute for Neural Computation, University of California, San Diego, La Jolla, CA, (2)Neurosciences, University of California, San Diego, La Jolla, CA

Background: In addition to the social, communicative and behavioral triad of symptoms that define Autism Spectrum Disorders (ASD), individuals with ASD have difficulty re-orienting attention quickly and accurately. Similarly, fast re-orienting saccadic eye movements are also inaccurate and more variable in both endpoint and timing in individuals with ASD. The brain circuitry that guides the redirection of spatial attention is shared with the circuitry used to shift gaze. This suggests that gaze-contingent training could be a unique way to improve attention orienting skill.
Objectives: 1) Demonstrate the feasibility of using gaze-contingent video games for low cost in-home training for high functioning adolescents with ASD. 2) Demonstrate improvement of spatial attention orienting and eye movement behavior after 8 weeks of play on these gaze-contingent games in a small group of adolescents with ASD.
Methods: We designed and deployed PC-based gaze-contingent video games using the Unity game engine and an EyeTribe eye tracker (see Figure). The games were designed around training principles to train fast and accurate attention orienting behavior as well as stable fixation.   In addition, the game system was designed to be sufficiently robust for long-term at-home use. Eight adolescents with ASD participated in an 8 week training, flanked by pre- and post-testing of eye movement and attention control.
Results: Six of eight adolescents completed the 8 weeks of training and all of those six showed improvement in attention orienting, eye movement control or both. All of the game systems remained intact for the duration of training. Each participant could use the system independently.
Conclusions: We delivered a low cost and robust gaze-contingent game system for home use that, in our pilot training sample, improved the attention orienting and eye movement performance of adolescent participants in 8 weeks of training. The next steps involve a small clinical trial to assess the importance of gaze-contingency and what aspects of training, if any, transfer to real-world tasks.

151 **109.151** Privileged Role of Symbolic Number Sense in Mediating Math Abilities in Children with Autism

M. Rosenberg-Lee[1], A. Hiniker[2] and V. Menon[3], (1)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (2)Human Centered Design and Engineering, University of Washington, Seattle, WA, (3)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA

Background:
Despite reports of enhanced mathematical ability in individuals with autism, little is known about basic number processing abilities in children with the disorder. In typically developing (TD) children, both *non-symbolic* (the ability to compare quantities of dots) and *symbolic* (the ability to compare Arabic numerals) number sense have been linked to individual differences in math ability. Based on known strengths in individuals with autism, including local processing bias and hyperlexia, both non-symbolic and symbolic processing could be important components of number sense that contribute to math skills in this group. Understanding basic quantity processing abilities and their relationship to math ability has the potential to inform the design of educational interventions and employment opportunities for individuals with the disorder.
Objectives:
We first investigated whether non-symbolic and symbolic number sense are spared or enhanced in children with ASD. We then investigated whether children with ASD show the same pattern of relations between number sense and math ability as their TD peers.
Methods:
We examined number sense in 36 high functioning children with ASD and 61 matched controls (aged 7-12). In separate tasks, participants identified the larger value in pairs of either Arabic numerals or arrays of dots. Number sense acuity was measured using the Weber fraction (w), which captures the

smallest ratio that an individual can reliably discriminate. We examined the relationship between *w* and math ability, as measured by participants' math composite score on the Wechsler Individual Achievement Test-II. Finally, we used a mediation model to assess the extent to which symbolic number sense mediates the relationship between non-symbolic number sense and math ability.
Results:
Children with ASD had intact symbolic estimation skills but showed significant impairments in non-symbolic (dot) estimation relative to TD children. For both groups, symbolic acuity was a stronger predictor of math performance than non-symbolic acuity, but this effect was more pronounced in children with ASD. Finally, we found that symbolic comparison ability mediated the relationship between non-symbolic comparison and math performance in children with ASD, but not in TD children.
Conclusions:
Contrary to previous suggestions of superior non-symbolic number sense in ASD, our results indicate that children with the disorder are impaired in non-symbolic estimation, and relative to their TD peers, this capacity plays a weaker role in the development of math skills in children with ASD. Intact symbolic number sense and its strong correlation with math achievement scores together suggest a privileged role for symbolic processing in the acquisition of mathematics proficiency in ASD. Building on symbolic strengths in children with ASD may facilitate acquisition of mathematical skills in a way that non-symbolic quantity information may not. Our findings further suggest that symbolic notation may be a useful tool for organizing imprecise, continuous information in children with ASD.

152 **109.152** Procedural Learning and Language Impairment: Evidence of a Deficit in Autism Spectrum Disorder with LI but Not in Specific Language Impairment

*H. Bani-Hani[1] and **A. Nadig**[2], (1)School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada, (2)McGill University, Montreal, QC, Canada*

Background: In language development procedural memory has been implicated in learning and storing regularities and rule-based information, as required for phonology and grammar (Ullman, 2001). Deficits in procedural memory have been hypothesized to explain language impairment in Autism Spectrum Disorders (ASD) as well as in Specific Language Impairment (SLI) (Ullman, 2004). The hypothesized language-linked deficit in procedural memory would be most apparent in the subgroup of ASD children with concomitant language impairment. Yet, few studies have investigated procedural memory in *language-impaired* children with ASD, and none have compared their performance to that of children with SLI on the same measure.
Objectives: To clarify whether proposed procedural memory deficits are shared across children with language impairment or if deficits are disorder-specific we compared the performance of language-impaired children with ASD and children with SLI on a visual procedural learning task.
Methods: We tested 14 language-impaired children with ASD and 14 children with SLI, matched on age (6-to 10-years-old) and NVIQ on a Serial Reaction Time task (SRT; Thomas & Nelson,2001). The SRT assesses implicit learning of a visual pattern presented on a computer screen. It involves five blocks of 40 trials: in blocks 2,3, and 5 the child sees a dog appear in one of four quadrants of the screen in a repeated 4-item sequence. In blocks 1 and 4 the dog moves randomly. The child is instructed to "catch" the dog as fast as possible by pressing a button corresponding to the quadrant of the screen where it appeared. Sequence learning is indicated by significantly faster reaction times in block 5 (sequence) in comparison to block 4 (random). This was measured by a *sequence learning* score (mean of block 4 – mean of block 5)/(mean of block 4 + mean of block 5). After the task we asked participants if they had noticed a pattern that helped them "catch the dog," providing a measure of *explicit knowledge of the sequence.*
Results: Groups showed similar ability to perform the SRT task as indicated by the number of errors in blocks 4 and 5; $U=82$, $p=.47$. However, the *sequence learning score* in the ASD group (*Mdn*=0.05) was significantly lower than in the SLI group (*M*dn=.18); $U=52.5$, $p=.04$, $r=-0.4$. Within-group comparisons showed significantly faster responding in block 4 than 5 in the SLI group; $T=0$, $p<.001$, $r=.88$, but not the ASD group; $T=30$, $p= .17$, indicating that the SLI group learned the sequence while the ASD group did not (Figure1). Finally, similar proportions of children with ASD (5 of 14) and SLI (4 of 14) showed explicit knowledge of the sequence and were able to recreate the sequence they had learned.
Conclusions: Our results demonstrate diminished sequence learning in a language-impaired ASD group but intact learning in an SLI group matched on age and NVIQ. This suggests that procedural learning deficits are not shared across forms of language impairment and that they are particulary implicated in ASD. If replicated, procedural learning could be used to differentiate SLI from ASD and be integrated in ASD treatment.

153 **109.153** Psychometric Properties of the Revised Executive Function Challenge Task (EFCT)

L. Kenworthy[1], K. M. Dudley[2], Y. Granader[2], C. Luong-Tran[1], C. E. Pugliese[2], K. Harmon[3], J. F. Strang[2] and L. G. Anthony[2], (1)Children's National Medical Center, Rockville, MD, (2)Center for Autism Spectrum Disorders, Children's National Medical Center, Rockville, MD, (3)Children's National, Rockville, MD

Background:
Children with ASD have flexibility and planning deficits that inhibit their ability to socialize, succeed in mainstream school settings and complete every day tasks. Recent reviews of the literature reveal difficulty consistently capturing these observed executive functioning (EF) deficits with laboratory measures (Kenworthy et al., 2009; Geurts et al., 2009). We have previously described a treatment sensitive observational measure, the EFCT, which challenges children to be flexible and planful (Kenworthy, Anthony et al., 2014).

Objectives:
To investigate the internal consistency and validity of the EFTC and to explore its ability to distinguish children with autism spectrum disorder (ASD) from typically developing children (TDC).

Methods:
30 TDC (age M=10.2 years, SD=1.7; FSIQ M=115.9, SD=11.3) and 63 children with ASD (age M=9.5 years, SD=1.1; FSIQ M=108.3, SD=18.1) were evaluated with a shortened form of the EFCT, three standardized activities on which behavior is coded for flexibility and planning. Examiners achieved inter-rater agreement >90%. Parents completed the Behavior Rating Inventory of Executive Function (BRIEF).

Results:
Chronbach's alpha statistics indicate good internal consistency for the EFCT average Flexibility Scale (FS; α=0.79) and Planning Scale (PS; α=0.69) scores, and item total correlations are all in the acceptable range. Convergent validity was demonstrated between the FS and PS and the parent reported BRIEF Shift and Plan/Org scores (r's > 0.42, p's < 0.001) for the combined TDC/ASD data. The FS and PS clearly distinguished individuals with ASD from the TDC group (t's > 7.3, p's < 0.001). The larger ASD and TDC groups were not matched for age, sex or FSIQ, however. A subset of the ASD (n=20) and TDC (n=20) participants more closely matched for those variables (p's > 0.39) was investigated regarding EFCT FS and PS scores, revealing significantly greater problems in the ASD than the TDC group (t's >4.0, p's < 0.001). See Table. Discriminant function analysis indicated that the EFCT total score correctly classified 85% of the children with ASD and 90% of the TDC children.

Conclusions:
In addition to showing sensitivity to a cognitive behavioral EF treatment, the EFCT: can be coded reliably; has good internal consistency; distinguishes children with ASD, who are know to have flexibility and planning deficits, from TDCs; and is moderately correlated with parent report of flexibility and planning problems. The EFCT has the potential to capture a unique set of EF behaviors that are important in characterization and treatment research efforts.

Table: Demographic and EFCT Scores ASD and TDC Groups

	Total Sample			Matched Sample		
	ASD (N=63)	TDC (N=30)	p value	ASD (N=20)	TDC (N=20)	p value
Male	88.9%	50%	.000	70%	65%	.500
	Mean(SD)	Mean(SD)		Mean(SD)	Mean(SD)	
Age in years	9.55(1.1)	10.19(1.7)	.071	9.87(1.3)	9.66 (1.5)	.636
FSIQ	108.32(18.1)	115.87(11.1)	.016	116.10(16.7)	119.85(10.3)	.398
BRIEF Shift	70.25(12.68)	45.10(8.93)	.000	69.80(10.91)	43.75(7.69)	.000
BRIEF Plan/Org	66.35(12.71)	46.93(10.2)	.000	65.75(13.05)	45.55(9.85)	.000
EFCT Flexibility	.97(.59)	.23(.36)	.000	.82(.62)	.18(.33)	.000
EFCT Planning	1.43(.47)	.29(.37)	.000	.90(.34)	.13(.27)	.000
EFCT Composite Score	1.20(.42)	.26(.29)	.000	.86(.40)	.16(.19)	.000

154 **109.154** Reduced Anticipatory Responses during Dynamic Object Interactions in Autism

A. L. Cardinaux[1], K. Tsourides[2], H. Nejati[2], D. Jin[3], T. K. Gandhi[4], **M. M. Kjelgaard**[5] and P. Sinha[2], (1)Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA, (2)Brain and Cognitive Sciences, MIT, Cambridge, MA, (3)Massachusetts Institute of Technology, Cambridge, MA, (4)Defence Institute of Physiology and Allied Sciences, New Delhi, India, (5)MGH Institute of Health Professions, Boston, MA

Background: The dynamic world presents challenges to those with autism. Previous studies indicate difficulties in navigating traffic and driving (Autism Wandering and Elopement Initiative, awaare.org; Feeley, 2010). First person accounts highlight difficulties with dynamic playground games (Robison, 2006). These reports are puzzling given that moving objects are not inherently aversive to those with autism. Indeed, many individuals with autism are especially drawn to moving objects, enjoy video games (Mazurek et al., 2012), repeatedly set objects in motion, and engage in visual stimming involving motion. What then underlies autistic individuals' difficulties with dynamic objects? Several studies have shown that basic motion detection and direction perception thresholds are largely unimpaired in autism (Bertone et al., 2003; Milne et al., 2005; Mottron et al., 2006). However, interacting with dynamic objects involves a crucial step beyond detection: anticipating where the moving object will be and adjusting motor movements to intercept/avoid the object. Computational systems for dynamic object tracking rely on predictive techniques such as Kalman filtering (Welch and Bishop, 2001; Gao et al., 2005). They demonstrate that a key consequence of impaired prediction is errors in online position estimation. In daily life, these errors would render difficult seemingly straightforward tasks like catching an object or avoiding an oncoming car, even when basic motor skills are seemingly adequately developed.
Objectives: This study tested whether the difficulties that autistic individuals face in interacting with dynamic objects may arise from impairments in prediction. The task of ball-catching, combined with high speed video recording and computational analysis, were employed to reveal differences in predictive abilities with dynamic objects.
Methods: High-speed video recordings were captured of neurotypical and autistic children performing ball-catching. Throws varied systematically in distance from the participants, sometimes eliciting reaching, thereby testing participants abilities in anticipating the ball's trajectory. Three observers reviewed the videos and assigned a rating to the participant's predictive abilities. Additionally, computer vision techniques were applied to extract flow fields from each video, providing a detailed, quantifiable trajectory for both the ball and the child's hands.
Results: Initial individual data suggest that autistic participants exhibit reduced accuracy of spatio-temporal relations between the hands and ball, compared to age-matched controls. Anticipation scores for ASD participants were lower on average than those of neurotypicals. The patterns seen in a small number of detailed computer vision tracings of the hand and ball quantify increased accuracy in prediction in NT participants relative to ASD participants (Fig 1).
Conclusions: This study is consistent with impaired spatial-motor anticipation in ASD. Results mesh with a broader hypothesis of impaired prediction in autism, and may help to explain broader impairment in interactions with dynamic objects in ASD. Future experiments will investigate variations on the features of dynamic stimuli, such as speed, size, and task demands. Future work will evaluate differences in other dynamic object tasks and correlate performance with features of the autism phenotype, as well as examine specificity to autism. Results could translate into development of effective safety skills and other dynamic tasks that autistic individuals encounter in everyday life.

155   **109.155**   Self-Referential Metacognition in Adolescents with ASD Learning Mathematics

M. Brosnan[1], H. Johnson[1] and B. Grawemeyer[2], (1)University of Bath, Bath, United Kingdom, (2)Birkbeck College, London, United Kingdom

Background:
Theory of mind has been argued to comprise of two distinct sets of processes: an understanding of one's own mental states (self-referential metacognition) and the mental states of others (other-referential mindreading). A wealth of research has focused upon deficits in the appreciation of the mental states of other people ('mindreading') in ASD, yet there is little research has explored whether this deficit extends to an appreciation of their own mental states ('metacognition'). The limited research to date suggests that children and adults with ASD can have deficits in metacognition and it has been argued that metacognition may be more impaired than mindreading in ASD. One area that metacognition has been found to be highly predictive is with respect to learning performance (more predictive than IQ). As an example, knowing we have made an error ourselves (metacognitive awareness) can be important for responding appropriately (metacognitive regulation) to guide future learning.
Objectives:
To identify if learners of mathematics with ASD have impairment in metacognition, specifically: 1) knowing when they have made an error (metacognitive awareness); and 2) when an error has been made, thinking that they meant to make the error (metacognitive regulation).
Methods:
This study explored metacognitive awareness and regulation in 21 males with ASD and 16 typically developing male controls who were being educated at the same level. An index of IQ (WASI-UK, Wechsler, 1999) was also taken for the ASD sample. Verbal IQ ranged from 63 to 108 (mean = 89.69, sd=10.59) and performance IQ ranged from 60 to 126 (mean = 96.42, sd = 16.46). Participants were asked a series of fifteen mathematics questions. Based upon previous research, after each question they were asked two metacognitive questions: 1) whether they thought they had got the answer correct or not (or 'don't know') and, 2) whether they meant to get the answer correct or not (or 'don't know').
Results:
Participants with ASD were significantly more likely than the typically developing group to erroneously

think that they had got an incorrect answer correct. Having made an error, those with ASD were also significantly more likely to report that they had meant to make an error. Different patterns in the types of errors made were also identified between the two groups.
Conclusions:
Deficits in metacognitive awareness and regulation were identified for the ASD group in the learning of mathematics. This is consistent with metacognitive research from different contexts. Interventions based upon developing metacognitive skills have been found to be highly beneficial within the typically developing population and should be evaluated for those on the autism spectrum who may have specific metacognitive deficits.

156 **109.156** Skill Learning in Young Minimally-Verbal Children with Autism and the Effect of Vestibular Stimulation

G. Katz-Nave[1], Y. Adini[2], O. Hetzroni[1] and Y. S. Bonneh[3], (1)Special Education, University of Haifa, Haifa, Israel, (2)Vision Research Inst., Kiron, Israel, (3)University of Haifa, Haifa, Israel

Background: People with autism spectrum disorder (ASD), and especially the severe minimally-verbal individuals, often fail to learn basic perceptual and motor skills despite intensive repetitive practice. The reason for this learning deficit is currently unknown and overcoming it could have significant therapeutic implications. Previous findings suggest beneficial effects of vestibular stimulation in the normal, ADHD & LD populations, but the data regarding ASD are limited.
Objectives: to investigate the evolution in time and basic characteristics of skill (sequence) learning and the modulatory effect of vestibular stimulation in 3 groups of children ages 6-13: minimally-verbal ASD, ADHD and typical development (TD).
Methods: All children (N=39) were trained on a touch version of the cognitive related, visual-motor SRT task, with 10 short (<300 trials, few minutes) weekly practice sessions. In the task, a fixed sequence of 12 spatial locations, cyclically repeated 8 times in each block of trials, was introduced via visual cues on a touch tablet. The responses were made by rapidly touching the cued location with a finger, thus, unbeknown to the children, the cues introduced a sequence of lateral movements to be learned. The measure for learning was the median of the series response-time (RT). Each group was divided into two sub-groups, one of which received a vestibular stimulation prior to each training session. Most children were also tested on a second sequence to examine the sequence-specificity of the learning gains.
Results: All groups showed a gradual median RT improvement with significant and similar speed gains across the training period (~150 ms, 15-30% of initial RT). The ASD children (n=9) were overall slower (by ~300 ms), with initial intermittent pauses that required prompting to resume, but each individual child showed significant speed gains across the training days. Importantly, the ASD sub-group who received vestibular stimulation (n=5) had larger median speed gains compared to the other sub-groups (by ~100 ms), with a significantly larger effect observed when comparing the sequence trials with the fastest RTs (first decile values), which correspond to sub-sequence improvements. In comparison, vestibular stimulation had only a small or minimal effect on the non-ASD groups, but increased sequence-specificity of learning in all groups.
Conclusions: These results suggest that contrary to some previous findings, minimally-verbal children with ASD can acquire and consolidate procedural skills with few short training sessions, spread over weeks, and with a similar time course as non-ASD controls. Our current (limited) data also support the hypothesis of a positive effect of vestibular stimulation on learning in the severely autistic, which may have important therapeutic implications.
We suggest that the difficulty of severely autistic children to learn even basic skills is not due to a primary deficit in procedural learning, but in the translation of explicit knowledge to procedures.

157 **109.157** Superior Vocal Identity Memory in Autism

I. F. Lin[1], T. Yamada[2], Y. Komine[3], N. Kato[3] and M. Kashino[1,4], (1)NTT Communication Science Laboratories, Atsugi, Japan, (2)Department of Psychiatry, Medical Institute of Developmental Disabilities Research, Showa University, Tokyo, Japan, (3)Medical Institute of Developmental Disabilities Research, Showa University, Tokyo, Japan, (4)Department of Information Processing, Tokyo Institute of Technology, Yokohama, Japan

Background: Faces and voices are the most important social stimuli in the visual and auditory domains. Individuals with autism have difficulty in memorizing faces. Since children with autism exhibit less preference toward mother's voice, and brain activation related to voice perception is less significant in individuals with autism than in neurotypical individuals, it is important to investigate how individuals with autism perceive voices.
Objectives: This study adopted a quantitative methodology to examine vocal identity recognition in individuals with autism.
Methods: Fourteen individuals with autism (3 females) and 14 age- and IQ-matched neurotypical adults (3 females) participated in this study. The study consisted of three experiments: (1) gender discrimination, (2) vocal identity recognition via naming, and (3) a familiarity test. In the first experiment, the participants identified the genders of the speakers (5 female and 5 male speakers). In the second experiment, the participants learned the correlation between the voices (heard in the first experiment) and their names. In the third experiment, the participants identified familiar voices

(from the 10 previously heard speakers) and unfamiliar voices (from another 10 speakers).
Results: In the first experiment, the performance of both groups reached the ceiling level, and there was no significant difference between the groups. In the second experiment, the performance of both groups improved after training, and there was no significant difference between the groups. In the third experiment, the performance of the autism group was significantly better than that of the control group.
Conclusions: The results show that individuals with autism could recognize speakers' gender and memorize speakers' identity. The superior performance in the familiarity test contrasts with the mixed results in previous studies where the performance of the autism group was similar or worse. When compared with previous studies using long uttered sentences, the short uttered words used in this study provided timbre cues instead of prosody cues for vocal identity recognition. Therefore, the superior performance in the autism group might result from their superior perception of timbre cues in voices.

158 **109.158** The Co-Occurrence of Autistic and Dyspraxic Symptomatology in the General Population

D. Smith, D. Ropar and H. A. Allen, School of Psychology, University of Nottingham, Nottingham, United Kingdom

Background: 21-100% of individuals with an Autism Spectrum Disorder (ASD) present with motor abnormalities similar to that seen in dyspraxia (Gowen & Hamilton, 2012), indicating motor impairment as a potential diagnostic symptom in ASD. Individuals with dyspraxia (Creavin et al., 2014) and those with ASD (Anketell et al., 2013; Coulter et al., 2013) are more likely to have poor stereopsis. Stereopsis, or depth perception, may play a fundamental role in motor coordination activities such as navigation/object avoidance, reaching, grasping and object manipulation. To date, no systematic study has investigated the relationship between autistic traits (such as social difficulties) and reduced motor ability (increased 'clumsiness') in the general adult population and whether poor stereopsis may contribute to this association.
Objectives: To determine whether autistic and dyspraxic characteristics co-occur in a large, typical population-based sample and if poor stereopsis plays a role in this relationship.
Methods: Three validated questionnaires – the Stereopsis Screening Inventory (Coren & Hakstian, 1996), the Adult Developmental Coordination Disorder Checklist (Kirby, Edwards, Sugden, & Rosenblum, 2010), and the Autism-Spectrum Quotient (Baron-Cohen et al, 2001) - were used to explore whether stereopsis was correlated with dyspraxic symptomology (clumsiness) and/or autistic traits. 650 participants completed the questionnaires. 290 cases were missing a response for at least one item; missing data was imputed using random forest modelling. Factor analysis was used to determine whether clumsiness and autistic traits shared the same underlying basis (stereopsis).
Results: Preliminary analyses showed that both stereopsis (r = 0.29, p < 0.001) and clumsiness (r = 0.64, p < 0.001) correlated with autistic traits and with each another (r = 0.27, p < 0.001). An exploratory factor analysis (EFA) on all items from all screening measures revealed ten underlying factors. Factors were largely composed of items from a single scale, indicating that any co-occurrence of poor stereopsis, clumsiness and autistic traits cannot be attributed to a single underlying mechanism.
However, when the factor scores from the EFA were correlated with one another, it was found that stereopsis correlated with social skills (r = -0.22, p < 0.001) and isolation due to motor proficiency (r = 0.27, p < 0.001). As stereopsis became worse, social skills decreased and isolation due to motor proficiency increased. Interestingly, social skills showed a negative correlation with isolation due to motor proficiency (r = -0.43, p < 0.001). These results indicate that isolation due to motor proficiency mediates the relationship between stereopsis and social skills.
Conclusions: Although autistic and dyspraxic characteristics co-occur in the general adult population, they are independent of one another and do not share the same underlying mechanism. However, there is a relationship between reduced stereopsis and poor social skills that is mediated by motor ability. This is in line with the literature indicating that motor skill proficiency plays a role in the development of social communication skills. Determining the specific aspects of motor skill acquisition that are affected by poor stereopsis could inform social skill interventions for individuals with ASD.

159 **109.159** The Cost of Attentional Engagement: Target Switching during Visual Search in 2-Year-Old Toddlers with ASD

H. Smith, A. S. Carter, E. Blaser and Z. Kaldy, Department of Psychology, University of Massachusetts Boston, Boston, MA

Background: Children with ASD exhibit over-focused attention at times and excessive distractibility at other times. The development of attentional factors that contribute to these seemingly contradictory behaviors are not clear. Earlier, we found that young toddlers with ASD are able to deploy their visual attention in a highly goal-driven manner (Blaser et al., 2014, *Sci Rep*; Smith et al., 2014, *VSS*), yet they may be inefficient in responding to changes in the environment (Greenaway & Plaisted, 2005, *Psych Sci*).
Objectives: We investigated the cost of increased attentional engagement during visual search. We modified the classic visual search paradigm to test whether toddlers with ASD and age-matched typically developing toddlers (TYP) are able to switch their task goal from one search target to

another.

Methods: 15 ASD and 28 TYP toddlers participated (ASD: 14 males, mean age: 28.3 months, MSEL Composite: 63.1; TYP: 11 males, mean age: 26.6 months, MSEL Composite: 103.5). Participants sat on their caregivers' lap while a Tobii T120 eye-tracker recorded their eye movements. A block of 20 trials were presented: two familiarization trials, three single-feature training trials, then a sequence of 15 feature-conjunction test trials. Stimuli were 8 items defined by a feature-conjunction of color (isoluminant orange/green) and shape (apple/carrot). Feature-conjunction displays consisted of a target and a non-target (a green apple [A] and orange carrot [C]), plus 6 distractor items (green carrots and orange apples). Importantly, the 15 feature-conjunction trials were broken into three five-trial Phases defined by which object was highlighted as the target (counterbalanced across participants [ACA or CAC]). Each trial started with the target flying in and jumping up-and-down in the center of the screen (highlighting). Then, the search display appeared for 4 s, after which the target rotated back-and-forth for 2 s, accompanied by a sound effect; acting as both feedback and reward.

Results: In Phase 1, ASD and TYP toddlers found (fixated) the target more often than the non-target, and looked longer at the target than any other item in the display; an indication of task understanding. After the target switch (Phase 2), search performance of both groups decreased, and looking duration to the non-target increased. Interestingly, in Phase 3, when the target was again the same as in Phase 1, TYP toddlers recovered their initial search performance, whereas toddlers with ASD did not. This difference was also reflected in total looking durations.

Conclusions: Toddlers with ASD are capable of exercising goal-driven attention during visual search, yet this attentional focus appears to come at a price. ASD toddlers demonstrated an inability to flexibly change task goals, even when the initial task rules were reinstated. Our finding suggests that in young children with ASD, attention is over-focused at the level of task goal selection.

160 **109.160** The Go/No-Go Task Online: Evidence of an Inhibitory/Excitatory Imbalance in Autism in a Large Sample

F. Uzefovsky[1], C. Allison[2], P. Smith[3] and S. Baron-Cohen[1], (1)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (3)Autism Research Centre, Cambridge University, Cambridge, United Kingdom

Background:
One theory of the aetiology of autism spectrum conditions (ASC) implicates an inhibitory/excitatory (E/I) imbalance in the brain. This theory has been supported by neuroimaging findings, findings implicating GABA receptor genes, and the comorbidity of epilepsy. However, behavioural manifestations of this imbalance, i.e. motor inhibition, primarily measured as an increase in false alarm response during a Go/No-go (GNG) paradigm, have been mixed. Some studies report decreased inhibition in individuals diagnosed with ASC relative to controls, others find this effect under specific conditions only (e.g. higher working memory load, social GNG) and others still find no difference between ASC and controls.

Objectives:
In the current study we aimed to better understand behavioural inhibition in ASC by examining GNG performance in a large sample of ASC and controls.

Methods:
Participants were 213 high-functioning adults diagnosed with ASC (103 females) and 414 controls (285 females) who completed a GNG task. The GNG task consisted of 300 trials; 220 trials elicited a Go response (pressing an arrow key) and 80 trials (26.7%) elicited a No-go response (not pressing any key). A Go response in a No-go trial was counted as a false alarm (FA) response. The effect of diagnosis on FA was examined.

Results:
As predicted by the E/I theory, individuals diagnosed with ASC had a significantly higher rate of FA errors than controls ($t_{(625)}=-3.45$, $p<.001$, Cohen's d=-.28).

Conclusions:
Utilizing a large sample of high-functioning individuals diagnosed with ASC and controls we find a significant effect of diagnosis on number of FA errors. This finding should be explored as a behavioural phenotypic measure alongside neuroimaging studies of motor inhibition, measures of GABA-ergic activity, and in the context of polymorphisms in the GABA receptor genes, to better understand its potential role in the aetiology of autism.

161 **109.161** The Relation Between Classical Conditioning and Prototype Learning in Individuals with ASD

P. S. Powell[1], A. T. Meyer[2], L. G. Klinger[3] and M. R. Klinger[4], (1)University of North Carolina, Chapel Hill, NC, (2)Psychology, University of North Carolina, Chapel Hill, NC, (3)TEACCH Autism Program; Department of Psychiatry, University of North Carolina, Chapel Hill, NC, (4)Allied Health Sciences, University of North Carolina, Chapel Hill, NC

Background:
Studies of implicit learning have indicated a mixed pattern of impaired and intact performance in individuals with ASD (Eigsti & Mayo, 2011). Several studies of implicit learning in ASD have indicated a

relationship between implicit task performance and verbal and non-verbal reasoning abilities (Gastgeb et al, 2012; Klinger et al., 2007). Taken together, these findings suggest better performance on implicit learning tasks may be directly related to better reasoning in individuals with ASD.

Objectives:
The primary objective of this study was to examine the relation between implicit learning and verbal reasoning in ASD across two implicit learning tasks. Participants participated in a classical fear conditioning and prototype learning task.

Methods:
Twenty children with ASD and 17 age- and IQ-matched children with typical development (ages 7 to 14 years) completed two implicit learning tasks. The conditioning task consisted of three phases (habituation, acquisition, and extinction). During acquisition, one color (i.e., the conditioned stimulus) was paired with a loud noise (i.e., the unconditioned stimulus). Skin conductance responses were recorded. The prototype task consisted of a familiarization and test phase. Eight different members from a category were presented during the familiarization phase. The test phase consisted of old, new, and prototype (i.e., mathematical average of category members) test trials and participants made "yes/no" recognition judgments. Prototype learning was measured as false recognition of the prototype animal which, in fact, was not shown during familiarization. Verbal Reasoning was measured by the vocabulary and similarities sub-test of the WASI (Wechsler, 2000).

Results:
Linear regression analyses were conducted to examine the relation between verbal reasoning and diagnosis to both classical conditioning task performance (CCTP) and prototype learning task performance (PLTP). For each model, verbal reasoning, diagnosis, and a diagnosis by verbal interaction term were hierarchically included. Diagnosis significantly predicted CCTP, $F(1, 34)=11.18$, $p<.01$, however no significant effect was found for verbal reasoning or the interaction with diagnosis (p's>.42). In contrast, verbal reasoning significantly predicted PLTP ($F(1, 34)=8.32$, $p<.01$), with a small effect of diagnosis, $F(1, 34)=3.06$, $p=.09$, and a small interaction between verbal reasoning and diagnosis, $F(1, 34)=2.85$, $p=.10$. A final regression analysis examined the relationship between PFTP and CCTP. Using PLTP as the dependent variable, CCTP, diagnosis, and diagnosis by CCTP interaction were hierarchically included in the model. Results indicated a significant diagnosis by CCTP interaction, $F(1, 33)=5.00$, $p=.03$, and no significant effects for CCPT or diagnosis (p's>.20) showing that CCTP and PLTP were highly related for participants with ASD but not for participants with typical development.

Conclusions:
The present findings observed impairments in two implicit learning tasks in individuals with ASD. A marginally significant interaction between diagnosis and verbal reasoning was also seen in the prototype task (but not the conditioning task) suggesting explicit reasoning may play a role in implicit learning for individuals with ASD but not for individuals with typical development. Conditioning and prototype task performances were highly related for participants with ASD but not typically developing participants suggesting that these tasks tap common characteristics only for those with ASD.

162   **109.162** The 'Reading the Mind in the Eyes' Test: Complete Absence of Typical Sex Differences in Performance in ~400 Men and Women with Autism

S. Baron-Cohen[1], D. Bowen[2], R. Holt[2], C. Allison[3], B. Auyeung[1], M. V. Lombardo[4], P. Smith[2] and M. C. Lai[1], (1)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (2)Autism Research Centre, Cambridge University, Cambridge, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (4)Department of Psychology, University of Cyprus, Nicosia, Cyprus

Background:
The 'Reading the Mind in the Eyes' test (Eyes test) is an advanced test of theory of mind. Typical sex differences have been reported (female advantage). Individuals with autism show more difficulty than typically developing individuals, yet it remains unclear how this is modulated by sex, as previous studies have been relatively small scale and females with autism have been under-represented.

Objectives:
We recruited a large, sex-balanced sample to test for the effects of sex, diagnosis, and any interaction of these, on the performance of the Eyes test. We also tested if the patterns of group differences fit predictions from the 'extreme male brain' (EMB) theory of autism.

Methods:
The Eyes test was administered online to 395 adults with autism (178 males, 217 females) and 320 typical adults (152 males, 168 females). Performance was examined in terms of total correct score, using a 2 x 2 factorial design. Correlation between Eyes test correct score and self-reported empathy (measured using the Empathy Quotient, EQ) and autistic traits (measured using the Autism Spectrum Quotient, AQ) were examined separately for the four groups. Support Vector Machine (SVM) classification, stratified by sex, was also performed.

Results:
Two-way ANOVA showed a significant sex-by-diagnosis interaction ($F(1,711) = 5.090$, $p = 0.024$, $\eta_p^2 = 0.007$) arising from a significant sex difference between typical males and typical females, and a complete abolition of sex difference in males and females with autism ($p = 0.907$, $d = 0.01$). Case-

control differences in males and females were observed. The pattern of group differences was in line with the EMB theory predictions (typical females > typical males > males with autism ≈ females with autism). Eyes-EQ and Eyes-AQ correlations were significant only in females with autism ($r = 0.35$, $r = -0.32$, respectively), but not in males with autism, typical males, or typical females. SVM on Eyes items classified autism diagnosis at higher accuracies for females than males (males, 63%; females, 72%). Furthermore, an SVM model trained within one sex generalizes equally well when applied to the other sex.
Conclusions:
In a large adult sample we confirmed that performance on the Eyes test is a *sex-common* phenotypic marker of autism, reflecting core social-communication difficulties in autism. Given the existence of typical sex differences, performance of females with autism differs from same-sex controls more than that of males with autism. The findings also provide support for the EMB theory predictions in both sexes in terms of overall performance.

163 **109.163** Thermal Pain Perception in Adults with Asperger Syndrome

H. Haker[1,2], *F. Hagenmuller*[2,3] *and W. Rössler*[2,4], (1)Translational Neuromodeling Unit, University of Zurich and ETH Zurich, Zurich, Switzerland, (2)Collegium Helveticum, University of Zurich and ETH Zurich, Zurich, Switzerland, (3)Psychiatric University Hospital Zurich, Zurich, Switzerland, (4)Department of Psychiatry, Laboratory of Neuroscience (LIM-27), University of Sao Paulo, Sao Paulo, Brazil

Background:
Case studies and caregiver reports often describe pain hypo- or insensitivity in individuals with autism spectrum disorders. Diminished or altered observable reactions to pain might have several reasons, including true hyposensitivity but also communication deficits or altered emotional expression in body language or a different understanding of the concept of pain. Experimental studies that assessed pain perception in autism spectrum disorders are rare. To our knowledge, no study has measured pain thresholds in individuals with autism spectrum disorders empirically yet.
Objectives:
The aim of our study was to assess objective pain measurements in the thermal domain (absolute temperature thresholds) in individuals with Asperger syndrome and typically developed control participants, and to relate these measures to their subjective pain experience in terms of intensity and quality ratings and verbal attributes at the measured heat levels as well as to autistic personality traits.
Methods:
Thermal pain onset (TPO - the temperature at which heat perception turns into pain) and thermal pain tolerance (TPT - the temperature at which pain perception is not tolerated any longer) were measured at the volar forearm in 29 adults with Asperger syndrome (AS) and 29 control participants (CG). To prevent injuries, thermal stimulation stopped automatically at a temperature of 52°C. Thermal pain range was calculated as the difference of the mean TPT and TPO. Subjective pain experience was rated at TPO and TPT regarding quality (from neutral to uncomfortable) and intensity (from no pain to maximal self experienced pain) and additionally assessed with the McGill Pain Questionnaire. Autistic personality traits were assessed with Baron-Cohen's Autism Questionnaire (AQ), Alexithymia was assessed with the Toronto Alexithymia Scale. Performance and verbal IQ were estimated with two tests of the Wechsler Adult Intelligence Scale (WAIS-III).
Results:
Thermal pain range was higher in the AS group. Absolute temperature levels of thermal pain onset and thermal pain tolerance did not differ significantly between the two groups. Neither differed the subjective pain intensity and pain quality ratings of the two groups. However, within the AS group, individuals with more pronounced autistic traits (in terms of higher AQ scores) tolerated significantly higher temperatures and rated their subjective pain experience as lower regarding pain intensity and pain quality. The same was observed in AS individuals with higher alexithymia scores, which themselves were highly correlated with the AQ scores. AS individuals with higher AQ scores chose less words on the McGill Pain Questionnaire to describe their pain experience. Over all participants, those with higher IQ estimates showed lower pain quality ratings at pain onset (TPO).
Conclusions:
Our results could be interpreted as signs of an altered understanding of the concept of pain in individuals with Asperger syndrome especially those more severely affected. The absolute temperature thresholds of thermal pain onset and tolerance did not differ from the not affected control group, indicating intact thermal pain sensitivity.

164 **109.164** Three Facets of Visual Orientation Processing in ASD

F. Shafai[1,2], *K. Armstrong*[3], *G. Iarocci*[3] *and I. Oruc*[1], (1)Department of Ophthalmology & Visual Sciences, University of British Columbia, Vancouver, BC, Canada, (2)Graduate program in Neuroscience, University of British Columbia, Vancouver, BC, Canada, (3)Department of Psychology, Simon Fraser University, Burnaby, BC, Canada

Background: It has been suggested that altered visual perception, such as superior visual abilities, underlies some of the social difficulties associated with the Autism Spectrum Disorder (ASD)

phenotype (Dakin & Frith 2005; Behrmann, Thomas, & Humphreys 2006). The precise source for these atypicalities, however, remains a source of debate. The crux of the argument is whether the differences arise at the level of basic, low-level visual processing or further downstream at stages involving more complex, higher-level tasks and stimuli. A recent study has shown visual acuity in ASD to be equivalent to that of neurotypical controls. This suggests the earliest levels of retinal processing to be an unlikely candidate as the source of differences (Tavassoli et. al. 2011). The next potential level for divergent visual processing are those involved in processing simple aspects of visual stimuli, such as orientation and spatial frequency, considered to be functions of early visual cortical processing. One study supporting the low-level view of atypical perceptual abilities found that participants with ASD were superior in identifying the orientation for simple, first-order gratings at cardinal angles (Bertone, Mottron, Jelenic, & Faubert 2005). Yet, other, more rudimentary aspects of orientation perception, such as detection and discrimination, have not been assessed systematically within this population. Characterizing differences in the most basic visual abilities is necessary to determining the origins of these variances within the ASD phenotype, and what impact these alterations have for more complex levels of visual perception.

Objectives: The goal of this study was to characterize (i) sensitivity, (ii) precision, and (iii) accuracy for perceiving orientation in the same cohort of participants with ASD in comparison to age- gender- and IQ-matched neurotypical controls. Each experiment allows for both qualitative and quantitative assessment of the *oblique effect*i.e., the typical finding of superior performance at cardinal and as compared to oblique orientations.

Methods: In three psychophysical experiments we measured (i) contrast detection thresholds (ii) orientation discrimination thresholds and (iii) biases in perceived orientation of a 3 cycles/degree Gabor patch of varying base orientation.

Results: For all three experiments, our results indicated that participants with ASD perceive orientation of low-level stimuli in a qualitatively as well as quantitatively similar manner to neurotypical controls. Oblique effect was evident in both groups: at cardinal orientations (i) stimuli were easier to detect (ii) precision was higher and (iii) perception was veridical as opposed to oblique orientations where perception is found to be biased. Additionally, performance in all three tasks were quantitatively indistinguishable in the two groups of participants. We found no evidence of superior processing in detection, precision, and accuracy aspects of orientation perception in participants with ASD.

Conclusions: Our findings suggest that low-level visual processing of orientation is unremarkable for people with ASD. These results suggest that the source for altered perceptual abilities should be sought elsewhere, possibly in subsequent levels of visual processing.

165 **109.165** Time Course of Facial Emotion Recognition in First-Degree Relatives of Individuals with ASD: An Eye-Tracking Study

A. Lartseva[1], T. Dijkstra[2], F. Huettig[3] and J. K. Buitelaar[4], (1)Donders Centre for Neuroscience, Nijmegen, GE, Netherlands, (2)Donders Centre for Cognition, Radboud University Nijmegen, Nijmegen, Netherlands, (3)Psychology of Language Department, Max planck Institute for Psycholinguistics, Nijmegen, Netherlands, (4)Department of Cognitive Neuroscience, Radboud university medical center, Nijmegen, Netherlands

Background: Previous studies have found impaired facial emotion recognition and atypical gaze fixation patterns when looking at faces in participants with Autism Spectrum Disorders (ASD) (Klin et al, 2002). Specifically, participants with ASD look more at the mouth and less at the eyes, while typically developing participants show an opposite pattern. Several studies found the same pattern in unaffected siblings and parents of children with ASD, suggesting that it may be a feature of Broad Autism Phenotype (BAP) (Adolphs et al, 2008). However, this finding has not always been replicated; furthermore, it was proposed that other traits, such as alexithymia, can better explain the atypical eye:mouth ratio found in ASD (Bird et al, 2011).

Objectives: Little is known about the time course of gaze fixation on faces in relation to ASD symptoms. Preference for looking at the eyes or the mouth could be a consequence of automatic tendency to immediately fixate on the eyes, in which case the difference would be seen early on, or be a part of a conscious strategy. Averaging total fixation duration over a given interval of time (which was commonly done in previous studies) does not allow to disambiguate between these two factors. Our aim was to investigate the time course of facial emotion processing in first-degree relatives of individuals with ASD.

Methods: We employed the visual world paradigm: At the beginning of each trial participants heard a word indicating a target emotion, and at the same time saw photos of four different people presented in the four quadrants of the screen. The task was to respond whether one among the four photos expressed the target emotion. The outcome variable was the probability of fixation within a given region of interest at each time point.

Results: Preliminary data from 7 parents of children with ASD and 15 control participants indicate that participants from both groups start to look towards the target emotion around 150-200 ms after trial onset. However, the probability of fixation on target emotion increased at significantly slower rate in the BAP group (compared to control). With respect to eye:mouth ratio, both participant groups initially looked more at the mouth, but later switched towards looking at the eyes. In the typical group, probability of fixation on the mouth continued to increase, albeit at a slower rate, while the BAP group fixated mainly on the eyes (Group (BAP, Control) *Region (Eyes, Mouth) * Time (300, 500,

700 ms) interaction, $F(2,40)=5.61$, $p=.021$).

Conclusions: Eye:mouth ratio is task-dependent, and it follows a particular time course. Contrary to previous findings, the BAP group did not avoid looking at the eyes, arguing against lower eye:mouth ratio being an endophenotypic feature of ASD. However, the BAP group focused exclusively at the eyes, while the typical group explored all facial features in parallel, suggesting that just like people with a clinical diagnosis of ASD, their first-degree relatives analyze facial expressions based on single feature.

166 **109.166** To See but Not to See: Visual Perception Mediates Imitation in ASD

H. Stieglitz Ham[1], G. Rajendran[2], M. Corley[3], S. Vaz[1], M. Falkmer[1], A. Bartolo[4] and T. Falkmer[1], (1)Curtin University, Perth, Australia, (2)Heriot-Watt University, Edinburgh, Scotland, United Kingdom, (3)Psychology, PPLS, University of Edinburgh, Edinburgh, United Kingdom, (4)Psychologie, Laboratoire URECA, Université de Lille Nord de France, Lille, France

Background: The ability to imitate is an early and important developmental milestone providing the foundation for turn taking, joint attention and theory of mind. Imitation deficits are well documented in individuals with Autism Spectrum Disorder (ASD). Impairments in imitation performance have been identified in meaningful gestures (i.e., goal-directed action), meaningless gestures and even style (e.g., harsh versus gentle). The Self-Identification theory suggests that individuals with autism fail to imitate the style of the examiner due to a lack of interpersonal connectedness. Underlying cognitive factors, including the relationship of visual perception to the imitation of style, have not been fully explored. To our knowledge, this is the first study to design perceptual tasks assessing discrimination of *style* in ASD.

Objectives: A case-control study was conducted to: a) determine if individuals with ASD are successful in imitating and discriminating the goal and the style of actions; and b) to investigate the role of underlying cognitive mechanisms including visuomotor integration (VMI), working memory (WM), visuoperceptual processing (VP) and discrimination of style in predicting group membership.

Methods: Nineteen adolescents with high functioning autism (HFA) and 22 typically developing controls (MA = 12.1, SD = 2.4 and MA =12.2, SD = 1.9 respectively) were tested on four newly designed tasks of discrimination of style (e.g., harsh versus gentle and fast versus slow) of object use, intransitive (social) gestures and pantomimes. Four imitation tasks, adapted from Hobson and Lee (1999), were tested: Strumming a pipe rack on a stick, using a stamp and ink pad, flattening a toy frog with a roller and pressing a bobble head.

Results: No significant between group differences were evident in imitating the goal; however, the ASD group was significantly poorer at imitating the *style* of the action: pipe rack and stick, [X^2 (1, N = 41) = 5.13, p = .038; stamp and ink pad X^2 (1, N = 41) = 5.26, p = .036; frog and roller x^2 (1, N = 40) = 19.93, p = <. 001 and atypical use of the bobble-head, x^2 (1, N = 41) = 15.33, p = .003]. Results from a series of multivariate logistic regression models suggested that visuomotor integration and discrimination of the style of intransitive gestures successfully predicted group membership, [OR = .89, p - .013; OR = .38, p = .020]. Results of the discrimination tasks showed significant between-group differences in discrimination of transitive gesture style, t_{39} = -2.54, p = .015, Cohen's d =-.79, and intransitive gesture style, t_{39} = -2.99, p = .005, Cohen's d = -.92.

Conclusions: Our findings support and extend the results of Hobson and Lee (1999) revealing significant difference in the imitation of *style* in ASD and highlight that impairments in visuomotor integration as well as the ability to discriminate the style of gestures may account for this imitative deficit. These findings replicate and extend the original study of Hobson and Lee (1999) suggesting that a primary deficit in visual perception may underlie a deficit in imitation of style in ASD.

167 **109.167** Transitive Inference in Children with Autism Spectrum Disorder and Limited Verbal Ability

C. T. Derwent, S. B. Gaigg and D. M. Bowler, Autism Research Group, City University London, London, United Kingdom

Background: Memory functioning in Autism Spectrum Disorder (ASD) follows a characteristic pattern, including good rote memory (Kanner, 1943) and cued recall (Bowler, Matthews & Gardiner (1997). Impairments have been demonstrated in the free recall of semantically related items (Tager-Flusberg, 1991), and the recognition of combinations of features (Bowler et al., 2008, 2014). This suggests a difficulty with *relational binding*- the ability to encode items and events, and the relationships between them, to allow for adaptive use of the information (Opitz, 2010).

Objectives: Studies of relational binding in ASD have mainly been carried out with verbally able adults, using verbalisable stimuli (e.g. words). The current study aimed to extend these findings to lower-functioning individuals with ASD. A non-verbal transitive inference paradigm (if A > B, and B > C, then A > C) was adapted (Maclean et al., 2008). Typical adults tend to use a relational strategy during these tasks (Moses, Villate, and Ryan, 2006), whereas non-human animals tend to use an associative, pair-by-pair strategy (von Fersen et al, 1991), suggesting that language may be important in the construction of relational strategies.

Methods: 24 children with ASD and limited verbal ability (AD), and 24 typically developing children (TD), matched on non-verbal IQ. Pairs of stimuli were presented in hierarchical order; participants were required to find the "higher-ranked" of the two by touching it onscreen; feedback was given after each trial regarding their choice. A test phase was then presented, comprising two trial types:

adjacent pairs of stimuli already seen during the training phase, and re-pairings of the stimuli into novel combinations of non-adjacent stimuli (e.g. B-D). Participants must use information from the adjacent training pairs to infer the higher-ranked stimulus of a non-adjacent pair, which requires the flexible processing of the relations between pairs. The current study predicted no group differences during the test phase where adjacent stimuli were presented, whereas participants with ASD would be impaired in the non-adjacent pairs, because of the flexible relational binding required to solve those trials. An additional task in which participants were shown all the stimuli on the screen and asked to "put them in order" was included to determine participants' awareness of the hierarchy. **Results:** Performance during training in the transitive inference task was > 70% for all participants. During the test phase no group differences in performance were found between the two trial types (adjacent and non-adjacent); indicating that the level of performance was comparable between the groups, regardless of trial type. However, there was a significant group difference in the stimulus hierarchy awareness task, $t(46) = -3.0$, $p = .004$, with impaired performance in the AD group. **Conclusions:** Results indicate that children with ASD and limited verbal ability can solve a task requiring transitive inference. However, these participants also appear to be less aware of the stimulus hierarchy, which may imply that they are using an associative rather than a relational strategy, and therefore support the idea of the importance of language in the construction of relational strategies.

168 **109.168** Understanding of Prior Intention in the Children with Autistic Spectrum Disorder

C. H. Chiang[1], C. T. Huang[2] and C. Y. Hung[2], (1)Department of Psychology, National Chengchi University, Taipei, Taiwan, (2)Psychology, National Chengchi University, Taipei, Taiwan

Background: Young children with Autistic Spectrum Disorder (ASD) have some understanding of others' intention. However, it remains to be seen whether they understand others' prior intention. Objectives: This study extended the Carpenter et al. (2002) paradigm and explored whether young children with ASD benefited from others' prior intention in social learning of a causal task. Methods: Participants consisted of 24 young children with ASD (M= 46 months), 16 children with developmental delay (DD) who were CA- and MA-matched, and 24 typical developmental children (TD) who were MA-matched. They were diagnosed by a multidisciplinary team using ADI-R, ADOS and clinical judgment with DSM-IV. Children from each group were randomly assigned to one of two conditions: Prior Intention and No Prior Intention conditions. Children in the Prior Intention condition knew what the experimenter was trying to do (opened a series of containers) before demonstrating how to open a wooden box via two action steps; children in the No Prior Intention condition saw the demonstration paired with irrelevant actions on the containers. Results: Results revealed that TD (91.7%) and DD (100%) children opened the box significantly more often than children with ASD (58.3%) in the Prior Intention condition. There was no group difference in No Prior Intention condition (ASD: 58.3%, DD: 75%, TD: 58.3%). ASD children opened the box equally frequently in the Prior Intention and No Prior Intention conditions. By contrast, children from the TD and DD groups were more successful in the Prior Intention condition than in the No Prior Intention condition. Conclusions: The findings showed that contexts of prior intention facilitate observational learning in TD and DD children but not in young children with ASD. Theoretical and clinical implications were discussed in relation to their difficulty in understanding a person's intention within the context of the task.

169 **109.169** Use of an Experimental Design to Examine Factors That Contribute to Episodic Memory Deficits in Children with High Functioning Autism

K. Zielinski, University of California, Los Angeles, Hermosa Beach, CA

Background: Children with autism spectrum disorders (ASD) have been found to demonstrate impairment in episodic memory (EM). Factors that could contribute to or magnify EM impairment in ASD have not been examined.
Objectives: To examine factors, specific to ASD, that potentially influence EM performance on conventional assessments such as impaired expressive language, the method of prompting (verbally or visually) for memory recall, the salience of the event to the individual, and various cognitive factors.
Methods: This study examined 62 children (56 males, 6 females), aged 6-13 years, with High-Functioning ASD assessed for participation in a study using CBT to treat core ASD symptoms. During the administration of the experimental assessment, participants were shown a series of five slide shows, each of which depicts an emotion (happy, sad, angry, nervous, and embarrassed) and consists of a story that ends with a film of a child portraying the emotion which corresponds to the story. Methods of recall were systematically varied as participants were then asked to recall the stories verbally and non-verbally to examine the role of expressive language in memory recall, with a visual or verbal prompt to understand if method of cueing effects memory recall, and events that were of either high or low preference to determine if salience impacts quantity and quality. Additionally all participants were administered the WISC to determine their IQ.

Correlations were run using the EM measure's T scores and the participant's scores on the WISC (full scale IQ and subscales) to determine the relationship between various cognitive processes and EM performance. An Analysis of Variance (ANOVA) was also run to examine if participants demonstrated a difference in performance in various conditions of recall, thus implicating potential

confounds in EM assessment.

Results: Verbal ability and working memory scores as determined by WISC subscales were found to correlate with all EM conditions and total scores with the exception of the non-verbal response. The ANOVA indicated that there are differences in recall across all four conditions and that the number of details recalled accurately as well as the chronological order of recall are impacted by the salience of the event and method of recall.

Conclusions: The EM measure sought to examine if expressive language deficits, method of recall and salience of the event impacted EM recall in children with ASD. It was found that both the salience of the incident to the individual and the role of expressive language impacted the participant's memory for details and sequential recall of events. It appears that children with ASD may recall more details than they are able to verbalize without a given structure. Additionally, cognitive factors such as working memory and verbal ability may also impact EM performance. The results suggest that the presentation and severity of EM deficits in children with ASD could be due to or impacted by outside cognitive factors.

---

170 **109.170** Vertical but Not Oblique Line Orientation Discrimination Is Disturbed in ASD Children

*O. V. Sysoeva[1], M. S. Davletshina[2], E. Orekhova[1] and **T. A. Stroganova[1]**, (1)MEG Centre, Moscow State University of Psychology and Education, Moscow, Russia, (2)MEG Center, Moscow State University of Psychology and Education, Moscow, Russia*

Background: Neurophysiological studies suggested that excitation/inhibition (E/I) imbalance might underly visual perception abnormalities observed in some children with Autism Spectrum Disorder (ASD). Behaviorally, the E/I imbalance in visual cortex can affect the "oblique effect" - better discrimination ability for cardinal compared to oblique line orientations. Previous studies on typical developing subjects (TD) failed to find association between autistic traits and cardinal orientation discrimination thresholds, but found it for lines with oblique orientation (Brock et al., 2011, Dickinson et al., 2014). No studies examined the "oblique effect" in ASD children.

Objectives: The aim of our study was to examine the orientation discrimination threshold for oblique and cardinally orientated lines in TD and ASD children.

Methods: Subjects were 16 ASD boys and 32 TD boys, aged between 6 and 15 years with IQ > 71: intellectual ability was assessed by the Kauffman Assessment Battery (Kauffman&Kauffman, 2004). The experimental procedure was similar to those used by Dickinson et al., 2014. The orientation of the first grating was held fixed at 0° in the "vertical" condition and 45° in the "oblique" condition, the second grating was rotated either clockwise or counterclockwise. The orientation difference between the gratings was adjusted using two interleaved one-up two down staircases that converged on 71% correct performance. Participants were asked to judge the direction of this rotation. The logarithm of orientation discrimination threshold for vertical and oblique lines assessed in degrees was taken as a dependent variable.

Results: The ANCOVA with Orientation (Vertical vs. Oblique) as a within-subject factor, Group (ASD vs. TD) as a between-subject factor, and Age and IQ as the covariates was applied to the data. The effects of interaction Orientation*Group and Orientation*Age were significant, and the univariate ANCOVA was further applied separately for Vertical and Oblique conditions. For the Oblique condition the only significant effect was the effect of Age: the oblique lines' orientation discrimination improves with age in both groups. Noteworthy, the ASD and TD groups had similar oblique discrimination thresholds (10.8±1.5º vs. 9.0±0.6º). However, the significant Group effect was present in the Vertical condition: ASD boys had enhanced discrimination threshold as compared to TD boys (4.7±1.1º vs. 1.4±0.1º). The significant Group*Age interaction suggested that difference between ASD and TD diminished with age.

Conclusions: Our study provides evidence for a reduced "oblique effect" in ASD boys comparing to their TD peers. Unexpectedly, this was due to ASD difficulties with orientation discrimination of vertical lines, whereas the threshold for oblique line orientation did not differentiate ASD and TD boys. Previously, it was shown, that "oblique effect" increases with age, potentially reflecting the tuning of neuronal network to the environmental statistics through GABAergic modulation (Liang et al., 2007, Girshick et al. 2011, Shen et al., 2014). Therefore, the deficits in vertical orientation processing, seen in ASD children, might represent the E/I imbalance, which delays adequate visual system tuning and reduces the natural bias toward cardinal orientation.

---

171 **109.171** Writing Ability and Working Memory in Children with Higher Functioning ASD

__M. C. Zajic[1]__, N. S. McIntyre[1], L. E. Swain-Lerro[2], T. Oswald[3] and P. C. Mundy[4], (1)UC Davis, Davis, CA, (2)School of Education, UC Davis, Santa Rosa, CA, (3)2825 50th Street, UC Davis, Sacramento, CA, (4)2825 50Th Street, UC Davis, Sacramento, CA

Background: Children with high-functioning ASD (HFASD) or ADHD have difficulty with writing (Myles et al., 2003; Pennington & Delano, 2012; Re, Pedron, & Cornoldi, 2007). One possibility is that problems with working memory lead to the problems in both groups (Mayes, Calhoun, Mayes, & Molitoris, 2012; McCutchen, 2006).

Objectives: This study examined the degree to which school-age children with HFASD and ADHD exhibit similar or different difficulties with writing. It was also designed to examine the role of working memory in writing development in these children.

Methods: Seventy-two children with HFASD (age=11.29 years (SD=2.12), FIQ=100.37 (SD=14.30)) were compared to 38 children with ADHD (age=11.78 years (SD=2.35), FIQ=101.03 (SD=15.23)) and 39 children with typical development (TD) (age=11.59 years (SD=2.24), FIQ=115.22 (SD=14.56)). HFASD was confirmed with the ADOS–R, and ADHD was assessed with parent report on the Conners–3. Working memory was measured with the Wide Range Assessment of Memory and Learning–2 (WRAML). IQ was assessed with the Wechsler Abbreviated Score of Intelligence–II. Writing was assessed with the Wechsler Individual Achievement Test–3.

Results: A Diagnostic Group ANCOVA of the WIAT overall writing score, with IQ as a covariate, revealed a significant group effect, $F(2,143)=7.62$, $p<.001$, $eta^2=.10$ (see Figure 1). The clinical groups were significantly lower than the TD group on writing achievement, but the former did not differ. MANCOVA indicated that the groups also differed on the four WRAML measures, $F(8, 298)=6.01$, $p<.001$, $eta^2=.14$. On story memory, the HFASD group was significantly lower than the ADHD and TD groups, which did not differ (ps<.001). On verbal working memory, the HFASD group was lower than the ADHD group ($p<.03$), which was lower than the TD group ($p<.003$, see Figure 2). Regression analyses revealed that age ($\beta=-1.9$), symbolic working memory ($\beta=2.38$), and story memory ($\beta=2.68$) made significant contributions to explaining variance on the overall writing score, $R=.49$, adjusted $R^2=.18$, $F(5, 65)=4.21$, $p<.002$. In the ADHD group, story memory (2.18) and finger windows (-3.48) explained variance in overall writing scores, $R=.66$, adjusted $R^2=.34$, $p<.002$. The regression model with working memory and age was not significant in the TD sample.

Conclusions: School-aged children with HFASD and ADHD display comparably lower quality written texts than TD peers. However, regression analyses suggested that different factors were associated with writing difficulties in the two clinical groups. In the HFASD but not ADHD group, relative writing performance deceased with advances in age. Symbolic working memory was a factor for the HFASD sample but not the ADHD sample. Alternatively, story memory, which may reflect an executive capacity to organize memory along organized narrative lines, impacted writing in both groups. These results provide information relevant to the educational needs of school-age children with HFASD and can help understand how working memory may be playing specific roles during writing tasks.

172 **109.172** "Scattered Attention" in Face Perception: The Case of Co-Morbid ASD+ADHD

J. Parish-Morris[1], B. E. Yerys[2], L. Antezana[3], A. de Marchena[3], C. Chevallier[3], N. J. Sasson[4] and R. T. Schultz[3], (1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)Psychiatry, University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)University of Texas at Dallas, Richardson, TX

Background: Early atypical attention to faces in ASD is hypothesized to lead to downstream effects on social cognition, causing impairment in everyday social interaction. Although some research using infrared eye tracking paradigms suggests reduced attention to faces (particularly the eye region) in ASD versus typical development, many other studies find no effects. These null results may partially result from small sample sizes and significant within-group heterogeneity in ASD (e.g., high rates of co-morbid ADHD that likely affect gaze patterns). To our knowledge, large-scale eye tracking studies of ASD plus co-morbid ADHD do not exist in the literature.

Objectives: Compare large samples of children with ASD+ADHD vs. ASD alone on an eye-tracking metric of "scattered visual attention" to faces and objects, as well as eyes and mouths.

Methods: Children with ASD (N=125) and ASD+ADHD (N=110) watched 3 16-second sets of 4 video clips, 1 in each quadrant of a 32-inch screen, while their gaze data was collected at a rate of 60 Hz using a Tobii X120 system. Groups did not differ on sex-ratio, age (mean=10y), or IQ (mean=103; all participants >70). Each set of videos included 2 naturally moving neutral faces and 2 moving objects (e.g., car on highway). Areas of interest (AOI) included faces, objects, eyes, and mouths. The number of visits made to faces vs. objects and eyes vs. mouths were compared between diagnostic groups using omnibus repeated measures ANOVA with planned t-tests to determine directionality.

Results: Overall visual attention to the screen did not differ by group ($t=-.08$, $p=.93$). An index of "scattered attention" (visit count to the four screen quadrants) was significantly higher in the ASD+ADHD group than the ASD alone group ($t=3.24$, $p=.001$). A 2x2 repeated measures ANOVA on visit count with Stimulus (face, object) as a repeated measure and Group (ASD, ASD+ADHD) as a factor revealed a main effect of Group ($F=10.48$, $p<.001$, $\eta_p^2=.04$) and no Group x Stimulus interaction. A similar ANOVA focused within the face with Stimulus (eyes, mouth) as a repeated measure revealed a main effect of Group ($F=7.16$, $p=.008$, $\eta_p^2=.03$) and a Group x Stimulus interaction ($F=4.17$, $p=.04$, $\eta_p^2=.02$). Planned t-tests revealed that the ASD+ADHD group looked more frequently at the eyes than the mouth, whereas the ASD only group did not, and this translated to longer raw time spent on the eyes in the ASD+ADHD group than the ASD group (all $ps<.05$).

Conclusions: Children with ASD and ADHD attend to faces differently than those with ASD alone, focusing relatively more on the eyes, and they are significantly more active in their exploration of visual information. This might represent ADHD-driven "scattered attention" or other fundamental differences between the ASD groups, such as decreased social motivation in those with ASD alone. Ongoing analyses are exploring these hypotheses, as well as relationships to face recognition ability and neural representations measured with fMRI (e.g., FFA activation).

173 **110.173** Are Social Cognitive Deficits Relative in Autism? Examination Using a Social Versus Nonsocial Salience Paradigm

K. Unruh[1,2], *N. J. Sasson*[3] *and J. W. Bodfish*[4,5], *(1)Vanderbilt Brain Institue, Nashville, TN, (2)Vanderbilt University, Nashville, TN, (3)University of Texas at Dallas, Richardson, TX, (4)Vanderbilt Brain Institute, Nashville, TN, (5)Vanderbilt University School of Medicine, Nashville, TN*

Background: When left to their own, how do children with autism "spend" their attention and time, and what might this suggest to us in our search for models of pathogenesis and treatment of autism? As parents of children with autism know, these children spend a disproportionate amount of time seeking out and engaging in idiosyncratic and primarily nonsocial patterns of behavior and interest.
Objectives: When viewed from the perspective of experience-dependent brain and behavioral development, such a narrow, nonsocial pattern of behavior and interests likely diminishes social experience, and, in turn opportunities for social learning and development. *Does this pattern of autistic development unfold as a result of a predisposition to avoid social stimulation, or a predisposition to approach nonsocial stimulation?*In this study we examine if the presence of nonsocial stimuli can alter social information processing in children with ASD.
Methods: Preferential viewing tasks can serve as objective measures of salience, with a greater proportion of viewing time to one item indicative of increased salience. The current task used gaze-tracking technology to examine patterns of visual attention to stimulus pairs that varied in social and nonsocial content. Pairs included a social image (face) and a picture of one of two types of objects: objects found in previous studies to be of high interest to individuals with ASD (HAI images; e.g. trains, electronics) and objects found to be of low interest to individuals with ASD (LAI images; e.g. clothing, furniture). Participants included both adolescents diagnosed with ASD (N = 33, mean age = 13.9 years) and typically developing (TYP; N = 32, mean age = 14.1 years); groups were matched on IQ and gender.
Results: Repeated measures ANOVA revealed an increased latency to social images in individuals with ASD only when the social image was paired with an HAI nonsocial image [$F(1,63) = 4.3, p = .042$]. Individuals with ASD spent a greater proportion of time looking to objects, regardless of array type [$F(1,63) = 15.4, p = .005$], while TYP individuals spent a greater proportion of time looking to social images [$F(1,63) = 20.1, p = .001$]. Fixation patterns differed between groups only for social images, with TYP individuals displaying significantly longer fixations to social images than ASD, regardless of array type [$F(1,63) = 25.7, p = .0001$]; object fixation duration did not differ between groups [$F(1,63) = .22, p = .794$] or between array types [$F(1,63) = 1.0, p = .31$].
Conclusions: These results suggest that in ASD, deficits in social information processing may be relative and context-dependent, as opposed to being a fixed core feature of the disorder. In this model, social inattention may occur as a secondary byproduct of a positive attention bias to nonsocial information. In ASD, the presence of nonsocial sources of stimulation can significantly increase the latency of look time to social sources of information. In an ecologically valid context, this could translate to either delays in social information processing or to missing critical social information entirely.

174 **110.174** Examining the Impact of Repetitive and Restricted Behaviors on Adaptive Functioning of Children with ASD

S. Maisel[1], *K. L. Campe*[2] *and E. Hanson*[1], *(1)Boston Children's Hospital, Boston, MA, (2)Developmental Medicine, Boston Children's Hospital, Boston, MA*

Background: Restricted and repetitive behaviors (RRBs) include a broad category of behaviors which are considered core characteristics required for a diagnosis of Autism Spectrum Disorder (ASD) according to the Diagnostic and Statistical Manual (DSM-V; American Psychiatric Association, 2013). RRBs can be subdivided into Repetitive and Sensory Motor behaviors (RSM) and Insistence on Sameness behaviors (IS). In previous studies, researchers found significant negative correlations between IQ and RSM behaviors and positive correlations between IQ and IS behaviors (Richler et al. 2010). Bishop et al. (2006) found stronger relationships between RRBs and IQ with increasing age in children with ASD. However, earlier research may be difficult to generalize, since those studies tended to focus on a limited number of RRBs, measured predominantly by tools designed for assessing ASD and not RRB's per se. This study uses a newly standardized measure, the Behavior and Sensory Interest Questionnaire (BSIQ) to classify a wide range of RRBs. Furthermore, subject characteristics such as age, cognitive and adaptive functioning, gender and autism severity will be utilized to compare children with high and low RRBs.
Objectives: By utilizing the BSIQ, this study aims to compare a wide range of RRBs and there relationship to subject characteristics (age, cognitive and adaptive functioning, gender and autism severity). In addition, the total and type of RRBs will be examined.
Methods: A sample of 237 children with ASD (85% male; NVIQ=93.7, SD=20) was drawn from the Simons Simplex Collection and the Boston Autism Consortium. Participants ages were between 27-272

months, (mean=94.9, SD=49.6). The BSIQ, designed to evaluate the number, type, and intensity of RRBs, was administered to a parent. Testing also included child cognitive, behavioral and adaptive functioning assessments. Generalized linear models were employed to explore the relationship between different subject characteristics, cognitive functioning and RRBs.

Results: Analyses revealed a significant weak negative trend of age on RSM behaviors (p=0.004) when controlling for IQ, however no significant trend was revealed of age on IS behaviors. It is important to note that a significant interaction of age and IQ was found for RSM but not IS behaviors. Furthermore, RSM behaviors had a significant negative impact on overall adaptive behaviors as measured by the Vineland composite standard score (p=0.02) however the same effect was not observed with IS behaviors (p=0.51). All analyses were controlled for IQ, age and gender.

Conclusions: Expanding on previous research, we employed a more comprehensive measure to observe the impact of age and IQ on RRB's. We found significant effects of RSM but not IS on adaptive functioning. Further research is necessary to determine which adaptive behavior subdomains are directly impacted by RSM and not IS behaviors. Furthermore it's important to determine if RRB severity differentially affects adaptive functioning to attempt to understand the impact of RRB's on the functioning of children with ASD.

175   **110.175** Grit in Children and Adolescents with Autism Spectrum Disorder

C. McMahon[1], J. Haut[2], R. Schatz[3], T. Otero[2] and A. Merrill[4], (1)3C Institute, Cary, NC, (2)Indiana University, Bloomington, IN, (3)Counseling and Educational Psychology, Indiana University, Bloomington, IN, (4)School Psychology, Indiana University, Bloomington, IN

Background:
Grit is defined as "perseverance and passion for long-term goals" and is composed of two primary factors: consistency of interests over time and perseverance of effort (Duckworth et al., 2007). Grit is strongly predictive of a variety of long-term positive outcomes, ranging from higher academic GPA to greater job retention (e.g., Duckworth et al., 2007; Eskreis-Winkler et al., 2014). Despite the long-term positive outcomes associated with grit, there are no studies in the extant research literature that have examined grit in children and adolescents with Autism Spectrum Disorder (ASD).

Objectives:
The aim of this study was to examine diagnostic group differences in grit between children and adolescents with ASD and typical development.

Methods:
Children and adolescents with typical development ($n = 8$) and ASD ($n = 10$), as well as their parents, participated in the current study. Children and adolescents ranged in age from 9-17. Diagnostic groups were matched on age, $t(16) = -0.96$, $p = 0.35$, verbal IQ, $t(16) = 1.62$, $p = 0.12$, performance IQ, $t(16) = 0.56$, $p = 0.58$, and gender, $\chi^2 (1, N = 18) = 0.68$, $p = 0.41$. Parents used the Short Grit Scale to report on their child's level of grit (Duckworth & Quinn, 2009). Preliminary ANCOVAs was used to evaluate the effect of diagnostic group (typical development vs. ASD), controlling for age and verbal IQ, on three dependent variables: the Grit Total Scale, the Consistency of Interests Subscale, and the Perseverance of Effort Subscale. As age and verbal IQ did not have a significant effect in any of the preliminary analyses, they were removed from the final analyses.

Results:
There was a significant effect of diagnostic group on the Grit Total Scale, $F(1, 16) = 7.42$, $p = 0.02$, $\eta^2_p = 0.32$, and the Consistency of Interests Subscale, $F(1, 16) = 19.35$, $p < 0.01$, $\eta^2 p = 0.55$, such that parents rated children and adolescents with typical development as being more gritty and having more consistent interests over time than children and adolescents with ASD. There was not a significant effect of diagnostic group on the Perseverance of Effort Subscale, $F(1, 16) = 0.34$, $p = 0.57$, $\eta^2 p = 0.02$.

Conclusions:
This study suggests that children and adolescents with ASD are less gritty than children and adolescents with typical development, due almost exclusively to less consistency in interests over time. Although children and adolescents with ASD consistently show restricted interests over time (e.g., Joseph et al., 2013), the specific nature of these restricted interests may change over time, making it difficult for children and adolescents with ASD to steadily focus on and pursue long-term goals. Old goals associated with old restricted interests may be replaced by new goals associated with new restricted interests, such that goals are regularly replaced and rarely attained. This research suggests that maintaining consistent interests over time may be integral to building grit in children and adolescents with ASD and attaining long-term social, educational, and/or vocational goals.

176   **110.176** Hobbies in Adults with ASD: An Exploratory Descriptive Analysis

S. Pacey-Smith[1], B. A. D'Entremont[1], S. Nichols[2], S. D. Voyer[1] and S. Byers[1], (1)Psychology, University of New Brunswick, Fredericton, NB, Canada, (2)ASPIRE Center for Learning and Development, Melville, NY

Background:
Hobbies make up an integral aspect of peoples' everyday lives. In neuro-typical individuals these activities foster social relationships, increase positive emotions, increase skill and knowledge

acquisition, and generally improve quality of life (Brajsa-Zganec & Merkas, 2011). Unfortunately, almost no research exists examining the nature of interests and hobbies in adults with ASD. Two studies suggested that adults with ASD engage in interests that are more "systemizing" than those of neuro-typical controls (Caldwell-Harris & Jordan, 2013; Jordan & Caldwell-Harris, 2012). However both studies used the Cambridge University Obsessions Questionnaire to either elicit or classify responses, potentially constraining the breadth of possible responses. Given the lack of empirical data on the interests and hobbies of adults with ASD, in order to gain a full understanding it is important to have adults with ASD identify their interests and hobbies without a priori structuring of response categories in a manner that reflect researchers' conceptualizations.

Objectives:
This study will describe the interests and hobbies of a sample of community-based, high-functioning adults with ASD. Understanding of the nature these interests and hobbies can lead to their integration into therapeutic programs for improving the communication, vocational and social skills of these individuals.

Methods:
Participants were 397 individuals between the ages of 21 and 73 years (M=37.2) who met a conservative cut off score of 32 on the Autism-Spectrum Quotient (Woodbury-Smith, Robinson, Wheelwright & Baron-Cohen, 2005) and completed an online survey. Participants were asked, via an open-ended question, to indicate their top five hobbies/ interests. Participants' hobbies were coded into six categories: Cognitive (e.g., video gaming; WWII history; reading), Social (e.g., my children; autism advocacy; sex), Physical (e.g., soccer; weight-lifting; walking), Passive Entertainment (e.g., listening to the radio; Japanese animation), Domestic (e.g., gardening; cooking; hobby farming) and Music/Cultural (e.g., composing music; going to the theatre). Category construction was based on previous research and overarching themes in the data.

Results:
First, we determined the number of hobbies participants identified. Of the 397 participants, 1% identified as having no hobbies, 23.4% identified hobbies fitting into only one category, 38.5% identified hobbies fitting into two categories, 28% identified hobbies fitting into three categories, 6.8% identified hobbies fitting into four categories, 0.8% identified hobbies fitting into five categories and 2.5% of participants indicated no hobbies or did not respond. Next we determined the relative frequency of the various categories. The most frequent type of hobby/interest reported was Cognitive (96.9%) followed by Physical (32.7%) and Music/Cultural (32.7%), Passive (22.5%), Domestic (20.2%) and Social (13.6%).

Conclusions:
The results demonstrate that interests are broader than typically conceptualized. That is, although many participants reported highly specific interests (e.g., geodesic domes; collecting 78 rpms records), many also reported a large number reflecting typical interests (e.g., snowboarding, reading, watching TV). These findings most likely reflect this study's open response format as well as the general focus on hobbies/interests as opposed to special interests. Implications for future research and clinical practice are discussed.

177 **110.177** Measuring Restricted Interests and Repetitive Behaviors in Infant Siblings at-Risk for ASD: Comparing Home Setting Versus Clinic Performance of 12 Month Olds

N. Brane[1], M. Lewis[1], E. S. McGarry[1], K. Fiorello[1], S. E. Gillespie[2] and A. M. Wetherby[3], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Pediatrics, Emory University School of Medicine, Atlanta, GA, (3)Florida State University Autism Institute, Tallahassee, FL

Background:
Approximately 20% of younger siblings of children with autism spectrum disorder (ASD) are at an increased risk for developing ASD (Ozonoff, 2011). According to the DSM-5, ASD symptomatology involves restricted, repetitive patterns of behavior (RRB), interests, or activities; however, these indicators are not yet thoroughly researched in very young siblings. During the second and third year, repetitive hand and finger mannerisms become more pronounced among children with ASD and less pronounced among children with developmental delays (DD) and typical development (TD). (Chawarska & Volkmar, 2005; Evans et al., 1997; Moore & Goodson, 2003; Werner et al., 2005). More recently, Stronach and Wetherby (2012) examined RRB among toddlers at a mean age of 20 months in the clinic and home settings, identifying a higher presence of RRB in the clinic, given the nature of structured probes and repeated presentations of objects.

Objectives:
The purpose of this study was to examine the relationship between home observation and clinical assessment of RRB of 15 (projecting 25 by May 2015) 12-month old infants considered at risk for ASD, given sibling status.

Methods:
High-risk, 12-month old infant siblings were seen for communication assessments as part of a large, federally-funded longitudinal study examining risk and resilience in the first two years. The assessment battery included two samples of early social communication behavior: Communication and Symbolic Behavior Scales (CSBS-DP; Wetherby & Prizant, 1993) video-recorded in a clinic, and a video-recorded home observation. The Systematic Observation of Red Flags of ASD (SORF), an ASD-specific screening instrument, was used to rate early symptomatology within clinic and home

observations. Analysis included examining differences/similarities regarding 4 of the 22 SORF red flags, specifically: (1) repetitive movements with objects, (2) repetitive body movements/posturing, (3) sticky attention to objects, and (4) unusual sensory exploration/excessive interest in sensory aspects of environment. Differences in SORF values between clinic/home observations were assessed using paired t-tests and Wilcoxon signed-rank tests. Pearson's correlation was utilized to gauge linear association between total clinic/home SORF results.

Results:
Pearson's correlation indicated a moderate but non-significant association between total red flags on home SORF and clinic SORF ($r = 0.302$; $p = 0.246$). However, total red flags on home SORFs were significantly lower than clinic SORFs, ($p = 0.006$). Clinic SORFs picked up significantly more RRB red flags than home SORF ($p < 0.001$). There was no significant difference for Social Communication and Social Interaction Impairment items on the clinic SORF versus home SORF ($p = 0.060$). In addition, clinic SORFs revealed significantly higher scores than home SORFs for RRB items including: repetitive movements with objects ($p = 0.010$), repetitive movements or posturing of body ($p = 0.005$), sticky attention to objects ($p = 0.026$), and unusual sensory exploration/excessive interest in sensory aspect of environment ($p = 0.016$).

Conclusions:
Findings suggest that while the CSBS is primarily examining communication, structured tasks involving objects and communicative temptations may reveal increased amounts of RRB, and therefore, expose earlier symptomatology and provide more quantitative assessment of red flags in this diagnostic domain.

178 **110.178** Modeling Higher-Order Repetitive Behavior in the C58 Mouse Strain

C. M. Whitehouse[1], R. L. Shafer[2] and M. H. Lewis[1], (1)University of Florida, Gainesville, FL, (2)Vanderbilt University, Nashville, TN

Background: The diagnostic domain of restricted, repetitive behavior (RRBs) represents a heterogeneous set of behaviors but has been shown to cluster into two subtypes: lower-order repetitive body movements (e.g., hand flapping) and higher-order repetitive behavior, such as circumscribed interests and insistence on sameness. Most work with mouse models relevant to the repetitive behavior in ASD have focused on lower-order repetitive behaviors with less attention to modeling higher-order repetitive behaviors. The C58 inbred mouse strain exhibits a robust lower-order repetitive behavior phenotype involving high levels of hindlimb jumping and backward somersaulting (Muelhman et al., 2012; Ryan et al., 2010). This model has yet to be systematically characterized for the presence of higher-order repetitive behaviors. Understanding the pathophysiology of the full range of repetitive behaviors is critical to identifying therapeutic drug strategies for individuals with ASD.
Objectives: The purpose of this study was to extend characterization of the C58 animal model to include higher-order repetitive behavior by examining resistance to change or inflexibility using reversal learning of a positional discrimination as well as extinction of this conditioned behavior. C58 mice were compared to control (C57BL/6) mice on these measures using an appetitive operant nose-poke task.
Methods: C58 (n=11) and C57BL/6 (n=8) mice of both sexes were tested for lower-order motor stereotypy at 8 weeks of age. At 9 weeks of age, all mice were food deprived across 3-4 days to approximately 85% of their free feeding weight and behavioral testing sessions were conducted daily. Each session was 70 minutes, which included a 10 minute habituation session in the operant chamber with the house light off prior to each 60 minute operant session. During the operant testing, mice were reinforced on a fixed ratio schedule (FR1) to either the right or left side of the operant chamber. Once a mouse met acquisition criterion of 85% correct for 4 consecutive days, reversal learning was tested by switching the nose poke side associated with reinforcement. Once the reversal learning criterion was reached (85% correct, 4 consecutive days), the mouse entered the extinction phase and nose pokes to either side of the chamber did not result in reinforcement.
Results: Our findings demonstrated that C58 mice had greater difficulty in switching during reversal learning and exhibited higher rates of perseverative responding during extinction compared to C57BL/6J mice. Additionally, frequency of hind limb motor stereotypy was directly correlated with perseverative errors.
Conclusions: Overall, these findings suggest that C58 mice demonstrate cognitive inflexibility relative to C57/BL6 mice and that the two forms of RRB may have overlapping neurocircuitry. Futhermore, these data show the viability of the C58 stain as a model for both higher-order and lower-order repetitive behavior. Extending animal model work to include higher order repetitive behavior is critical to identifying the underlying novel potential therapeutic targets that can be used in the development of pharmacotherapies for ASD.

179 **110.179** Obsessive and Circumscribed Patterns of Interest (OCPI) of Children with Autism Spectrum Disorder

M. Verile[1], M. D. Forsythe[1], J. Shenouda[2] and W. Zahorodny[3], (1)Pediatrics, New Jersey Medical School- Rutgers University, Newark, NJ, (2)Rutgers New Jersey Medical School, Newark, NJ, (3)Pediatrics, Rutgers New Jersey Medical School, Newark, NJ

Background:
Obsessive and circumscribed patterns of interest (OCPI) have been a hallmark of Autism Spectrum Disorder (ASD) across diagnostic systems and eras. Studies of OCPI in ASD have been mostly conducted with small samples of high-functioning adolescents. There is little information on the prevalence or expression of OCPI in ASD from large, well-defined, populations. By specifying systematic aspects of OCPI, it may be possible to develop interventions to improve the social and communication skills of individuals with ASD.
Objectives:
The objectives of this study were to: determine the prevalence of OCPI in a large cohort of ASD children, assess whether there were demographic or functional differences between ASD children who exhibited OCPI and ASD children without indication of OCPI and to describe the most frequent topics of OCPI, among children with ASD.
Methods:
A complete cycle (2010) of data from ASD surveillance in the New Jersey metro region, according to the Centers for Disease Control and Prevention (CDC) multiple source ascertainment method was analyzed for the presence of OCPI. OCPI was defined as one or more indications of such interest, in one or more professional evaluations. Sex, and race information was recorded from the source documents. Cognitive status and severity of ASD impairment were derived from source documents and the standard ASD case determination process. Chi-square tests were used to determine if race, sex, IQ and level of impairment were associated with OCPI. Subjects with only non-specific indication(s) of OCPI were removed from further analysis. The topics of OCPI were described by percentiles.
Results:
Overall, 401 (males = 340, 85%; females = 61, 15%) in a total population of 696 (58%) 8-year old children with surveillance-confirmed ASD had documented OCPI in professional evaluations, through age 8. Sex was not associated with the likelihood of displaying OCPI, but race was associated with likelihood of OCPI. White non-Hispanic, children were more likely to exhibit OCPI than African-American non-Hispanic and Hispanic children (p<.01). Level of impairment due to ASD and cognitive level were not associated with the likelihood of displaying OCPI. Each specific indication of OCPI was sorted into a category based on preferred topic: vehicles (17%), television shows (15%), reading/letters (11%), animals (6%), time/clocks (6%), videogames (5%), dolls (1%) and balls (1%).
Conclusions:
A significant proportion (approximately 60%) of ASD children showed OCPI prior to age 9, underscoring the relevance of this area of impairment. White children were more likely to have OCPI. Additional study is needed to understand this association and to determine the extent to which OCPI varies with age. The most frequently-occurring topics of OCPI: vehicles, television shows and reading/letters were identified in only 17%, 15% and 11%, respectively, of the children with OCPI indicates the significant diversity of the topics of OCPI across ASD children. Additional research is needed to assess the relation of OCPI to other features of ASD and to determine how awareness of an individual's OCPI can be used to develop approaches aiming to enhance the functional status of individuals with ASD.

180   **110.180** Repetitive Stereotyped Behaviour or "Stimming": An Online Survey of 100 People on the Autism Spectrum

R. L. Steward, *Robyn Steward, Suffolk, United Kingdom*

Background:
Repetitive stereotyped behaviour is often described as a core symptom of autism spectrum disorder. There is, however, a disparity between how the scientific and broader autism communities view and describe these behaviours. Within the autism community, so-called repetitive behaviours are commonly described as "stimming", and are considered an important coping mechanism. Also, many self advocates describe autism as an important part of themselves and inseparable from the rest of them (just like gender or sexuality) and therefore, for some, stimming would be considered part of this identity. Yet many of these reports are anecdotal, which means we know very little of peoples' actual experience of stimming.
Objectives:
This research, conducted by an autistic self-advocate, sought to understand the experiences of stimming from people on the autism spectrum, specifically why the person feels that they stim, whether there are any benefits/pifalls, and whether they need additional support.
Methods:
100 participants, ranging in age from 16 to 65 years, completed a 10-item online survey anonymously. Of the 100 participants, the majority (75%) had a formal diagnosis of an autism spectrum condition, and the remaining were self diagnosed, in the process of obtaining a diagnosis or answering on behalf of their autistic children. Participants were largely female (66%). participants were asked a range of questions, including why they stimmed, what kind of stims they had, had they been asked not to stim, and if they had always stimmed.
Results:
Across participants, there were 11 types of commonly observed stims. The most commonly reported included rocking (48.94%), leg shaking (48.94%) and foot shaking (47.87%). In addition, people listed 73 other types of repetitive routine behaviours, compiled in Figure 1. Participants offered a wide

range of reasons for why they stim. The most commonly cited reasons were to reduce anxiety (71.88%), calm down (68.75%) and when overstimulated (57.29%). 80% of participants said they liked to stim generally or sometimes, 9% said they did not like to stim, and 11% said it depended on the stim.

Conclusions:

People on the autism spectrum have a wide range of reasons for stimming, many of which suggested that they viewed stimming as a coping mechanism. Future research should extend this research to researchers and professionals in order to examine potential differences between autism and researcher/practitioner communities. Such research could provide a stimulus for discussion of the value of such behaviours in the lives of people on the autism spectrum.

181   **110.181** Restrictive and Repetitive Behaviors in Young Children with Autism:

*M. Baker-Ericzen[1], **M. Kinnear**[1], M. Ballatore-Weinfeld[2], M. Fitch[1], S. Kanne[3] and M. O. Mazurek[3], (1)Child and Adolescent Services Research Center, Rady Children's Hospital, San Diego, San Diego, CA, (2)Autism Discovery Institute, Rady Children's Hospital, San Diego, San Diego, CA, (3)University of Missouri, Columbia, MO*

Background: Restricted and repetitive behaviors (RRB) comprise one of two core symptom domains in DSM-5 Autism Spectrum Disorder (ASD; American Psychiatric Association, 2013). RRBs reportedly decrease with age across the life span (e.g., Esbensen et al., 2009) but may develop or remain constant in young children with ASD (Harrop et al., 2014). Further, parents report their child's RRB differently than clinicians (Lemler, 2012). Additional research is necessary to characterize the nature of the relationship between age and RRBs in young children with ASD and by informant.

Objectives: To investigate (1) the relationship between RRBs and age in young children with ASD, and (2) correlations between parent and clinician ratings of RRBs.

Methods: Preliminary data are drawn from a comprehensive baseline assessment of an ongoing R01 study conducted in a community clinic parent training therapy program. Parents completed the Repetitive Behavior Scale- Revised (RBS-R; Lam & Aman, 2007) with six dimensions: stereotyped, self-injurious, compulsive behaviors, ritualistic, sameness and restricted interests plus a total score and demographic forms. The Autism Diagnostic Observation Schedule, 2nd edition (ADOS-2; Lord et al., 2012) and Ohio Autism Clinical Impression Scale (OACIS; Butter & Mulick 2006) were administrated by trained, research reliable project staff. This sample includes 45 children (80% male) ages 2-10 ($M = 4.7$ years; $SD = 2.4$), 31% Hispanic, 20% autistic disorder, 2% Asperger's, 16% pervasive developmental disorder, and 56% autism spectrum disorder (all cases validated by positive ADOS-2) and their primary caregivers. Regression analyses were conducted to examine child age associated with each outcome variable. Age groups were constructed: 2 yrs, 3-4 yrs and 5+ yrs; to compare RRBs by age and informant. Pearson correlation coefficients were used to examine relationships between the three measures for each age group.

Results: There was a significant positive relationship between age and both clinician rated scales and parent rated scale, total score on RBS-R, such that as age increases, scores on the RRB measures also increase (see Tables 1 & 2 for all results reported in this section). There was no correlation between any of the RBS-R subscales or total score with clinician rated measures for the overall sample indicating poor agreement of RRBs between parent and therapist. When comparing age categories, a few RBS-R subscales became correlated with clinician ratings. However, these results should be considered exploratory at this point due to the small n per group.

Conclusions: Findings suggest that age is associated with an increase in RRBs for young children with ASD. Overall, there were few reports of RRBs in toddlers compared to preschoolers and children. Additionally, there was poor agreement on RRBs between parent and trained clinical observer. This suggests that age and RRB likely have a unique relationship in early development, perhaps because RRBs are still emerging and may not be as apparent in the youngest age groups. The finding that parent report of RRBs does not correlate with clinician report of RRB also suggests that further research is needed to determine potential factors influencing this disparity.

182   **110.182** Sensory Processing Patterns in Dyads of Children with ASD and Their Parents

M. Glod[1], D. M. Riby[2], E. Honey[3] and J. Rodgers[1], (1)Institute of Neuroscience, Newcastle University, Newcastle, United Kingdom, (2)Department of Psychology, Durham University, Durham, United Kingdom, (3)School of Psychology, Newcastle University, Newcastle, United Kingdom*

Background: Sensory atypicalities are commonly reported in individuals with autism spectrum disorder (ASD) and their siblings (De La Marche et al., 2012; Leekam et al., 2007); and are included in the diagnostic criteria for ASD (APA, 2013). Heritability of sensory sensitivity has been shown in the general population (Goldsmith et al., 2006) however only one study has reported elevated levels of sensory atypicalities in parents of children and adolescents with ASD (Uljarevic et al., 2014). To date, the relationship between sensory atypicalities in dyads of children with ASD and their parents has not been investigated. Exploring the relationship between sensory processing difficulties in parents of children with ASD and their offspring is critical to understand how phenotypic profiles may be inherited within families.

Objectives: The aim was to explore the profile of sensory processing in child-parent dyads within ASD families.

Methods: Parents of 45 children with ASD, with and without learning disability (LD), aged between 3 and 15 years, and 31 parents of typically developing (TD) children aged between 4 and 13 years were recruited. Parents were asked to complete the Sensory Profile (SP; Dunn, 1999) to provide information about their children's sensory experiences and the Adolescent/Adult Sensory Profile (AASP; Brown & Dunn, 2002) to self-report their personal reactions to sensory events. They were also asked to complete the Social Responsiveness Scale (ASD families, SRS; Constantino & Grubber, 2005) or the Strengths and Difficulties Questionnaire (TD families, SDQ; Goodman, 1997).
Results: Children in both ASD groups (with and without LD) were reported by parents to show significantly more sensory atypicalities than their typically developing peers in all areas of sensory processing. 93.5% of parents of children with ASD reported themselves to have reactions to sensory events different from typical norms by at least 1SD in one or more sensory quadrants (Registration, Seeking, Sensitivity, and Avoiding). Significant group differences for the current cohort were found in the Sensitivity quadrant, where parents of children with ASD and LD had higher scores than parents of TD children ($F_{(2,73)}$=3.431, p=.038). There were no significant differences in any other sensory quadrant scores. Significant correlations were found in the TD dyads for Registration and Sensitivity scores (r=-.59, p<.001; r=-.45, p=.014 respectively). Intraclass Correlation Coefficient analysis (two-way mixed, consistency) did not show significant agreements for any sensory processing pattern between parent-child dyads in any subgroup.
Conclusions: This is a first study to investigate sensory processing atypicalities among parent-child dyads in ASD and TD families. The findings suggest that sensory processing patterns in parents of children with ASD and TD are similar and that there is a lack of association between parent-child scores in any of the sensory quadrants. These results have important theoretical and clinical implications. Familial factors are unlikely to play an important role in the development of the sensory difficulties for children with ASD. Further work is needed to explore genetic and environmental influences on developmental pathways of the sensory atypicalities in ASD.

183 **110.183** Sensory Processing Patterns, Activity Choice and Participation of Children with Autism Across Ireland

*R. Ferguson[1], **F. McCaffrey**[2], S. Cross[1], G. Kelly[3] and J. Casey[3], (1)Research & Development, Middletown Centre for Autism, Armagh, United Kingdom, (2)Research & Development, Middletown Centre for Autism, Armagh, Northern Ireland, (3)Life and Health Sciences, University of Ulster, Antrim, United Kingdom*

Background:
Participation in daily activities is fundamental to children's social, cognitive and physical development (Law et al., 2004). Many studies highlight that children and young people with autism participate less frequently in less diverse activities than children with other developmental disabilities and typically developing peers (Rodger and Umaibalan, 2011; Marquenie et al., 2011; LaVesser and Berg, 2011; Houchhauser and Engel-Yeger, 2010; Hilton et al., 2008),
Participation in all activities of daily living requires exposure to a plethora of sensory stimuli. Previous research suggests that the sensory preferences of children with autism are related to decreased participation in school, social, physical, leisure and family activities (Zingervich and LaVesser, 2009; Hochhauser and Engel, 2010; Bagby et al., 2012). However, these studies used small sample sizes and are limited by geographic location; no large scale research has investigated the impact of sensory preferences on activity choice and participation of children with autism in Ireland.
Objectives:
The purpose of this study was to determine the relationship between the sensory preferences of children with autism and the types of activity which they choose to participate in and to examine if the level of participation in these activities is affected by sensory preferences.
Methods:
Ethical approval was gained from the University of Ulster Ethical Filter Committee. A convenience sample of parents of children with autism were recruited from all over Ireland (N = 161) through Middletown Centre for Autism. Participants completed and returned two questionnaires, Participation and Environment Measure -Children and Youth (Coster et al., 2010) and the Sensory Profile (Dunn, 1999). All data were analysed using SPSS software (Version 21). Descriptive statistics were used to determine the type and frequency of participation in each activity and to identify the sensory characteristics of the population. Multiple regression was used to examine the extent to which sensory preferences and family demographics were related to the PEM-CY categories.
Results:
This study demonstrated significant relationships between sensory processing patterns and participation and engagement in activities. Multiple regression analysis revealed that having atypical responses to sensory stimuli accounted for a small (<20%) but significant (p<.05) amount of the variance in the frequency and intensity children with autism engaged in a range of activities.
Conclusions:
Results of this study contribute to current knowledge by suggesting that sensory preferences influence the frequency and level of engagement children with autism participate in a range of activities in the home, school and community environment.

184 **110.184** Sensory Response Patterns As Predictors of Adaptive Outcomes in Children with ASD or

Other Developmental Disabilities

L. R. Watson[1], G. T. Baranek[2], J. Sideris[3], J. C. Bulluck[4], A. V. Kirby[2] and K. Williams[2], (1)Division of Speech and Hearing Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Division of Occupational Science and Occupational Therapy, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Frank Porter Graham Child Development Institute, Chapel Hill, NC, (4)Department of Allied Health Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: Sensory response patterns of hyperresponsiveness, hyporesponsiveness, and sensory seeking are highly prevalent in children with autism spectrum disorder (ASD) (Baranek et al, 2006; Ben-Sasson et al., 2009; Wiggins et al, 2009). Among children with ASD and other developmental disabilities (DD), significant concurrent negative correlations have been found between hyporesponsiveness and social adaptive skills as measured by the Vineland Adaptive Behavior Scales (Watson et al., 2011). Hypothetically, disruptions of sensory processing impact the development of adaptive skills; longitudinal research on associations between early sensory patterns and later adaptive outcomes can provide support for this hypothesis.

Objectives: (1) to determine the predictive association between earlier sensory response patterns and later adaptive behavior outcomes among children with ASD and DD; (2) to determine whether these associations differ by group.

Methods: The study included 57 children with ASD and 34 with DD. At Time 1 (ages 2 – 12 years), two parent report measures (Sensory Experiences Questionnaire, Sensory Profile) and two observed measures (Sensory Processing Assessment, Tactile Defensiveness and Discrimination Test-Revised) were used. Adaptive outcomes were measured at Time 2 (3-5 years later) with the Vineland Adaptive Behavior Scales (VABS). Separate general linear models were run for the two parent report measures (combined) and the two observed measures (combined) to examine the predictive association between Time 1 hyporesponsiveness, hyperresponsiveness, and sensory seeking and Time 2 VABS Daily Living, Communication, Socialization and Adaptive Behavior Composite (ABC) scores. An interaction term for diagnosis (ASD/DD) and covariates (child's age, IQ, gender, time between assessments, mother's education and income) were included in each model.

Results: Parent-reported hyporesponsiveness and sensory seeking at Time 1 were significantly negatively related to VABS Communication, Socialization and ABC scores at Time 2 when accounting for all covariates. Behaviorally observed sensory response patterns at Time 1 did not predict Time 2 VABS scores. A significant interaction emerged between Time 1 observed hyperresponsiveness, diagnosis, and Time 2 VABS Socialization scores; for children with DD, as Time 1 hyperresponsiveness increased, Time 2 VABS Socialization scores decreased, whereas children with ASD showed the opposite linear trend.

Conclusions: The results suggest that earlier patterns of heightened sensory hyporesponsiveness and sensory seeking negatively impact later adaptive behavior outcomes, especially in the domains of communication and socialization skills, both for children with ASD and those with other DD. However, heightened sensory hyperresponsiveness at Time 1 is only associated with poorer adaptive outcomes for children with other DD. The finding that only parent-reported measures, but not observational measures, of sensory response patterns predicted adaptive outcomes in most models supports the importance of involving parents in the assessment process, in order to get more complete information on an array of sensory responses that may be difficult to fully elicit and observe in a clinical setting.

185   **110.185** Stability of Sensory Subtype One Year Following Diagnosis of Autism Spectrum Disorder

A. E. Lane and K. Philpott-Robinson, University of Newcastle, Callaghan, Australia

Background:
Distinct patterns of sensory features, known as sensory subtypes, have been identified in children with Autism Spectrum Disorder (ASD; Ausderau et al, 2014; Lane et al, 2014). Both studies - conducted independently and using different measurement tools - conclude that sensory features in ASD vary based on the severity of parent-reported symptoms, the nature of the sensory response and the sensory modalities affected. Taken together, the findings of these studies suggest that sensory subtypes may provide a profitable method of identifying clinically meaningful ASD phenotypes. The stability over time of classifications made on the basis of sensory subtype, however, has only been examined in a longitudinal design in a single cohort of individuals with ASD who were at varying points along their care pathways (Ausderau et al, 2014). While this study found that subtype membership was stable over time, previous cross-sectional research has suggested that sensory symptoms tend to become less severe with age. Further longitudinal analysis of change in sensory symptoms is warranted particularly as it relates to participation in therapy. Sensory features are a primary target for autism-specific interventions and, therefore, may be expected to vary in presentation as a function of length of time in therapy.

Objectives:
The purpose of this study was to examine the stability of sensory subtype classification one year immediately following ASD diagnosis. We hypothesized that in one-year following diagnosis, sensory symptoms would be less severe than that reported at diagnosis.

Methods:
Participants (n=62) were children aged 2-10 years presenting to a major, Midwestern autism specialist center for diagnostic assessment between 2008 and 2010. All participants were

administered the Short Sensory Profile (SSP) at diagnosis. This tool assesses parent-report of sensory symptoms from which sensory subtypes can be derived (Lane et al, 2014). One year following diagnosis, the SSP was re-administered. Participants were assigned to one of four sensory subtypes at each assessment point: 1) Sensory Adaptive, 2) Taste Smell Sensitive, 3) Postural Inattentive, or 4) Generalized Sensory Difference. A further classification of sensory symptom severity was made. Specifically, 'mild' severity comprised members of Sensory Adaptive; 'moderate' severity comprised members of Taste Smell Sensitive and Postural Inattentive; and 'severe' severity comprised members of Generalised Sensory Difference. We assessed the agreement in classification of sensory subtype and sensory severity between diagnosis and one-year follow-up using the Kappa statistic with 95% confidence intervals.

Results:
There was little evidence of change in sensory subtype classification from diagnosis to one-year follow-up (65% of participants remained in the same subtype; Kappa = 0.51, 95% CI: 0.34, 0.67). Further, most participants did not change sensory severity classification from diagnosis to one-year follow up (74% of participants remained in the same severity category; weighted Kappa = 0.52, 95% CI: 0.32, 0.72).

Conclusions:
The findings of this study suggest that sensory subtype as measured by parent-report is stable one-year following diagnosis. We did not observe significant abatement in sensory symptom severity in this timeframe.

186 **110.186** Stress Regulation in Children with Autism Spectrum Disorders (ASD): A Scoping Review

M. A. Braeken[1], *L. Van Schuerbeeck*[1], *J. Steyaert*[2] *and M. Vanvuchelen*[3], (1)Hasselt University, Diepenbeek, Belgium, (2)Leuven Autism Research (LAuRes), University of Leuven (KU Leuven), Leuven, Belgium, (3)Hasselt University Faculty of Medicine and Life Sciences, Diepenbeek, Belgium

Background:
Autism spectrum disorders (ASD) are characterized by difficulties with social interaction and communication. In addition, individuals with ASD tend to have limited interests and repetitive behaviors, which is often reflected in having trouble adapting to changes in routine or environment. The major neuroendocrine system that modulates our ability to react emotionally and physiologically to change and to the stress caused by a novel or challenging environment, is the hypothalamic-pituitary-adrenal (HPA) axis.

Objectives:
The present review aims to investigate the responses of cortisol, a neurobiological stress hormone reflecting HPA axis activity, in children with ASD.

Methods:
The review is organized around four main themes: the cortisol awakening response (CAR), diurnal cortisol variation, cortisol responses to stress and interventions affecting cortisol levels in children with ASD.

Results:
Our analysis of the literature shows strong indications that cortisol levels in children with ASD follow the same pattern as in children without ASD. This means that, similar to typical developing (TD) peers, children with ASD have a diurnal decrease in cortisol, with higher cortisol concentration in the morning than in the evening. Some studies found no differences in the overall level of cortisol in children with ASD compared to children without ASD, while others reported significant higher cortisol levels in children with ASD during the evening or the whole day.

Studies on the evaluation of the CAR in children with ASD are inconsistent. Some suggest that the CAR is mostly absent, while other studies indicate that are no differences in the magnitude, variability or presence of the CAR when compared to typically developing peers.

While children without ASD tend to show an increase in cortisol in response to the child version of the Trier Social Stress Test (TSST-C), children with ASD have been reported to display a reduced cortisol response. There also exists evidence that a playground social stressor or interactions with unfamiliar peers may provoke significantly higher activation when compared to TD children.

Furthermore, children with ASD and TD children potentially also differ in recovery from a social stress environment, as typical developing children showed a significant reduction in cortisol over time, whereas children with ASD maintained an elevated cortisol level. Nonsocial stimuli such as placement in a mock MRI or a blood draw stressor are associated with significantly greater reactivity of the HPA axis in children with ASD as compared to children without ASD.

Physical exercise and relaxation sessions tend to deliver a short-term reduction in levels of cortisol in children with ASD, but long-term significant reductions have not been found. Theatre-based and peer-mediated intervention programs have proven to yield a decline in cortisol by the end of treatment, but also during post-treatment situations.

Conclusions:
This analysis of the literature shows that altered stress regulation and HPA axis activity as measured by cortisol concentrations could form a promising biomarker for ASD, but more research is needed if we would like to understand the complex relationship between stress regulation and ASD.

187 **110.187** The Hardness of Standing Support Surfaces Influences Tip-Toe Behavior of Autistic Children: Evidence from a Pilot Study

*G. Valagussa, V. Balatti, L. Trentin, V. Terruzzi and **E. Grossi**, Autism Unit, Villa Santa Maria Institute, Tavernerio, Italy*

Background: As demonstrated in a previous study, 32% of autistic children observed in our Institute walk on their tiptoes (tiptoe behavior-TTB). TTB may occur in three modalities: class 1(TTB in standing, walking and running); class 2 (TTB in walking and running) and class 3 (TTB only during running). Thus far, the literature has yet to publish a standardized clinical method of assessment to "quantify" TTB during standing or walking.

Objectives: The aims of this pilot study are: 1) to propose a protocol to quantify TTB and 2) to assess whether the hardness of standing support surfaces influences motor behavior in children with ASD

Methods: Seven autistic children with TTB (6 males), age range from 7.1 to 16.4 years diagnosed according to the criteria of DSM V were admitted to this study. All subjects presented an ankle dorsiflexion range of motion wider than 90°. Video recordings were taken during a static task (playing in front of a playing table for 3 minutes) and during a dynamic task (transporting an object from the playing table to a therapist situated 2 meters away and back again for 15 times) over a hard floor surface. Each task was repeated on three different days. The three repeats were repeated again on a soft floor surface (foam mat). An independent therapist not involved in tests operation assessed the videos of the static task trials by calculating the time spent on full foot support versus on tiptoes. The videos of the dynamic task trials count the number of times the child was able to walk the full length with all steps on full foot support versus toe walking.

Results: On the hard floor surface, during the static tests, the subjects stayed on tiptoes for an average of 45.5/180 sec. During the dynamic tests the children toe walked an average of 23.6/30 times of the measured lengths. On the soft floor surface, during the static trials, the children used tip toe posture for an average of 24.6/180 sec. Meanwhile, during the dynamic trials they tiptoed an average of 11.2/30 times of the measured lengths. The p value of the differences were 0.11 for static tests and 0.008 for dynamic tests. The repeat observation values were consistent and reproducible.

Conclusions: The proposed evaluation protocol seems to be a useful tool to monitor TTB behavior. Footing on soft surfaces induces an increase in the time spent on non TTB during static and dynamic tasks. This finding suggests that TW is a reflection of a sensory integration dysfunction or of a vestibular derangement. Further evaluation is needed to clarify the potential pathophysiological implications of this phenomenon.

188   **110.188** The Relation Between Restrictive and Repetitive Behaviors and Family Routine Among Families of Children with Autism

S. A. Fox[1], C. Tam[2], K. V. Christodulu[3], M. L. Rinaldi[4] and A. C. Israel[2], (1)Clinical Psychology, University at Albany, State University of New York, Albany, NY, (2)University at Albany, State University of New York, Albany, NY, (3)Center for Autism and Related Disabilities, University at Albany, SUNY, Albany, NY, (4)University at Albany, SUNY, Albany, NY

Background:

Interventions aimed to benefit children with autism spectrum disorder (ASD) often emphasize the importance of implementing structure in the home environment (Wetherby & Woods, 2006). These interventions seek to increase predictability for children, thus reducing the potential for anxiety and ensuing challenging behaviors (Vismara & Rogers, 2010). While numerous studies have cited the benefits of routine implementation, little literature has examined the relation between specific characteristics of ASD and family routine (DeGrace, 2004; Schaaf, 2011). Of specific interest is the presence of insistence on sameness and ritualistic behaviors, which are categories of behaviors within the broad core characteristic of restrictive interests and repetitive behaviors (RRBs). Individuals with ASD who exhibit ritualistic behaviors and insistence on sameness seek to maintain rigid and highly routinized environments; however it remains unclear whether these behaviors are related to family structure and routine. The examination of this relation would help to shed light on when and for whom the implementation of family routine is likely to be most beneficial.

Objectives:

The present study sought to examine the relation between restrictive and repetitive behaviors (RRBs) among children with autism and the level of family routine implemented by their parents.

Methods:

Parent responses to the Repetitive Behavior Scale (RBS; Lam & Aman, 2007) were used to assess insistence on sameness and ritualistic behaviors and the Stability of Activities in the Family Environment (SAFE; Israel & Roderick, 2001) to assess family routine among a sample of parents of children with autism. The SAFE specifically measures the regularity of family activities and routines that occur both in the home (e.g. family meals), as well as family supported activities that occur outside the home or without family members. A rating of the overall regularity of routines and activities in the child's household was used to operationalize family routine for the purposes of the current study. A link to the survey was disseminated via e-mail to parents throughout New York State who were subscribed to a university autism center's mailing list. Additionally, a link was posted on the center's website and in a parent organization's newsletter. Data from 68 parents who completed the online survey were compiled and entered into a database for statistical analysis. A multiple linear regression was run to evaluate the predictability of child RRBs for family routine.

Results:

Multiple regression revealed that child insistence on sameness and ritualistic behaviors significantly

predicted family routine, $F(1,66)=5.597$, $p=.021$. The two predictor model accounted for eight percent of the variance in parent report of overall family routine.
Conclusions:
Results suggest that RRBs are significantly predictive of family routine. This finding may indicate that families of children with autism accommodate their children's symptoms of rigidity by adhering to routines in the home. Future longitudinal studies should be conducted to evaluate the directional nature of the relation, thus disentangling whether parental accommodation to child rigidity may reduce child flexibility over time.

189 **110.189** Toe Walking and Autism: Cross-Sectional Study on Presentation Patterns and Correlation with Autism Severity

G. Valagussa, V. Balatti, L. Trentin, S. Melli, M. Norsi and **E. Grossi**, *Autism Unit, Villa Santa Maria Institute, Tavernerio, Italy*

Background: According to the literature, about twenty per cent of individuals with autism walk on their tiptoes. "Toe walking" (TW) may present different functional patterns but thus far, there is no standardized clinical method of examination or assessment. Some authors describe TW as intermittent or persistent , while others grade TW by history and observation (e. g. absent, present in the past, intermittently present, and persistent). Moreover, it seems that the persistence of toe walking can be related to language impairment even if systematic observations in the literature are scarce.
Objectives: The aims of this cross-sectional study are: 1) to assess the prevalence of toe walking in an ASD cohort; 2) to describe the functional patterns of presentation of TW; 3) to evaluate the relationship between TW presentation patterns and the severity of autism with particular regard to language delay.
Methods: The study includes sixty nine consecutive children (56 males; 13 females; mean age = 12,4 years) diagnosed with Autism according to the DSM V criteria and under observation at our institute. A therapist assessed the presence of Tiptoe behavior(TTB) during standing, walking and running using direct observation and interview of the main caregiver living with the children. The severity of autism was established through ADOS (2^{nd}version)
Results: Overall: 22 children (31,88%) presented TTB. Ten children (14,49%) exhibited it while standing, walking and running (class 1), four (5,79%) only during walking and running (class 2) and eight children (11,59%) only during running (class 3). The overall ADOS mean score of all the children was 21.14 (7.93 SD). The ADOS mean score of non TTB children was 20.09 (7.66) vs a value of 23.41 (8.5 SD) in TTB children. There were no significant differences in the mean overall ADOS score of the TTB children according to the three TTB classes 24.9 (9.0 SD), class1 vs 20.25 (7.5 SD), class 2 and vs 23.13 (8.38 SD), class3. We divided the children in four groups, depending on the level of the language, according to the ADOS system: fluent language, able to produce simple sentences, able to produce single words, absence of any language(nonverbal). 44.6% per cent of non TTB children and 72.7% of TTB children were nonverbal (p<0.05). However, language delay severity was not correlated to the severity of TTB.
Conclusions: TTB frequently manifests itself in individuals with Autism. It may occur in three mutually exclusive modalities, which include what is commonly defined toe walking. The presence of TTB is not correlated to autism severity but rather to language delay.

1:45 **112.001** A Randomized Wait-List Control Trial of a Peer-Mediated, Theatre-Based Intervention to Improve Social Ability in Children with Autism Spectrum Disorder

B. A. Corbett[1], A. P. F. Key[1], S. M. Fecteau[2], C. R. Newsom[3], L. R. Qualls[4], P. J. Yoder[5], E. K. Edmiston[6], D. D. Jones[7] and B. D. Valencia[1], (1)Vanderbilt University, Nashville, TN, (2)Psychoeducation and psychology, Université du Québec en Outaouais, Gatineau, QC, Canada, (3)Pediatrics, Psychiatry, & Psychology, Vanderbilt University Medical Center, Nashville, TN, (4)Psychiatry, Vanderbilt University, Nashville, TN, (5)Special Education, Vanderbilt University, Nashville, TN, (6)Vanderbilt Brain Institute, Vanderbilt University, Nashville, TN, (7)Vanderbilt Kennedy Center Psychophysiology Services, Vanderbilt University, Nashville, TN

Background: Four interacting levels have been proposed involving the social brain, cognition, behavior, and functioning to explain variance in social ability. Impairment in social ability is central to autism spectrum disorder (ASD); therefore, treatments developed to improve social skills should aim to assess, treat and measure change across these levels. In the current intervention study, event related potentials (ERP) were used to measure brain activity, a neuropsychological task (NEPSY) measured cognition, direct group play observation measured behavior, and questionnaires measured social functioning to examine the complex construct of 'social ability'.
Objectives: The purpose of the study was to evaluate and extend the impact of a peer-mediated, theatre-based intervention on children with ASD with an emphasis on social functioning. The 10-session program incorporates theatrical approaches, trained typically developing peers and established behavioral strategies. Previous studies using pre-post designs have reported improvement in several skills, such as face memory, theory of mind and social cognition. A primary objective of this investigation was to utilize a true experimental design while evaluating social ability across multiple levels of analysis including neuropsychological, cognitive, behavioral, and functional outcomes.
Methods: Participants included 30 youth with ASD between 8 to 16 years randomly assigned to the Experimental treatment group (EXP, N = 17) and Wait-list control group (WLC, N = 13). Measures included ERP (incidental memory), cognitive (memory for faces immediate and delayed), behavioral (group play) and functional (Social Responsiveness Scale, SRS) conducted before and after treatment and at a two-month follow-up. An Analysis of Covariance (ANCOVA) model was used in which the post-intervention score served as the outcome variable, group (experimental or waitlist control) as a main independent variable, and baseline (pre-intervention) score as a covariate.
Results: Significant differences were observed between the EXP and the WLC groups on memory for faces immediate (MFI) $F_{(2,28)} = 4.02$, $p = 0.05$ and memory for faces delayed; MFD) $F_{(2,28)} = 6.01$, $p = 0.02$. Moreover, significant differences were observed on an incidental memory ERP task in which the EXP group showed increased parietal response to repeated faces, which was not observed in the WLC group $F_{(8,122)} = 2.63$, $p=.01$. Differences were also observed in group play behavior $F_{(2,28)}$, 4.35, $p = 0.04$. Regarding social functioning, significant differences were observed on the SRS (e.g., Social Communication $F_{(2,28)}$ 5.37, $p = 0.03$), and gains were maintained at follow-up.
Conclusions: The study replicates and extends previous findings showing that the theatre-based intervention contributes to improvement in core areas of social ability for youth with ASD. In particular, gains in memory for faces and social interaction skills have been consistently demonstrated supporting the strong link between social cognition and behavior and how improvement in one level of processing can result in gains on another. The findings suggest that the intervention results in increased salience for social information even in the absence of explicit instruction. The importance of peer-mediation, reciprocal social engagement and active practice of socialization are discussed within the context of the findings.

1:57 **112.002** Students' Evaluation of an Autism Peer Education Program: Initial Impressions of the KIT for Kids

K. A. Scheil[1], J. Campbell[2], J. Bowers-Campbell[3], M. C. Davis[4], E. Caldwell[4] and R. Jacob[4], (1)Psychology, University of Kentucky, Lexington, KY, (2)Department of Educational, School, and Counseling Psychology, University of Kentucky, Lexington, KY, (3)Georgetown College, Georgetown, KY, (4)University of Kentucky, Lexington, KY

Background: The prevalence of autism spectrum disorders (ASD) is roughly 1 in 68 children. The increased identification of students with ASD has implications for public education as access to general education and instruction in the least restrictive environment are legal rights. Recent reports indicate that approximately 30-40% of elementary and middle school students with autism receive at least some of their instruction in general education settings. As such, students with ASD and typically developing peers will likely encounter each other during school hours. The practice of inclusive education for students with ASD is based upon protecting children's educational rights and, in part, improving social acceptance. Despite the potential social benefits of inclusion, inclusive education has yet to yield robust and consistent improvements in attitudes, social acceptance and social status for students with ASD. The Kit for Kids (KfK) was developed by the Organization for Autism Research (OAR; see attached Figure) in order to provide evidence-based educational messages to elementary and middle school students to improve peers' knowledge, initial attitudes, and behavior towards students with ASD.
Objectives: Investigators documented elementary and middle school students' initial impressions of

the KfK materials using a (a) 5-point rating scale and (b) semi-structured interviews. The overall goal of the research was to conduct an initial evaluation of the materials, particularly students' reactions to the materials and suggestions for improving peer education efforts on behalf of students with ASD. Methods: Researchers delivered the KfK program to five classrooms, two 8th grade classrooms and three 5[th]grade classrooms. One week later, 15 students, three per classroom, were randomly selected to complete (a) ratings of the materials and (b) semi-structured interviews about their impressions of the materials. Students rated the (a) information presented, (b) booklet, and (c) poster on a 5-point scale ["Excellent" (5) to "Poor" (1)]. Responses to the interviews were audio recorded, transcribed, and coded according to grounded theory.
Results: All selected students consented to take part in the project. Participant ages ranged from 10-15 years (M = 12.2 years; SD = 1.5). Participants rated the information (M = 4.53; SD = 0.64), booklet (M = 4.53; SD = 0.64), and poster (M = 4.53; SD= 0.64) favorably, with average ratings falling between the "Good" to "Excellent" range. Student responses were organized into nine familial codes that reflected students' impressions of the messages and quality of the materials. Students recalled specific details from the presentation regarding: sensory symptoms associated with ASD, a need to understand students with autism to change their behavior to support them in the classroom, and understand services delivered within the educational environment to support students with ASD.
Conclusions: Peers responded favorably to OAR's KfK materials. Interviews revealed that students recalled various aspects of the materials, particularly the need to better understand students with ASD to modify their own behavior to support their inclusion. Students recommended supplementing the presentation with guest speakers, video examples, and hands on activities to better understand autism.

2:09 **112.003** Randomized Controlled Trial of the Classroom Scerts Intervention Project for Students with ASD

__L. Morgan__[1], V. P. Reinhardt[1], N. Sparapani[2], C. Schatschneider[3] and A. M. Wetherby[1], (1)Florida State University Autism Institute, Tallahassee, FL, (2)Arizona State University, Phoenix, AZ, (3)Florida State University, Tallahassee, FL

Background: Current prevalence studies estimate that 1 in 68 children in the US is diagnosed with Autism Spectrum Disorder (ASD; CDC, 2014). The significant challenge and expense for schools to effectively educate this population makes the need for comprehensive, evidence-based interventions for students with ASD a priority. The Classroom SCERTS Intervention Project (CSI) is a classroom-based intervention using a cost-effective approach to achieve intensity of active engagement for young elementary students with ASD by training educators to implement SCERTS across the school day.
Objectives: The primary objective of this randomized controlled trial was to evaluate the efficacy of CSI for children with ASD in kindergarten through 2nd grade classrooms. A total of 235 students with ASD in 140 classrooms nested within 64 schools participated in the study. The two treatment conditions were as follows: 1) CSI was provided with access to a 3-day SCERTS training and ongoing coaching during the school year; and 2) Autism Education Training (AET) was provided with access to a series of web-based training resources for educators.
Methods: A stratfied randomized design was used wherein school pairs were matched on demographic variables (e.g., race, % free and reduced lunch, number of students) and randomly assigned to either CSI or AET for a 9-month school year. Effectiveness of CSI and AET was compared using direct observation of student active engagement. The Classroom Measure of Active Engagement (CMAE; Wetherby, Morgan, & Sparapani, 2014) is a multicomponent observational tool designed to measure active engagement in students with ASD. In addition, both conditions were compared using teacher report measures (SSRS, BRIEF), parent report of adaptive behavior (Vineland), and standardized measures of language.
Results: Baseline comparisons indicated equivalency of groups on all measures with one exception on the CMAE (Productivity). After 9 months, students in CSI made significantly greater gains than students in AET on two components of active engagement: (timeXcondition) productivity, F (1, 135)=4.32, p=0.042, and gaze to face, F (1,101)=7.19, p=0.009. On the SSRS, students in CSI made significantly greater improvement than AET on social skills, F (1,143)=12.38, p=0.001, and the problem behavior scale, F (1,143)=11.32, p=0.001. On the BRIEF, students in CSI also made significantly greater gains than AET on the initiate subscale, F (1,145)=6.59, p=0.011, the organization of materials subscale, F (1,145)=7.19, p=0.008, and the global executive functioning subscale, F (1,145)=7.52, p=0.007. On the Vineland, Students in CSI made significantly greater gains than AET on the communication subscale, F (1,116)=5.47, p=0.002, and on the Adaptive Behavior Composite, F (1,116)=4.07, p=0.046. Finally, students in both conditions showed significant improvement on standardized measures of receptive (PPVT) and expressive vocabulary (EOWPVT). These analyses are preliminary as we will use more sophisticated procedures (HLM) to confirm findings.
Conclusions: These findings support the effectiveness of CSI, classroom-based intervention with potential to be cost-effective. CSI demonstrated significantly greater efficacy than AET on measures of active engagement, social skills, executive functioning, and adaptive behavior. These findings are important given the dearth of evidence on comprehensive interventions for students with ASD in educational settings.

2:21   **112.004** Social Validation of Evidence-Based Practices in Autism: Investigating the Evidence of Social Validity for Empirically-Demonstrated Treatments Identified By the National Autism Center and National Professional Development Center on ASD

K. Callahan[1], H. L. Hughes[1], S. Mehta[2], S. M. Nichols[1], H. T. Wang[3] and M. Kutlu[4], (1)Kristin Farmer Autism Center, University of North Texas, Denton, TX, (2)Educational Psychology, University of North Texas, Denton, TX, (3)Special Education, National Taiwan Normal University, Taipei, Taiwan, (4)Special Education, Anadolu University, Eskisehir, Turkey

Background:
Empirically-demonstrated autism treatments considered to be "established" and "confirmed" as evidence-based practices (EBPs) have been identified by the National Autism Center (NAC) and National Professional Development Center on ASD (NPDC). An important factor in the effective and widespread use of these interventions is social validity, generally defined as consumer satisfaction with the goals, procedures, and outcomes of programs and interventions. The extent to which EBPs are socially validated by service providers plays a significant role in whether or not those treatments are adopted and implemented. Without evidence of social validity for empirically-demonstrated autism interventions, there is less chance these treatments will be used effectively in schools, clinics, and homes. Thus, social validity should be a consideration in the selection and effective use of EBPs.
Objectives:
The purpose of this study was to investigate the extent to which EBPs identified by the NAC and NPDC demonstrate evidence of social validation, and to determine the types of social validity used by researchers to provide evidence of social validation.
Methods:
Two separate analyses were conducted. First, researchers compared the correspondence of NAC and NPDC EBPs with 60 autism interventions previously determined to have social validity, as defined as perceived value for their use within a comprehensive autism treatment program (Callahan et al., 2008, 2010). This process resulted in 31 socially valid intervention components determined to align directly with one or more NAC/NPDC evidence-based practices. These interventions were validated by experts in the field of autism treatment to ensure that the socially validated treatments represented the same interventions as reported in the NAC/NPDC studies, with an overall agreement of 99.6%. Next, researchers analyzed all 942 articles cited by the NAC and NPDC studies for the 31 interventions to determine: (a) if the articles contained direct evidence of social validity, and (b) to identify which of seven categories of social validation (Reichow et al., 2011) were included by the authors. Inter-rater reliability ratings were conducted on 21.3% of the articles regarding the presence of social validation evidence, with an overall agreement of 97.4% across all EBPs. Assignment of evidence into social validity categories had an overall agreement of 88.4%.
Results:
Across all EBPs, 24.2% of the articles cited by the NAC and NPDC reported social validity. While all 31 EBPs had evidence of social validation, the results were variable, ranging from only 2.3% of articles for the use of "Extinction" to 60.5% for "Pictorial Story Board Simulations/Social Stories". The categories of "Consumers satisfied with results," "Clinically significant behavioral change," and "Socially important dependent variables" were the most frequently reported social validity indicators. Relatively few researchers addressed the time- and cost-effectiveness of interventions and the settings/service providers associated with the implementation of EBPs.
Conclusions:
The relatively low rates of reported social validity for autism EBPs, especially within behavioral journals, underscores the need for additional research about how best to define, conceptualize, measure, and report social validation in autism efficacy research. Such efforts will significantly improve the effectiveness of applied interventions and outcomes in autism.

Oral Session
113 - Interventions for Adults with ASD
2:40 PM - 3:30 PM - Grand Ballroom B

Session Chair: Nirit Bauminger-Zviely, *Bar-Ilan University, Ramat Gan, Israel*

2:40   **113.001** Designing and Evaluating a Summer Transition Program for Incoming College Students on the Autism Spectrum: A Participatory Action Approach

C. Shane-Simpson[1,2], E. R. Hotez[3], J. T. Pickens[1], M. Giannola[4], A. Donachie[5], J. D'Onofrio[6], A. Alvizurez[7] and K. Gillespie-Lynch[8,9], (1)Psychology, The Graduate Center at the City University of New York, New York, NY, (2)Psychology, College of Staten Island, Staten Island, NY, (3)Psychology, The Graduate Center at the City University of New York/Hunter College, New York, NY, (4)Psychology, The College of Staten Island, New York, NY, (5)College of Staten Island, Staten Island, NY, (6)Center for Student Accessibility, College of Staten Island, New York, NY, (7)Psychology, College of Staten Island, New York, NY, (8)Department of Psychology, College of Staten Island - CUNY, Staten Island, NY, (9)Department of Psychology, The Graduate Center - CUNY, New York, NY

Background: College students with autism may face unique challenges adjusting to college life, including difficulties with socialization, self-advocacy, and anxiety (Adreon & Proctor, 2010; Van Bergeijk et al., 2008). While transition planning is a priority (Interagency Autism Coordinating Committee, 2012), a recent review identified only 20 studies conducted with 69 autistic college students (Gelbar et al., 2014). This study utilized a participatory-action design to evaluate a week-long summer transition program for incoming college students with autism.

Objectives:
1. Identify self-reported needs and characteristics of college students with autism;
2. Evaluate a program designed to improve social skills, self-advocacy, technology skills, and classroom readiness.

Methods: Curriculum was adapted from our peer-mentorship program by incorporating written and focus group recommendations from previous mentors and mentees with ASD. Sessions were partially facilitated by previous mentors/mentees. Twelve autistic students enrolled in the program. Eleven students self-identified and/or were classified as autistic on IEP's. One student exhibited heightened autistic traits (SRS-2 of 92), but did not identify as autistic. Participants consisted of nine freshmen, one returning freshman who was gifted but whose behaviors made it unlikely that he could continue college without supports, and two sophomores with social difficulties (not considered transitioning in analyses). Pre-tests/post-tests assessed autistic traits (SRS-2; Constantino & Gruber, 2012), anxiety (Spielberger et al., 1983), self-esteem (Rosenberg, 1965), autism knowledge (Stone, 1987), disability identity (Darling, & Heckert, 2010), academic self-efficacy (Baker & Siryk, 1987), stigma (Bogardus, 1933), and included interviews assessing knowledge and recommendations. Nonverbal intelligence was assessed with the Test of Nonverbal Intelligence (Brown et al., 1997).

Results: During pre-program testing, students expressed interest in developing social skills (n=9). When asked to define self-advocacy, most could not (n=8), others thought it was standing up for yourself (n=4) or for others (n=1). Students reported varied technology needs ranging from help printing to programming and a variety of academic areas they needed help developing. Although participants' intelligences ranged from the 2nd to 90th percentile, intelligence was unrelated to baseline measures. However, Pearson's correlations (after ascertaining normality of data) revealed that autistic symptoms were positively correlated with anxiety (p=.002) and negatively with self-esteem (p=.04), self-efficacy (p=.045), and autism knowledge (p=.014). Thus, programming focused on core difficulties may be beneficial for autistic students with varied cognitive skills.

T-tests revealed decreased anxiety (p=.043), a trend towards decreased symptoms (p=.059), and increases in disability pride (p<.001), perceived exclusion (p=.033) and medical model orientations from pre- to post-test (p=.011). The same patterns were observed with only the transitioning students except that symptoms decreased (p=.028) and anxiety did not (p=.069). Students also reported learning how to self-advocate and gaining social support.

Conclusions: While improvements in autistic symptoms, anxiety, and disability pride suggest that transition programming may help incoming students with autism, increases in perceived exclusion suggest that programs should include peers with varied disabilities. Future programs should be guided by the interests/needs of autistic individuals and incorporate principles of universal design.

2:52 **113.002** Nonsymbolic Augmentative Communication for Minimally Verbal Adults with ASD and Severe Intellectual Disability: An Intervention Study

J. P. W. Maljaars[1] *and I. Noens*[2]*, (1)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (2)Leuven Autism Research (LAuRes), Leuven, Belgium*

Background: Communication is indispensable for human beings. Individuals with ASD and co-occurring intellectual disability (ID) form a particularly vulnerable group as often no verbal or other symbolic communication is present. Using symbolic communication strategies for someone who is unable to understand the meaning of symbols may lead to high levels of dependence, frustration, or challenging behavior. Nonverbal individuals are dependent on other communication strategies, such as augmentative and alternative communication (AAC). For individuals with ASD and severe to profound ID the common AAC systems are not applicable, because these typically assume symbolic understanding.

Objectives: Based on a repeated single case design using multiple dependent measures, this study aims to evaluate the effectiveness of individualized nonsymbolic augmentative communication strategies for adults with ASD and ID on individual outcome variables: level of independence, mood, and challenging behavior in daily life.

Methods: Nine participants were recruited from four residential services for adults with ID. Inclusion criteria were: (1) a clinical ASD diagnosis and an ASD classification on a screening questionnaire for ASD in individuals with ID (AVZ-R), (2) a level of severe ID (at least -4 *SD* scores or a developmental age < 48 months on the Vineland), and (3) a nonsymbolic level of sense-making based on the ComFor, an instrument for the indication of augmentative communication (Verpoorten et al., 2008). Based on the ComFor and video observation, an individualized intervention plan for augmentative communication was designed for one activity. Transitions between activities, different steps or choices within the activity were communicated by recognizable sensations, presenting functional objects or by assembling or matching methods. The single case designs comprised a baseline measurement phase (1-2 weeks) and an intervention phase (1-4 months). The dependent variables, level of independence, mood, and challenging behavior, were measured daily based on an observation form (diary card) for caregivers. A monthly video-taped situation will be coded by an

independent observer to measure inter-rater reliability for all three dependent variables and to code treatment fidelity.

Results: Single case results may be interpreted with the use of two different approaches: visual inspection and statistical analysis. To analyze the data, we used hierarchical linear models, a method for repeated single case designs. For level of independence, all participants showed progression during the intervention phases. The statistical results were significant for seven adults ($p < .05$). Mood improved significantly ($n = 6$, $p < .05$), remained stable ($n = 2$), or showed an unstable pattern during both baseline and intervention ($n = 1$). Four participants did not show challenging behavior during this activity; a significant decrease in challenging behavior (e.g., self-injurious behavior) was present in another four participants.

Conclusions: For all participants, improvement on one or more outcome measures was seen during the activity after individualized nonsymbolic augmentative communication was implemented. However, only a small number of participants were included in this study and a quasi-experimental AB-design was used. Possible influencing factors and suggestions for further research will be discussed.

3:04 **113.003** Examining PEERS® for Young Adults: Improvements in Social Responsiveness and Depression and Relations to EEG Activity

B. Dolan[1], K. A. Schohl[1], A. J. McVey[1], S. Stevens[1], K. Reiter[1], S. Potts[1], N. Gordon[1] and A. V. Van Hecke[2], (1)Marquette University, Milwaukee, WI, (2)Psychology, Marquette University, Milwaukee, WI

Background: Social skills deficits among individuals with ASD lead to isolation and lack of friendships. For adults with ASD, poor social skills translate to under- or unemployment and dissatisfying social relationships (Venter, Lord, & Schopler, 1992). The latter is particularly concerning given the high rates of comorbid depression and withdrawal that exist within the ASD population (Stewart, Barnard, Pearson, Hasan, & O'Brien, 2006). The *Program for the Education and Enrichment of Relational Skills for Young Adults* (Gantman, Kapp, Orenski, & Laugeson, 2012) is an empirically based, manualized, caregiver-assisted treatment program designed to teach motivated young adults with high-functioning ASD the social skills needed in order to make and keep friends.

Objectives: There are no published studies that have replicated PEERS for Young Adults outside of its site of development, and no studies that have evaluated effects on brain function. Thus, this study seeks to be an independent replication of PEERS for Young Adults in order to evaluate the effectiveness of the program for improving social skills and decreasing depression, and how the intervention affects measures of brain function related to emotion: EEG asymmetry and ERP responses to emotional face and non-face stimuli.

Methods: The analysis included 27 young adults (18 to 26 years old) with ASD. All participants had a verbal IQ > 70 and diagnoses were confirmed with the ADOS. The intervention was the 16-session PEERS for Young Adults. Measures were taken at pre- and post-intervention and included: (1) the *Social and Emotional Loneliness Scale for Adults* (SELSA: DiTommaso & Spinner, 1993); (2) the *Social Responsiveness Scale* (caregiver report; SRS: Constantino, 2005); (3) the *Beck Depression Inventory* (BDI: Beck, 1987); and (4) a 3-minute continuous, resting state EEG recording and an ERP paradigm including positive and negative social/nonsocial IAPS (International Affective Picture System: Lang, Bradley, & Cuthbert, 2008) images.

Results: For the experimental group, young adults' caregivers at post-treatment reported improvements in social awareness (Wilks' Lambda = .71, $F(1, 25) = 10.07$, $p < .05$), social communication (Wilks' Lambda = .82 $F(1, 25) = 5.48$, $p < .05$), and total social responsiveness (Wilks' Lambda = .82, $F(1, 25) = 5.34$, $p < .05$). On the BDI, group differences did not reach traditional levels of significance; however, young adults receiving PEERS demonstrated a trend toward a decrease in depressive symptoms at post-treatment while the waitlist group exhibited an increase in depressive symptoms. Group differences did not emerge on the SELSA. Planned analyses will include two additional cohorts to further assess PEERS in terms of caregiver-reported social responsiveness and self-reported depression and social loneliness, as well as analysis of the EEG asymmetry and ERP data.

Conclusions: Young adults receiving the PEERS intervention demonstrated a significant improvement in many domains of caregiver-reported social responsiveness. Young adults' self-reported depression also suggested a trend toward a decrease in these symptoms post-intervention. The results from this study corroborate findings reported in the initial pilot study (Gantman et al., 2012) and add to the minimal literature that has examined efficacious social skills interventions for adults.

3:16 **113.004** Increasing Strength and Flexibility of Adults Diagnosed with Autism Spectrum Disorder and an Intellectual Disability through a Strength and Conditioning Program

K. Carr, N. R. Azar, S. Horton and C. A. Sutherland, Kinesiology, University of Windsor, Windsor, ON, Canada

Background: While the prevalence of autism spectrum disorder (ASD) continues to rise, research focused on the adult population remains limited. This is troublesome as current trajectories report poor adult outcomes related to an ASD diagnosis, especially in the presence of an intellectual disability (ID). Though these poor adult outcomes are often attributed to the core symptoms of ASD, health and lifestyle factors should also be considered. For example, during childhood and adolescence, individuals with ASD have lower levels of physical activity compared to typically

developing peers, with participation in sedentary behaviours increasing with age. This trend is evidenced by poor measures of fitness, and increased rates of obesity and secondary health conditions within this population. Therefore, an adapted physical exercise (APEX) program focused on strength and conditioning may be a viable intervention strategy to alter current health patterns and improve adulthood trajectories for individuals with ASD and an ID.

Objectives: To assess the impact of a 12-week APEX program on heart rate, blood pressure, flexibility, and isometric strength in adults with ASD and an ID.

Methods: Fourteen adults with ASD and an ID (age range = 18-62 years; 2 females; IQ scores from previous clinical assessment = 20 to 70) participated in an APEX program twice per week for twelve weeks. Each APEX session was 90-minutes in length and consisted of cardiovascular training on a stationary bike, strength training using weight machines and free weights, and sports and games. All participants completed fitness testing pre-, mid-, and post-program which included: (1) resting heart rate and blood pressure, (2) the sit and reach test as a measure flexibility, and (3) a measure of isometric strength for the upper and lower body.

Results: Significant improvements in upper body strength of the right (F[1,10] = 5.058, p = 0.049, ω^2 = 0.25) and left bicep (F[1,10] = 8.109, p = 0.017, ω^2 = 0.37) were found from pre- (right bicep: M = 21.61 lb.; left bicep: M = 20.62 lb.) to post-testing (right bicep: M = 28.83 lb.; left bicep: M = 29.82 lb.). Significant increases were also found from pre- (M = 10.72 cm) to post-testing (M = 16.63 cm) for flexibility (F[1,11] = 5.690, p = 0.036, ω^2 = 0.27). No significant changes were found for resting heart rate, systolic or diastolic blood pressure, or lower body strength (p > 0.05).

Conclusions: Twelve weeks of APEX programming provided a significant increase in upper body strength, as well as flexibility in adults diagnosed with ASD and an ID. While the remaining fitness measures did not experience significant changes, the observed improvement in lower body strength (right quadricep: 18% increase, ω^2 = 0.16) has potential to yield practical health benefits for participants. Therefore, an APEX program focused on strength and conditioning is a worthwhile service option for adults with ASD and an ID as it elicits improvements in measures of fitness, which may translate into improved outcomes in adulthood.

Oral Session
114 - Prenatal Risk Factors and ASD
1:45 PM - 2:35 PM - Grand Ballroom A

Session Chair: Margaret Fallin, *Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*

1:45   **114.001**   Maternal Mid-Gestational Serum Cytokines and Chemokines and the Risk of Autism with Intellectual Disability: The Early Markers of Autism (EMA) Study

K. L. Jones[1], *L. A. Croen*[2], *C. K. Yoshida*[2], *L. S. Heuer*[1], *P. Ashwood*[3] *and J. Van de Water*[4], (1)University of California, Davis, CA, (2)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (3)UC Davis/MIND Institute, Sacramento, CA, (4)MIND Institute, University of California - Davis, Sacramento, CA

Background: Increasing evidence suggests a link between immune system dysregulation and autism spectrum disorders (ASD), with immune abnormalities described in individuals with ASD as well as their family members. Furthermore, numerous studies have suggested that maternal immune activation during gestation may negatively impact fetal development, potentially resulting in ASD-like behaviors in the offspring. However, few studies have directly investigated the role of prenatal cytokine and chemokine profiles on neurodevelopmental outcomes in humans.

Objectives: To characterize mid-gestational serum profiles of cytokines and chemokines in mothers of children with ASD, of children with developmental delay without ASD, and of children considered to be typically developing.

Methods: Using a large, population-based, nested case-control study design, maternal serum samples were collected during weeks 15-19 of gestation. The mothers included in this study gave birth to: A) a child with ASD (n = 397), B) a child without ASD but with a developmental delay (DD, n = 163), or C) a child with no known neurodevelopmental disability (TD, n = 439). The ASD group was further divided into those with intellectual disabilities (DQ<70) (ASD-ID; n = 187) and those without (DQ≥70) (ASD-no ID; n = 210). All maternal mid-gestational samples were quantified for 22 cytokines and chemokines using Luminex multiplex analysis technology. Levels of cytokines and chemokines were compared between groups using crude and multivariate logistic regression analyses, adjusting for maternal age, ethnicity, birth country of mother, and weight, as well as matching criteria of infant gender, birth year, and birth month.

Results: Mothers of children subsequently diagnosed with both ASD and intellectual disability (ASD-ID) had significantly elevated mid-gestational serum cytokine and chemokine levels compared to mothers of other children. For example, this group displayed significantly **elevated** levels of serum GM-CSF, IFN-γ, IL-1α, and IL-6 compared to mothers of children with ASD without intellectual disability (ASD-no ID), of children with DD, as well as those with TD children. Conversely, mothers of children with ASD-no ID had significantly **lower** levels of IFN-γ, IL-8, and MCP-1 than mothers of TD children, and they showed no significant differences compared to mothers of children with DD. Similarly, mothers of children with DD had significantly **lower** levels of IL-8 and MCP-1 compared to mothers of

TD children.

Conclusions: Our results suggest that mothers whose children have both ASD and intellectual disability have significantly elevated mid-gestational levels of numerous cytokines and chemokines in comparison to all other groups examined. The immunologic distinction between mothers of children with ASD-ID and those with ASD-no ID or DD suggests that the intellectual disability associated with ASD might be etiologically distinct from DD without autism. This differential gestational immune profile could provide a better understanding of the early mechanisms leading to altered neurodevelopment. Additionally, these findings contribute to the ongoing efforts toward identification of biological markers specific to sub-phenotypes of autism.

1:57 **114.002** Organochlorine Chemical Concentrations in Maternal Mid-Pregnancy Serum Samples: Association with Autism Spectrum Disorders in the Early Markers of Autism Study

K. Lyall[1], L. A. Croen[2], O. Zerbo[2], C. K. Yoshida[2], M. Kharrazi[1] and G. C. Windham[1], (1)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (2)Division of Research, Kaiser Permanente Northern California, Oakland, CA

Background: Polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs), widely detectable environmental contaminants in human populations, are known neurodevelopmental toxicants and have been associated with adverse developmental outcomes. Whether prenatal exposure to these pollutants influences development of autism spectrum disorder (ASD) is unknown.
Objectives: In this study, we examined whether concentrations of PCBs and OCPs measured in maternal mid-pregnancy serum samples were associated with risk of ASD in the offspring.
Methods:
Data are from the Early Markers for Autism (EMA) study, a population-based nested case control study that includes women who participated in the prenatal expanded alphafetoprotein screening program in Southern California and delivered children between 2000-2003. Birth certificates were linked to the California Department of Developmental Services (DDS) client databases to identify children with autism and a control group with developmental delay without autism (DD). General population (GP) controls were randomly selected from the remaining birth certificates, matched to cases on child month and year of birth and sex. Final diagnostic status, based on DSM-IV-TR criteria, was determined by expert clinical review of abstracted diagnostic and clinical information in DDS client records. Concentrations of 37 PCBs and 9 OCPs were measured in stored second trimester maternal serum samples and were available for 545 ASD, 181 DD, and 418 GP children. Analytes detectable for at least 60% of the study population were examined in further analyses; this included 11 PCBs (28, 99, 118, 138/158, 153, 170, 180, 190, 196/203, and 199, as well as their sum) and 2 pesticides (a breakdown product of dichlorophenyltrichloroethane (DDT)- p,pDDE and trans-Nonachlor, a component of oxychlordane). Descriptive statistics were compared between diagnostic groups. Conditional logistic regression was used to calculate crude and adjusted odds ratios (OR) and 95% confidence intervals (CI) for ASD compared to GP controls by quartiles of analyte concentrations, accounting for study matching factors and potential confounding factors based on associations with the analytes and known associations with ASD.
Results: Higher concentrations of PCBs were associated with several demographic factors (higher maternal and paternal age, maternal birthplace, lower maternal education), and several PCB congeners displayed higher geometric means in the ASD group as compared to both DD and GP groups. Overall, positive associations were found with most PCB congeners and ASD; associations remained statistically significant in adjusted analyses accounting for parental age and other demographic factors for two PCBs (for the highest quartile compared to lowest, PCB138/158 adjusted OR=1.83, 95%CI 1.12, 2.99; PCB153 adjusted OR=1.84, 95% CI 1.10, 3.07; p for trend across quartiles=0.03 for each). No significant associations were found with risk of ASD for the two OCPs examined in this study.
Conclusions: Our results suggest that exposure to PCBs during pregnancy could increase risk of ASD. PCBs and other organohalogens should be examined further as potential risk factors for ASD during critical periods of neurodevelopment.

2:09 **114.003** Maternal Sub-Clinical Hypothyroidism and Risk of Autistic Endophenotype in a Risk-Enriched Pregnancy Cohort

I. Burstyn[1,2,3], N. L. Lee[3], E. Schriver[2], J. Pandey[4], L. A. Croen[5], M. D. Fallin[6], I. Hertz-Picciotto[7] and C. J. Newschaffer[2], (1)Environmental and Occupational Health, Drexel University, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)Epidemiology and Biostatistics, Drexel University, Philadelphia, PA, (4)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (6)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (7)Public Health Sciences, University of California, Davis, Davis, CA

Background: There has been a long-standing speculation about prenatal hypothyroid state as an ASD risk factor. Animal models suggest that maternal hypothyroidism is associated with dysregulated myelination, synaptogenesis, neuronal migration, and arborization in the fetus and there is clear evidence of associations with other disorders involving the brain.
Objectives: To investigate the association between the concentration of maternal thyroid hormones

during pregnancy and early ASD-related phenotype in an ASD high-risk pregnancy cohort (the EARLI cohort – comprised of mothers of a child with ASD followed from the start of a subsequent pregnancy). Specifically, we assessed whether elevated prenatal levels of thyroid stimulating hormone (TSH) and reduced levels of free thyroxin (fT4) (indicative of a hypothyroid state) were associated with elevated scores on the Autism Observation Scale for Infants (AOSI) at 12 months. Methods: Thyroid hormone levels were measured in the earliest available prenatal serum samples for 180 mothers (29, 124, and 27 from the 1st, 2nd and 3rd trimesters, respectively).   The association between ln(thyroid hormone concentration) and AOSI score alternatively parameterized as continuous (ln(total AOSI+1)) and dichotomous (total AOSI≥7) outcomes was estimated using regression approaches with adjustment for potential confounders.

Results: There were 56 (31%) children with total AOSI score ≥ 7. None of the mothers had both hormones outside clinical norms (TSH within 0.35 – 3.30 μ-IU/mL and fT4 within 0.56 – 1.64 ng/dL). However, cases had higher maternal TSH and lower maternal fT4 concentrations compared to referents (*table*). After adjusting for potential confounding by child's sex and gestational age at birth, maternal pre-pregnancy BMI, parity, maternal age, race, ethnicity, and income, we still observed an increased risk of ASD endophenotype with increased concentration of TSH and decreased concentration of fT4. As shown in the *figure* (displaying predicted mean and 95%CI),within normative ranges a doubling of TSH concentration increases risk of a child having an AOSI ≥7 by about 35% (adjusted RR=1.4, 95%CI: 1.0-2.0) and the corresponding effect of halving fT4 doubled the risk (adjusted RR=1.9, 95%CI: 0.9-4.0). The adjustment for potential confounders had negligible impact on effect estimates. Similar results were seen when AOSI was parameterized as a continuous variable or dichotomized AOSI ≥ 6 (68 cases).

Conclusions: Although effect estimates from this analysis are imprecise and should be interpreted with some caution, results support the hypothesis that subclinical maternal hypothyroidism is associated with early ASD-related phenotype.   Other findings from our cohort suggest that 12month AOSI is predictive of 36 month ASD diagnosis (i.e., AOSI≥7 having 70% sensitivity and 90% specificity for 36mos best estimate clinical diagnosis).   The relationship between subclinical maternal prenatal hypothyroidism and ASD risk remains of interest because maternal hypothyroidism is amenable to treatment and there are numerous environmental exposures implicated in causing hypothyroidism which could suggest strategies for primary prevention.

2:21 **114.004** Maternal Blood DNA Methylation during Pregnancy and Autism Observational Scale for Infants (AOSI) Score at 12-Months in the Early Autism Risk Longitudinal Investigation (EARLI)

K. M. Bakulski[1], J. I. Feinberg[2], S. C. Brown[3], C. J. Newschaffer[4], L. A. Croen[5], I. Hertz-Picciotto[6], R. J. Landa[7], S. E. Levy[8], S. Ozonoff[9], J. Pandey[10], A. P. Feinberg[2] and M. D. Fallin[11], (1)Johns Hopkins University, Baltimore, MD, (2)Medicine, Johns Hopkins University, Baltimore, MD, (3)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)Drexel University, Philadelphia, PA, (5)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (6)Public Health Sciences, University of California, Davis, Davis, CA, (7)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD, (8)Developmental & Behavioral Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, (9)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis Medical Center, Sacramento, CA, (10)The Children's Hospital of Philadelphia, Philadelphia, PA, (11)Johns Hopkins School of Medicine, Baltimore, MD

Background: Genetic, environmental, and parental demographic factors confer risk of autism spectrum disorders (ASD) through incompletely characterized mechanisms. Epigenetic status represents the intersection of these factors and previous work has shown DNA methylation differences comparing individuals affected with ASD to controls. Maternal genome-wide DNA methylation during pregnancy has not yet been compared with prospective offspring ASD risk.

Objectives: To test the association between maternal pregnancy whole blood DNA methylation and offspring scores on the 12-month Autism Observational Scale for Infants (AOSI) scale.

Methods: In an ASD-enriched birth cohort, the Early Autism Risk Longitudinal Investigation (EARLI), genome-wide maternal pregnancy blood DNA methylation was measured using two complementary techniques: comprehensive high-throughput arrays for relative methylation (CHARM) and the Illumina Infinium 450k HumanMethylation array. Multivariable linear regression was used to test the association between percent methylation and offspring log transformed 12-month AOSI score (ln(AOSI+1)), adjusting for cell composition, laboratory batch, maternal age, and race. Due to differences in probe density between the methods, CHARM data was used to test for differentially methylated regions and 450k array data was used to identify differentially methylated single CpG sites. As a secondary analysis, we also tested AOSI as a dichotomous variable predicting ASD risk (AOSI < 7 vs. AOSI >=7). We tested for enrichment of locations of DNA methylation differences in gene ontology biological processes as well as autism-associated genes in the Simons Foundation Autism Research Initiative (SFARI) autism-related database.

Results: Paired maternal 450k DNA methylation data from any time during pregnancy and 12-month offspring AOSI scores were available on 79 EARLI families. Infant scores ranged from 0-20 (mean(SD)=5.4(4.8)). Across 450k array single-site models from 485,512 CpGs, we observed a lambda genomic inflation factor of 1.06 and top statistically significant CpG sites associated with offspring AOSI scores overlapped previously identified ASD genetic risk loci. CHARM data from over 2.1

million probes linked with AOSI scores were available from up to 4 repeated visits per mom (V1, n=77; V2, n=76; V3, n=59; V4, n=16), which are now being used to characterize any longitudinal trajectories of ASD-associated maternal DNA methylation differences.

Conclusions: We identified genomic locations of DNA methylation sites measured in maternal pregnancy blood that are associated with ASD-related phenotype at 12-months. These appear to be enriched for genes already implicated in ASD risk through traditional genetic associations and thus may provide further insight about the role of maternal genetic and epigenetic influences on the biology of ASD risk. Further work is needed, including replication in additional populations and model organisms, to clarify ASD mechanisms or the potential role of maternal DNA methylation as a risk biomarker.

Oral Session
115 - Neuropeptide Hormones in ASD
2:40 PM - 3:30 PM - Grand Ballroom A

Session Chair: Margaret Fallin, *Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*

2:40 **115.001** Affect, Social Behavior and Communication Among Children Prenatally Exposed to Oxytocin Receptor Antagonists

E. Friedlander[1], D. Mankuta[2], M. Yaari[1], A. Harel[1], R. Ebstein[3] and N. Yirmiya[1], (1)Psychology Department, Hebrew University, Jerusalem, Israel, (2)Department of Obstetrics and Gynecology, Hadassah Ein Kerem University Hospital, Jerusalem, Israel, (3)Department of Psychology, National University of Singapore, Singapore, Singapore

Background: Prematurity is the major cause of neonatal death and morbidity in the developed world. Therefore, measures are taken to delay preterm labor as long as possible. These measures generally include pharmacological inhibition of uterine contractility to allow the administration of corticosteroids to enhance fetal lung maturation. Different agents including calcium channel blocker (e.g. Nifedipine) and oxytocin receptors (OTR) antagonists such as tractocile (Atosiban) can inhibit myometrial contractions. These drugs were recommended as first line of treatment. Atosiban is considered to have minimal adverse effects. However, recent evidence shows that Atosiban had similar tocolytic efficacy as betamimetics and placebo, and more maternal side-effects requiring cessation of treatment. In randomized control trials comparing Atosiban and Nifedipine for treatment of preterm labor, women who were treated with Nifedipine had a lower rate of preterm deliveries and delivered a week later than women treated with Atosiban. More neonates in the Atosiban group were hospitalized at the neonatal intensive care units and for a longer time than those from the Nifedipine group.

A large body of evidence shows oxytocin modulate behavior and cognition across species as well as social memory. Moreover, oxytocin partially mediates the risk of perinatal risk factors in Autism. Although Atosiban crosses the placental barrier and the blood brain barrier rather freely, its long-term effect on brain development has not been examined yet.

Objectives: We hypothesize that we will observe deficits in affect, social behavior and communication even in the absence of autism spectrum disorder (ASD) or social communication disorders in children prenatally exposed to OTR antagonists.

Methods: 162 children between the age of 3:0 and 7:6 (years: months) participated in the current study. The Atosiban group consisted of 71 children prenatally exposed to Atosiban as well as Nifedipine to inhibit premature labor, whereas the comparison group consisted of 91 children who were exposed only to Nifedipine. All children were born between 2003 and 2010 at the Hadassah Medical Centers in Jerusalem to Hebrew-speaking mothers and were assessed between 2009 and 2013. The developmental assessment consisted of state of the art developmental assessment tools: The Mullen Scales of Early Learning, The Vineland Adaptive Behavior Scales and the Autism Diagnostic Observation Scale (ADOS).

Results: The cognitive and the adaptive behavior and daily functioning of the Atosiban group were similar to those of the comparison group. However, there were significantly more social communication abnormalities in the Atosiban group than in the comparison group (F (1,142) = 6.29, p = .013).

Conclusions: The current findings suggest that OTR antagonists may hold additional risk for deficits in affect, social behavior and communication even in the absence of ASD, in comparison to Nifedipine treatment. Therefore, the use of Atosiban to delay labor may have subtle effects on brain development which cannot be detected in the neonatal period, and clinically manifest only later in life. More research, including randomized control studies is needed to further examine these initial findings.

2:52 **115.002** Lessons Learned from Phase I Proof-of-Mechanism and Biomarker Studies in ASD: Measurement and Trial Considerations

---

Background: Next generation trials of drugs targeting ASD core domains will depend on precision of measurement of social dimensions. From studies investigating biomarkers and potential efficacy signals of antagonists of arginine vasopressin 1a receptor (AVPR1A), data enable comparative analyses of a multi-level panel of potential endpoints. The presentation will present analyses comparing sensory, cognitive, and clinical endpoints from two studies: 1) a single administration study of effects of V1a receptor antagonist RG7713 in ASD; and, 2) a comparative biomarker study testing measures in patients and healthy controls. Possible relevance to RDoC domains will be discussed.

Objectives: To present analyses comparing sesnory, cognitive, and clinical endpoints from two studies.

Methods: In Study 1, 19 adults with ASD (mean age=23.4 ± 5.16 (SD) years (range: 18-40) participated in randomized, double-blind, placebo-controlled, cross-over study. Single doses of RG7713 or placebo were administered intravenously on two different days one week apart. Measures of eye-tracking, affective speech recognition (ASR), emotion processing ("Reading the Mind in the Eyes Test [RMET))", olfactory recognition, social communication, parent-rated measures of social behavior (ABC-scale, 28 item adapted for the study with items 3,4 and 18 removed), and global improvement as measured by blind raters were obtained and compared. Additional comparisons with baseline assessments including the ADOS and Vineland are included. In Study 2, 19 healthy controls (mean age=26.68±4.33 (range 20-35)) and 19 adults with ASD (mean age=24.89±6.45 (range 19-39)) were assessed in a two-visit study of a similar battery used in Study 1. Separate and combined analyses were performed to examine associations; comparisons between post-treatment scores were calculated, as well as overall comparisons between both treatment conditions versus baseline assessments.

Results: Several unique patterns of correlations were observed between measures. Correlations of medium-large (|r|>0.5) effect are emphasized.

For social communication measures, correlations were:

- positive between baseline ADOS social interaction scores and post-treatment ABC adapted (rs~-0.58 – 0.68)
- negative between baseline ADOS subtest scores and post-treatment Scripted Interaction (total) (rs~-0.56 – 0..93)
- negative between ABC adapted and Scripted Interaction total score (negative correlation, r~-0.8)
- negative between ABC adapted and VABS Social Communication (rs~-0.6 – 0.64)

For social perception measures, correlations were:

- positive between baseline RMET and ASR scores (r~ 0.48)
- positive between RMET % correct responses and Smell test scores (positive correlation, r~0.5-0.6). RMET % correct responses were also positively correlated with Verbal and Full scale IQ (rs~ 0.52 – 0.72).
- not seen between eye tracking and other social perception measures

Conclusions: Results from these preliminary comparisons of multiple domains of social behavior, communication, and perception support their consideration as largely independent, though related, dimensions. The high proportion of shared variance of several measures, such as the ABC SW and Scripted interaction, with other well-established clinical tools such as the ADOS and VABS support their further use as ASD trial endpoints.

3:04 **115.003** Effects of Intranasal Oxytocin on Systemizing and Empathizing Tasks in Children with and without Autism

L. Strathearn[1], S. Kim[2], U. Iyengar[3], S. Martinez[3] and P. Fonagy[4], (1)Pediatrics, Psychiatry and Neuroscience, Baylor College of Medicine, Houston, TX, (2)Menninger Department of Psychiatry and Behavioral Sciences, Baylor College of Medicine, Houston, TX, (3)Children's Nutrition Research Center,

Baylor College of Medicine, Houston, TX, (4)University College London, London, United Kingdom

Background: In Baron-Cohen's Empathizing-Systemizing Theory of Autism, social deficits are described along the continuum of empathizing ability, or the ability to understand and respond to the emotions of others. Non-social aspects are characterized in terms of an increased preference for patterned or rule-based systems, called "systemizing."

Objectives: We developed automated eye-tracking tasks to measure visual attention to 1) more highly organized and structured real-life images ("systemizing"), and 2) images of human eyes in the "Reading the Mind in the Eyes" task ("empathizing"). Then, as part of a randomized, double-blinded, placebo-controlled crossover study, we examined the effect of intranasal oxytocin in 16 male children and adolescents with autism spectrum disorder (ASD), compared with 16 matched-controls.

Methods: In the systemizing task, participants viewed 14 slides, each containing 4 related pictures (e.g. of people, animals, scenes, or objects) that differed primarily on the degree of systemization. In the empathizing task, participants viewed 25 slides containing a picture of human eyes that characterize a particular emotion, and were asked to choose one of four surrounding words or phrases that describe the emotion portrayed. Visual attention was defined in terms of the observation time and count for each image, and was compared between ASD and control groups after receiving either oxytocin or placebo.

Results: In the systemizing task, individuals with ASD preferred to fixate on more highly systemized pictures, while control subjects showed no gaze preference. Intranasal oxytocin reduced systemizing preference in ASD participants, but increased this preference for control subjects. In the empathizing task, ASD participants were significantly less accurate in identifying the correct emotion. While oxytocin did not enhance accuracy, it did increase the time spent by ASD participants viewing the eye region, while decreasing the relative time spent by control subjects (2-way interaction effect).

Conclusions: These results suggest that, while intranasal oxytocin has a contrasting effect in ASD and typical control children, it may enhance empathizing and decrease systemizing in children and adolescents with autism.

3:16 **115.004** A New Vasopressin V1a Antagonist Restores Normal Social Behavior and Reveals a Specific Brain Network in the Rat Valproate Model of Autism

C. Grundschober[1], T. Mueggler[2], F. Knoflach[3], C. Risterucci[3], P. Schnider[4] and B. Biemans[3], (1)Hoffmann-La Roche Ltd, 4070, Switzerland, (2)Roche Pharmaceuticals, Basel, Switzerland, (3)Neuroscience Discovery, F. Hoffmann-La Roche, pRED, Pharma Research & Early Development, Basel, Switzerland, (4)Medicinal Chemistry, F. Hoffmann-La Roche, pRED, Pharma Research & Early Development, Basel, Switzerland

Background: The neuropeptide vasopressin plays an important role in regulating social behavior. In humans, prenatal exposure to the anticonvulsant drug valproate (VPA) has been associated with an increased risk of autism in the newborn. In rats, a single injection of valproate to pregnant dams at day 12.5 of gestation, the time of the neural tube closure, induces a range of behavioral abnormalities in the offspring, such as deficits in social behavior, working and spatial memory and increased locomotor activity. Based on synaptic and phenotypic similarities, the rat VPA model can be considered a valid model of human autism.

Objectives: Investigate the role of central vasopressin 1a (V1a) receptor signaling on the phenotype of the rat valproate model of autism.

Methods: From postnatal day 60 on rats prenatally exposed to VPA were treated daily during 3 weeks with a new brain penetrant V1a receptor-specific small molecule antagonist. Their behavior was assessed in the Morris water-maze and in the 3-chamber social interaction test. Long term potentiation was measured in hippocampal slices. Finally, VPA rats and wild-type controls were scanned by functional magnetic resonance imaging at postnatal day 60 and after 1-week chronic V1a antagonist treatment, to reveal changes in brain perfusion due to prenatal exposure to VPA and potential normalization by V1a antagonism.

Results: Chronic treatment for 3 weeks with our V1a receptor-specific small molecule antagonist completely reversed the impairments in social behavior, spatial memory and learning typically seen in VPA rats. In line with the behavioral finding, the hippocampal LTP deficit seen in VPA rats was normalized by the compound. In functional magnetic resonance imaging VPA rats were found to be characterized by reduced brain perfusion in cortex, nucleus accumbens, hippocampus and amygdala and increased brain perfusion in VTA, dorsal striatum and thalamus compared to control rats. Chronic V1a antagonism specifically normalized brain perfusion in amygdala, dorsal striatum and VTA.

Conclusions: Our data show that chronic inhibition of vasopressin V1a receptors restores normal behavior in VPA rats by normalizing perfusion in a brain network important for salience detection, repetitive behavior and reward. These results suggest that V1a antagonists have the potential to improve social interaction in autism, a core symptom for which there is currently no drug treatment.

Oral Session
116 - International Cross-Cultural Perspectives on Identification
1:45 PM - 2:35 PM - Grand Ballroom C

1:45 **116.001** What Will It Take to Improve Early Identification and Intervention Globally?

M. Elsabbagh[1], P. J. de Vries[2] and .. The Global SIG Team[3], (1)McGill University, Montreal, PQ, Canada, (2)Child and Adolescent Psychiatry, University of Cape Town, Cape Town, South Africa, (3)McGill University, Montreal, QC, Canada

Background: Early Identification and intervention in community based setting remains a major challenge. While this situation applies globally, the challenge is even greater in communities where issues of survival and physical health are also a priority. In global health research, the 10/90 gap refers to the finding that only 10% of spending on health research and development is directed towards problems impacting 90% of the world's population.
Objectives: The INSAR Special Interest Group on Early Identification and Intervention (Global SIG) was set up in 2012 to systematically explore facilitators and barriers to early identification and intervention in community-based settings. A knowledge brokering approach was used to elicit expert input that directly responds to needs and priorities of diverse communities. The Global SIG currently groups 177 members from 21 countries.
Methods: The Global SIG organized four workshops over three years focused on early identification and intervention in diverse settings. Prior to each session, participants were invited to complete a survey in which they submit questions on the topic of research priorities (session 1), screening and diagnosis (session 2), intervention (session 3), and specific considerations in low-resource settings (session 4). Using thematic analysis, results from the survey were used to structure the discussions. Topic experts were then identified and invited to address this participatory agenda and to interact with SIG members. Further thematic content analysis on transcripts of each session was conducted after the sessions.
Results: The Global SIG highlighted a number of facilitators and barriers to early identification and intervention that need to be carefully considered when translating evidence into community based settings. The three categories identified relate to (1) current advances and limitation of research in this area, (2) heterogeneity in the characteristics, needs, and capacity in different communities, and (3) translational issues bridging the state of the science with these needs (e.g., cost-effectiveness, scalability, equity, and cultural sensitivity of existing evidence-based tools and models).
The following cross-cutting lessons emerged across sessions: First, there is a need to integrate advances in autism research with broader child development, human rights, and global health approaches. Second, solutions for autism need to focus on enhancing capacity in and leveraging the strengths of existing health and social systems. Finally, efforts to build capacity for identification should go hand in hand with capacity to address the needs of those affected by the condition.
Conclusions: The Global SIG used a participatory process to bridge expert perspectives with real-world challenges impacting diverse communities. In doing so, the SIG identified several knowledge gaps, addressed misconceptions about research, and facilitated exchange of evidence-based models of care in different communities.

1:57 **116.002** Screening for Autism Spectrum Disorders in Low and Middle Income Countries: An Integrative Review

L. Stewart[1] and L. C. Lee[2], (1)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Background:
In many low-resource communities globally, screening all children for Autism Spectrum Disorder (ASD) at clinical or educational settings is currently infeasible due to a lack of clinical and professional resources. Multistage case identification using standardized screening and diagnostic tools seems the most feasible option for epidemiological studies of ASD in these settings. However, little is known about the use of ASD screening tools outside of the higher income nations in which they were first developed and validated. The reported psychometric properties of ASD screeners in low-resource settings have not been compared across studies to provide guidance for screener selection. Additionally, recent studies suggest that variation may exist in the cross-cultural appropriateness of screener measures and administration methods.
Objectives:
To review the use of standardized screening tools in low-resource settings and to make recommendations for screening instrument selection and screening approaches in these settings.
Methods:
An integrative review was conducted to understand the use of ASD screening instruments in low- and middle-income countries from studies published between 1992 and 2014. Studies had to use or adapt an established ASD screener in a World Bank designated low or middle-income country and be published in English.
Results:
Twenty-one studies met the inclusion criteria and were reviewed: two were in low-income countries and nineteen in middle-income countries. Among these twenty-one, seventeen different screening instruments were used. Study populations ranged from children ages 18 months to adult. Of the twenty-one studies, thirteen reported psychometrics.
Common screeners included the Modified Checklist for Autism in Toddlers (M-CHAT) (sensitivity ranged

0.25-0.86, specificity ranged 0.77-0.80), Autism Behavior Checklist (sensitivity ranged 0.78-0.98, specificity 0.91) and the Social Communication Questionnaire (sensitivity ranged 0.66-0.94, specificity ranged 0.70-0.89). Sixteen studies assessed or sampled children in a clinical setting. Five studies were non-clinical, community-based. Two out of these five reported psychometric properties: the Twenty-Three questions (23Q) (sensitivity ranged 0.55-0.80, specificity ranged 0.77-0.92) in a Ugandan sample and M-CHAT (sensitivity 0.25, specificity: 0.77) in a Sri Lankan sample.

The majority of screening tools were administered to parents as self-complete. Due to study populations' reported low-literacy and unfamiliarity with completing checklists, four studies administered screeners through an interview with caregivers. Translation and cultural adaptation of screeners were rarely reported or defined. Four studies reported collaboration with local community organizations and clinical resources during study design, recruitment, or screener translation and validation.

Conclusions:

This review found that seventeen different ASD screeners have been used in low-and middle-income settings with wide ranges of sensitivity and specificity. Clinical-based screening for ASD was the most widely reported method. However, community-based screening was also shown to be an effective method for identifying ASD in communities with limited clinical resources. Few studies reported collaboration with local community and clinical resources to ensure appropriate screener adaptation and study design, a practice in other branches of global mental health research. Improved reporting of psychometrics as well as screener administration and adaptation methods will enable the field to establish best practices for ASD research in low-resource settings globally.

2:09 **116.003** Findings from the Minneapolis Somali Autism Prevalence Project

K. Hamre[1], A. S. Hewitt[2], A. N. Esler[3] and J. Hall-Lande[1], (1)University of Minnesota, Minneapolis, MN, (2)Institute on Community Integration, University of Minnesota, Minneapolis, MN, (3)Pediatrics, University of Minnesota, Minneapolis, MN

Background: The Minneapolis Autism Spectrum Disorder Prevalence Project is the largest project to date that has looked at the number and characteristics of Somali children with autism spectrum disorder (ASD) in any U.S. community. The project focused on comparing Somali and non-Somali children in Minneapolis to respond to community concerns about ASD in the Somali community. Objectives: The project was developed to answer the question, "Is there a higher prevalence of ASD in Somali children who live in Minneapolis versus non-Somali children?" Expanded research questions included investigating where children with ASD were more likely to be identified, at what age were children with ASD more likely to be classified, and determining if children with ASD had a co-occurring intellectual disability. Comparisons were made between Somali children and children not of Somali descent.

Methods: The project adopted methodology from the Centers for Disease Control and Prevention's Autism and Developmental Disabilities Monitoring Network (ADDM). There were two phases to the research. In the initial phase, health and special education records were systematically reviewed to identify children with ASD behaviors. The abstracted information was then reviewed by trained clinicians to determine if the child meets the definition of ASD using the DSM-IV-TR criteria.

Results: Results indicate that Somali (1 in 32) and White (1 in 36) children were about equally likely to be identified with ASD. Somali and White children were more likely to be identified with ASD than Black and Hispanic children. In addition to information on autism prevalence, data on intellectual disability was collected. Among those children confirmed with autism spectrum disorder, all Somali children on whom intellectual data were available were found to have co-occurring intellectual disability (ID). The age at first ASD diagnosis was around 5 years for Somali, White, Black, and Hispanic children. In confirming cases, a panel of experts reviewed records and determined case status based on information contained in records, including narrative descriptions of behaviors. These behaviors are categorized in ADDM methodology as associated features and discriminators. Associated features are those behaviors that are not part of DSM-IV-TR criteria but that commonly occur with ASD. Over 80% of children with confirmed ASD were identified with having abnormal mood/affect, argumentative/oppositional, hyperactivity/attention problems, and odd response to sensory stimuli. The most frequent discriminators identified included impaired social skills, previous ASD diagnosis, the need for sameness or routine, and unusual sensory reactions.

Conclusions: This study found similar prevalence rates for Somali and White children and lower rates for Hispanic and Black non-Somali children. Rates were unable to be calculated for Asian and Native American groups due to low numbers of children identified with ASD among these groups. Results of this study highlight the need for improved outreach to culturally diverse families to improve identification of ASD. Further work is needed in understanding why Somali children with ASD had such high rates of co-occurring ID.

2:21 **116.004** Factors Associated with the Utilization of Services for Children with Autism in Saudi Arabia

F. Alnemary[1], H. Al-Dahlaan[2] and F. Alnemary[1], (1)University of California, Los Angeles, Los Angeles, CA, (2)King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

Background: Services for children with autism spectrum disorders (ASD) are limited in Saudi Arabia and little attention has been directed towards examining the factors associated with the use of

available ones.

Objectives: The aim of this study is to provide an estimate of services use among children with ASD in Saudi Arabia and to examine family and child characteristics associated with the utilization of ASD services.

Methods: An online parent survey was developed and its link was distributed by local professionals and through parent support groups in Saudi Arabia. A total of 205 caregivers, mostly fathers (61%), of children who had ASD and were younger than 21 ($M = 7.9$) years submitted usable forms during the 3-month survey period. (*See table 1 for sample characteristics*). Multivariate regression analysis was used to examine the characteristics of family (e.g., SES, city of residence, knowledge about autism) and children (e.g., severity of the child autistic symptoms) with ASD services use (i.e., age at start of the first treatment and the number of treatments utilized).

Results: The average age at starting the first treatment was 3.3 years. The average age of starting the first treatment increased 0.8 for each year of age of diagnosis and decreased 0.5 years for parents with high educational attainments. With respect to the use of ASD treatments, the majority of parents reported utilizing non-medical treatments (NMD; 94%; e.g., speech therapy, applied behavior analysis therapy, occupational therapy) followed by biomedical treatments (MD; 88%; vitamin and supplements, Hyperbaric Oxygen Therapy, special diets) and cultural/religious treatment (CR; 86%; e.g., reciting Quran, honey, visiting religious/traditional healers). While the average number of NMD treatments decreased 1.1 treatments for children who were diagnosed in non-major cities, it increased 1.5 treatments for mothers who were 45 years or older, 1.2 for children who received at least one treatment out of Saudi Arabia, 1.0 for families with household incomes above the mean of Saudi population's household income, and 0.3 for each MD treatment. The average number of biomedical treatments decreased 0.1 treatments for parents who were more knowledgeable about children with ASD's social and communicative features whereas it increased 0.6 treatments for children who received treatments out of city of residence, 0.5 treatments for fathers of high educational attainment, 0.4 for comorbidity, 0.2 for the number of CR treatments, 0.1 for the number of NMD treatment, and 0.1 for parents who were more knowledgeable about children with ASD cognitive features. The average number of cultural/religious treatments associated with 0.1 treatments for parents who were more knowledgeable about children with ASD social and communicative features. (*See table 2 for linear regression modeling*).

Conclusions: Disparities in service utilization associated with SES factors and cities where services were received point to the need to develop policy, practice and family-level interventions that can mitigate the limited services for children with ASD in Saudi Arabia. Further, understanding the decision-making processes that underlie treatment selection by parents of children with autism in Saudi Arabia is critical for future implementation research.

Oral Session
117 - Scaling Autism Interventions Across Cultures in Community Settings
2:40 PM - 3:30 PM - Grand Ballroom C

Session Chair: Mayada Elsabbagh, *McGill University, Montreal, PQ, Canada*

2:40 **117.001** A Cross-Cultural Comparison of a Caregiver-Mediated Joint Attention Intervention for Children with Autism Spectrum Disorders (ASDs): Malaysia and the UK

A. Pushparatnam *and C. Hughes, Centre for Family Research, University of Cambridge, Cambridge, United Kingdom*

Background: While there is a growing literature on interventions for children with ASDs, there is a dearth of information on the cross-cultural applicability of these interventions. Given the situation for children with ASD and their families in Malaysia, it was decided that parent-mediated interventions would be the most appropriate for the Malaysian context. Thus, an evidence-based caregiver-mediated intervention was chosen that focuses on increasing caregiver-child dyads' joint engagement and encouraging joint attention behaviours in the children.

Objectives: The aim of this study was to compare the efficacy of a caregiver-mediated joint attention intervention for children with ASDs in Malaysia and the UK using a single-subject multiple-baselines design.

Methods: Four Malaysian and three British mother-child dyads participated in the intervention. At the start of the intervention, the children were aged between 3y 3m to 5y 5m, and the mothers were aged between 35y 5m and 43y 3m. Extensive observational data were gathered across 24-27 baseline, intervention, and follow-up sessions per dyad. These quantitative data were examined to identify any improvements in the mothers' accurate use of intervention strategies ('fidelity' to intervention strategies), the children's response to joint attention, and the dyad's quality of interaction as a result of the intervention. The data were analysed in two ways: via visual inspection, as is traditional for single-subject designs, and via multilevel modeling. In addition, qualitative parent- and interventionist-report measures were used to gain insights into the mothers' experiences of having participated in the intervention.

Results: As predicted, there were cross-cultural differences in the baseline levels of the mothers' fidelity to the intervention strategies, with the Malaysian mothers scoring below the British mothers;

however, the treatment effects of the intervention on the mothers' fidelity did not differ across cultures. Thus, the Malaysian mothers started and ended the intervention at lower levels of fidelity than the British mothers (Figure 1). There were also cross-cultural differences in treatment effects with regard to the children's joint attention skills, with the British children showing larger improvements than the Malaysian children (Figure 2). There were no cross-cultural differences in baseline levels of or treatment effects on the dyads' joint engagement. The secondary outcome data revealed that the observed cross-cultural differences could be linked to cultural variations in parenting practices (particularly with regard to the mothers' interaction styles within play settings) and in parents' developmental priorities (e.g., the Malaysian mothers were more concerned than the British mothers about their children's academic abilities). The data also indicated ways in which the length, format, and content of the intervention could be adapted to better suit the Malaysian context. *Conclusions*: The findings from this study illustrate that cross-cultural differences in parenting can have an impact on the outcomes of a parent-mediated intervention for children with ASD. Thus, the findings underscore the importance of further research into cultural factors that may influence the outcomes of interventions for children with ASD, with the goal of establishing interventions that are effective within different cultural and economic settings.

2:52 **117.002** Parent Mediated Intervention for Autism Spectrum Disorder in South Asia (PASS) a Randomized Control Trial

*J. Green[1], **G. Divan**[2], U. Hamdani[3], V. Vajaratkar[2], A. Minhas[4], C. Taylor[5], C. R. Aldred[6], K. Leadbitter[6], R. Emsley[7], A. Rahman[8], V. Patel[9] and P. Cardozo[2], (1)Institute of Brain, Behaviour and Mental Health, University of Manchester, Manchester, United Kingdom, (2)Sangath, Porvorim Bardez Goa, India, (3)Human Development Research Foundation, Islamabad, Pakistan, (4)Institute of Psychiatry, Rawalpindi, Pakistan, (5)University of Manchester, manchester, United Kingdom, (6)University of Manchester, Manchester, United Kingdom, (7)Centre for Biostatistics, Institute of Population Health, University of Manchester, Manchester Academic Health Science Centre, Manchester, United Kingdom, (8)Liverpool University, Liverpool, United Kingdom, (9)London School Of Hygiene and Tropical Medicine, London, United Kingdom*

Background: Low and middle income countries have the majority of the world's children; simultaneously these areas are the most under resourced for services for complex neuro-developmental disabilities such as Autism Spectrum Disorders (ASD). Families of children with ASD countries face two primary challenges; firstly the lack of access to evidence based interventions which have been adapted and evaluated for acceptability, secondly the paucity of trained professionals to deliver outside the reach of specialist centres. This results in a 'treatment gap' leaving most children with ASD without services.
Objectives: This research study aimed to evaluate a systematically adapted intervention for acceptability and feasibility of a parent-mediated communication intervention through a randomised control trial. The original communication intervention, the Preschool Autism Communication Therapy (PACT); had substantial trail evidence supporting it. The aims were to evaluate a) feasibility and acceptability of the resulting PASS intervention b) the success of the "task-shifting" approach in delivering fidelity to the intervention c) The effectiveness of the adapted intervention in replicating original treatment effects the UK trial.
Methods:
Site: This study was carried out in two sites in South Asia; Goa, India and Rawalpindi, Pakistan. Both sites followed similar procedures in the adaptation and trial.
Participants: 30 eligible families were enrolled at each site, and the adapted intervention was delivered to fifteen per site, with an equal number in the treatment- as-usual arm. Eligibility criterion was a confirmed diagnosis of ASD in the 2-9 age group. Exclusion criterion included a non-verbal age equivalent to 12 months or younger; epilepsy with seizures in the previous six months; severe hearing or visual impairment in a parent or the child; or a parent with a severe psychiatric disorder.
Outcome assessments took place 8 months after baseline assessment. The primary outcome was the Dyadic Communication Measure for Autism, a parent-child interaction measure used in the UK trial. This consists of rating a naturalistic play session on three pre-specified variables: proportion of parental synchronous communications with the child; proportion of child communications that were initiations; and proportion of time spent in mutual shared attention.
Results: On parental synchronous interaction, there was a substantial positive treatment effect in favour of the PASS; with adjusted mean difference (AMD) of 0.25(95% CI 0.14-0.37). There was also a positive treatment effect on Child Communication Initiations with parent; AMD 0.15 (95% CI 0.05-0.24)). In both the confidence intervals include values from a small positive to a moderate positive effect. On the third interaction outcome of shared attention there was evidence of a negative effect of treatment; AMD -0.16 with (95% CI -0.278, -0.032).
Conclusions: This moderate-sized initial randomised controlled trial is the first systematic intervention study in relation to ASD undertaken in LMIC. The trial served as a successful test of the effectiveness of the cascade training and supervision model both to achieve adequate non–specialist fidelity; as well as an initial test of whether the adapted intervention could reproduce the treatment effects found in the UK study.

3:04 **117.003** Autism in the African American Community of South Los Angeles: A Community

Partnered Participatory Research Approach

T. Carr[1], C. Franklin[2], A. Gulsrud[3], F. Jones[2], L. Jones[2], C. Kasari[4], E. Lizaola[1], J. Panganiban[5], J. Smith[1], K. White[2], B. L. Williams[6] and A. Wright[2], (1)University of California Los Angeles, Los Angeles, CA, (2)Healthy African American Families, Phase II, Los Angeles, CA, (3)UCLA, Los Angeles, CA, (4)UCLA Center for Autism Research & Treatment, Westwood, CA, (5)University of California, Los Angeles, Arcadia, CA, (6)University of California Los Angeles, Culver City, CA

Background: As treatments for ASD gather empirical support, there is increased need to implement effectiveness trials at the community level. The need for research methods promoting community engagement has been highlighted, but there are few guidelines on appropriate methods in under-resourced communities. Community Partnered Participatory Research (CPPR) has emerged as an effective approach promoting equity and bi-directional learning (Wells et al., 2013).
Objectives: The present study represents the first phase of a project examining the effectiveness of an empirically-supported intervention in South Los Angeles. Rather than extending an existing treatment protocol to the community without first consulting community members, the project began with the formation of a partnership between university academics at UCLA and community stakeholders at Healthy African American Families. It was decided an important initial goal in the collaboration would be to implement a conference informing the community about autism and educating researchers about community-reported issues related to ASD.
Methods: Biweekly workgroups were held to plan the conference. Conference presenters included a combination of academic researchers and community members. Data collected were quantitative and qualitative and were culled from anonymous survey responses, audio-recordings, and observational notes assessing perceptions of ASD in the community.
Results: 250 individuals attended the conference and 140 completed evaluation surveys. 81% of respondents reported knowing an individual with a diagnosis of ASD (11% parents, 28% other family member, 32% friend of family, 29% service provider). 52% of respondents reported knowing an individual whom they thought *might* have an autism diagnosis (8% parents, 23% other family members, 36% friends of family, and 33% service providers).
When asked about ASD resources in the community, the majority of participants endorsed Doctors/Other healthcare providers (80%), followed by the Internet (59%), Autism Research Center (59%), and Books/Newspapers/Magazines (44%) as the most likely places they would seek advice and information if they had concerns about a child's development. Common barriers to accessing services included lack of knowledge about ASD (83%), lack of knowledge about local ASD resources (79%), and concerns about an individual being labeled as having ASD (64%). When asked about what kinds of ASD services would benefit the community, parent-mediated treatment (88%), part-C-funded early intervention (78%), and clinician-mediated intervention (72%) were the most endorsed. Preliminary qualitative analyses of conference discussions indicated several themes, including stigmatization of individuals with ASD, difficulties navigating healthcare/school districts to access services, the receipt of punitive consequences, rather than appropriate intervention, and the lack of ASD research including participants of color.
Conclusions: Community responses showed that most participants knew an individual with autism, suggesting that knowledge of the disorder is reaching the South Los Angeles community, although services may be more difficult to access. Overall, the conference reflected a strong interest in increasing and improving the quality of local ASD resources. The CPPR approach will continue, directly informing the implementation of sustainable intervention research that will better address the needs of under-resourced communities impacted by ASD.

3:16 **117.004** Potential Ethnic Disparities in Special Education Classroom Quality in a Large Urban County

A. C. Stahmer[1], J. Suhrheinrich[2] and S. R. Rieth[3], (1)Psychiatry, University of California, San Diego, San Diego, CA, (2)University of California, San Diego, La Jolla, CA, (3)Child and Family Development, San Diego State University, San Diego, CA

Background:
Although many evidence-based practices for ASD exist, our understanding of how prepared community-based providers are to deliver high-quality intervention to children with ASD is limited. Additionally, limited data have examined disparities in educational services based on minority populations in ASD specific classrooms. Careful characterization of usual care settings and identification of specific areas of strength and weakness may enhance professional development efforts and increase quality care across populations. This information may help researchers and providers optimally match evidence-based interventions and training programs to community settings based on characteristics of the intervention, student and teacher population, and current community practice, and thereby improve the likelihood of effective implementation.
Objectives:
The purpose of this study is to systematically evaluate special education classroom quality in a large sample of urban classrooms and to compare quality in classrooms across districts serving a high proportion of Hispanic students with those serving a high proportion of White students.
Methods:
Data were collected from 109 special education teachers in a large urban county who participated in

an effectiveness trial for a classroom-based intervention for students with ASD. All teachers had at least one student with ASD in their classroom and represented a wide range of classroom types, teaching experience, and education levels. Trained members of the research team with classroom experience conducted the Professional Development Assessment (PDA), an evaluation for programs serving children with ASD. The PDA includes a 2-hour observation, a 30-min teacher interview and educational records review. PDA outcome scores were averaged across seven domains (Teaming, Classroom Structure, Classroom Environment, Curriculum, Social/Peer Relationships, Management of Challenging Behavior, Instructional Climate) and compared across districts based on majority student ethnicity. Teacher and student demographic data were gathered through self (or parent) report for all participants.

Results:
Overall, classroom quality was high across classrooms except in the domain examining supports for Social/Peer Relationships. The quality of special education classrooms varied by domain and majority student ethnicity (Hispanic or White) across school districts. Significant differences in quality were identified across 5 domains (Classroom Structure, Classroom Environment, Social/Peer Relationships, Management of Challenging Behavior, and Instructional Climate) with classrooms in districts with 50% or more Latino students demonstrating lower overall quality as compared to districts with less than 50% of students reporting ethnicity as Latino.

Conclusions:
Special education classrooms in one urban county have a high level of quality and therefore may represent good environments for the implementation of evidence-based practice. However, differences in quality associated with student ethnicity indicate potential disparities in school-based programs for Latino children with ASD. Methods of adapting training procedures to address disparities will be discussed.

Oral Session
118 - Neural Signatures of Social Perception and Reward Motivation in ASD
1:45 PM - 2:35 PM - Grand Ballroom D

Session Chair: Robert Schultz, *Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

1:45 **118.001** Parsing Heterogeneity: Additive Effects of Oxytocin Receptor Gene Polymorphisms on Reward Circuitry in ASD

L. M. Hernandez[1,2,3], S. A. Green[1,2], K. Krasileva[2,4], L. Sherman[2,5], R. McCarron[1,2], C. Ponting[1,2], D. H. Geschwind[1,4], S. Y. Bookheimer[1,6] and M. Dapretto[1,2], (1)Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (2)Ahmanson-Lovelace Brain Mapping Center, UCLA, Los Angeles, CA, (3)Interdepartmental Neuroscience Program, UCLA, Los Angeles, CA, (4)Department of Neurology, David Geffen School of Medicine, UCLA, Los Angeles, CA, (5)Department of Psychology, UCLA, Los Angeles, CA, (6)Center for Cognitive Neuroscience, UCLA, Los Angeles, CA

Background: Autism spectrum disorders (ASD) are genetically complex. Single nucleotide polymorphisms (SNPs), which individually confer a small risk for neurodevelopmental disorders, may act additively to significantly increase risk for ASD (Gaugler 2014). A recent meta-analysis of SNPs on the oxytocin receptor gene (OXTR) suggests that multiple loci on OXTR increase the likelihood of developing ASD (LoParo 2014). Animal models have suggested that OXTR risk loci impact biological circuits relevant to ASD symptomatology; presynaptic oxytocin receptors in the nucleus accumbens (NAcc) are required for mice to exhibit a socially conditioned place preference (Dolen 2013). Importantly, neuroimaging research in ASD suggests that the NAcc is hypoactivated during reward processing compared to typically-developing (TD) controls (Dichter 2010; 2011). Together, these studies suggest a link between genetic and biological correlates of the oxytocin receptor, atypical social behavior, and hypoactivity in reward-related brain regions. Here, we explore these links using resting state functional connectivity magnetic resonance imaging (rs-fcMRI).

Objectives: 1) Examine the link between variability in number of OXTR risk polymorphisms across four SNPs and rs-fcMRI of the NAcc. 2) Investigate how altered reward-system connectivity relates to measures of ASD symptomatology.

Methods: DNA was extracted from saliva samples and genotyped for four ASD-associated OXTR SNPs (rs53576, rs237887, rs2254298, rs1042778). Participants were 29 children with ASD and 30 TD children ages 9-17. Children participated in a six-minute eyes-open resting-state fMRI scan. Data were preprocessed using standard methods followed by motion scrubbing (Power 2012). To assess connectivity, rs-fcMRI activity in the bilateral NAcc (defined using the Harvard-Oxford Atlas thresholded at 25% probability) was extracted and correlated with all other brain voxels. Single-subject whole-brain rs-fcMRI maps were combined and compared at the group level, modeling the number of OXTR risk alleles as a covariate of interest. All results were thresholded at z>2.3, corrected for multiple comparisons at p<0.05.

Results: In both ASD and TD participants, the bilateral NAcc showed connectivity with frontal cortex, anterior cingulate, and subcortical regions including caudate, putamen, thalamus, and amygdala. In the TD group greater numbers of OXTR risk alleles were associated with *increased* NAcc connectivity

with the frontal pole and paracingulate gyrus; in contrast, in the ASD group risk status was not associated with increased connectivity. Furthermore, there were no regions in the TD group for which greater numbers of risk alleles were associated with *decreased* NAcc connectivity, whereas in the ASD group greater aggregate risk was associated with decreased connectivity with the insula, anterior cingulate, bilateral caudate, thalamus, pallidum, putamen, and amygdala. This decreased connectivity in the ASD group was associated with ASD greater symptomatology – for example, reduced connectivity between the NAcc and amygdala was correlated with more severe preoccupations and mannerisms scores on the ADI-R.

Conclusions: These findings indicate that multiple OXTR risk polymorphisms have an additive effect on intrinsic reward system connectivity in children with ASD. Furthermore, this modulatory effect of OXTR SNPs on NAcc connectivity was related to ASD behavioral deficits. This work suggests a mechanism by which to parse genetic, neural, and behavioral heterogeneity within ASD.

1:57   **118.002**   Neural Reward Imbalance Between Social Incentives and Circumscribed Interests in Autism Spectrum Disorder

G. Kohls[1], M. Mosner[2], L. Antezana[2], R. T. Schultz[2] and B. E. Yerys[3], (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, RWTH Aachen University, Aachen, Germany, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)Psychiatry, University of Pennsylvania, Philadelphia, PA

Background: Neurobiological research in autism spectrum disorders (ASD) has largely focused on the social impairments, with restricted and repetitive behaviors and interests (RRBIs) being much less well studied, particularly with regard to functional neuroimaging. A common notion in the field suggests that the two core symptom clusters share a modest neurobiological overlap. In fact, accumulating evidence indicates an imbalance in the brain's reward system reactivity may contribute to both social deficits and RRBIs (Kohls, Yerys, Schultz 2014, *Biol Psychiatry*).

Objectives: This study's central aim was to determine if preoccupying special interests engage the brain's reward system in a fashion comparable to other incentives (e.g., social reward such as approval), and to compare brain responsivity to these different incentives in youth with ASD vs. typically developing control (TDC) children.

Methods: We conducted a 3T functional magnetic resonance imaging (fMRI) study to investigate the blood-oxygenation-level-dependent (BOLD) effect of social reward vs. personalized interest rewards (based on self-report) in 35 children with ASD relative to 19 TDC. To probe the reward system we used short video clips of actors providing social approval (social reward condition) and movies reflecting personal special interests (interest condition) as incentive stimuli, i.e., rewards. This optimization increases the task's ecologically validity compared to still pictures that are often used in this literature.

Results: There were no group differences with regard to type and number of individual interests, but children with ASD were rated to pursue their interests with greater intensity (according to parent report on the Interest Scale: Cohen's d=1.42). Behavioral task performance on the incentive delay task was similar in both groups with faster responses and better accuracy under reward conditions vs. non-reward. As predicted, however, the imaging data revealed greater reward circuitry activation in children with ASD vs. TDC in response to individual interest rewards. Significant group differences were found in the ventral and dorsal striatum, thalamus, precuneus, dACC, OFC and insula (whole-brain cluster-corrected at p=<0.05). dACC activity was correlated with ASD symptom severity (ADOS: r=0.39, p=0.023). By contrast, amygdala activation was diminished in ASD vs. TDC in response to social reward as revealed by ROI analyses.

Conclusions: The current data corroborate and extend prior findings that the brain's reward circuitry in ASD, particularly frontostriatal areas, selectively overreacts to RRBIs like restricted interests, whereas it underreacts to social rewards. Because ASD may be rooted in the powerful reward circuitries that shape a great deal of behavior, strategically targeting the role of reward mechanisms promises to improve current treatment practices for individuals with ASD and their families.

2:09   **118.003**   Joint Attention and Brain Functional Connectivity in Infants and Toddlers

A. T. Eggebrecht[1], J. Elison[2], E. Feczko[3], J. D. Lewis[4], S. Kandala[5], A. Todorov[6], J. J. Wolff[2], A. Z. Snyder[7], L. McEvoy[8], A. M. Estes[9], L. Zwaigenbaum[10], K. N. Background: Autism Spectrum Disorder (ASD) is a common neurodevelopmental disorder defined by impaired social interactions, repetitive behaviors, and altered communication. The Communication and Symbolic Behavior Scale (CSBS) is a semi-structured assessment of social communication, a domain profoundly affected in individuals with ASD.

Objectives: The purpose of this work is to investigate whether particular patterns of correlations between brain regions, as measured with resting state functional connectivity MRI (fcMRI), relate to initiation of joint attention (IJA) as measured with the CSBS.

Methods:

This work focuses on fcMRI and CSBS data collected from N=107 12- and N=94 24- month old (m.o.) children across four sites within IBIS, an NIH ACE Network study.

Cohorts: Children were classified as high risk (HR) if they had a sibling with ASD, or low risk (LR) if they had only siblings without ASD. Groups were assigned by research clinical best estimate using the DSM-IV-TR checklist at 24-m.o. (HR+/HR-/LR-: 12-m.o. n=17/62/28; 24-m.o.: n=22/49/23).

fcMRI data: For each child, fcMRI data were acquired in up to three resting state BOLD runs (130 frames, each TR=2.5 seconds), and processed using standard protocols including motion scrubbing (FD level 0.2 mm). Analyses utilized 150 frames of clean fcMRI data from each subject. Time traces from 230 functionally-defined regions of interest (ROI) throughout the cerebrum and cerebellum (Figure 1a) were correlated to yield fc values (Figure 1b), and sorted into one of 15 putative functional networks (Figure 1a) based on Infomap clustering of fcMRI data from the 24-m.o. children.

CSBS data: Question 7 (Q7) of the CSBS provided a dimensional metric of IJA: acts used to direct another's attention to an object, event, or topic (Figure 1c).

Brain-behavior analysis: For each age group, fc values were correlated against CSBS Q7 score (Figure 1d,e). A 2x1 χ^2 test was calculated to determine if the number of strong correlations (uncorrected $p<0.05$, Figure 1e) within each network-pair of the matrix was significantly greater than the number expected by chance (Figure 1f); only a few blocks survived Bonferroni correction (Figure 1g). For each block, a 2-sided t-test was calculated across age groups.

Results: Analyses revealed specific groupings of significant network-pair correlations of fc with IJA (Figure 1d-g) that differ between age groups (Figure 1h), e.g. the Dorsal Attention Network (DAN) and the Supplementary Visual (SV) exhibit strong negative correlations with behavior in 12-m.o. (blue shading in DAN-SV block in Figure 1d, top) and modest correlation magnitudes in 24-m.o. (green shading, Figure 1d, bottom). Age-dependent differences are also apparent between other key network pairs (Figure 1h). Further analyses on the risk and diagnostic groups are forthcoming as we acquire more subjects.

Conclusions: Herein we have shown that IJA correlates with fcMRI, with different specific network-pair interactions in 12-m.o. and 24-m.o. children. Inclusion of the children at high risk for ASD and those with a positive diagnosis provided a unique opportunity to explore a wide range of IJA behavior. Thus we have shown evolving brain-behavior relationships for one affected domain in ASD over the second year of life, when ASD symptoms emerge.

2:21 **118.004** Emotion Processing in Adolescents with ASD: Using Multiple Measures and Varying Intensities

R. Luyster[1], C. A. Nelson[2] and E. Auguste[3], (1)Emerson College, Boston, MA, (2)Division of Developmental Medicine, Boston Children's Hospital, Harvard Medical School, Boston, MA, (3)Mt. Holyoke College, South Hadley, MA

Background: Adolescents with ASD often have difficulty monitoring facial expressions in daily interactions. Despite these 'real world' deficits, two previous studies reported no differences between children with ASD and control children in experimental measures of facial emotion processing (Hileman et al., 2011; O'Connor, Hamm & Kirk, 2005). One possible explanation for this discrepancy lies in the inconsistency between stimuli used across studies – typically prototypical, exaggerated exemplars of emotion – and the subtle expressions typically encountered in social interactions.

Objectives: To characterize the neural and behavioral response to low- and moderate-intensity facial expressions in adolescents with and without ASD.

Methods: Preliminary analyses include 29 12-year-olds: 15 typically developing (TD) children and 14 with ASD. Children were fitted with a high density EEG/ERP sensor nets and presented with 250 trials of facial expressions of anger, fear and happiness at 20%, 40% and 60% intensity. The component of interest was the face-sensitive N170, measured over the left and right occipito-temporal regions. Participants completed a behavioral sorting task: the child was presented with cards, each showing an expression, and asked to sort them by emotion. Faces included the same emotions at 10% increments of intensity, from neutral to 100%.

Both peak amplitude (in microvolts) and latency (in milliseconds) of the N170 were measured. For the behavioral data, the variables of interest were "threshold" – the intensity at which the participant

identified an emotion in the face (no longer identified the face as 'neutral') – and the number of errors made in emotion identification.

Results: [NOTE: Due to space limitations, only results pertaining to group will be elaborated.] Two 3 (emotion, within-subject) X3 (intensity, within-subject) X2 (region, within-subject) X2 (group, between-subject) repeated-measures ANOVAs were run for N170 latency and peak amplitude. In order to correct for multiple comparisons, the Greenhouse-Geisser test was used. Main effects of emotion (F=5.35, p= .01) and intensity (F=9.04, p=.001) were found; no main effect or interactions of group were found. For peak amplitude, an emotion X group X region interaction was revealed (F=4.32, p=.02). Follow up analyses revealed that the peak amplitude to fear was significantly smaller over the right than left hemisphere, but only for the ASD group (t=2.27, p=.04). No group differences were found in number of behavioral errors made, and although the groups were similar in their thresholds for anger and fear, the ASD group had a higher threshold for happy than the TD group (t=2.34, p=.03).

Conclusions: These results provide a valuable follow-up to previous studies; for the first time, research stimuli have included the low-intensity emotional expressions commonly encountered in daily interactions. These preliminary findings indicate that – even with subtle emotional expressions – response in an experimental task may be remarkably intact, though with some variability across emotion type. This result is encouraging for clinical applications, because it suggests that there may not be a pervasive deficit in the detection of emotional expressions, but rather that the impairment lies in adapting one's social response, an area that is a natural target for intervention.

Oral Session
119 - Relationships between Behavior and Sensorimotor Circuitry in ASD
2:40 PM - 3:30 PM - Grand Ballroom D

Session Chair: Robert Schultz, *Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

2:40 **119.001** Cortico-Cerebellar Dysfunctions Associated with Visuomotor Abnormalities in Autism Spectrum Disorder Vary According to the Quality of Visual Feedback

M. W. Mosconi[1], S. P. Coombes[2], L. M. Schmitt[3], G. Magnon[4], D. E. Vaillancourt[2] and J. A. Sweeney[1], (1)Center for Autism and Developmental Disabilities, UT Southwestern Medical Center, Dallas, TX, (2)University of Florida, Gainesville, FL, (3)Center for Autism and Development Disabilities, UT Southwestern Medical Center, Dallas, TX, (4)University of Texas Southwestern Medical Center, Dallas, TX

Background: Sensorimotor impairments are present in the majority of individuals with autism spectrum disorder (ASD). We recently documented increased force variability during visually guided precision gripping in ASD that scaled with the gain of visual feedback. Here, we used functional MRI (fMRI) to characterize the cortical and cerebellar abnormalities underlying visuomotor abnormalities in ASD.

Objectives: To characterize cortico-cerebellar alterations associated with increased visuomotor variability in ASD, and to determine whether brain alterations vary in relation to the gain of visual feedback.

Methods:
Twenty individuals with ASD and 23 healthy controls matched on age, nonverbal IQ and handedness performed an fMRI test of visually guided precision grip force (Figure 1). During the test, participants pressed with their thumb and index finger on a force transducer while viewing a white FORCE bar on a screen that moved upwards with increased force toward a fixed green TARGET bar. Participants were instructed to maintain the FORCE bar at the level of the TARGET bar which was set to 15% of each individual's maximum force. Subjects also completed a rest condition in which they viewed the two bars on the screen. Both conditions lasted 26 s and they were alternated 3 times during each run. To assess the impact of changes in visual feedback on force control and brain activation, separate runs were completed at three different visual gains. Visual gain was manipulated by varying the vertical distance the FORCE bar moved per Newton of grip force. Visual gain was increased by moving the FORCE bar a greater distance for every Newton of force generated.

Results:
Subjects with ASD showed increased force variability relative to controls that was most severe at the lowest and highest gain levels compared to the medium gain level. At low visual gain, individuals with ASD showed reduced activation in contralateral primary motor cortex, thalamus, bilateral anterior cerebellum (lobules I-IV) and ipsilateral cerebellar lobules V/VI. At the medium visual gain level, reduced activity in ASD was seen in primary motor cortex, inferior parietal lobule and middle occipital gyrus. Individuals with ASD showed increased activity in lingual gyrus and superior temporal gyrus. When visual gain was high, individuals with ASD showed increased activation in right cuneus and precuneus, supplementary motor area, middle frontal gyri, right superior temporal gyrus, and right superior parietal lobule.

Conclusions:
Our results indicate that increases in force variability at high and low visual gains reflect different

underlying cortico-cerebellar dysfunctions in ASD. At low visual gain, individuals with ASD show reduced activation in parietal cortex, cerebellum, thalamus and primary motor cortex indicating that failure to minimize motor variability may reflect under-responsiveness throughout the visuomotor circuit. When visual gain was high, individuals with ASD showed over-activity of extrastriate and parietal cortices suggesting increases in motor variability may reflect hyperactivity during visual processing. These findings provide new insights into the brain mechanisms underlying sensorimotor abnormalities in ASD, and suggest that multiple distinct cortico-cerebellar systems are involved in the neurodevelopmental alterations that cause this disorder.

2:52 **119.002** Atypical Lateralization of Motor Circuit Connectivity in Children with High-Functioning Autism Is Associated with Motor Deficits

D. L. Floris[1,2], A. D. Barber[2,3], M. B. Nebel[2,3] and S. H. Mostofsky[2,3,4], (1)Autism Research Centre, Cambridge, United Kingdom, (2)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD, (4)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD

Background:
Atypical lateralization of language-related functions has repeatedly been shown in individuals with autism. No studies have however investigated deviations from typically occurring asymmetry of other lateralized cognitive and behavioural domains such as motor skills. Motor deficits are among the earliest and most prominent symptoms in individuals with autism and precede core social and communicative symptoms.
Objectives:
We have previously shown that leftward lateralization of motor circuit connectivity is associated with better motor performance in typically developing children. Here we aim to investigate whether motor circuit connectivity is (1) atypically lateralized in children with autism and (2) whether this relates to core autistic symptoms and motor performance.
Methods:
Participants comprised 45 right-handed children with high-functioning autism (37 boys; 8 girls) and 87 typically developing children (61 boys; 26 girls) matched for age (8-12), performance IQ and sex. Autistic symptoms were assessed by the ADI-R, ADOS and SRS. Motor performance was assessed by the Physical and Neurological Examination for Subtle Signs (PANESS).
Functional images were slice time and motion corrected, co-registered and normalized to a symmetrical age- and gender matched TPM. Six absolute and six differential motion parameters and nuisance variables (CSF and WM) were removed using CompCor and spatial smoothing (6 mm) and temporal filtering (0.01--0.1 Hz band-pass filter) were performed.
Six-millimeters-radius 3D seeds were generated based on peak coordinates of activations previously identified during right-handed finger sequencing. Homotopic seeds were generated by flipping the left hemisphere seeds along the x-axis. Time series from the seeds were extracted and pairwise correlations were conducted in each hemisphere separately. Laterality indices were calculated with the formula: R-L. Statistical analyses were carried out in SPSS.
Results:
A univariate ANOVA controlling for sex showed a significant difference in laterality of motor circuit connectivity of the left-hemisphere network ($F=5.01$; $p=0.027$) between the two groups. Children with ASD showed rightward lateralization compared to typically developing children. Partial correlations controlling for sex resulted in a significant association between the laterality index and total PANESS Gait scores ($r=0.403$; $p=0.007$) and total PANESS scores ($r=0.45$; $p=0.002$) with stronger rightward lateralization being related to more motor impairment. There were no significant correlations with autistic symptoms.
Conclusions:
Atypical lateralization in autism is not restricted to language functions, but is also present in functional motor circuit connectivity and related to motor deficits. Greater rightward laterality in children with autism may underlie motor deficits. Future studies should investigate whether atypical lateralization is even more pronounced in left-handed individuals with autism and whether these asymmetries are related to atypical lateralization in the language domain, too.

3:04 **119.003** Post-Movement Beta Rebound Is Decreased in Children with ASD

W. C. Gaetz[1], L. Blaskey[2], E. S. Kuschner[2], L. Bloy[2], R. Murray[3], C. Fisk[4], M. Ku[4], D. Chudnovskaya[4], J. W. Dell[5], R. Golembski[4], P. Lam[4], S. E. Levy[6] and T. P. Roberts[2], (1)The Children's Hospital of Philadelphia, Bala Cynwyd, PA, (2)Children's Hospital of Philadelphia, Philadelphia, PA, (3)Radiology, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Children's Hospital of Philadelphia, Philadelphia, PA, (5)CHOP MEG Lab, The Children's Hospital of Philadelphia, Philadelphia, PA, (6)Developmental & Behavioral Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA

Background:
A variety of motor impairments have consistently been associated with ASD, such as low muscle tone, coordination/balance and imitation impairments, dyspraxia and motor stereotypies. However, the neurophysiological mechanisms underlying these motor impairments remain obscure. Movement-

induced cortical rhythms have been investigated recently in ASD during tasks involving motor imitation and observation. These studies indicate a deficiency in beta (15 to 30 Hz) rhythm function associated with the imitation and observation of movement. It remains unclear however, whether these deficiencies are also evident when performing simple motor responses.

Objectives:

To compare movement-related cortical oscillations in TD and ASD children performing a simple button-press task.

Methods:

Neuromagnetic activity was recorded in 12 children with ASD (mean 12.4 years) and 12 TD children (mean 12.2 years), during a task requiring a right index finger response. A visual contrast grating stimulus was presented adjacent to a central fixation cue once every 4 s. Subjects were required to maintain fixation and press a button at the disappearance of the grating stimulus (1.75 s duration; +-0.25 s). 100 responses were collected over a 400 s MEG recording period. Movement related oscillatory changes for beta (15 to 30 Hz) and gamma (60 to 90 Hz) frequency bands were then assessed using beamformer spatial filter analysis. Beta ERD (event-related desynchronization), a decrease in movement-related resting beta band power was assessed at movement onset (active window; -0.3 to 0.2 s, with the button press at time 0 s) compared to a pre-movement baseline (-1.8 to -1.3 s) time period. Following movement, the expected re-synchronization of beta-band power (post-movement beta-rebound; PMBR) was assessed using a 0.5 to 1.0 s active time window compared to the pre-movement baseline (-1.8 to -1.3 s). Movement-related gamma-band synchrony (MRGS) was also assessed at the time of the button-press response using an active window of -0.1 to 0.2 s compared to the pre-movement baseline.

Results:

Right index finger movement was associated with strong contralateral modulations in beta band power as expected. In the contralateral left hemisphere, beta ERD power was observed maximally from primary motor cortex (MI), and was of similar magnitude for both TD and ASD (N.S.). Similarly, MRGS was observed maximally in contralateral MI and was not significantly different for both ASD and TD groups. In contrast, PMBR was significantly reduced or absent in ASD subjects compared to TD control children (p=0.04).

Conclusions:

These results provide physiological evidence for a distinct functional deficit in motor cortical responses for children with autism. These results may be important for interpreting related studies using more complex tasks such as action/observation methods to investigate "mirror-neuron" function from autistic children and adults. PMBR is generally associated with motor deactivation or inhibition and PMBR power has been shown to correlate directly with GABA concentration in TD adults (more GABA results in stronger beta rebound). Reduced PMBR in autism is also interesting in light of a recent study from our group showing decreased GABA level in the motor cortex in ASD.

3:16   **119.004** Praxis-Related Alterations of Cortical Oscillations in Children with Autism: Associations with Symptom Severity, Repetitive Behaviors and Motor Planning

J. B. Ewen[1], B. M. Lakshmanan[2], A. S. Pillai[3], M. Hallett[4], N. E. Crone[5] and S. H. Mostofsky[6], (1)Kennedy Krieger Institute/Johns Hopkins School of Medicine, Baltimore, MD, (2)Kennedy Krieger Institute, Baltimore, MD, (3)Neurology and Developmental Medicine, Kennedy Krieger Institute, Baltimore, MD, (4)Human Motor Control Section, NIH/NINDS, Bethesda, MD, (5)Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, (6)Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD

Background: The ability to perform praxis gestures--learned, skilled movements--has been linked both theoretically and empirically with the cardinal features of autism spectrum disorders (ASD). Because the praxis network is well characterized, and because motor behaviors are relatively easy to quantify and manipulate, praxis function serves as an excellent model system in ASD. To explore frontal-parietal network function in ASD, subjects performed a praxis task during EEG recording.

Objectives: To assess the specificity of task-related oscillatory differences in ASD as well as their relationship to key behavioral measures.

Methods: 20 children with ASD and 28 controls (typically developing; TD) ages 8-12 years performed a praxis preparation and execution task while EEG was recorded. We assessed broad-band event-related spectral perturbations (ERSP; task-related change in signal power). We specifically examined the premotor (central) and parietal regions known to be related to praxis function. Behavioral assessment included the Autism Diagnostic Observation Schedule (ADOS), the Autism Diagnostic Interview (ADI) and the Postural Knowledge Test (PKT; a "perceptual" test of praxis ability).

Results: Event-related synchronization (ERS; task-related increases in signal power) were seen in the theta band (2-8 Hz), and event-related desynchronization (ERD; task-related decreases in power) were seen in alpha (7-13 Hz) and beta (18-22 Hz) bands in both groups. The groups differed specifically in magnitude of beta ERD in left central channels as well as alpha ERD in left posterior channels. Further, the degree of posterior alpha ERD attenuation was associated with increased autism severity overall as well as impaired performance on a perceptual "praxis" task in the ASD group. The degree of attenuation of central beta ERD was correlated with restricted/repetitive behaviors and interest on both the ADOS and ADI.

Conclusions: Consistent with predictions, the ASD patients had an attenuation of task-related EEG oscillatory responses. The nature of these group differences, however, was quite specific: differences

were only seen on the left, consistent with the known lateralization of the praxis network. Deficits in central beta suppression (ERD) in ASD were associated with degree of restricted/repetitive behavior; this may be due to the putative role of central beta as a mediator of *"status quo"* activity. Deficits of posterior alpha suppression were associated with impairment of "perceptual" or posterior aspects of praxis function as well as overall ASD symptom severity, thus adding to the evidence supporting the role of frontal-parietal networks in motor as well as social/communicative aspects of the autistic phenotype. Further, deficits in oscillatory activity may implicate inhibitory interneurons, whose function is thought to be altered in ASD. The results provide specific evidence that impaired modulation of oscillatory activity may have a direct effect upon autistic symptoms.

Oral Session
120 - Experiencing Autism: First-Hand and Sibling Perspectives
1:45 PM - 2:35 PM - Grand Salon

Session Chair: Alison Singer, *Autism Science Foundation, New York, NY*

1:45   **120.001**   How Should We Describe Autism? Perspectives from the UK Autism Community

L. Kenny[1], C. Hattersley[2,3], B. Molins[3], C. Buckley[4], C. Povey[3] and E. Pellicano[1], (1)Centre for Research in Autism and Education (CRAE), Institute of Education, London, United Kingdom, (2)Providence Row, London, United Kingdom, (3)The National Autistic Society, London, England, United Kingdom, (4)Royal College of General Practitioners, London, United Kingdom

Background: The language used to describe autism has undergone considerable changes since autism was first described. Changes have come from the medical and scientific communities, as diagnostic criteria and understanding of the condition have evolved, and from parent and self-advocacy groups, as the disability rights and neurodiversity movements have gained in prominence. These changes have been brought about partly due to important tensions in what people believe autism to be. Such changes also have important consequences as the way in which people choose to describe autism influences personal and societal perceptions of what the condition entails.
Objectives: We aimed to understand the current views and preferences of community members (autistic adults, parents and professionals) about the terms they use to describe autism, and to determine potential differences, if any, between community groups in the UK.
Methods: 3,808 people (aged 18 years and over), recruited largely through the database of the UK's National Autistic Society, responded to an online survey. These included autistic adults, parents of people with autism, professionals and family members and friends. The survey asked participants (1) to identify, by selecting from a list, which terms they prefer to use when communicating about autism; (2) to identify which terms they would use to describe themselves or the person with autism that they live/work with/know; (3) to rate their preference for a series of terms used to describe autism on a 5-point scale; and (4) to specify, by selecting from a list, which *one* term they would use to describe autism. Finally, in an open question, participants were given an opportunity to provide comments relevant to the issue of describing autism.
Results: Examination of the quantitative data showed that people use many terms to describe autism. The most highly endorsed terms were 'autism' and 'on the autism spectrum', and to a lesser extent, 'autism spectrum disorder (ASD)' for which there was general agreement across community groups. Community members disagreed, however, on the use of several terms. The term 'autistic' was endorsed by a large percentage of autistic adults (61%), family members/friends (54%) and parents (50%) but by considerably fewer professionals (38%). In contrast, 'person with autism' was endorsed by almost 50% of professionals but only by 26% and 22% of autistic adults and parents, respectively. Analysis of the qualitative data provided reasons underlying these preferences, particularly for the lack of unanimity within community groups.
Conclusions: This study demonstrated for the first time that there is no single way of describing autism that is universally accepted and preferred by the UK's autism community. Instead, autism is currently described in a multitude of ways, with little consistency across – and even within – community groups. The context in which language is used is paramount and goes some way to explaining the variety of terms used. These findings have important implications for how we describe autism in research, policy, clinical and colloquial terms.

1:57   **120.002**   "What 'Being on the Spectrum' Means to Me": How Adolescents with Autism Spectrum Disorder Understand and Explain Their Diagnoses

L. Berkovits[1], B. L. Baker[1] and J. Blacher[2], (1)UCLA, Los Angeles, CA, (2)University of California - Riverside, Los Angeles, CA

Background: Although ASD has wide-ranging influences on individuals' lives, little research has been conducted to understand the personal experiences and perceptions of individuals with ASD. Research is particularly lacking during the formative years of adolescence, when one's self-concept undergoes substantial development and changes (Sebastian, Burnett, & Blakemore, 2008). Ruiz Calzada and colleagues (2012) explored both parent and adolescent perceptions, but focused on the impact of the diagnostic label itself, rather than on experiences of the disorder and perceptions of its

influence. Thus, the self-concept of adolescents with ASD and their understanding of their diagnoses remain understudied.

Objectives: To elicit and describe the experiences of adolescents with ASD as collected via semi-structured interviews, in order to understand their perceptions of their diagnosis and what "being on the spectrum" means to them. Specific research questions addressed in this paper include: (1) To what extent do adolescents describe their diagnoses in positive and negative terms? (2) How to adolescents perceive the impact of their diagnoses (e.g., permanency of symptoms and perception of others)? (3) How do adolescent perceptions of their diagnoses relate to autism symptomatology, cognitive abilities, and social functioning?

Methods: This study examined perceptions of ASD in 15-year-old adolescents with ASD (N=48; Mean IQ=92, SD=24), using data obtained from the last time-point of a multi-site longitudinal study. Adolescents were asked a series of questions, using the family's preferred label for the ASD diagnosis (e.g., *"What does [ASD] mean to you?"* and *"Do you think you will always have difficulties associated with [ASD]?"*). Quantitative coding was completed to capture adolescents' responses based on yes/no categories and valence of their perceptions.

Results: In response to the question, "What does [ASD] mean to you?" 32% of adolescents responded with a predominantly negative valence (e.g., "I take things overly literally, it makes conversation harder"), 42% with solely neutral or factual material, 10% with mixed positive and negative valence, and 17% positive valence (e.g., "It helps me feel like an individual and think outside the box"). The sample was mixed regarding the perceived permanency of their difficulties (33% permanent; 38% possibly permanent; 30% not permanent). The sample was also mixed regarding beliefs of how others perceive them (52% differently from their peers; 48% not differently) and the valence of these perceived differences (20% negative; 24% neutral; 40% mixed; 16% positive). Further analyses will relate adolescents' perceptions to other facets of their functioning, including IQ, social skills, and mental health comorbidities.

Conclusions: Adolescents with ASD described a variety of perceptions regarding what it means to for them to have an ASD diagnosis and what impact the disorder has on their current and future functioning. Obtaining a better understanding of these perceptions will inform effective services for adolescents with ASD by highlighting ways in which their perceptions of their diagnoses may influence their current functioning and by targeting services to areas of perceived deficits.

2:09 **120.003** Encouraging Participant-Centered Autism Research: What We Know from Potential Participants

A. R. Marvin[1], C. A. Cohen[2], J. K. Law[3] and P. H. Lipkin[4], (1)3825 Greenspring Avenue/Painter Building 1st Floor, Kennedy Krieger Institute, Baltimore, MD, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD, (4)Pediatrics/Neurology and Developmental Medicine, Kennedy Krieger Institute/Johns Hopkins School of Medicine, Baltimore, MD

Background:
Engaging individuals with ASD and their families is critical for subject recruitment; however, there has been little research into the motivators for engagement.

Objectives:
The goal of the study was to understand motivations and research interests in a population of families affected by autism in order to improve the recruitment and retention process in autism research.

Methods:
An anonymous survey (two versions: (i) adults with ASD; (ii) parents of a child of any age with ASD) administered by the Interactive Autism Network, an internet-mediated autism research registry, ran 08/01/2014-08/11/2014. Links to the survey were distributed by e-mail to registry participants and community website subscribers. Links were also posted on the registry's community website and Facebook page.

Results:
141 adults with ASD and 1,122 parents with a child with ASD completed the survey (514 parents of a young child <13 years; 347 parents of a teen aged 13-17 years; and 261 parents of an adult ≥18 years). Exclusions: non-affirmation of ASD diagnosis or indication of age-category of individual with ASD.

53% of adults and 63% of parents had previously participated in research. 98% were willing to participate in future research, depending on the nature and demands of the study.

All groups listed that a "convenient location" was a high/moderate motivator: 88% were prepared to travel 30 minutes each way; 62% one hour; 33% two hours. 21% of adults were prepared to travel more than 3 hours. All groups were prepared to spend a considerable amount of time participating: 77%≤4 hours; 37%≥8 hours.

Respondents across all groups indicated that altruism (helping others, advancing science) and receiving personalized reports were high/moderate motivators (>90%). All groups were very/somewhat likely to participate in studies about genetics (89%) and associated mental health conditions (91%), but less like to join studies that required prescription medication (31%). All groups indicated a willingness to participate in longitudinal studies. Online surveys and paper surveys were preferred to telephone surveys, especially by adults with ASD.

All parents were highly/moderately motivated to learn more about their child (94%) and were

very/somewhat likely to participate in a study on the effects of autism on the family (88%). Parents of adults and teens were especially interested in research on transitioning to more independent living (90% very/somewhat likely). Parents of young children were less willing to travel and more motivated by the availability of child care for their other children while participating; they were especially motivated by research into behavioral therapies, education, and speech/language (all ≥90%). All groups expressed that they were highly/somewhat motivation by reimbursement for time and travel (79%), but indicated less interest in actual dollar amounts or gift codes. Few were motivated by drawings for gifts (<40%). This suggests incentives should be framed in terms of reimbursement for time/travel expenses.

Conclusions:
Research must be designed with participants in mind. Autism research requires consideration of location, convenience, research topic, methodology, and such motivators as altruism and reimbursement. Researchers should be prepared to provide individual feedback, in addition to generalized outcome reporting.

2:21   **120.004** The Sibling Experience: Quality of Life and Adjustment in Siblings of Individuals with Autism Spectrum Disorder in Adolescence

L. L. Green and S. Gavidia-Payne, Health Sciences, RMIT University, Bundoora, Australia

Background:
The sibling bond is the marathon of human connection; it is the longest lasting relationship, enduring from the birth of the youngest sibling to the death of the first to go. It is reasonable to assume the importance of this relationship across the lifespan, but what impact arises when the normal sibling relationship is altered by developmental disability?

ASD is a particularly stressful disability for families (Orsmond & Seltzer, 2009; Quintero & McIntyre, 2010). With the large commitment that family members make to ensure an individual with autism has an environment that caters for their complex needs, it is empirically intuitive to assume that quality of life (QoL) is impacted in these families. This has yet to gain scholarly support, with a lack of research focusing on QoL outcomes in ASD families. In endeavouring to address the gaps in the autism literature pertaining to sibling developmental trajectories, the current study aimed to examine the QoL of autism siblings within the context of a biopsychosocial model of teenage experience.

Objectives:
Siblings of children with ASD have been shown to exhibit higher levels of internalising and externalising disorders (Rodrigue, Geffken, & Morgan, 1993; Ross & Cuskelly, 2006), social and behavioural adjustment problems (Orsmond & Seltzer, 2007), hassles with sibling behaviour (Moyson & Roeyers, 2011), and guilt (Opperman & Alant, 2003). Although this literature is well established, adolescent siblings are afforded less research attention than children and adults. The objective of the present study was to investigate the factors contributing to psychosocial outcomes of young people growing up with a sibling with autism. Specifically, it aimed to examine the profile of psychological adjustment, stress levels, and QoL of 13-14 year old siblings.

Methods:
Two matched groups of participants were recruited: a group of 13-14 year old siblings of individuals with autism and a control group. Each adolescent and their parent completed a survey. The adolescents responded to items regarding: Quality of Life; Daily Hassles, Coping and Accommodations; Internalising and Externalising Disorders; and, Stress and Cognitive Processes. The parents completed questionnaires on: Quality of Life of the Typically-developing Child; Severity of ASD; Family Coping; and, Parent Well-being.

Results:
Data is currently being analysed to determine group differences and predictors of sibling QoL.

Conclusions:
The National Disability Insurance Scheme (NDIS), an Australian funding program for families of people with disabilities, has identified that financial support is critical for siblings of people with disabilities. However, policy makers are yet to devise policies that inform practice in this area. Increased knowledge of the sibling experience will allow policy development to cater for siblings within the family unit in a meaningful way. Identification of at-risk adolescents will allow funding to be appropriately channelled into sibling support programs to address diminished QoL; individual counselling for internalising and externalising disorders; and psychoeducation resources for families. This study is the first of its kind, leading the way for the development of evidence-based autism-specific sibling support interventions.

Oral Session
121 - Social Motivation, Social Reward, and ASD Traits in Clinical and Typical Samples
2:40 PM - 3:30 PM - Grand Salon

Session Chair: Jan Blacher, University of California - Riverside, Los Angeles, CA

2:40   **121.001** Perceived Social Support in Cognitively High Functioning Adults with Autism Spectrum

Disorder

S. Alvarez-Fernandez[1], H. R. Brown[1], J. A. Raithel[1], S. L. Bishop[2], S. B. Kern[1], C. Lord[3] and A. Di Martino[1], (1)Child Psychiatry, NYU Child Study Center, New York, NY, (2)Psychiatry, University of California, San Francisco, San Francisco, CA, (3)Weill Cornell Medical College, White Plains, NY

Background: The observation that perceived social support (PSS) is related to physical and mental well-being in typically developing individuals has motivated investigations of PSS in individuals with Autism Spectrum Disorder (ASD). However, prior efforts have been based on qualitative examinations in small samples without comparison groups of non-ASD adults.
Objectives: To provide quantitative characterization of PSS in adults with ASD we administered the Multidimensional Scale of Perceived Social Support (MSPSS), a self-report 12-item Likert scale examining PSS in three domains: friends, significant-others, and family. Secondary analyses explored the relationships between PSS and self-reported empathy and symptoms of comorbid psychopathology.
Methods: We obtained MSPSS scores from three groups of adults matched for age and IQ, including 41 adults with ASD (Mean age 30.5±11.2; Mean IQ 109±14), 61 with ADHD, and 69 neurotypical controls (NC). There were significantly fewer males in the ADHD group (46% vs. 73% and 73% in ADHD, NC and ASD, respectively). To measure cognitive and affective empathy, as well as comorbidity, participants completed the Interpersonal Reactivity Index (IRI) and the Symptom Checklist-90-Revised (SCL-90-R) questionnaires, respectively. Their scores were related to the MPSSS scores in the two clinical groups.
Results: ANOVA adjusted for sex followed by pairwise group comparisons revealed significantly lower total MSPSS scores in ASD vs. adults with ADHD and NC (F= 3.460, p=0.02). Examinations of MSPSS subscore profiles highlighted that the MSPSS total score difference was primarily driven by the *friend* subscore (F=7.659, p<0.001), as no significant group differences emerged for the *family* and *significant other*subscores. MSPSS total scores were significantly and negatively related to scores on SCL-90-R global indices in adults with ADHD, indicating that lower PSS is related to higher levels of psychopathology in ADHD. This relationship was not significant in adults with ASD. Further, MPSS total scores were significantly and positively related to the empathic concern subscale score of the IRI (indexing affective empathy) in adults with ASD (r=0.545, p<0.001), but not in the ADHD group. No relationships were evident with regards to perspective taking scores indexing cognitive empathy.
Conclusions: Relative to both NC and individuals with ADHD, cognitively high functioning adults with ASD reported significantly lower PSS, primarily as related to friends. This finding, along with the significant correlation between PSS and affective empathy skills in the ASD group only, suggest ASD-specific mechanisms leading to poorer PSS in autism. Findings of a significant relationship between comorbid psychopathology and PSS in the ADHD but not the ASD group were unexpected. These findings need to be interpreted with caution given the exclusive reliance on self-report measures and the relatively selected sample of adults with ASD. They may suggest that the traditional relationships between social support and mental well-being may not apply in the same way to adults with ASD. Future studies with a wider range of measures from multiple informants are needed to confirm the present findings.

2:52 **121.002** Measuring the Value of Social Stimuli in Autism Spectrum Disorders

I. Dubey[1], D. Ropar[1] and A. Hamilton[2], (1)School of Psychology, University of Nottingham, Nottingham, United Kingdom, (2)Institute of Cognitive Neuroscience, UCL, London, United Kingdom

Background: An increased preference for non-social over social stimuli is reported in autism Spectrum Disorders (ASD). A recent theory describes this in terms of reduced motivation to engage with others (Chevallier, Kohls, Troiani, Brodkin, & Schultz, 2012). However, there are currently few simple behavioural ways to test this claim or to quantify social motivation in individuals with or without ASD.
Objectives: In this study we aimed to develop a method to measure social motivation and determine if the behavioural preference for social / non-social stimuli differs between people with and without ASD.
Methods: We used a simple behavioural paradigm called Choose-a-movie (CAM) that measures preference for social versus non-social stimuli in adolescents and adults with and without ASD. On each trial, participants chose which of two movies to watch, and must consider their movie preferences against the amount of effort (key-hits) required to see a movie. Three different movie categories were compared: movies of adult actors with direct gaze, adult actors with averted gaze, and non-social movies of object rotating on a table. Each trial presented two movies from these categories.
In experiment one, 40 adolescents with ASD and 40 age/IQ matched typical adolescents completed the CAM paradigm with one set of paired stimuli (i.e. direct gaze versus object movies). In experiment two, 29 adults with ASD and 24 age/IQ matched typical adults completed the CAM paradigm with three sets of paired stimuli: a) direct gaze versus objects, b) averted gaze versus objects, c) direct versus averted gaze movies.
Results: The results from experiment one showed that adolescents with ASD tended to invest more effort to watch object/ non-social movies than to watch direct gaze social movies. In experiment two, adults with ASD showed a significantly reduced preference for direct gaze social movies than matched comparison group. They invested more effort to look at the object/non-social movies than direct or averted gaze social movies. When presented with two social movies (direct versus averted gaze),

typical adults preferred to view direct gaze movies but adults with ASD showed no preference between these categories.

Conclusions: Together, these studies show differences in the value associated with social stimuli between adults and adolescences with and without ASD. Both adults and adolescents with ASD value non-social stimuli more than matched adults and adolescents without ASD. These data provide a precise quantification of social motivation, and advance our understanding of how value of social engagement may differ between those with and without ASD.

3:04   **121.003** Bridging the Gap Between Social Motivation and Empathy: Autistic Traits Modulate Spontaneous Facial Mimicry of Social Rewards in Individuals with ASD

J. Neufeld[1,2], *T. B. Sims*[1] *and B. Chakrabarti*[1], *(1)Centre for Integrative Neuroscience and Neurodynamics, School of Psychology and Clinical Language Sciences, University of Reading, Reading, United Kingdom, (2)Center for Neurodevelopmental Disorders, Karolinska Institute, Stockholm, Sweden*

Background: Individuals with Autism Spectrum Disorders (ASD) typically show deficits in measures related to empathy, including spontaneous facial mimicry. Atypical responsivity to social rewards has been suggested to underlie such deficits (Chevallier et al., 2012). In a previous study we found that typically developing individuals show enhanced spontaneous facial mimicry towards faces associated with high reward value compared to those associate with low reward value (Sims et al., 2012). Importantly, the difference in mimicry for high compared to low reward faces was negatively correlated with autistic traits, suggesting a weakened link between reward and mimicry in individuals high in autistic traits. However, it is unknown how autistic traits modulate this link in individuals with a clinical diagnosis of ASD.

Objectives: We tested the modulation of the reward-mimicry link by autistic traits (as measured by the Autism Spectrum Quotient, AQ) in individuals with a clinical diagnosis of ASD, using a paradigm identical to the one used previously in neurotypicals (Sims et al. 2012).

Methods: 25 adult participants with a DSM-IV/ ICD-10 based diagnosis of Autism/ ASD/ Asperger Syndrome (13 female; age range 19-50 years [$M = 30.63, SD = 11.73$]) took part in an implicit reward conditioning the experiment. Briefly, it involved watching a set of faces in the context of a card game, where different identities were conditioned with different levels of reward (win/lose outcomes: POS faces were associated with wins, NEG faces with losses). Consequently, participants watched short videos of the same faces (as in the conditioning phase) making happy expressions, while facial EMG was recorded. Zygomaticus Major response to happy faces was used as a measure of spontaneous facial mimicry and compared between POS and NEG faces.

Results: In contrast to the finding reported by Sims et al. (2012) in neurotypicals, no increased mimicry for the POS vs NEG faces were noted in the whole sample (t=1.227, p=0.223). However, greater autistic symptoms (as measured by higher AQ scores) were associated with smaller difference in the extent of spontaneous mimicry for POS vs NEG faces (r= -0.457, p=0.016).

Conclusions: We conclude that autistic traits modulate the link between reward and spontaneous facial mimicry, in individuals with ASD. While there was no difference in the spontaneous facial mimicry of POS vs NEG faces in the whole sample, individual scores on autistic traits were strongly associated with the extent to which POS faces were mimicked greater than NEG faces. This further supports the idea that while there may not be a fundamental deficit in the mimicry mechanisms in ASD, an atypical modulation of these mechanisms due to reduced reward responsivity to social stimuli might underlie the previously observed deficits in spontaneous facial mimicry. This observation thus provides a potential bridge between theoretical models of autism that suggest reduced social motivation and those that suggest reduced empathy. The results further underline the importance of studying individual differences within people with a clinical diagnosis of ASD.

3:16   **121.004** Relative Contributions of BAP Subdomains to Social Relationships and Loneliness

J. C. Bush *and D. Kennedy, Psychological and Brain Sciences, Indiana University, Bloomington, IN*

Background: The broader autism phenotype (BAP) is a milder expression of social, nonsocial and language impairments seen in autism spectrum disorder (ASD). Previous research shows that individuals with high BAP scores have greater social cognitive difficulties, including emotion recognition, face processing, and gaze reciprocity, similar to the social difficulties that affect those with ASD. Individuals with BAP exhibit poorer quality of interpersonal relationships and are also generally lonelier. But, how different aspects of the broad autism phenotype contribute to specific aspects of their social relationships remains less unclear.

Objectives: This study aims to elucidate the relationships between BAP characteristics and its subdomains (i.e. social aloofness, pragmatic language difficulties, and rigidity) and various aspects of social relationships and self-reported loneliness in a large sample of non-ASD individuals.

Methods: One thousand six hundred fifty nine neurotypical undergraduate students (1113 female) participated in this study. All participants completed the Broader Autism Phenotype Questionnaire (BAPQ) (Hurley et al., 2007), the Friendship Questionnaire (FQ), which measures the extent to which people enjoy close friendships (Baron-Cohen & Wheelwright, 2003), the UCLA Loneliness Scale (Russell, 1996), and a romantic relationship questionnaire consisting of questions about current relationship status and future marital aspirations.

Results: Total BAP scores were negatively correlated with quality of friendships (FQ; r=-0.37; p<0.001) and positively correlated with loneliness (r=0.59; p<0.001) – i.e., individuals with more BAP characteristics had lower quality friendships and were lonelier. Multiple regression analyses revealed that the different BAP subscales (i.e. aloof, pragmatic language and rigidity) contributed in different ways to both friendship quality and loneliness. High levels of aloofness (β=-0.48, p<0.001) negatively predicted the quality of friendships, while high levels of rigidity was related positively, though weakly (β=0.07, p=0.004). Pragmatic language impairment was unrelated to the quality of friendships (β=0.02, p=0.51). However, pragmatic language impairment was a positive predictor of loneliness (β=0.21, p<0.001) as was aloofness (β=0.47, p<0.001), while rigidity was unrelated (β=0.02, p=0.30). In terms of romantic relationships, participants who were single compared to those in committed relationships reported greater pragmatic language difficulties (t[1434]=2.21, p=0.027) and higher levels of loneliness (t[1490]=2.81, p=0.005). Finally, those participants who reported not having any future thoughts about marriage had higher levels of aloofness (t[1596]=6.77, p<0.001) and exhibited greater pragmatic language difficulties (t[1577]=4.22, p<0.001).

Conclusions: These findings replicate and extend previous research (Jobe & White, 2007; Wainer et al., 2013) suggesting individuals with greater BAP traits show difficulties in interpersonal relationships and higher levels of self-reported loneliness. Additionally, we find that various components of BAP that may be uniquely associated with different aspects of interpersonal relationships. For example, pragmatic language difficulties predicted relationship status and loneliness, but not the quality of friendships, highlighting the role of pragmatic language in initiating these relationships. In contrast, aloofness seemed to have a different role, affecting friendship quality, and loneliness but not one's relationship status. Overall, these results suggest that there may be specific targets of intervention within the triad of difficulties that can help promote the successful formation and maintenance of social relationships in individuals with ASD.

Poster Session
122 - Family Issues and Stakeholder Experiences
5:30 PM - 7:00 PM - Imperial Ballroom

---

1   **122.001** Face Processing and the Broad Autism Phenotype

B. H. Feldman[1] and A. Dimitropoulos[2], (1)Case Western Reserve University Dept. of Psychological Sciences, University Heights, OH, (2)Department of Psychological Sciences, Case Western Reserve University, Cleveland, OH

Background: The Broader Autistic Phenotype (BAP) consists of milder Autistic Spectrum Disorder (ASD) characteristics that occur in some relatives of individuals who have ASD. The core ASD deficits in communication, socialization, and stereotyped/repetitive behavior have been found to manifest themselves separately in the BAP. Due to the strong hereditary nature of ASD, the autistic symptomatology expressed in ASD family members meeting criteria for the BAP can serve as endophenotypes in the study of ASD. Many of the social problems experienced by people with ASD stem from deficits in facial processing. Since the BAP consists of mild socialization impairment, face processing has also been studied in ASD relatives, in particular parents, with mixed results of subclinical similarity and dissimilarity to ASD. Lacking in these face processing studies has been: the examination of typical ASD face processing strategies, as well as measures of both face identity and emotion recognition.

Objectives: The present study sought to explore the effects of Gender and BAP level on face processing deficits in parents and siblings of individuals with ASD. We aimed to assess if gender and BAP levels would each account for differences on face processing tasks, as well as if an interaction effect of gender and BAP level could be found.

Methods: 178 biological parents and siblings, (62 males and 116 females), of individuals with ASD (Mean IQ=109.63) were assessed on: IQ (Wonderlic-WPT-Q), the Let's Face It Skills Battery (LFI), the Broad Autistic Phenotype Questionnaire (BAPQ), and the Social Communication Questionnaire (SCQ). Specifically, the LFI evaluates 10 areas of face processing involving subtests of face discrimination, emotion recognition, and non-face objects. The BAPQ measures an overall BAP level as well as three sub levels of: aloofness, pragmatic language, and rigidity. All assessments were conducted on-line.

Results: Results suggest that relatives of ASD children performed at normal levels of face processing. A 2x2 Manova was conducted with gender and each of the BAP criteria levels. Gender x Total BAPQ: only gender showed a main effect, on discrimination Pillai's Trace V=.094, F (5, 136)=2.81, p<.05, no interaction effect. Gender x Aloofness: the main effect of Gender approached significance, on discrimination Pillai's Trace V=.074, F(5, 136)=2.18, p=.059, no interaction effect. Gender x Pragmatic Language: Gender revealed a main effect, on discrimination Pillai's Trace V=.091, F(5, 136)=2.73, p<.05, no interaction effect. Gender x Rigidity: both Gender, on discrimination Pillai's Trace V=.092, F(5, 136)=2.77, p<.05 and Rigidity showed a main effect, on discrimination Pillai's Trace V=.101, F(5, 136)=3.06, p<.05 and on non-face objects Pillai's Trace V=.070, F(2, 147)=5.50, p<.01, no interaction effect.

Conclusions: Evidence suggests that Gender and BAP level differentially effect ASD family members and may contribute to mild social skill difficulties that mimic those difficulties typically found in biological relatives who have an ASD diagnosis. These findings suggest that effects of BAP level can

be distinguished from gender differences. These results give further insight into the investigation of endophenotypes of ASD as expressed in the BAP, as well as the need to examine the influence of family environment.

2   **122.002**   A First-Hand Account of Raising a Child with ASD

A. Mao, Psychiatry and Behavioral Sciences, Baylor College of Medicine, Houston, TX

Background: Parents raising children with Autism Spectrum Disorder (ASD) face unique stressors and challenges. Among these is a sense of crisis and trauma after receiving an ASD diagnosis, as parents grieve the loss of their "typically developing" child. Despite being at increased risk to experience depressive and anxiety symptoms, especially at times when they contrast their child's development with those of a typically developing child, there are few interventions aimed at supporting parents of children with ASD. Given the complexity and parental frustration with the ASD diagnostic process, the myriad available clinical interventions, and the amount of ongoing research, parents of children with ASD can feel powerless, overwhelmed, and confused at the very time when they are left in charge of a complicated network of professional providers. This has led to a demand for information about how to best support parents of children with ASD.
Objectives**:** Attendees will learn how to:

1. Recognize the importance of providing support and education to parents of children with ASD immediately after diagnosis.
2. Help parents make treatment decisions that optimize the child's independent functioning and improve learning and skills acquisition.
3. Identify unique stressors for the parents/caregivers that occur in each stage of development for the child that may require special intervention.
4. Assist parents in developing a treatment plan for their child with ASD that integrates pharmacological, behavioral and educational interventions.

Methods: Drawing from both personal experience as the parent of a child with ASD and professional experience as a physician, the presenter will discuss the unique challenges facing parents of children with ASD. The discussion will include empirical evidence on caregiver stress for families raising a child with ASD, along with potential barriers for provision of optimal treatment created by denial, lack of resources, or inadequate information. The presentation will also include key points on how to support parents during the diagnostic process, identify parental obstacles to obtaining treatment for ASD, and emphasize the need for early interventions for the parents of children with ASD.
Results: Participants will be able to recognize the emotional and practical obstacles that parents face in accessing appropriate care for their child with ASD. Clinicians will be able to work collaboratively with families to develop a comprehensive multi-modal treatment plan encompassing emotional and educational support for the parents, psychopharmacology interventions for problematic behaviors, and individualized educational/behavioral interventions. In addition, audience members will become more knowledgeable about the nature and magnitude of the task of parenting a child with ASD.
Conclusions: This presentation will address ways that families can best manage challenges experienced during the life of their child with ASD by reviewing evidence-based educational interventions focused on predictable phases that families transition through as they cope with an unanticipated traumatic life change. If prepared to provide support and educational interventions, clinicians can help families accept and adapt to the chronic nature of living with ASD, and develop successful coping strategies throughout the child/family's lifespan.

3   **122.003**   Evidence-Based Treatment and Assessment of Autism Spectrum Disorder

A. S. Weitlauf, Vanderbilt Kennedy Center, Nashville, TN

Background: Although every person on the autism spectrum presents with certain levels of social-communication and behavioral symptoms, the high degree of variability across individuals in symptom profiles can complicate the diagnostic and treatment process. This variability can make it difficult for parents, professionals, and investigators to understand what happens during the diagnostic process, especially for young children, and what evidence-based treatments are available.
Objectives: To provide a summary of the findings from the recently updated Agency for Healthcare Research and Quality (AHRQ) report on Therapies for Children with Autism Spectrum Disorder: Behavioral Interventions Update, and to familiarize participants with common diagnostic tools and criteria.
Methods: Information regarding the strength of evidence for behavioral interventions will be drawn from the most recent (2014) Agency for Healthcare Research and Quality (AHRQ) review of behavioral therapies for children with ASD. This collaborative work comprehensively reviewed existing evidence for behavioral interventions through an exhaustive systematic review framework. Some of the most frequently studied interventions and their effectiveness for improving aspects of children's development will be briefly described. Additional information will be presented on common screening tools and "gold standard" diagnostic instruments, highlighting the core social-communication and behavioral symptoms that define ASD.
Results: The updated AHRQ review documented a substantial increase in available evidence for the positive effects of behavioral interventions for young children (under 12 years) with ASD. The

strongest evidence base was documented for (1) early intensive behavioral intervention with regards to improvements in cognitive and language outcomes and (2) the use of cognitive behavioral therapy for children with ASD and anxiety. Data on parent training, social skills, and relationship-based approaches showed a less substantial evidence base.

Conclusions: The 2014 AHRQ report reflects increases in the number and methodological rigor of studies available. Consistent with the 2011 report, however, important gaps remain in what we know about behavioral interventions for ASD. In particular, more research is needed on why certain treatments seem to benefit some children more robustly than others.

4   **122.004** Parents with Autism of Children with Autism

S. Begeer[1], M. Wierda[2] and H. M. Koot[2], (1)Department of Psychology, Vrije Universiteit Amsterdam, Amsterdam, Netherlands, (2)Developmental Psychology, VU University Amsterdam, Amsterdam, Netherlands

Background: Despite the high heredity of autism, relatively little is known about parents with autism of children with autism. There are reasons to expect beneficial effects of an autism diagnosis in parents, as they are more aware of the disorder and likely have access to care and treatment. However, the social communicative problems of autism may also be a burden for parental and child wellbeing.

Objectives: To explore the characteristics and overall quality of life of parents with autism who have one or more children with autism.

Methods: Using data from the Netherlands Autism Register, we analysed 211 parents with autism (135 fathers, 76 mothers), 191 parents of who had one child with autism, and 20 who had 2 children with autism. We analysed their wellbeing and living standard (employment, social relations) as well as their diagnostic and demographic background.

Results: Preliminary findings indicate that parents with autism who have a child with autism generally reported average or above average intelligence and had paid employment in almost half the cases. Their self reported wellbeing and social relations were not markedly high. The interplay of these factors will be analysed further and presented.

Conclusions: While having autism may hinder one's outcomes in life, having a child with autism offers many additional challenges that have not been addressed before in the literature. We will highlight the advantage and the disadvantage of autism in both parent and child, and provide recommendations for future studies on this understudied topic in autism research.

5   **122.005** A Compass for Hope: A Parent Training and Support Program for Children with ASD and Problem Behavior

A. D. Rodgers[1], A. P. Ables[2], J. A. Odom[1], T. M. Belkin[3], G. Mathai Kuravackel[2], R. J. Reese[1] and L. A. Ruble[1], (1)University of Kentucky, Lexington, KY, (2)University of Louisville, Louisville, KY, (3)Indiana University- Purdue University Indianapolis, Indianapolis, IN

Background: Parents of children with ASD are at greater risk for stress and depression than parents of children with other developmental disorders (Montes & Haltherman, 2007). Some explanations come from child and environmental factors, such as severity of child problem behavior (Hayes & Watson, 2013) and the effectiveness of interventions (Baker et al., 2005). Unfortunately, there are limited evidence-based programs available to clinicians in outpatient settings that target parent stress, parent self-efficacy, and child problem behavior. One exception is Stepping Stones Triple P, for which a meta-analysis has shown significant effect sizes for reducing child problem behavior, as well as for parenting satisfaction and efficacy (Tellegen & Sanders, 2013). We aim to develop a new manualized program that can allow for adaptation and customization appropriate for caregivers with limited socioeconomic resources. Building on the ecological-systems framework described by Ruble and Dalrymple (2002) called the Collaborative Model for Promoting Competence and Success (COMPASS), we are currently developing and testing an 8-week parenting intervention program called COMPASS for Hope (C-Hope) using an iterative approach. Additionally, to facilitate access to services from underserved portions of Eastern Kentucky, we will evaluate outcomes from the C-Hope program delivered to parents using videoconferencing technology.

Objectives: The purpose of this study is threefold: (a) to test and adapt the C-Hope program, using an iterative process that includes evaluating each of the sessions and making modifications based on qualitative and quantitative outcomes, including feedback from families, child problem behavior, parent self-efficacy, and parenting stress using a pre-post design; (b) to formally evaluate the efficacy of the modified C-Hope program by randomly assigning families to the intervention or waitlist control condition, and measuring outcomes; and (c) to compare the outcomes based on type of delivery format (videoconferencing vs face-to-face).

Methods: After adaptation of C-Hope, a waitlist control design will be used to compare outcomes. Table 1 describes demographic information of the pilot participants. For the waitlist control condition, two groups (n = 10) are concurrently underway, and two additional groups (n = 13) will begin in January 2015 and end in March 2015 (providing more data for analysis for IMFAR 2015). The program is manualized and includes four, 1-hr, individual sessions and four, 2-hr, group sessions. Outcome measures include the Eyberg Child Behavior Inventory, measuring child problem behavior, as well as the Being a Parent Scale and the Parenting Stress Index, measuring parent self-efficacy and stress.

Results: Visual analysis of preliminary data shows that after the pilot group, parents who participated reported increased self-efficacy and decreased distress, dysfunction, and overall stress. Additionally, children were reported to have decreased externalizing behaviors. Child internalizing behaviors increased slightly, and parental report of having a difficult child remained the same. Mean scores for the pre- and post-measures are shown in Table 2. Additionally, pilot parents reported high satisfaction with the program.

Conclusions: We anticipate that overall findings will show that C-Hope improves outcomes of parents and caregivers of children with ASD.

---

6   **122.006** ASD Symptoms As Predictors of Negative Outcomes in Parents and Typically-Developing Siblings

T. S. Tomeny[1], L. K. Baker[1] and T. D. Barry[2], (1)Department of Psychology, The University of Alabama, Tuscaloosa, Tuscaloosa, AL, (2)Psychology, The University of Southern Mississippi, Hattiesburg, MS

Background: Literature examining typically-developing (TD) siblings and parents of children with ASD suggests that both may be at risk for negative outcomes due to a variety of factors. However, because many TD siblings and parents adjust appropriately, maladjustment in family members seems to only occur under certain conditions. Research has shown that characteristics of children with ASD may predict adjustment in family members. Due to the heterogeneous nature of ASD symptoms, it follows that family adjustment may differ according to ASD symptom manifestation.

Objectives: This exploratory study investigated how different ASD symptom domains predicted parental stress and psychopathology as well as parent- and self-reported emotional and behavioral maladjustment in TD siblings.

Methods: A total of 113 families participated. Ages of children with ASD ranged from 3-17 years ($M = 11.98$, $SD = 3.29$); ages of TD siblings ranged from 11-17 years ($M = 13.32$, $SD = 1.81$). Parents completed the Strength and Difficulties Questionnaire (SDQ) about the TD sibling (assessed emotional and behavioral functioning) and the Children's Social Behavior Questionnaire (CSBQ) about the child with ASD (assessed ASD symptom severity). Parent also completed the Questionnaire on Resources and Stress – Short Form (assessed parental stress) and Symptom Checklist-10-Revised (assessed parental psychopathology) about themselves. Finally, TD siblings self-reported via the SDQ.

Results: Preliminary correlations (Table 1) showed that general ASD symptoms in children with ASD significantly related to parental stress, ($r = .51$, $p < .001$), parental psychopathology ($r = .33$, $p < .001$), parent-reported maladjustment in TD siblings ($r = .43$, $p < .001$), and self-reported maladjustment in TD siblings ($r = .23$, $p = .01$). To better understand the nature of these relations, four separate regression analyses were conducted to examine which specific ASD symptom domains uniquely predicted the aforementioned criterion variables (if any), while accounting for variance contributed by other symptom domains (Table 2). Parental stress and parental psychopathology scores were separately regressed onto CSBQ subscales scores (i.e., the ASD symptom domains). Stereotyped behavior ($\beta = .27$, $p = .01$) was the only unique predictor of parental stress. The overall model predicting parental psychopathology was significant ($R^2 = .14$, $p = .01$); however, none of the ASD symptom domains emerged as unique predictors. Both parent- and self-reported TD sibling SDQ Total scores were separately regressed onto CSBQ subscale scores. Behavior not appropriate to social situations/aggressive ($\beta = .28$, $p = .01$) and stereotyped behavior ($\beta = .22$, $p = .04$) emerged as significant predictors of parent-reported TD sibling maladjustment, whereas social withdrawal/lack of social interest ($\beta = .28$, $p = .01$) emerged as the only significant predictor of self-reported TD sibling maladjustment.

Conclusions: Results indicate that certain types of ASD symptoms may relate differently to negative outcomes in family members. Additionally, these associations appear to vary for different family members and according to who serves as the reporter (e.g., parent versus typically-developing sibling). These findings can guide further research on predictors of maladjustment among families of a child with ASD and also can inform interventions for these families.

---

7   **122.007** Applying Principles of Community-Based Participatory Research in Autism Biomarker Discovery

A. Yusuf[1] and M. Elsabbagh[2], (1)Department of Pscyhiatry, McGill University, Montreal, QC, Canada, (2)Department of Psychiatry, McGill University, Montreal, QC, Canada

Background: Identifying biological markers or *biomarkers* for autism can potentially help to diagnose the condition and reduce overall burden of autism. Some scientific advances in biomedical research have already been integrated in clinical care for autism. However, considering the complex and changing nature of biomedical discoveries in this area, translating such knowledge into clinical applications has been challenging (Walsh et al., 2011). As many families experience challenges in accessing services and navigating treatment options, engaging families could clarify how the impact of putative biomarkers could support the process of identification and access to care.

Various models to engage families in research exist, but few have been used in autism research. One such model is community-based participatory research (CBPR). CBPR is defined by specific key principles, namely involving a unit of identified "community" in an equitable and collaborative way in all stages of research (Israel et al., 1998). While some perceive biomedical research to be at odds with

participatory and community-based approaches, our previous work suggest that several factors influence these perceptions (Elsabbagh et al., 2014).

Objectives: Using a scoping review methodology (Arksey & O'Malley, 2005), we systematically identified studies of stakeholder engagement in biomedical autism research and evaluated the extent to which they are consistent with nine CBPR principles articulated by Israel et al. (1998). These principles include defining a unit of "community", building on strengths and resources within the community, and adapting the principles to different contexts with "flexibility, constant reflection, and critical analysis".

Methods: We identified studies from the following databases: Medline, CINAHL, Ovid, and PubMed. Author lists and references were also cross-referenced for potentially relevant articles. One reviewer retrieved titles and abstracts from these databases and reviewed them for further inclusion. Another reviewer independently retrieved and read included full-text articles and extracted relevant information into a database. They both reviewed the database to evaluate the extent to which CBPR principles are used in autism biomarker discovery research.

Results: A total of 73 full-text articles were assessed from 342 retrieved records. Seven examples of empirical studies were identified. A synthesis of these studies suggests that two CBPR principles are consistent with autism biomarker discovery research. The first is community involvement in setting priorities and research questions through understanding parents' attitudes and expectations towards the application of autism biomarkers in their lives. The second is collaborating with parents in devising experimental protocols. These studies also advocate the need to understand parents' views on ethical issues related to biomarker discovery.

Conclusions: We summarize and attempt to reconcile where CBPR principles are adapted to biomarker discovery in autism research. We raise the challenge of public engagement imposing pressure on the scientific community to produce outputs relevant for society at the risk of undermining scientific integrity. We reconcile this issue by proposing that public engagement is best developed in global priority setting in the process of translation, and protecting a space for scientific discovery.

8   **122.008** Assessment of Transportation and Mobility Adults on the Autism Spectrum in NJ

C. Feeley[1], *D. Deka*[2], *A. Lubin*[2] *and M. McGackin*[3], *(1)Center for Advanced Infrastructure and Transportation, Rutgers University, Piscataway, NJ, (2)Alan M. Voorhees Transportation Center, Rutgers, The State University of New Jersey, New Brunswick, NJ, (3)Autism Family Services of New Jersey, Family Support Center of New Jersey, Brick, NJ*

Background: Although many advances have been made in other fields related to quality of life improvements for persons with ASD, efforts have been more limited in the realm of transportation planning and policy. Most organizations involved in transportation planning and policy collect travel data for broad population groups such as persons with disabilities instead of collecting data for specific population groups like persons with ASD. As a result, very little is known about the travel patterns, needs, and barriers of persons with ASD. The primary focus of the research is to gain insights about the transportation barriers experienced by the New Jersey adult ASD population. Additionally this research is seeking to identify the characteristics and traits commonly found in adults with ASD and their impacts on transportation choices, which in turn affects employment opportunities, community involvement, and overall quality of life.

Objectives: The broad objective of this study is to demonstrate the specific transportation and mobility needs and barriers of New Jersey adults with ASD so that greater efforts are made by planning agencies and service providers to meet their unmet transportation and mobility needs. Another objective is to educate agencies and officials assisting persons with ASD with work-related skills about the importance of transportation for gainful employment and independence. The research is focused on examining all types of mobility needs and transportation barriers as they relate to pedestrian skills; public transportation including, fixed-route and paratransit services; and driving.

Methods: The research is being conducted utilizing a four-pronged information and data collection approach that includes a review of existing literature, studies and data, followed by 25 structured interviews with a targeted set of experts, then a scientific survey focused on documenting the transportation needs and barriers of adults with ASD, and concluding with a series of focus groups with adults with ASD in New Jersey.

Through conducting 25 key informant interviews with an array of expert stakeholders, the research team was able to document how the characteristics of persons with ASD relates to their travel needs and the barriers they encounter.

Because of the difficulties in identifying adults with ASD for the survey, a convenience sampling methodology was used. The internet survey was disseminated through a variety of agencies including Autism New Jersey, ASPEN, DJFF, and Autism Family Services. The survey allows respondents to complete it on their own or have their guardian/caregiver complete the survey for them.

The focus groups provide a deeper insight and perception about the transportation needs and barriers of adults with ASD. While the analysis of survey data will primarily provide associative results, the focus groups contribute a richer understanding of the observed associations.

Results: The stakeholder interviews resulted in emergence of 8 commons themes including barriers begin with lack of access to public transport services and there are few opportunities in adult services to learn transportation and mobility skills. Currently there is data from over 500 respondents

and preliminary survey analysis will be conducted this winter.
Conclusions: N/A

9   **122.009** Autism Spectrum Disorders- Understanding Parental Pursuit to Access Speech-Language Services in the Indian Context

S. S. Meera[1], R. G. Shankar[1], B. S. Mathew[2], A. J. S. Mohammed[3] and N. Shivashankar[4], (1)NIMHANS, Bangalore, India, (2)Fr. Muller College of Speech and Hearing, Mangalore, India, (3)Dr. S. R. Chandrasekhar Institute of Speech and Hearing, Bangalore, India, (4)Dept. of Speech Pathology and Audiology, NIMHANS, Bangalore, India

Background: An alarming increase in the prevalence rate of Autism Spectrum Disorders (ASD) is a major concern for health care providers. Of foremost concern to Parents of children with ASD (PASD) are communication deficits. Accessing appropriate Speech-Language Services (SLS) for early intervention is the challenge. An average of 350 children with ASD seek SLS at the institute where the current study was undertaken. The intention was to understand the delays in reaching SLS, misperception the PASD hold, other obstacles that come in their way to access SLS. This understanding is of paramount importance to demystify misconceptions and develop professional and public education programs.
Objectives: To examine issues encountered by parents in accessing services of a Speech-Language Pathologist (SLP).
Methods: All children with confirmed ASD (n=65) seen in a span of 2 months were recruited for the current study. PASD were asked to fill a questionnaire that was specifically designed for this study. Some of the areas covered in the questionnaire included, age when parents started becoming concerned about their child (AOC=Age Of Concern), nature of these concerns, Age of Diagnosis (AOD), Age Of first visit to SLP (AOSLP), details of the hearing status, diagnosis and guidelines provided by the medical fraternity.
Results: All families belonged to middle economic status (MES). The mean age (in months) of AOC, AOD and AOSLP was 28.28±7.50, 35.00±15.29 and 43.32±23.26 respectively. The mean time gap (TG in months) between i) AOC-AOD was 7.09±14.06), ii) AOD-AOSLP was 8.32±18.70, indicating an overall delay of about 15 months (15.05±21.99) from AOC to AOSLP. In spite of this long delay in reaching out to Speech Language Therapy (SLT), 72.3% of the children were admitted into a normal school (no special services for a child with ASD) by the age of 48 months, indicating that parents were insistent on the child receiving academic inputs. Some of the common misconceptions and challenges included: 60% of PASD had the notion that speech will develop naturally later in life; 38.5% and 76.9% PASD believed that medicines and TV/mobile apps respectively, would help the child speak. In 44.6% cases the family doctor assured that the child had no significant problems and would improve as the days pass by. Though none of the children had a hearing loss (based on informal screening protocols), 75.4 % underwent an audiological evaluation. Not responding to name call was the single largest reason for referral and evaluation (78.75%). Three major concerns which parents had about their child included, the inability to speak adequately, followed by poor eye-contact and not following commands (75.4%, 29.2%, and 21.5% respectively). Findings are further discussed.
Conclusions: The current study has revealed a definite delay in the child receiving SLT and identified significant misperceptions PASDs hold. Delay in identification and rectifying the misperceptions can be addressed by sensitizing the medical professionals and through public education programs for parents and caregivers.

10   **122.010** Challenges Facing Families with a Child with ASD

*C. A. Cohen[1], **A. R. Marvin**[2], J. K. Law[3] and P. H. Lipkin[4], (1)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (2)3825 Greenspring Avenue/Painter Building 1st Floor, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD, (4)Pediatrics/Neurology and Developmental Medicine, Kennedy Krieger Institute/Johns Hopkins School of Medicine, Baltimore, MD*

Background:
Priorities for autism research should focus in those areas that make a difference to people's day-to-day lives.
Objectives:
The goal of the current survey was to understand and quantify the greatest challenges facing children with ASD and their families with a view to developing relevant research priorities.
Methods:
An anonymous survey that ran 08/01/2014-08/11/2014 targeted parents of a child of any age with ASD. Parents were asked the following open-ended questions:
(i)   If your *child* could get help for one autism-related challenge, what would it be?
(ii)   If your *family* could get help for one autism-related challenge, what would it be?
The survey was designed and administered by the Interactive Autism Network (IAN), a large, US-based internet-mediated autism-research registry. Links to the survey were distributed by e-mail to registry participants and informational website subscribers. Links were also posted on the registry's informational website and Facebook page.
Results:

There were 888 and 773 responses from parents of a child with ASD to the questions about challenges facing their child and family, respectively. Distribution of child ages for parent responses to both questions: 46% children aged<13 years; 29% teens aged 13-17 years; 25% adult children aged ≥18 years. Responses were coded and categorized into themes and sub-themes. Some responses spanned more than one theme or sub-theme and were coded in multiple categories and, thus, coded responses total more than 100%.

The greatest autism-related challenge that parents said that their children faced were general living skills (58%), most notably communication (19%) and social engagement (15%). The next most challenging category related to behavior (31%), most notably anger, aggressive behaviors, and self-injurious behaviors (19%). The other major challenge related to dealing with psychological comorbidities (14%), especially anxiety.

The greatest autism-related challenges that parents said that their families faced were their child's behavioral issues (20%), especially anger, aggressive behaviors, and self-injurious behaviors (15%). Families were concerned about transition issues and how their child would live independently (19%). Families were also challenged by financial issues (16%) and obtaining the services and help that they needed (18%), including respite care and emotional support, which are challenges that are also reflected in the general stress that families were reporting (18%). Family also reported challenges relating to their child's general living skills (19%).

Conclusions:
Children with ASD and their families face numerous autism-challenges in daily life. Both research and community resource priorities should focus on alleviation of these challenges.

11   **122.011** Compassion Meditation in Parents of Children with ASD and Potential Effects on Stress, Parenting Skills and Children's Outcomes

S. Fernandez-Carriba[1], E. Robbins[2], B. Ozawa-de Silva[3], B. Dodson-Lavelle[4], T. Pace[5], C. L. Raison[6], P. Rochat[2], L. T. Negi[7] and E. Jarzabek[8], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Psychology, Emory University, Atlanta, GA, (3)Life University, Marietta, GA, (4)Mind and Life Institute, Hadley, MA, (5)College of Nursing, University of Arizona, Tucson, AZ, (6)Psychiatry, University of Arizona, Tucson, AZ, (7)Emory-Tibet Partnership, Emory University, Atlanta, GA, (8)Pediatric Neurodevelopmental Clinic, Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA

Background:
Recent studies suggest that the practice of compassion meditation is associated with stress reduction as well as an increase in the ability to benefit from social support (Cosley et al, 2010). Cognitively-Based Compassion Training (CBCT) is a meditation protocol developed at Emory University that combines mindfulness and analytical meditation techniques that specifically promote compassion toward self and others. Six to eight weeks of CBCT practice on adults without prior experience in meditation shows reduced immune inflammatory and emotional distress responses to psychosocial stressors (Pace et al., 2009) as well as enhancement of empathic accuracy when assigning emotions to other people's faces with changes in the neurobiology supporting it (Mascaro et al., 2013).

Objectives:
The goal of this research is to pilot-test CBCT with typically developing school-aged children, teachers, and parents of children with ASD to promote relational competence in these populations, enhance adult-child interactions, and reduce stress in the parents.

Methods:
Participants in Study I included 53 children (7-10 years, M±SD = 8.77±0.61, 30 girls) at a private school in Atlanta, GA. Participants were randomized to mindfulness training and CBCT over the course of 12 weeks and completed three pre-post measures: the Implicit Association Task as a measure of racial stereotype, the Social Circles Task for friendship networks, and the MacArthur Story Stem Task for moral reasoning. An on-going follow-up study at a second elementary school aims to replicate and expand these findings by involving teacher personnel. In a third ongoing study at the Marcus Autism Center data is being collected on parents of children with autism (n=10). Pre-post measures are being taken on parent stress and acceptance (Parenting Stress Index, Perceived Stress Scale, and Acceptance and Action Questionnaire), empathy and compassion (Interpersonal Reactivity Index), behavioral flexibility (Mindful Attention Awareness Scale and Behavior Rating Inventory of Executive Function), parent-child relationship (Parenting Sense of Competence Scale), and children's symptoms as reported by parents (Aberrant Behavior Checklist).

Results:
In Study I, the proportion of children that included at least one peer in their inner Social Circle was larger post-intervention (92.6%) than pre-intervention (55.6%) for the CBCT group only (Fisher's p=.004, two-tailed). In the MacArthur Story Stem Task, post-intervention overall narrative scores were also higher for CBCT (M±SE= 6.09±.437) relative to mindfulness (M±SE = 4.33±.464) (p=.008) and also in the following subscales: emotionality, compassion, equanimity, and mentalizing (p<.05). Data from Study II, while ongoing, are already suggestive of positive effects of CBCT on prosocial behavior, stereotype, and bullying. Early descriptive and qualitative analyses of results from Study III, also ongoing, show a positive effect of CBCT on parent well-being, parent-child interactions, and parent reported symptoms in their children.

Conclusions:
Taken together, these results suggest that CBCT is a feasible training program for children, teachers, and parents of children with special needs, with benefits for the children regarding prosocial behavior. The potential benefits for teachers and parents in terms of relational competence (prosocial behavior, stress reduction and parenting skills), and the impact of these on the children, warrant further consideration.

12   **122.012** Concerns of Parents and Teachers of Children with Autism in Elementary School

G. Azad[1], *M. Kim*[2] *and D. S. Mandell*[3], (1)University of Pennsylvania School of Medicine, Hamilton, NJ, (2)Temple University, Philadelphia, PA, (3)Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA

Background: Numerous conceptual articles attest to the importance of parents and teachers openly communicating about their concerns regarding their children and coming to a consensus on which are the most important to address and how to address them. For children with autism, establishing and maintaining a collaborative partnership between families and schools has been encouraged on theoretical grounds, but rarely operationalized. The limited research in this area suggests that teachers and parents of children with autism may not collaborate to the extent warranted. Barriers to effective partnerships may include a lack of agreement about children's concerns, an inability to communicate about these concerns, or both.
Objectives: The purpose of this study is twofold: 1) to examine whether parents and teachers agree about their concerns for elementary children with autism and 2) to examine whose concern is discussed when these parents and teachers are observed communicating with each other.
Methods: Participants were 39 parent-teacher dyads of children with autism in kindergarten-through-fifth grade autism support classrooms. Each parent and teacher was interviewed separately about their concerns and then observed together in a discussion about the child.
Results: Parents' primary concerns involved deficits in social interaction (28%), problem behavior (26%), and academics (18%). Teachers' primary concerns were about problem behaviors (31%), followed by an equal concern for deficits in social interaction (18%) and restricted, repetitive, and stereotyped behaviors (18%). Parents' secondary concerns involved problem behavior (36%), academics (18%) and social interaction (15%). Teachers had an equal secondary concern for deficits in social interaction (26%) and problem behavior (26%), followed by academics (20%). When given an opportunity to communicate their concerns, 49% of the parent-teacher dyads discussed problems that neither reported as their primary concern, and 59% discussed problems neither reported as their secondary concern.
Conclusions: Our results indicated that parents and teachers generally agreed about their concerns when asked to report on multiple concerns. However, when they talked with each other, parent-teacher dyads discussed concerns that neither reported previously. Our findings are inconsistent with prior investigations that have shown that parents and teachers do not share the same concerns. It is likely that our findings differ from previous research because we asked parents and teachers to report on multiple concerns, whereas prior studies have only focused on one main concern. There are at least three possible reasons why parents and teachers may have discussed neither person's concerns. First, parents and teachers may not have been comfortable with each other because of a potential adversarial relationship. Second, parents and teachers may not know how to effectively negotiate with each other in choosing a topic of concern. It is also possible that parents and teachers do not remember their concerns when they feel pressured, especially when being observed by a researcher. These findings suggest that intervention efforts should focus on targeting parent-teacher communication, rather than agreement, to facilitate home-school collaboration.

13   **122.013** Daily Hassles and Relationship Satisfaction in Parents of Pre-School and School-Aged Children with Autism Spectrum Disorder: The Moderating Role of Spousal/Partner Support

H. L. Schneider[1], *C. S. Ghilain*[1], *M. V. Parlade*[1], *N. Ekas*[2] *and M. Alessandri*[1], (1)Psychology, University of Miami, Coral Gables, FL, (2)Texas Christian University, Fort Worth, TX

Background: Few studies have examined relationship satisfaction of parents of children with autism spectrum disorder (ASD). Yet, parents of children with ASD report lower levels of marital/relationship satisfaction and higher divorce rates than parents of children without a disability (Gau, et al., 2010; Hartley et al., 2010). Thus, an important area of study is identifying factors that may impact and protect marital/relationship functioning among parents of children with ASD.
Objectives: The current study examined the relationship between daily hassles associated with children's challenging behaviors, spousal/partner support, and relationship satisfaction among parents of children with ASD. Specifically, it was hypothesized that greater levels of daily hassles would be significantly associated with lower levels of relationship satisfaction. Additionally, spousal/partner support was expected to be positively associated with relationship satisfaction. Furthermore, spousal/partner support was expected to moderate the association between daily hassles and relationship satisfaction.
Methods: The current study consisted of 130 parents (65 dyads) of children with ASD (2.5-10.8 years of age) who participated in a larger study examining the association between child symptomatology and parental well-being and family functioning. Parents were between the ages of 27

– 62 years, and represented a diverse range of ethnicities (54% White/Hispanic, 35% White/Non-Hispanic, 11% Other/Mixed Ethnicity). Parents completed the Parenting Daily Hassles Scale as a measure of every day parenting stress associated with challenging behaviors (Crnic & Greenberg 1990; Crnic & Booth 1991), the Couples Satisfaction Index as a measure of relationship satisfaction (CSI; Funk & Rogge, 2007), and the Informal Social Support scale as a measure of spousal/partner support (Schuster et al., 1990; Whalen & Lachman, 2000).

Results: A hierarchical regression analysis was used to examine links between daily hassles, spousal/partner support, and relationship satisfaction. Results indicated that higher levels of daily hassles was related to lower levels of relationship satisfaction (F (1,128) = 4.217, p <.05) and higher levels of spousal/partner support was related to higher levels of relationship satisfaction (F (2,127)= 93.795, p <.001). Furthermore, spousal/partner support was found to buffer the relationship between daily hassles and relationship satisfaction (F (3,126) = 71.389, p <.001). Post-hoc analyses revealed that when spousal/partner support was low, increased daily hassles was significantly associated with lower relationship satisfaction (t (126) = -2.679, p = .008). When spousal/partner support was high, increased daily hassles was not significantly associated with relationship satisfaction (t(126)= -1.294, p = .198).

Conclusions: Results suggest that parenting stress associated with daily hassles may have adverse effects on marital/relationship functioning. However, spousal/partner support protected against the negative effect of daily stress associated with challenging behaviors. Future interventions should stress the importance of dyadic coping in the face of such challenges, thus strengthening parents' relationship.

14   **122.014**   Development of a Parent Mentor Training Program in Japan

T. Takezawa[1], H. Haraguchi[2], T. Yoshikawa[3], M. Ogura[4], J. Adachi[5] and M. Inoue[6], (1)Education and Social Service, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan, (2)Child and Adolescent Mental Health, National Center of Neurology and Psychiatry, Kodaira, Japan, (3)Child and Adolescent Psychiatry, Central Hospital, Aichi Human Service Center, Kasugai, Japan, (4)School of Basic Research and Improvement of Practice for Education, Naruto University of Education, Naruto, Japan, (5)Special Education, Hokkaido University of Education, Asahikawa, Japan, (6)Faculty of Medicine, Tottori University, Yonago, Japan

Background: Parent to parent programs have come to be widely recognized as an effective means of supporting parents of children who have special needs. Similarly in Japan, "parent mentors," parents of individuals with Autism Spectrum Disorders (ASD) and/or other developmental disabilities (ODD), have been engaging in supporting other parents. Parent mentor activities include telephone, one-on-one, and group counseling services. Parent mentors also provide outreach services such as lectures on disabilities and simulation activities. The Ministry of Health, Labor and Welfare indicates the importance of parent mentor activities and training programs in the context of providing family-centered services. The authors have been working with parent mentors by providing support for their activities and developing a Parent Mentor Training Program (PMTP).

Objectives: The objective of this study is to develop a comprehensive PMTP. The purpose of the study is to investigate the effectiveness of the PMTP by conducting a pre- and post-survey on basic and follow-up training programs.

Methods: Participants included a total of 203 parents of individuals with ASD and/or ODD. The two-day basic program included; 1) a lecture on ASD and ODD, 2) a workshop on local resources of social welfare, 3) a lecture on basic counseling techniques, 4) a role-play session on one-on-one counseling. The two–day follow-up program, for those who had received the basic program, included; 1) a lecture with the last updated information on administration and education, 2) a lecture on intermediate counseling techniques, 3) a role-play session on telephone and group counseling. The authors made a questionnaire on 5-point Likert scale, consisting of 20 items and 4 subscales: 1) skills and attitudes, 2) topics of conversation, 3) anxiety and stress, 4) confidence as a parent mentor. Positive scores on this questionnaire indicated high level of aptitude/competence as a parent mentor. The participants answered the questionnaire before and after each program.

Results: As for the basic program, the post-test score of items such as "respect for human rights," "listen carefully," "feel sad and angry (inverted)," and "sense of self-composure," significantly increased, whereas the score on "feel stress when talking with clients" tended to decline. Overall, the scores for the follow-up program were higher than those for the basic program. For the follow-up program, the post-test score of the item "respect for human rights" increased, and the scores on "talk on experience" and "feel stress when talking with clients" declined.

Conclusions: We found that the participants obtained knowledge and skills needed to be a parent mentor through the basic and follow-up programs. We also found that the participants were more likely to feel anxiety and stress after the program. This is partly because they could realize the difficulty to talk with their clients through the programs including the role play sessions. We assume that many parent mentors feel anxious when talking with their clients and have difficulty dealing with the stress. It is necessary to find the way to reduce their anxiety and stress by introducing elements of training in stress management into the PMTP.

15   **122.015**   Early Access to Care in the Province of Quebec: A Policy Analysis Framework

K. Shikako-Thomas[1], T. Savion-Lemieux[2], L. Stern[3], M. Steiman[3], R. Simon[4], L. Girouard[5], A. Yusuf[6]

and M. Elsabbagh[7], (1)School of Environmental Design, University of Montreal, Brossard, QC, Canada, (2)Psychiatry, McGill University, Montreal, QC, Canada, (3)Montreal Children's Hospital, Montreal, QC, Canada, (4)Psychology, Montreal Children's Hospital - McGill University Health Centre, Montreal, QC, Canada, (5)2155 Guy Street, 5th Floor, McGill University Health Centre - Research Institute, Montreal, QC, Canada, (6)Department of Pscyhiatry, McGill University, Montreal, QC, Canada, (7)McGill University, Montreal, PQ, Canada

Background: Prevalence estimates suggest that Autism Spectrum Disorder (ASD) affects 1-2% of children globally (Elsabbagh et al., 2012). There is consensus that early identification and intervention for ASD can improve child functioning and family well-being, thereby reducing costs and burden to society in the long run (Khan et al., 2012). However, serious barriers currently hamper access to care across the world (WHO, 2013). Further investigations are needed to explore how policy and/or implementation barriers contribute to these delays and barriers to care.

Objectives: To identify the congruence between existing policies supporting early identification and intervention for ASD and the actual state of community-based early identification and intervention services in Quebec (QC), Canada.

Methods:
We conducted a scoping review of QC policies related to ASD (Stephenson & Mccoll, 2008) and developed an analysis framework to map existing policies to actual reports of access to care through administrative and family-based sources. Relevant provincial, federal, and international policy documents were identified. Each policy, statement, act, program description or governmental body that was identified as a primary source. Using a snowballing technique, we identified new documents or references from these primary sources. A policy analysis framework (Hill & Bramley 1986; McColl and Jongbloed, 2006) was used to extract the following data: the policy's stated objectives, its desired outcomes, benchmarks and work plans, and mechanisms for policy implementation. A stakeholder focus group of parents, researchers, and health care professionals was held and asked to consider the extent to which identified policies are perceived as effective in achieving their stated objectives.

Results:
The analysis suggested a wealth of articulated policies grounded in international guidelines protecting the rights of children and consistent with medical models for chronic care (life-span, evidence-based, family-centred, and coordinated).
The stated objectives of most policies were to ensure early access to comprehensive care for families and children affected by ASD across the lifespan. The desired outcomes were to optimize access and develop specific mechanisms so that children and families can receive complementary and coordinated services across sectors (e.g. education, health). Very few policy documents described benchmarks or working plans to ensure implementation of their policies considering the systems constraints.
Review of administrative data from a large university health center alongside stakeholder input from a focus group suggested that QC is far from implementing its articulated policies. The following patterns were specifically highlighted as conflicting with these policies: (1) long wait times (up to 2 years) for diagnostic and intervention services, (2) poor care coordination across different levels of service, (3) inadequate support for caregivers, (4) disparities in care access and utilization negatively affecting families from lower socio-economic backgrounds or recent immigrants.

Conclusions: Major disparity exists between articulated policies and their enactment in Quebec. The lack of implementation mechanisms (e.g., an analysis of system's barriers and facilitators) may contribute to gaps in access to care.

16   **122.016** Early Intervention Services and Effects on Parent Stress

N. Broderick[1], A. Stainbrook[2], C. G. Herrington[3], A. P. Juárez[4] and Z. Warren[1], (1)Vanderbilt University, Nashville, TN, (2)Department of Pediatrics, Vanderbilt Kennedy Center, Nashville, TN, (3)Vanderbilt Kennedy Center, Vanderbilt University, Nashville, TN, (4)Pediatrics & Psychiatry, Vanderbilt Kennedy Center, Nashville, TN

Background:
Parents of children with Autism Spectrum Disorder (ASD) experience greater parenting stress than parents of children who are typically developing and children with other disabilities. A recent meta-analysis of parenting stress literature suggested future research should attempt to *explain*increased parental stress in this population in order to promote parent resilience. Programs that emphasize the quality of parent-child interaction yield the largest effects on child and parent behavior, which could influence parent stress and resilience.

Objectives:
Consistent with these aims, this study investigates the relationship between parenting stress, parent depression, and an early intervention program emphasizing the transactional nature of child development following an initial diagnosis of ASD.

Methods:
Through collaboration between a university based ASD institute and a state department of education, 60 families of young children (ages 18-36 months) are receiving services following a psychologist's diagnosis of ASD or related developmental delay. All families participate in two home-based sessions

involving consultation and training on evidence-based practices for young children with developmental differences. Half of these families (n=30) participate in an additional 12-visit series providing support guided by the Early Start Denver Model (ESDM) curriculum. At pre-test, all primary caregivers complete a Parenting Stress Index, 4[th]edition – Short Form (PSI/SF) and a Center for Epidemiologic Studies Depression Scale (CES-D). All primary caregivers who participate in the two-visit series complete the PSI/SF and CES-D at the end of that series. The primary caregivers who participate in the 12-visit series (n=30) complete the PSI/SF and CES-D after all 14 visits.

When data collection is complete, initial descriptive analyses will be conducted to summarize parenting stress and depression across and within groups. Following descriptive analyses, Pearson Correlation Coefficients will be calculated to investigate the relationship between Parent Stress and Parent Depression. An ANCOVA will be conducted with post-test scores as the primary outcome variables, group status (2-visit versus 12-visit series) as the primary independent variable, and pre-test scores as the covariate.

Results:

Implementation

Consultation implementation at 95% fidelity across both models (Two and 12-visit). Consultants covered 90% of the ESDM curriculum; parents demonstrated 70% of strategies covered. Consultants and caregivers observed minimal-moderate levels of improvement in child behavior after two visits and moderate-significant levels of improvement following 14 visits.

Current Sample (n=20 at pre-test)

PSI-SF at-risk threshold is 85th percentile; clinical threshold is 90[th]percentile.

- 70% indicated an at-risk score; 60% indicated a clinically significant score
- mean %ile=90.45, sd=10.45

CES-D clinical threshold is 16.

- 40% indicated a score above 16
- mean=13.80, sd=8.93

Anticipated Results

Results regarding Pearson Correlation Coefficients and ANCOVA, and any follow-up analyses, will be presented upon completion of data collection.

Conclusions:

Researchers anticipate a difference in perceived parent stress and/or depression across the intervention groups. If analyses reveal a difference, then regression will be used with existing child clinical data to determine which child characteristics are associated with parent stress, parent depression, and parent responsiveness to intervention. Chi-Square may also be conducted to evaluate differences in status on stress and depression according to support series provided.

17 **122.017** Effects of Sensory Sensitivity and Intolerance of Uncertainty on Anxiety in Mothers of Children with Autism Spectrum Disorder

M. Uljaravic[1], S. Carrington[2], S. Leekam[1] and M. Prior[3], (1)Wales Autism Research Centre, Cardiff University, Cardiff, United Kingdom, (2)Wales Autism Research Centre, Cardiff, Wales, United Kingdom, (3)Department of Psychology, University of Melbourne, Carlton North, Australia

Background: Parents of individuals with autism spectrum disorders (ASD) consistently report elevated levels of anxiety. Such anxiety may be linked to the stress of managing their child's ASD symptoms, but it is also likely to be influenced by individual characteristics in the parent. Identifying the influence of individual parent factors is important given that anxiety has negative implications for interpersonal relations. In this study we focus on two key individual traits that are associated with anxiety in the general population; intolerance of uncertainty, defined as a "relatively broad construct representing cognitive, emotional, and behavioral reactions to uncertainty in everyday life situations" (Freeston et al., 1994) and sensory sensitivity, a trait that predisposes individuals to be more sensitive to various stimuli from the social and physical environment.

Objectives: This study examined the relations between anxiety in mother and other personal characteristics of sensory sensitivity and intolerance of uncertainty. Given previous research in general population samples, it was predicted that both IU and sensory sensitivity would have a direct effect on maternal anxiety. However, IU and sensory sensitivity might also have an indirect effect on anxiety according to several different models: the relation between IU and anxiety may be mediated by sensory sensitivity (model 1) or the relation between sensory sensitivity and anxiety may be mediated by IU (model 2).

Methods: Fifty mothers of children and adolescents with ASD (mean age of children = 10 years 7 months (10.7), SD= 3.10; mean age of mothers = 44.4; SD= 6.3) completed the Hospital Anxiety and Depression Scale (HSP), the Highly Sensitive person scale and the Intolerance of Uncertainty (IU) Scale. None of the mothers had a diagnosis of ASD.

Results: Almost half (46%) of mothers met the cut-off criterion for clinically significant anxiety; these mothers significantly differed from the non-anxious mothers in terms of their IU (t= 3.01; p= .004; Cohen's d= .85) and HSP total scores (t= 2.22; p= .03; Cohen's d= .63). A three-way interrelationship between sensory sensitivity, IU and anxiety was found. In order to characterize the nature of this interrelationship, two mediation analyses were performed using the serial mediation model in PROCESS (Hayes, 2012) testing two above described models. Mediation analyses showed direct effects between anxiety and both IU and sensory sensitivity but a significant indirect effect was found only in model 2 in which IU mediated between sensory sensitivity and anxiety. Our findings

supported the second mediation model. In other words, the presence of high sensitivity and a susceptibility to being overwhelmed by environmental stimulation, may lead to an experience of the world as highly unpredictable. Such increased unpredictability could make even the most simple situations and events uncertain and difficult, thereby provoking anxiety.
Conclusions: This is the first study to characterize the nature of the interrelation between intolerance of uncertainty and sensory sensitivity in predicting the levels of anxiety.

---

18   **122.018** Emotion Regulation and Depression in Parents of Children with Autism Spectrum Disorder
A. Costa and G. Steffgen, University of Luxembourg, Walferdange, Luxembourg

Background: Research findings prove that parents of children with autism spectrum disorder (ASD) have more depressive symptoms than parents of typically developing (TD) children (Olsson & Hwang, 2001; Davis & Carter, 2008). Experienced stress related to the child difficult behavior and restrictions in personal life imply a higher risk for depression (Olsson & Hwang, 2001). However, studies with TD children also show that children of depressed parents are at risk of developing low emotion regulation (ER) ability (Feng, Shaw, Kovacs, Lane, O'Rourke, & Alarcon, 2008; Hoffman, Crnic, & Baker, 2006). Therefore, it is hypothesized that ER abilities in children with ASD and depressive symptoms in parents are related.
Objectives: Analyze the relationship between depressive symptoms in parents and ER of children with ASD.
Methods: 31 parents answered questionnaires about themselves and their children. Parents were aged 31 to 54 years old and their children 5 to 12 years old. 9 children were diagnosed with ASD accompanied by intellectual and language impairments, 9 were diagnosed with ASD without intellectual and language impairments, and 13 were TD children. The following questionnaires have been applied: the Difficulties in Emotion Regulation Scale for adults (DERS; Gratz & Roemer, 2004), which assesses emotional dysregulation; the Emotion Regulation Questionnaire (ERQ; Gross & John, 2003), which assesses cognitive reappraisal and expressive suppression; the Center for Epidemiologic Studies Depression Scale (CES-D scale; Radloff, 1977), which assesses depressive symptomatology; the Autism Spectrum Quotient Questionnaire for Children (AQ-Child; Auyeung, Baron-Cohen, Wheelwright, & Allison, 2008) which assesses autistic traits; and the Emotion Regulation Checklist of children (ERC; Shields & Cicchetti, 1997) which assesses ER and lability-negativity.
Results: Parents of children with ASD with intellectual and language impairments had a significantly higher score in the DERS ($\chi^2(2)$=7.54, p<.05) and parents of children with ASD without intellectual and language impairment reported using more reappraisal than parents of TD children (U=36, p<.05). Furthermore, a positive correlation was found between the use of reappraisal in parents and the score on the AQ-Child ($r_s(29)$=.38, p<.05). Finally, no relations were found between the parents score on the CES-D and the 3 groups of children ($\chi^2(2)$=2.42, p=.30) or the score on the AQ-child ($r_s(29)$=.19, p=.15). However, parents' score on the CES-D was positively correlated to their score on the DERS ($r_s(29)$=.33, p<.05) and negatively correlated to the children's score on the ER scale of the ERC ($r_s(29)$=-.30, p<.05).
Conclusions: Parents of children with ASD with intellectual and language impairments reported having more ER difficulties. The more the autistic traits appear in children; the more parents used cognitive reappraisal as an ER strategy. Furthermore, parent style of ER and their children ER ability proved to be related to depressive symptoms. However, the causality of this relation is yet to be defined. Parents' depressive symptoms and difficulties in ER might be risk factors for children with ASD developing low ER abilities. On the other hand, children's difficult behavior and difficulties regulating themselves might lead to higher stress levels and depression in parents.

---

19   **122.019** Evaluation of a Support Group for Fathers of Children with Autism Spectrum Disorder
M. Elfert[1,2] and P. Mirenda[3], (1)Reach Child and Youth Development Society, Delta, BC, Canada, (2)Douglas College, Coquitlam, BC, Canada, (3)University of British Columbia, Vancouver, BC, Canada

Background: Parenting a child with ASD can present significant challenges for parents, and various supports have been designed to help parents in this task, including support groups, which focus on parents' emotional and psychological concerns and issues. Scant research has examined support group participation and effectiveness, either for parents in general or for parents of children with ASD, and there are a number of methodological flaws (e.g., outcome measures with no psychometric properties). Furthermore, as is the case with other research in field of ASD and special needs, the majority of participants have been mothers. However, qualitative research suggests that fathers would attend such groups if they were available. More research on fathers and their experiences is needed.
Objectives: The purpose of this study was to evaluate the impact of a support group for fathers of children with ASD, using quantitative measures and a measure of social validity to examine participants' psychological experiences.
Methods: Two groups of six fathers (N = 12) attended eight weekly 2-hour sessions that focused on various topics related to parenting a child with ASD. Sample topics included fathers' experiences with the diagnosis, dealing with the education system, and the impact on personal and professional relationships of parenting a child with ASD. Pre- and post-intervention, participants completed the Beck Depression Inventory-II, the Dyadic Adjustment Scale (DAS), the Parenting Stress Index 4th

Edition, the Life Orientation Test-Revised, the Ways of Coping Questionnaire, a demographic form, and a social validity questionnaire. In addition, participants in one group also completed these same measures four months after the support group concluded.

Results: Results of a series of paired samples t-tests indicated no significant changes over time for the groups on any of the measures. However, responses to the social validity measure indicated that all fathers found the groups to be meaningful and helpful, enjoyed listening to and sharing personal experiences with other men in similar circumstances, and strongly recommended a similar group to other fathers of children with ASD. Although no statistically significant improvements in psychological functioning were observed within or between groups, there were a number of changes in individual scores, indicating improvements in well-being.

Conclusions: The vast majority of research conducted with parents of children with ASD still includes mostly mothers as participants. Research on fathers' experiences has increased over time, but more is needed. From an empirical perspective, studying fathers provides important information about their unique experiences and how they differ (or are similar to) those of mothers. Furthermore, it demonstrates respect and appreciation for the unique identity and contributions of fathers. From a clinical perspective, the information gathered via research can be used to develop effective interventions to support and assist fathers to be better parents and partners. In this study, although significant changes were not found on standardized measures of fathers' well-being, the participants reported that the group was valuable and worthwhile and recommended it highly to other fathers, pointing to an important and exciting area for future research and community intervention.

20   **122.020** Examining Changes in Parental Distress, Self-Efficacy, and Children's Problem Behaviors from Admission to 2-Month Follow-up within the Autism Inpatient Collection (AIC) Sample

K. A. Smith[1], *T. Flis*[2], *R. Chappell*[3], *B. L. Handen*[4] *and M. Siegel*[5], *(1)Maine Medical Center Research Institute, Portland, ME, (2)Child and Adolescent Neuropsychiatry Unit, Sheppard Pratt, Baltimore, MD, (3)Sheppard Pratt, Baltimore, MD, (4)Psychiatry, University of Pittsburgh Medical Center, Pittsburgh, PA, (5)Maine Medical Center Research Institute, Westbrook, ME*

Background: Parents of children with Autism Spectrum Disorder (ASD) have reported increased stress, which is associated with lower parental self-efficacy and child behavior problems. There is a lack of research examining changes in parental distress, self-efficacy and children's problem behavior over time, and whether differences in outcome occur based upon children's verbal ability.

Objectives: To analyze preliminary data from the Autism Inpatient Collection (AIC) examining changes in parental distress, parental self-efficacy, and parent's reports of children's problem behaviors from admission, discharge, and 2-month follow-up. Further, to explore potential differences in problem behavior between children with limited verbal ability and fluent speech.

Methods: Children and adolescents aged 4-20 years, with an Autism Diagnostic Observation Schedule-2 (ADOS-2) supported autism diagnosis and admitted to specialized inpatient psychiatry units were prospectively enrolled in a six-site study examining patient phenotypes and behavioral outcomes. Parent measures, including the Parental Stress Index (PSI-SF 4) Parental Distress (PD) subscale, Difficult Behavior Self-efficacy Scale (DBSS), and the Aberrant Behavior Checklist - Irritability subscale (ABC-I), were collected at admission, discharge, and 2-month follow-up. ADOS-2 Modules 1&2 were administered to patients with limited verbal ability, while Modules 3&4 were administered to patients with fluent speech. Repeated measures analysis of variance (RMANOVA) was conducted to examine for changes in scores over time.

Results: Mean age of the first 108 enrolled children was 12.70 years (SD=3.50), 24% female, 77.8% Caucasian and 91.4% Non-Hispanic/Non-Latino. Average length of stay across the six-sites was 25.35 days (SD=23.21, Median=19.0, Range=4-130). Approximately half the sample (56%) was administered ADOS-2 Modules 1&2. Preliminary results are based on complete data from forty-four parents with data from all three time points. The majority of parent report measures came from patients' biological mothers (70.7%), followed by biological father (9.8%), step/foster/adoptive mother (9.8%) or father (2.4%), and grandparent (7.3%). Average age of parent respondents was 44.56 years (SD=10.30), 52% married, with an average annual household income <$35,000. Parents reported a significant decrease in their child's problem behavior between admission, discharge and 2-month follow-up, F=12.75, p<0.001, though this difference did not significantly vary between patients with limited verbal ability and fluent speech, F=0.23, p=0.79 (see Figure 1). Parents also reported a significant decrease in parental distress between admission, discharge and 2-month follow-up, F=6.94, p=0.002. There was no significant difference in parents' report of their confidence in their ability to parent a difficult child (self-efficacy) between admission, discharge and-2 month follow-up, F=0.27, p=0.61. Cronbach's Alpha was >0.70 for all scales at all three time points indicating good scale reliability.

Conclusions: Preliminary data suggests that parents with children in specialized psychiatric inpatient units reported a significant reduction in their own distress and their child's problem behavior from admission to 2-months post-discharge, regardless of the child's verbal ability. There was no change in parents' report of their self-efficacy in managing problem behavior over time. Future research should examine how parent self-efficacy and mindfulness based stress reduction techniques may mediate parental distress and behavioral outcomes in children with autism.

21   **122.021** Factors Influencing Relocation for Military Families with Children with ASD

J. Davis and E. H. Finke, *Communication Sciences and Disorders, Pennsylvania State University, University Park, PA*

Background:
Military families are an underrepresented group in the ASD literature, despite the number of military dependents with a diagnosis of ASD reaching approximately 23,500 (Tricare, 2011). There has been little peer-reviewed research to date on military families with children with special needs or children with ASD; however, previous research has indicated the presence of need within this population. A survey by Ferrell and colleagues (2014) found that military spouses with a child with special needs perceived less informal and formal support than other military spouses. Davis and Finke (in review) interviewed 15 military spouses with children with ASD about their therapeutic experiences. Military spouses reported challenges with relocation, separation, Tricare, and military programs that resulted in negative impacts on their child's autism related services. In order to inform clinical practice for professions, provide evidence for policy, and improve services and outcomes for military families, the experiences and needs of a larger sample of military families with children with ASD should be examined. Military families have specific characteristics that may impact their experiences with services related to autism and; therefore, may have unique service needs. The purpose of the current study was to describe the therapeutic experiences of military families with a child with ASD to determine needs of this population in a larger sample.
Objectives:
The main objectives of this investigation were to determine what factors influence the military spouses' perception of services at different installations, effects of relocation on the child with ASD and family, and factors influencing relocation satisfaction.
Methods:
In order to determine the experiences of a larger sample of military families with children with ASD, a self-administered online survey design was chosen. Surveys allow researchers to collect self-reported data on personal experiences and generalize findings from a small population to a larger one in a time and cost efficient manner (Rea & Parker, 2005). An online mode was chosen because online surveys extend the "reach" of respondents who may live in a number of geographic regions, are cost effective, contain no interviewer bias or data entry error, and allow for easy follow-up and quick data collection (Rea & Parker, 2005; van Selm & Jankowski, 2006). The questions and response choices in this survey were generated from a review of the literature on families of children with ASD and/or other disabilities (e.g., Renty & Roeyers, 2006; Dunst, Jenkins, & Trivette, 1984) and military families (e.g., Huebner et al., 2010; Blue Star Families, 2013).
Results:
Approximately 200 military spouses with children with ASD completed the online survey. Data analysis is currently on-going, but preliminary results suggest military families with a child with ASD experience challenges related to frequent relocation including provision of therapeutic services, child and family adjustment, and access to supports.
Conclusions:
Data analysis is currently on-going, but conclusions may impact clinical service providers, military programming and providers, and laws and policies.

22   **122.022** Fathers' and Non-Fathers' Physiological Responses to Distress Vocalizations of Infants with Autism Spectrum Disorders

G. Esposito[1,2], S. Valenzi[3], T. Islam[3] and M. H. Bornstein[4], (1)Department of Psychology and Cognitive Science, University of Trento, Rovereto, Italy, (2)Nanyang Technological University, Singapore, Singapore, (3)RIKEN Brain Science Institute, Wako-Shi, Japan, (4)Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD

Background: Children with ASD, even before receiving a formal diagnosis, express atypical patterns of cry (higher fundamental frequency and shorter inter-bout pauses) in response to social and non-social stressors. Cries of children with ASD are also perceived differently from other cries, and these perceptual differences may alter parent-infant interaction.
Objectives: To test multiple physiological responses to atypical distress vocalizations (crying of ASD children) acoustically matched with typical distress vocalizations (crying of typically developing children) and with positive vocalizations (laughter of typically developing children).
Methods: The experimental procedures were designed measure how components of the autonomic nervous system respond to typical and atypical infant distress vocalizations. We employed three convergent methodologies. (i) Emotional arousal was assessed using the Galvanic Skin Response (GSR). (ii) Assessments of excitability were conducted monitoring cardiac dynamics via Inter-Beat Interval (IBI). (iii) Promptness to action was measured as temperature increases of the right hand (Right Hand Temperature Change – RHTC), which is associated with arousal and activation. These physiological assessments were performed on two groups with contrasting caregiving experience: fathers (n=10) and non-fathers (n=10).
Results: Inferential analysis was performed considering two groups (fathers vs non-fathers) and three stimulus types (ASD cry, TYP cry, laughter) for the three measures (GSR, IBI, RHTC). Both fathers and non-fathers showed greater negative response (increased GSR) to ASD cries compared to TYP cries and laughter ($p < .001$). Fathers showed higher IBI compared to non-fathers while hearing both typical and atypical crying ($p < .05$), and for the RHTC fathers showed greater temperature increases

than non-fathers while listening to typical and atypical cries ($p < .05$).
Conclusions: In agreement with behavioral studies that have been conducted mainly in females and mothers, fathers and non-fathers show more emotional arousal mediated by sympathetic activation (measured as increased GSR) while listening to cries of children with ASD. In other terms, it seems that ASD cries are processed as more negative. This result is likely driven by specific characteristics of ASD cries (high frequency and shorter pauses). Fathers were calmer (lower IBI) than non-fathers while listening to cries, perhaps because fathers have more experience in caring for crying infants. Fathers were more prompted to act (increase of the RHTC) than non-fathers while listening to cries. However, we found no differences between fathers and non-fathers in reaction to non-distress vocalizations. Sensitivity to infant cries may be tuned by fathering experience. These findings highlight both similarities and differences in fathers' and non-fathers' physiological responsiveness to crying of children with ASD and can provide information to guide specific intervention programs for parents of children at high-risk of ASD.

23   **122.023** First Concerns Among Latino Parents of Children with Autism Spectrum Disorder

*S. Magana[1], **M. Rivera**[2] and E. S. Robb[1], (1)Disability and Human Development, University of Illinois at Chicago, Chicago, IL, (2)Communication Sciences and Disorders, University of Wisconsin-Madison, Madison, WI*

Background:
Autism spectrum disorders (ASDs) are neurodevelopmental disorders that are estimated to affect 1 in 67 children in the U.S. Typically, diagnosis is made at 3 or 4 years although it is believed that reliable diagnoses can be made as early as 2 years. Unfortunately, studies show that African American and Latino children are under-diagnosed and when diagnosed, receive a later diagnosis than White children. It is believed that earlier recognition and diagnosis leads to improved child outcomes due to enrollment in early intervention services to address speech/language, cognitive, social, and self-help skills. There is some evidence that first concerns expressed by parents about their children are important factors in early diagnosis. However, little is known about the first concerns expressed by Latino parents of children with ASD.
Objectives:
Our research questions for this study are: 1) what are the first concerns of Latino parents of children with ASD and developmental disabilities (DD)?, and 2) how do first concerns differ between Latino parents of children with ASD compared to parents of children with other DDs?
Methods:
We analyzed qualitative responses from 27 Latino parents of children with ASD (n=18) and other DDs (n=9). Each of the authors reviewed the transcripts independently and identified themes in response to our 2 research questions. We then met to agree upon working definitions of themes and proceeded to recode transcripts independently. When saturation was achieved, the authors reviewed the coded transcripts and reached agreement.
Results:
Five categories emerged from our analysis: communication concerns, behavior or temperament concerns, social concerns, concerns about physical milestones, and sensory concerns. The vast majority of parents expressed first concerns about communication or language challenges of their children regardless of whether they had ASD or another DD. However, parents of children with ASD had more concerns about problem behaviors and social development. Surprisingly, the parents of children with other DD had more concerns about sensory issues than the parents of children with ASD in our sample.
Conclusions:
Our findings are consistent with the literature on first concerns (based primarily on White parents of children with ASD). Our results suggest that it is important that pediatricians and health care providers respond appropriately to parent's first concerns about their children's development (i.e., conduct screenings, make referrals for evaluation), particularly when there is a concern about language. Children whose parents also express concerns about social and behavioral issues may especially warrant screening for ASD.

24   **122.024** Implementation of Early Service Interventions and Its Effects on Parent Resilience

K. Herrington[1], A. Stainbrook[2], N. Broderick[3], A. P. Juárez[4] and Z. Warren[5], (1)Vanderbilt University, Nashville, TN, (2)Department of Pediatrics, Vanderbilt Kennedy Center, Nashville, TN, (3)Kennedy Center, Vanderbilt University, Nashville, TN, (4)Pediatrics & Psychiatry, Vanderbilt Kennedy Center, Nashville, TN, (5)Pediatrics, Vanderbilt University, Nashville, TN

Background:
It is well established that parents of children with autism spectrum disorder (ASD) experience significant stress; however, far less is known about parental characteristics that may promote family resilience, defined as the ability to adapt to stressful life events and changes (Hayes and Watson 2013). A review by Bekhet and colleagues (2012) suggests that parents of children with ASD who possess indicators of resilience are more equipped to handle the stress that often accompanies caring for children with ASD. Specifically, parental self-efficacy – parents' beliefs about their ability to parent successfully – is identified as an important predictor of resilience. Further, research

demonstrates an inverse relation between parental self-efficacy and depression (Kuhn and Carter 2006), highlighting the deleterious effects of depressed mood on parents' sense of competency.
Objectives:
The purpose of this study is to evaluate the impact of early intervention services for parents of children with a recent diagnosis of ASD or a related diagnosis. A primary objective of this investigation is to learn whether the enhancement of parental resilience is an outcome of early intervention services. The relation between parental self-efficacy and parental depression will also be explored.
Methods:
Participants include 60 families with children ages 18-36 months that are receiving support services following an ASD or related diagnosis. All families participate in two home-based sessions that include behavioral consultation and training on evidence-based practices for children with ASD. Half of these families (N = 30) participate in an additional 12-visit series providing education and support from the Early Start Denver Model (ESDM) parent training curriculum. Pre- and post-intervention measures include the Parenting Sense of Competence Scale (PSOC) and the Center for Epidemiologic Studies Depression Scale (CES-D). An Analysis of Covariance (ANCOVA) model will be used in which the post-intervention scores serve as the outcome variable, group (brief consult or ESDM) as the main independent variable, and baseline (pre-intervention) scores as the covariate. Pearson correlation coefficients will be used to determine the relation between self-efficacy and depression.
Results:
Preliminary data suggest that the consultants were able to implement the training model designed for each service with 95% fidelity. Additional data suggest that consultants were able to cover over 90% of the ESDM curriculum across the 12 visit model and that parents were able to demonstrate over 70% of those strategies covered within treatment sessions. Preliminary data indicate heightened levels of parent depressive symptoms pre-intervention (CES-D: M=13.80; SD=8.93) and moderate levels of parental self-efficacy (PSOC: M=74.44; SD=11.5) with an inverse relation between depression and self-efficacy (r = -0.7, p= .001).
Conclusions:
The current study aims to further our understanding of the factors that promote parents' resilience following the significant life event of a child's ASD or related diagnosis. Prior to intervention, parents endorsed elevated levels of depressive symptoms and moderate levels of self-efficacy. Subsequent analyses will examine whether a brief consultation or a longer-term intervention differentially confer benefits to parents' self-efficacy and depressive symptoms. This information will guide future endeavors for enhancing parental well-being.

25 **122.025** Influence of Pre and Post Doctoral Fellowships on Autism Research Career Trajectory
A. K. Halladay and A. T. Singer, *Autism Science Foundation, New York, NY*

Background: Investing in the training of junior level researchers at critical points in their academic careers has been an important strategy of public and private funding agencies. This support helps both recruit and cultivate new investigators so that they develop into the next generation of productive autism scientists. However, tracking the short and long term activities of these researchers has not been well documented or published publically.
Objectives: This analysis examined data from 2010 to 2014 from both pre doctoral and postdoctoral research grants awarded from a private funding agency. Diversity of research topics as well as metrics of potential future success as researchers was analyzed and presented
Methods: Trends across time and award type were made and compared. Funding amount and standardized return on investment measures including number of new grants, publications, presentations to scientific and lay audiences, retention in the field of autism and documented collaborations outside the mentor/trainee relationship were recorded and tracked. The last metric has been demonstrated previously as a method for identifying successful scientists within the field of autism (Goldstein et al, 2014).
Results: Data was tracked for 1 year following the end of the award for 14 pre doctoral and 11 post doctoral fellows, who received awards from 2010-2013. During this time period, the 14 predoctoral fellows published 6 articles in books or scientific journals, conducted 41 presentations, and established documented collaborations with 30 scientists who were outside the original pre doctoral training plan. At the time of survey, all were still working in the field of autism. The 11 postdoctoral fellows published 9 articles, made 46 presentations and had established connections with 33 other scientists during their fellowship. More than half had received additional funding for autism research and all were still working in the field of autism research. For predoctoral fellowships, the most popular field of study was molecular and cellular biology (28%); for postdoctoral fellowships it was brain function (30%). Communication and language ranked second for both groups.
Conclusions: These descriptive results demonstrate the critical importance of funding of early career researchers to support the career development of researchers studying ASD. Comparison data from pre doctoral fellows who did not receive specific research and mentorship support, as well as those outside autism research, will be presented at IMFAR. In the future, additional effort should be made to recruit fellows from additional fields of interest for training in autism-specific fields of study.

26 **122.026** Intensity of Parenting Stress, Child Negative Emotionality, and the Interaction of Parent's Self-Regulation Skills
B. J. Wilson[1], T. Ward[1], E. F. Geib[1], T. Estrada[2], R. Kramer[1], S. Nanda[2], E. Lovell[2] and J. Kim[2],

(1)Clinical Psychology, Seattle Pacific University, Seattle, WA, (2)Seattle Pacific University, Seattle, WA

Background: Parenting a child with autism spectrum disorder (ASD) is often associated with high levels of parenting stress (Steijn, Oerlemans, Aken, Buitelaar, & Rommelse, 2013). Research suggests children's individual characteristics, specifically negative emotionality, also affect parenting stress (Pesonen et al., 2008; Tomanik, Harris & Hawkins, 2004). Additionally, maternal self-regulation has been established as a contributing factor to parenting stress (Bridgett, Burt, Laake, & Oddi, 2013; Evans & Wachs, 2011).
Objectives: Consistent with previous research, we propose self-regulation skills of negative emotions may serve to moderate the effects of children's negative emotionality on parental stress regardless of developmental status.
Methods: Our preliminary sample included 61 children (ages 3:1 to 6:11) and their parents. Thirty-eight children (45% female) were typically developing; 23 children with ASD (17% female). Intensity of parenting stress was measured using the parent-reported Parenting Events Questionnaire (Crnic & Greenberg, 1990), which assesses the frequency and intensity of parenting stress. Negative emotionality was measured by parent ratings of their child's emotional intensity using items adapted from Larsen and Diener's Affective Intensity Measure (1987). Parents' self-regulation skills were coded from audiotaped responses to the Meta-Emotion Interview (MEI; Katz & Gottman, 1986).
Results: Hierarchical regression analysis was utilized to examine the influence of status and negative emotionality (NE) in children with ASD and TD and parent's self-regulation skills (SR) on parenting stress. In our preliminary research, we found that that neither diagnostic status, child NE nor the interaction between status and child NE significantly predicted intensity ratings for parenting stress (t = .537, p = .594; t=.057, p = .295; $F(1,56)$F= 0.691, p= .409, respectively). However parent SR was a significant predictor of parenting stress intensity (t =-2.933, p = .005). In the current study we investigated whether the relation between child NE and stress intensity was moderated by parents' self-regulation. Diagnostic status, parent self-regulation, and child negative emotionality were entered in the first step and predicted significant variance, ΔR^2 = .16, $F(3, 57)$ = 3.70, p = .017. The interaction between child negative emotionality and parent self-regulation skills entered in the second step, accounted for significant variance in parenting stress intensity, ΔR^2 = .23, $F(1, 56)$ = 4.618, p= .036. As can be seen (see Figure 1), parents' strong SR skills appeared to buffer them from high stress intensity even when their child was high in NE. In contrast, the stress of parents with lower SR skills was strongly linked to their child's NE.
Conclusions: Our findings suggest that parenting stress may be related to child characteristics and parent resources. Specifically, our study suggests that parent self-regulation strategies of negative emotions moderate the relation between negative emotionality and parental stress. Furthermore, the findings are significant for children with ASD and TD providing promising evidence for the role of parental self-regulatory techniques for reducing parental stress, especially the intensity of stress. Future research should investigate the different types of parental regulation techniques used with children with ASD and TD to reduce parental stress.

27 **122.027** Keeping up with the Times: Measuring the Stress of Parents of Children with ASD over Email

B. L. Ncube[1], J. M. Bebko[1], M. Thompson[2], M. Spoelstra[2] and L. Verbeek[2], (1)Psychology, York University, Toronto, ON, Canada, (2)Autism Ontario, Toronto, ON, Canada

Background:
Although increased support has been found to reduce the stress experienced by families of children with an autism spectrum disorder (ASD) (e.g., Weiss et al., 2013) Hall and Graff (2011) found that average parent ratings of support from professional organizations fell between a rating of 1 (not at all helpful) and 2 (somewhat helpful). Autism Ontario (AO) is a charitable organization that provides the leading source of information and referral on ASD in Ontario, Canada. Between 2007 and 2009, 63% of contact initiated by families to family support coordinators (FSCs) of AO occurred through email. It is more difficult to express emotions over email because of the absence of verbal and body language cues present during phone and in-person contact (Byron, 2008; Ekman et al, 2004) and, as a result, there is a greater risk for FSCs to misinterpret family stress over email, when compared to phone and in-person communication. Yet the ability of an organization to determine the stress of families that contact them is an important first step to responding appropriately, in a manner that best serves the family's needs.
Objectives:
This project presents the results of a program to measure the stress of families before and after email contact with AO FSCs.
Methods:
Four equally-spaced time points were selected for data collection throughout the past year. Each of the time points served as a trigger for FSCs to forward the email addresses of families who had contacted them in the preceding week to the AO research team. The researchers then sent these families an online survey that inquired about their overall experiences with email communication with AO that past week, including reporting on how much stress they were experiencing prior to contacting FSCs and how much stress they felt afterwards.
Results:
49 families responded in the round of the email stress survey being reported. The survey responses

indicated that families contacted the AO FSCs for various reasons (see Figure 1). A large number of the respondents considered themselves "very stressed" (35%) (see Table 1) prior to contacting FSCs. 53% of respondents reported a reduction in stress following their correspondence with FSCs while another 41% reported no change. For respondents that indicated a reduction in stress, the mean reduction was 1.77 points on a 5-point rating scale. The majority of the families indicated they were satisfied with their email communication with the FSCs (80%). Reasons families contacted FSCs were not significantly related to their reported stress or their satisfaction with their email communication.
Conclusions:
Online communication is convenient for families as it can be initiated at any time without scheduling limitations, and it has become the most common form of contacting FSCs at AO. Additionally, it allows for anonymity that reduces social stigma associated with seeking help (DuBois, 2004). The findings suggest that, despite the increased possibility of emotional detachment in email correspondence, it is still possible for organizations to measure and help alleviate the stress of families of children with ASD through email communication.

28 **122.028** Many Voices at the Table: Collaboration Between Families and Teachers of Somali Students with Autism

D. B. Baker, *Education, Hobart and William Smith Colleges, Ithaca, NY*

Background:
Somali refugee children are disproportionately likely to be diagnosed with autism (e.g., Estrem & Zhang, 2010), although autism is virtually unheard of within Somalia itself (McNeil, 2009). Data are inconclusive and several theories have been put forth to explain this pocket of elevated incidence (e.g., vitamin D deficiencies, duplicate vaccinations) (Barnevik-Olsson, Gillberg & Fernell, 2010; Delberto, 2011).
Family participation in the IEP process yields better outcomes for students with autism and other disabilities (e.g., Olvios, Gallagher, & Aguilar, 2010) and yet culturally and linguistically diverse (CLD) families tend to participate in the special education decision-making process at lower rates than their American-born white, English dominant counterparts (Lo, 2012). Certain best practices have been associated with more collaborative IEP meetings in both American-born white families and in majority CLD groups (e.g., African Americans, Asians, Latinos). Little research has examined the effectiveness of IEP practices in the context of a less familiar CLD group (e.g., first generation Somali refugee families).
Objectives:
Participants will learn about important themes related to the collaboration between Somali-American mothers of students with autism and American-born teachers in the IEP development process and how these themes yield practical implications.
Methods:
This qualitative multiple case study (Yin, 2009) examined the IEP process in the context of three Somali-American boys with autism. The student's mother and primary teacher were interviewed before, immediately following, and one month after the students' IEP meetings, using semi-structured interview protocols. Alongside these interviews, the researcher analyzed observations of the educational decision-making dynamics at the IEP meetings and pertinent educational documents from the students' files (e.g., draft and final IEPs, diagnostic reports). Theme analysis drew on both a priori and emergent codes and was informed by the constant comparative approach (Charmaz, 2000). Themes were organized into three phases: before, during, and after the IEP meeting.
Results:
Results of this study corroborate the importance of certain established best practices (e.g., structured agendas to structure IEP meetings, less reliance of special education jargon). However, the present study also extends and challenges previous research, suggesting that an over-emphasis on cultural sensitivity can in fact impede authentic communication between family members and special educators and highlighting the importance of culture in facilitating on-going educator/family member interactions (e.g., impromptu conversations at pick up and drop off) in addition to those related directly to the IEP process.
Conclusions:
A close analysis of the interactions among this very specific group of individuals can lead to important questions about how autism is understood. It is important for educators to understand the variety of beliefs about autism and autism education in order to enhance collaboration with CLD families.

29 **122.029** Maternal Depressive Symptoms and Child Sleep Quality in Young Children with ASD

M. M. Abdullah[1], J. Youssef[2], W. A. Goldberg[3], Y. Guo[4], C. Taylor Lucas[1] and K. Lakes[1], (1)Department of Pediatrics, University of California, Irvine, Irvine, CA, (2)Center for Autism and Neurodevelopmental Disorders, University of California, Irvine, Santa Ana, CA, (3)Psychology and Social Behavior, University of California, Irvine, Irvine, CA, (4)Department of Nursing Science, University of California, Irvine, Irvine, CA

Background: Parents of children with ASD are at increased risk for poor psychological well-being (Montes & Haltermann, 2007). Potential sources of maternal depressive symptoms include maternal and child factors especially disrupted child sleep (Hodge et al., 2013). 77.2%-80.9% (Mannion et al.,

2013; Rzepecka et al., 2011) of children with ASD demonstrate comorbid sleep problems. Limited studies have explored links between maternal well-being and child sleep quality.

Objectives: To examine the associations between maternal depressive symptoms and (1) child sleep quality, (2) child adaptive behavior, (3) maternal sleep quality, (4) maternal global self-rated health among mothers of young children with ASD.

Methods: Participants were 72 toddlers with ASD (24-39 months; 75% male) and their mothers (22-53 years; 54% Caucasian). Maternal depressive symptoms were assessed using an adapted version of the Patient Health Questionnaire (PHQ-9; Kroenke & Spitzer, 2002).   Children's sleep quality was assessed using the Children's Sleep Habits Questionnaire (CSHQ; Owens et al., 2000), which consists of seven subscales: (1) bedtime resistance, (2) sleep onset delay, (3) sleep duration, (4) sleep anxiety, (5) night wakings, (6) parasomnias, (7) sleep disordered breathing, and (8) daytime sleepiness. Children's adaptive behavior was measured using the Vineland Adaptive Behavior Scales (Sparrow et al., 2005). Maternal sleep quality was assessed using a single item from the PHQ-9. Maternal global self-rated health was evaluated using a single-item on a four-point scale (Surkan et al., 2009).

Results: Maternal reports of greater depressive symptoms were significantly linked to (1) shorter child sleep onset delay ($r=-.203$, $p=.044$), (2) poorer child sleep duration ($r=.418$, $p<.001$), (3) greater child sleep anxiety ($r=.272$, $p=.011$), (4) greater child night wakings ($r=.372$, $p=.001$), (5) greater child parasomnias ($r=.387$, $p<.001$), (6) greater child daytime sleepiness ($r=.399$, $p<.001$), (7) poorer child adaptive functioning ($r=-.367$, $p=.001$), (8) poorer maternal reports of sleep quality ($r=.600$, $p<.001$), and (9) poorer maternal reports of global self-rated health ($r=-.383$, $p<.001$). A regression analysis was used to examine the variance in maternal depressive symptoms accounted for by child sleep quality, child adaptive functioning, maternal sleep quality, and maternal global self-rated health. The four most strongly related child sleep quality subscales (i.e., sleep duration, night wakings, parasomnias, and daytime sleepiness) were selected for inclusion in the model predicting maternal depressive symptoms because of the limited sample size. The overall model predicted 52% of the variance in maternal depressive symptoms, $F(7,64)=9.95$, $p<.001$. Within the model, only child daytime sleepiness ($\beta=.20$ indicated a small effect) was significantly related to maternal depressive symptoms after adjusting for the other variables in the equation.

Conclusions: This study extends previous work examining the links between maternal well-being and child sleep quality among children with ASD (Hodge et al., 2013). Bivariate analyses indicated significant links between maternal depressive symptoms and child sleep quality; multivariate analyses pointed to toddlers' daytime sleepiness as an important contributor to maternal depressive symptoms. By teasing apart specific child sleep factors that may be important for maternal mental health, targeted priorities for behavioral parent training to address sleep disturbances among children with ASD may be empirically-driven.

30   **122.030** Maternal and Paternal Stress in Parenting Children with ASD

H. E. Friedman[1], D. Oosting[1], C. M. Keifer[1], A. J. Schneider[2], C. A. Paisley[2], J. Wolf[1] and P. Ventola[1], (1)Child Study Center, Yale University, New Haven, CT, (2)Center for Translational Developmental Neuroscience, Yale University, New Haven, CT

Background:
Extant literature demonstrates that mothers of children with ASD experience consistently higher levels of stress than mothers of typically developing (TD) children. Child variables such as autism symptom severity, age, behavior problems, and cognitive ability may contribute to this stress, though results vary. Research on paternal stress is limited.

Objectives:
We examined differences in parenting stress and symptoms of psychopathology between parents of children with ASD and parents of TD children. This is one of the first studies to include an equal number of mothers and fathers, which facilitated an examination of how child variables may differentially affect parenting and psychological stress for both mothers and fathers of children with ASD.

Methods:
Participants included the mothers and fathers of 30 cognitively able children with ASD aged between 4.4 and 17.4 years (M=10.50 years, SD=3.97 years) and mothers and fathers of 20 TD children aged between 4.2 and 17.1 years (M=10.58 years, SD=4.95 years). Parenting stress was assessed using the Parenting Stress Index- 4th Edition (PSI-4), and symptoms of anxiety and depression were assessed with the Beck Anxiety Inventory (BAI) and the Beck Depression Inventory-2nd Edition (BDI-II). In the ASD sample, autism symptom severity, behavior problems, and cognitive abilities were assessed with the Social Responsiveness Scale (SRS), the Child Behavior Checklist, and the Differential Abilities Scale-2nd Edition respectively.

Results:
Parents of children with ASD did not differ significantly from parents of TD children on measures of anxiety and depression (BAI and BDI-II). However, parents of children with ASD experienced significantly greater parenting stress (PSI-4) than did parents of TD children. Parenting stress for mothers and fathers of children with ASD did not differ. Externalizing behavior problems and autism symptom severity correlated with magnitude of parenting stress overall. While parenting stress did not differ significantly between mothers and fathers of children with ASD based on the age of the child, the specific factors that contributed to this stress did. Results indicated that externalizing

behaviors were associated with parenting stress for both mothers and fathers of younger (≤11 years) children. For parents of older children, autism symptom severity correlated only with paternal parenting stress.

Conclusions:

Parenting a child with ASD is associated with higher levels of stress than parenting a TD child, but our results illustrated that parents do not experience higher levels of anxiety and depressive symptoms. Importantly, though, since both mothers and fathers of children with ASD experience heightened parenting stress, it is crucial to support both parents when treating children with ASD. Our results suggest that the child variables contributing to parenting stress change throughout child development and may be different for mothers and fathers as children get older. These findings also underscore the importance of addressing comorbid externalizing behaviors when treating younger children with ASD as these behaviors lead to stress for parents.

31 **122.031** Mealtime Structure in Families with Children with ASD

K. K. Ausderau[1] and E. Laird[2], (1)University of Wisconsin - Madison, Madison, WI, (2)Common Threads, McFarland, WI

Background: Feeding challenges are highly prevalent among children with autism spectrum disorders (ASD) with up to 89% reported to have feeding difficulties impacting development, health, and social interactions, specifically parent–child relationships. These feeding difficulties create tension and disruption around mealtimes and have been shown to significantly increase parental stress within and outside feeding experiences.

Objectives: The purpose of this study was to examine how parents of children with ASD structure their mealtime routines using a grounded theory approach.

Methods: Families (n=16), primarily mothers, with a child with ASD, ages 2-8 years, participated in 2-3 semi-structured interviews, each lasting 1 to 2 hours in the home environment. Audio-recorded interviews and field notes were transcribed verbatim and used for data analysis. A grounded theory approach was used, including initial identification of codes and themes to organize data. Axial coding was used to draw connections among the concepts and categories that built on identified themes. Lastly, selective coding was used to describe the central phenomena of the data and develop a theory on family mealtime construction. In-depth interviewing, triangulation, and member-checking (i.e., verifying and clarifying information with participants at follow-up interviews) were used to establish scientific rigor in the qualitative data.

Results: Family construction of mealtimes are a dynamic and adaptive process that involved the interplay of five themes: Values (guiding principles and beliefs shaped by family culture, traditions, religion, and personal experiences), Balancing Demands (what parents prioritize with regards to feeding and mealtime in the context of their busy lives and family schedules), Parent Strategies (strategies individual parents implement with their children in varying mealtimes contexts that are guided by their values and realities of their daily schedules), Mealtime Happenings (actual mealtime process), and Adaptability (interactions and adaptations that occur based on child behaviors and context). Themes were used to construct a grounded theory to describe the process of how parents with children with ASD structure their mealtime routines. Figure 1 shows the relationship and interaction among the themes that describes the elaborate mealtime construction that arises in response to a child's feeding disorder. Many factors influence how parents of children with ASD attempt to structure their mealtime routines and consequently the actuality of the family mealtime experience, including parental values, balancing family demands, and the individual responses of the child to implemented parental strategies. In the described model, parent strategies were often the mediator between how the child behaviorally responded in mealtime contexts and the parent's attempt to balance family demands and values. Due to the complexity of mealtime construction in the presence of having a child with ASD and feeding challenges, parents were required to have constant adaptability to create "successful" family mealtimes.

Conclusions: Five distinct themes were identified and used to create a model of family mealtime construction using a ground theory approach. The explicit identification of mealtime routines will lead to targeted family-centered interventions that can be based on individualized family goals, values, and behaviors that can improve child eating and mealtime behaviors while decreasing parental stress.

32 **122.032** Mental Stress in Parents of Autistic Children: A Pilot Study of the Related Psychological Dimensions

S. Melli[1], C. Zarbo[2], A. Compare[2] and **E. Grossi[1]**, *(1)Autism Research Unit, Villa Santa Maria Institute, Tavernerio, Italy, (2)Human and Social Science Department, Bergamo University, Bergamo, Italy*

Background: Parental mental stress is clinically common in families of autistic children and adversely affects the care of the child. Moreover, parents of autistic children frequently experience feelings of guilt, maladaptive coping styles, lack of ability to forgive himself and the partner, and low mindfullness ability. However, is unclear which of these dimensions is predominant in these families and if it their associations are symmetrical in presence of high or low values.

Objectives: The aims of this pilot study are: 1) to evaluate the most predominant dimensions in parents of autistic children and to establish the hierarchy of their relationship; 2) to evaluate if psychological dimensions works in different way when they are high or low; 3) to establish if

psychological dimensions in parents of autistic children are related to the severity of the Autism Spectrum Disorder (ASD).

Methods: Demographic and psychological information about mental stress, feelings of guilt, ability to forgive, mindfullness ability and coping styles were collected through clinical interviews and self-report questionnaires in 28 parents (mean age 43.5 yrs; 22 mothers; 6 fathers) of autistic children (mean age: 12.2 yrs; 3 females; 25 males). Severity of the ASD was assessed through Autism Diagnostic Observation Schedule (ADOS). Artificial Neural Networks (Auto-CM system) were applied to highlight the associations among variables under study. Auto-CM is fourth generation Artificial Neural Network developed at Semeion Research Institute (Rome) and successfully applied in many complex chronic degenerative diseases, able to find out consistent trends and associations among variables creating a semantic connectivity map. The matrix of connections, visualized through minimum spanning tree filter, takes into account nonlinear associations among variables and captures connection schemes among clusters.

Results: Predominant dimensions in parents of autistic children were low feelings of guilt for himself and the partner, high levels of forgiveness of himself and the partner, and low levels of maladaptive coping responses. These three main dimensions are strictly related among themselves. While high parental mental stress was strictly related to high parental distress subscales, high maladaptive coping styles, and low self-forgiveness ability, conversely, low mental stress appeared to be marginal in relation to the other psychological dimensions. This behavior is typical of complex nonlinear systems. The severity of the ASD was not related to parental psychological dimensions. The ADOS scores, both low and high, were in fact marginal in the connectivity map in relation to the other dimensions.

Conclusions: The interplay of psychological factors related to parental stress is complex. Understanding these relationships is the starting point to activate and enhance parental resources essential to the wellbeing of both children and caregivers. Due to the complexity of these relationships and the lack of symmetry between associations of the same dimension when high or low, the approach with advanced neural networks is essential for the analysis of the patterns of relationships.

33 **122.033** Modeling Depressive Symptom Trajectories Among Mothers of Children with ASD from Diagnosis to Age 9

A. Zaidman-Zait[1], E. K. Duku[2], P. Mirenda[3], T. A. Bennett[2], P. Szatmari[4], S. E. Bryson[5], E. J. Fombonne[6], I. M. Smith[5], T. Vaillancourt[7], C. Waddell[8], L. Zwaigenbaum[9], S. Georgiades[10], M. Elsabbagh[11] and A. Thompson[2], (1)Tel-Aviv University, Tel-Aviv, Israel, (2)Offord Centre for Child Studies & McMaster University, Hamilton, ON, Canada, (3)University of British Columbia, Vancouver, BC, Canada, (4)University of Toronto, Toronto, ON, Canada, (5)Dalhousie University / IWK Health Centre, Halifax, NS, Canada, (6)Oregon Health & Science University, Portland, OR, (7)University of Ottawa, Ottawa, ON, Canada, (8)Faculty of Health Sciences, Simon Fraser University, Vancouver, BC, Canada, (9)University of Alberta, Edmonton, AB, Canada, (10)McMaster University, Hamilton, ON, Canada, (11)Department of Psychiatry, McGill University, Montreal, QC, Canada

Background: Elevated levels of depressive symptoms among mothers of children with ASD have been well documented (Davis & Carter, 2008; Montes & Halterman, 2007). However, few studies have examined mothers' depression longitudinally, and most have considered these mothers as a homogeneous group when examining their depressive symptoms. Although several studies suggest some degree of stability in maternal depression over time (e.g., Carter et al., 2009), none have considered the potential heterogeneity of developmental trajectories of maternal depression. Overall sample means and correlations may mask the presence of subgroups of mothers whose depression follows distinct patterns.

Objectives: The purpose of this study was two-fold: 1) to identify subgroups of mothers with different depression trajectories from the time of child diagnosis (between age 2-4) to age 8.5-9, in a large inception cohort of young children with ASD; and 2) to explore the associations between trajectory membership and key parent/family variables.

Methods: Data were drawn from the Canadian Pathways in ASD study and included the mothers of 284 children with ASD. At the time of initial data collection, which occurred within 4 months of diagnosis, the children's mean age was 40.33 months (SD=9.3). Mothers completed the Symptom Checklist-90-R (Derogatis, 1994) to assess their depressive symptoms at four time points: within 4 months of diagnosis, 24 months post-diagnosis, when the children were 7.5-8 years old, and when the children were 8.5-9 years old. In addition, at diagnosis, mothers completed a demographic survey, the General Functioning subscale of the McMaster Family Assessment Device (Byles, Byrne, Boyle, & Offord, 1988), and the Social Support survey (NLSCY, 2008-2009). Severity of children's ASD symptoms was assessed using the Autism Diagnostic Observation Schedule (Gotham, Pickles, & Lord, 2009). A semi-parametric, group-based analytical strategy in SAS, PROC TRAJ (Jones, Nagin, & Roeder, 2001), was used to examine individual differences in developmental trajectories.

Results: Three distinct trajectory groups provided the best fit to the maternal depression data over time. Group 1 (65.2% of the sample) had the lowest mean depression scores at diagnosis and a stable trajectory. Group 2 (27.3%) had moderate mean depression scores at diagnosis and a declining trajectory. Group 3 (7.4%) had the highest mean depression score at diagnosis and an inclining trajectory. Both family social support and family functioning distinguished between the

trajectories of Group 1 (low, stable), and Groups 2 (medium, declining) and 3 (high, inclining). In addition, older child age at the time of diagnosis was significantly associated with membership in Group 2 compared to Group 1.

Conclusions: There is considerable heterogeneity in the trajectories of maternal depressive symptoms. Lower levels of perceived social support, poorer family functioning, and higher child age at the time of diagnosis all appear to be associated with higher depressive symptomatology. While depression improves over time in some mothers, others experience increased symptoms. Additional research is needed to identify other variables contributing to these trajectories and intervention approaches for assisting these families.

34   **122.034** Parent Feeding Practices of Picky-Eating Children with and without Autism Spectrum Disorder

E. P. Trinh[1], F. J. Biasini[2] and A. R. Lemelman[1], (1)University of Alabama at Birmingham, Birmingham, AL, (2)Psychology, University of Alabama at Birmingham, Birmingham, AL

Background: "Picky eating" children with and without autism spectrum disorders (ASD) often exhibit a variety of eating problems (e.g., sensory sensitivity to the taste, texture, smell, or temperature of food) as well as a variety of mealtime problem behaviors (e.g., food refusal, aggression, and self-injurious behaviors). The feeding practices and parenting stress of parents of children with ASD, feeding disorders, or with typical development are not commonly studied in relation to each other. Several studies have found that parents may vary how they feed their child based on certain characteristics or behaviors of their child. For example, parent feeding practices such as providing specially tailored meals (e.g., pureeing foods, serving semi-liquid foods), providing preferred snack foods, being more controlling and coercive, providing a large variety of fruits and vegetables, using verbal positive persuasion, limiting snacks, or reducing fats were found to vary in relation to certain behaviors or characteristics of the child (e.g., having a texture sensitivity to food, feeding problems, or a diagnosis of ASD). Parents of children with developmental disabilities report helping and supervising during mealtime to be the most stressful parenting task. Further, parents of children with a diagnosis of ASD in combination with a behavior disorder report greater parenting stress than parents of children only diagnosed with an ASD, a behavior disorder, or who are typically developing.
Objectives: There is little research available examining how parent feeding practices may differ based on the interaction between characteristics/behaviors of the child and parenting stress experienced. Therefore, the purpose of the current study was to investigate differences in parent feeding practices based on parenting stress and child characteristics.
Methods: Variables were split into two levels based on respective grand means or clinical significance. Two-way factorial ANOVA's were used to analyze differences in 9 types of parent feeding practices based on interactions between different levels of parenting stress and characteristics of the child.
Results: Parents of children with and without an ASD with high sensory sensitivity to food were more likely to use verbal positive persuasion at mealtime ($p<.05$) compared to parents of children with low sensory sensitivity to food. Parents were more likely to provide many food choices and insist on eating if their child was typically developing compared to having a child with ASD ($p's<.05$). Several interaction effects were significant. For typically developing children, parents were more likely to limit snacks and reduce fats if their child had more mealtime problem behaviors. In contrast, parents of children with ASD were more likely to limit snacks or reduce fats if their child had less mealtime problem behavior ($p's<.05$).
Conclusions: Overall, it appears that parent feeding practices do differ based on level of parenting stress and certain characteristics of their child. Implications will be discussed.

35   **122.035** Parental Disclosure of a Child's Diagnosis of Autism Spectrum Disorder in the Emergency Department

B. Muskat[1], A. Greenblatt[2], D. B. Nicholas[3], C. Kilmer[4], P. Burnham Riosa[1], S. Ratnapalan[5], J. Cohen-Silver[6] and L. Zwaigenbaum[7], (1)The Hospital for Sick Children, Toronto, ON, Canada, (2)Social Work, The Hospital for Sick Children, Toronto, ON, Canada, (3)University of Calgary, Edmonton, AB, Canada, (4)Social work, University of Calgary, Edmonton, AB, Canada, (5)Paediatrics and Dalla Lana School of Public Health, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada, (6)Pediatrics, The Hospital for Sick Children, Toronto, ON, Canada, (7)University of Alberta, Edmonton, AB, Canada

Background: Children and youth with autism spectrum disorder (ASD) regularly access a variety of medical services, including those in the emergency department (ED). Within the ED, parents are tasked with having to make decisions about if, how, and when to disclose their child's ASD diagnosis to a health care provider (HCP). This disclosure process deserves focus and attention to ensure that HCPs can both communicate and provide effective care to families.
Objectives: This is a sub-study of a larger study focused on examining the experiences of children and youth with ASD, their parents, and their HCPs when accessing, receiving, and providing care in two pediatric ED settings. The objective of this study was to examine the dynamics involved in parents' decisions to disclose a child's ASD diagnosis within the ED. Specifically, we aimed to understand the factors that motivated parents to disclose, those that hindered these decisions, and the perspectives of HCPs as related to disclosure.

Methods: Parents with a child with ASD were recruited for the larger study upon visiting the ED in two paediatric acute healthcare settings. Parents (*n*=29), children (*n*=4), and their HCPs (*n*=22) were interviewed. Parents also completed measures of their child's adaptive functioning and social communication impairments. Participants reported on their experiences in the ED and interview data were analyzed using a grounded theory approach. Reports on the disclosure process were analyzed.
Results: Findings from our qualitative analysis yielded three themes related to parental disclosure of an ASD diagnosis in the ED: (1) the decision to disclose or not disclose, (2) the transmission of the ASD diagnosis throughout the ED system, and (3) suggestions for improving the disclosure process. While all parents in the sample ultimately disclosed, some experienced a significant decision-making process prior to disclosing. Parents who were hesitant to disclose did not want to do it publicly and/or in front of their children; they wanted to avoid negative labels. These parents also described HCPs who lacked an understanding of ASD. Parents identified the desire for expedited service, the need to prepare staff, and the avoidance of unwarranted labels as being reasons for their disclosures. HCPs acknowledged the importance of knowing about a child's ASD diagnosis in the ED, and that discomfort in disclosing in front of their children as well as a fear of stigma could be barriers to disclosure for parents. Parents also reported inconsistent experiences with communication following a disclosure, with some needing to repeat disclosures to multiple HCPs. Finally, to improve the disclosure process, parents suggested using a child's file to alert HCPs to an ASD diagnosis and also encouraging staff to ask questions.
Conclusions: Results from this study reveal that disclosure within an ED setting is both layered and dynamic. Parents and HCPs agreed that disclosure of a child's needs allows for effective preparation and accommodation for families. However, it is clear that conveying this information is not always straightforward for parents. These results have important implications for how HCPs decide to approach the issue of disclosure with parents.

36   **122.036** Parental and Child Characteristics That Contribute to Parental Concerns in Toddlers at High Risk for Autism Spectrum Disorder over Time

E. A. Karp, *L. V. Ibanez, S. R. Edmunds, C. Harker and W. L. Stone, Psychology, University of Washington, Seattle, WA*

Background: Parents of children with ASD commonly report concerns about their child's behavior or development before their child's second birthday (Baghdadli et al., 2003). These concerns correspond with clinical measures (McMahon et al., 2007), and may help identify children who may benefit from early intervention. However, less is known about the relative contribution of parent and child factors on the presence of concerns at different ages, especially in families who already have one child with ASD.
Objectives: To examine the extent to which parent well-being, child expressive language vocabulary (EL), and child social-communicative skills (SCS) contribute to parent concerns about their high-risk (HR) toddlers within the first 2 years of life.
Methods: Parents and HR toddlers (n=54 dyads) were part of a prospective multi-site study that assessed toddlers at multiple time points from 6-36 months. This study includes data from 18- and 24-month old visits. At both visits, parents completed the Parent Concerns Form, a 7-item questionnaire that probes for concerns in 7 behavioral domains. Scores were dichotomized to reflect "concerns" or "no concerns" at 18 and 24 months. All other measures were collected at the 18-month visit only. Parental well-being was based on aggregated scores from the Parenting Stress Index-Short Form (Abidin, 1990) and the Maternal Self Efficacy Scale (Teti & Gelfand, 1991). Child EL was measured using the "Understands and Says" subscale of the MacArthur Communicative Development Inventories (Fenson et al., 2007). Child SCS were assessed using the total score of the Screening Tool for Autism in Toddlers (Stone et al., 2008).
Results: Overall, 67% of parents expressed concerns about their child's development at 18 months (n=36) and 50% at 24 months (n=27). Logistic regression analyses were used to examine whether 18-month measures of parental well-being, child SCS and child EL increased the likelihood of parent concern measured concurrently (at 18 months) and predictively (at 24 months). Results revealed that parent concerns at 18 months were predicted by lower levels of parental well-being (OR=1.21, p<.01) and lower levels of child EL (OR=.98, p<.05). Parent concerns at 24 months were predicted by lower levels of parental well-being (OR=1.17, p<.01) and lower levels of child SCS (OR=6.02, p<.01).
Conclusions: This study revealed two important findings related to the concerns of parents of HR toddlers. First, parental well-being was found to influence parents' concerns about their child's development both concurrently and predictively. These results emphasize the importance of considering how elevated stress and/or self-perceptions of parenting competence may influence their evaluation of their toddler's development. Second, different aspects of child behavior appeared to influence parent concerns at different ages, with expressive language vocabulary contributing to concerns at 18 months and social-communication behaviors exerting more influence at 24 months. Expressive language may be more salient at younger ages because of the availability of common language milestones. In contrast, more subtle social-communication deficits such as imitation, play and joint attention may be more difficult for parents to recognize or detect until a bit later in development.

37   **122.037** Parenting Teenagers with an Autism Spectrum Disorder before and after the Transition to Secondary School

L. van Esch[1], K. Hannes[2], K. Van Leeuwen[1] and I. Noens[1,3,4], (1)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (2)Methodology of Educational Sciences, KU Leuven, Leuven, Belgium, (3)Leuven Autism Research (LAuRes), Leuven, Belgium, (4)Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, USA, Boston, MA

Background: In parenting, we can distinguish three main components: parenting behaviours, perceptions and cognitions. There is a growing number of studies investigating parental perception and cognition in parents with a child with an Autism Spectrum Disorder (ASD). However the number of studies investigating parenting behaviour is scarce, particularly for the target group, teenagers.

Objectives: We conducted an exploratory, qualitative study on parenting behaviour in parents raising a teenager with ASD. The first objective of this study was to conceptualise parenting behaviours among these parents. Secondly, we aimed to explore the potential relation between parenting behaviour and parental perception and cognition. Lastly, the influence of the transition to secondary school of the child on parental behaviour was examined.

Methods: Seventeen in-depth, semi-structured interviews were conducted with the mother, father or both parents of teenagers diagnosed with an ASD, within one year before or after the transition from primary to secondary school. A self-constructed interview covering the different components of parenting (parental behaviour, parental perception and parental cognition) was used. The interviews lasted between 70 and 130 minutes.

All interviews were transcribed and double coded. We used a hybrid deductive-inductive approach to analysis. An initial codebook was developed, based on an extensive study of the literature. New codes were inductively generated for findings that could not be classified in the predefined codebook. Constant comparative method was used to guide the analytic process. We conducted a member check to increase the validity of the findings.

Results: The main themes of parenting behaviour were warmth, control, stimulating the development and adapting the environment to the needs of the teenager with ASD. Within the main themes, several categories were discriminated. Categories within parental warmth were positive affect and time spent together. Within parental control, four categories were distinguished: pro-active control, rule setting, reaction on problem behaviour and reaction on positive behaviour. Autonomy-support and stimulating the abilities were categories of stimulating the development. Within adapting the environment, no further categories were discriminated. The reported behaviours within each category were very diverse.

By case-ordering the parents on which parenting behaviour they reported most, three different patterns could be noted. Four parents focused mostly on controlling the teenager, six parents on parental warmth and seven on stimulating the teenager. These patterns were related to the parental perception and cognition, such as reported child characteristics, wishes for the future and parental stress.

Only parents of children in primary school reported control as being the main focus of parenting behaviour. The two other groups included both parents of children in primary and secondary school. This suggests that parental control decreases with increasing child age, while stimulating and warmth are becoming increasingly important.

Conclusions: Using a qualitative design, different patterns of parenting behaviour could be distinguished. These patterns appeared to be related to parental perceptions and cognitions and to the age of the child. Based on the findings of this study, we suggest to further explore the relation between parental behaviours and their perceptions and cognitions using a more controlled design.

38 **122.038** Peer Responses to Mild Social Digressions By College Students Labelled with Autism Spectrum Disorder or Asperger Syndrome

M. Brosnan and E. Mills, University of Bath, Bath, United Kingdom

Background:
The 1990s saw a marked increase in the number of people diagnosed with an Autism Spectrum Disorder (ASD). This group is now reaching the age of going to university, and many people with an ASD express a strong desire to do so. While people with ASD can perform well at university, one impediment to academic and social success for students with ASD is peer attitudes and many people with ASD are reluctant to disclose their disability for fear of negative attitudes from peers. However failure to disclose diagnosis at university prevents potential support being put in place for college students on the autism spectrum. Societal issues such as stigma are under-researched within the ASD literature, although there is some evidence to suggest children are less accepting of a peer with ASD than a typically developing peer. However, for young adults at university, there is evidence that college students have a more positive attitude towards someone performing mild social digressions when the person is labelled 'High Functioning Autism (HFA)' than when they are labelled a typical student.

Objectives:
1) Do college students respond differently to those with a clinical label compared to typical students?
2) Do college students respond differently to an Asperger Syndrome label compared to an Autism Spectrum Disorder label?
3) Does knowledge of ASD impact upon these responses?

Methods:
120 college students (M = 55, F = 65) completed the PANAS assessment of positive and negative

emotional response to two scenarios: one containing a protagonist described as a typical student and one containing a protagonist described as having a clinical diagnosis (order rotated). The clinical diagnoses were either Autism Spectrum Disorder or Asperger Syndrome (or Schizophrenia as a control).

Results:

College students had a significantly more positive and significantly less negative emotional response to examples of mild social digressions when the protagonist was labelled with a clinical diagnosis then when the protagonist was labelled a typical student. This effect was comparable for all clinical labels (Asperger Syndrome or Autism Spectrum disorder or Schizophrenia) and level of prior experience with the autism continuum did not impact upon the results.

Conclusions:

The results suggest that, within a university context, peers are more accepting of those with a diagnostic label from the autistic continuum. This contrasts with research from younger age groups, and this negative experience at a younger age may underpin reluctance to disclose diagnosis at university. However, the findings are consistent with the advice of most university disability services that disclosure of diagnosis is to be encouraged. In addition, the nature of the label did not impact upon the effect, suggesting that an ASD label is not perceived differently from an Asperger Syndrome label (within a University context).

---

39 **122.039** Psychosocial Adjustment and Sibling Relationships in Siblings of Children with Autism Spectrum Disorder: Risk and Protective Factors

K. M. Walton[1] and B. Ingersoll[2], (1)Psychology, Nisonger Center, The Ohio State University, Columbus, OH, (2)Psychology, Michigan State University, East Lansing, MI

Background: Recent research has recognized the variability in outcomes for siblings of children with autism spectrum disorder (ASD). Given this variability, focus has shifted to identifying individual and family factors that may place some siblings at higher risk for experiencing psychosocial difficulties. Several recent studies have found support for a diathesis-stress conceptualization of sibling psychosocial difficulties. In this model, sibling broader autism phenotype (BAP) characteristics interact with family stressors to predict sibling difficulties. However, previous studies have used very small samples and have not examined the impact of these factors on the sibling relationship.

Objectives: This study aimed to investigate demographic factors (e.g., gender, birth order), sibling characteristics (e.g., BAP), and family stressors (maternal depression, child impact on family) in siblings of children with ASD (ASD-Sibs) and siblings of children with typical development (TD-Sibs) to identify risk and protective factors related to sibling behavioral and emotional adjustment and sibling relationship quality.

Methods: Mothers of ASD-Sibs (n=69) and TD-Sibs (n=93) completed online questionnaires about family demographics, sibling behavioral and emotional difficulties, sibling relationship quality, impact of the child on the family, and their own depressive symptoms. Sibling behavioral and emotional difficulties and sibling relationship quality were compared across groups. In addition, a series of MANOVAs and regression analyses were used to examine demographic and family factors that might predict which siblings were at higher risk for behavioral and emotional difficulties or poor sibling relationship quality.

Results: ASD-Sibs and TD-sibs demonstrated similar emotional and behavioral adjustment overall. ASD-Sibs demonstrated higher levels of prosocial behaviors compared to TD-Sibs. However, older brothers of children with ASD were at increased risk for difficulties compared to other groups of siblings. Sibling relationships of ASD-Sibs did not differ in overall level of positive or negative relationship behaviors. However, subscale-level patterns did differ between groups. Sibling relationships in ASD-Sibs involved less aggression, but also less involvement and more avoidance than those of TD-Sibs. Partial support for a diathesis-stress conceptualization of sibling difficulties was found for ASD-Sibs only. For TD-Sibs, broader autism phenotype (BAP) was related to psychosocial difficulties regardless of family stressors. For ASD-Sibs, BAP was related to psychosocial problems only when family stressors were also present.

Conclusions: These findings suggest that overall level of behavioral and emotional problems and sibling relationship quality is similar in ASD-Sibs and TD-Sibs. However, sibling relationship patterns may be qualitatively different in siblings of children with ASD. In addition, older brothers of children with ASD may be at increased risk for psychosocial difficulties. Finally, sibling broader autism phenotype characteristics were related to sibling adjustment and relationship difficulties. However, in the absence of additional family stressors, having a sibling with ASD appeared to confer a protective effect that reduced the negative impact of these BAP characteristics for the siblings. The researchers hypothesize that parents of children with ASD may have developed strategies for effectively coping with these characteristics in siblings due to their experience parenting their child with ASD.

---

40 **122.040** Questioning, Directing, and Commenting: Parent-Child Talk in Autism

C. Kang[1] and C. Kasari[2], (1)Graduate School of Education and Information Studies, University of California, Los Angeles, Los Angeles, CA, (2)UCLA Center for Autism Research & Treatment, Westwood, CA

Background: Parent-child interactions are an important influence on children's language

development. Several studies have established that parents of children with autism interact with their children differently than parents of typically developing children (Kasari, Sigman, Mundy, & Yirmiya, 1988; Lemanek, Stone, & Fishel, 1993; Doussard-Roosevelt, Joe, Bazhenova, & Porges, 2003). However, there has been less focus on how parents communicate with their children in relation to their child's individual characteristics.

Objectives: The purpose of this study was to examine the association between parent language use and child's baseline characteristics (i.e., receptive and expressive language abilities) in minimally verbal preschoolers diagnosed with ASD.

Methods: This study is a secondary analysis of an ongoing randomized controlled trial targeting social communication in minimally verbal preschoolers (1R01 MH084864, Kasari, et al). The sample consisted of 59 parent-child dyads from the greater Los Angeles area. All children had a diagnosis of ASD and used less than 30 functional words across behavioral assessments. Each parent-child dyad completed a 10-minute free play assessment using a standardized set of toys. These videotaped assessments conducted prior to beginning the randomized controlled intervention study were frequency coded for the following types of parent language: 1) test questions, which have known answers; 2) directives, which are direct instructions to the child, and 3) comments, which include statements that convey information about events or objects within shared attentional focus. Types of parent language were converted to proportions and were then analyzed for correlations with child's baseline language abilities.

Results: Overall, parents used a higher proportion of directives (41%) than comments (28%) and questions (19%). Parent questions were associated with children who had higher baseline language skills from the Mullen Scales of Early Learning (receptive: $r_s = .528$, $p < 0.05$; expressive: $r_s = .623$, $p < 0.05$). Conversely, parent directives were negatively correlated with child expressive language ($r_s = -.337$, $p < 0.05$). Parent comments were not related with child language level; however, they were negatively correlated with parent directives ($r_s = -.673$, $p < 0.05$).

Conclusions: These results suggest that parent language use is related to child's language ability. As language is often an intervention target for minimally verbal children, understanding the baseline relationship between parent and child language may be important especially within the context of parent training. Further research is warranted to determine if parent training will modify the proportions of parent talk and if parent comments will also be related to child language ability when provided with training.

41 **122.041** Raising a Child with Autism: A Developmental Perspective on Parental Adaptation

C. Dissanayake[1], R. McStay[1] and D. Trembath[2], (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)School of Allied Heath Sciences, Griffith University, Gold Coast, Australia

Background: While raising a child with an Autism Spectrum Disorder (ASD) is known to produce chronic stress and strain on families, positive family outcomes are also evident. Past research has supported the utility of the Double ABCX model of family adaptation in understanding the experience of parents raising a child with ASD. To date, this model has supported the unique prediction of child related stressors and specific coping strategies on mainly negative maternal outcomes. While the experience of fathers has recently been considered, what remains unclear is the impact of family-related variables on positive as well as negative outcomes in both mothers and fathers within the same family.

Objectives: We sought to provide a coherent understanding of the role of child age and parental gender on family outcomes by charting the trajectory of family stress and coping associated with raising a child with autism. Our objective was to investigate the potential predictors of both maternal and paternal stress and family quality of life in an Australian sample of parents of children with ASD.

Methods: Participants were 196 parents of children aged 3 to 16 years. Using a cross-sectional design, these 98 parental dyads (mother-father matched pairs) of children across four key stages of childhood (preschool, early school years, middle school, early high school) completed questionnaires assessing factors within the Double ABCX model attributed to family adaptation. The questionnaires assessed child behaviour, family functioning, social support, family appraisal and coping strategies including the outcome variables of family quality of life and parental and life stress.

Results: The results revealed that mothers were more stressed than fathers and also reported poorer family quality of life. While parents of older children reported significantly less support from professionals than parents of younger children, no differences were found between parental reports on measures of family outcomes across the four child age cohorts. This was despite a significant increase in child internalizing behaviour between early and middle school years.

Conclusions: The findings support previous research suggesting that time spent caring for a child with ASD has a strong predictive impact on parental stress and coping. They also confirm the negative impact of child externalising behaviours on parent perceptions of FQoL. Importantly, the findings highlight the importance of family sense of coherence on positive parental outcomes. Parents appear to demonstrate stable levels of coping and stress despite fluctuations in child behaviour, indicating that factors other than support and family functioning investigated in the current study (i.e., locus of control) may play an important role in family adaptation. Study implications for future research, including the identification of protective and risk factors for family adaptation, are discussed.

122.042 Rural Parents' Knowledge of Autism and Child Development

A. B. Barber[1], L. G. Renfroe[1], L. K. Baker[2], D. Ray[3], T. S. Tomeny[2], S. E. Strickland[3] and A. Evans[4], (1)Communicative Disorders, University of Alabama, Tuscaloosa, AL, (2)Department of Psychology, The University of Alabama, Tuscaloosa, Tuscaloosa, AL, (3)University of Alabama, Tuscaloosa, AL, (4)Pediatrics, University of Alabama, Tuscaloosa, AL

Background:
Literature suggests that children in rural areas and from poorer households receive diagnoses 5 to 8 months later than those in urban and middle class homes (Mandell et al., 2005) and these families have limited to no accessibility to trained professionals specializing in autism (Stahmer, 2007) as well as limited accessibility to reliable information about autism (Peacock et al., 2012). Parents play a critical role in the early identification process by relaying developmental information and concerns to their physician (Woods & Wetherby, 2003). However, very little is known regarding rural parents' general knowledge about autism and child development, which limits the development of appropriate dissemination materials.

Objectives:
To obtain a baseline measure of rural parents' knowledge about autism and child development.

Methods:
Rural primary caregivers of children under 6 years of age who live in a rural area as designated by the 2010 US Census Bureau (under 2,500 people) were invited to complete a 20-question survey via Qualtrics online survey software. Participants are recruited through their local community events such as holiday festivals and school events. Researchers also distributed CDC Learn the Signs-Act Early Alabama program handouts to participants.

Results:
Thus far, 57 surveys have been collected and analyzed. Recruitment is ongoing to achieve a proposed sample size of 500. Theme analysis will be completed on open-ended survey questions such as "What do you think causes autism?". Descriptive data will be presented on multiple choice survey questions. Preliminary analyses on a small sample of questions are presented here. Eighty-nine percent of rural parents felt that early intervention could improve autism symptoms. Eleven percent thought that autism runs in families; 42 percent thought it does not run in families, and the remaining respondents were unsure. Regarding development, eighty-six percent indicated that children could learn language skills through play and 90 percent thought that talking to children helps them learn language. When parents were asked at what age autism can be diagnosed, responses ranged from birth to early school age. When asked whom they should contact with concerns about their child's development, only 44 percent would contact their physician. Other responses included "DHR," "a child development center" and "a friend who is a doctor." Finally, when asked what behaviors were characteristic of autism, only twenty-five percent indicated diagnostic symptoms related to social interaction, communication or repetitive behavior (DSM-V, APA, 2013). Other responses included, "hyper," "get really annoyed," "no emotion," "smart," loner" and "great in math." Additional data collected prior to the 2015 IMFAR annual meeting will also be presented.

Conclusions:
Based on preliminary analysis in this limited sample, parents seem more knowledgeable about certain areas of development (age of first words) and autism (age of diagnosis) than others (symptoms of autism). Yudell et al. (2012) suggested that novel and culturally sensitive materials regarding autism should be developed for underserved communities. This project is an important first step to meeting this need as results could directly inform dissemination research efforts, thereby improving the accessibility and quality of care available to rural families.

122.043 Severity of Child Autistic and Comorbid Symptoms, Parent Mental Health and Parenting Behaviors

M. Tsujii[1] and H. Ito[2], (1)Chukyo University, Toyota, Aichi, Japan, (2)Hamamatsu University School of Medicine, Nagakute, Aichi, Japan

Background: Families with children with developmental disorders face unique challenges. Several studies have reported an association between the severity of autistic symptoms and mental health problems among parents (Kasari & Sigman, 1997; Hastings & Johnson, 2001). Some authors have argued that externalized problems are the most important predictors of parental stress in the context of children with disabilities, including ASD (Baker et al., 2002; Lecavalier, Leone, & Wiltz, 2006). To date, the majority of previous studies on parental stress have been conducted in Western countries. Almost no studies examining the mental health of parents with children who have ASD have been conducted in Asian countries. Furthermore, previous studies have not addressed parental stress as a potential mediator in the relationship between severity of symptoms and parenting behavior.
Objectives: The present study examined the effects of children's autistic (social communication and restricted interests) and comorbid symptoms (inattention/hyperactivity, sensory symptoms, anxiety/depression, and conduct problems) on parent mental health in Japan. In addition, we tested whether or not parental stress mediates the relationship between severity of child symptoms and parenting behavior (positive and negative parenting).
Methods: The participants were the parents of 778 children and adolescents with ASD (572 boys; M age = 10.6, SD = 3.5, range 3-18). The following questionnaire scales were used: the Autism

Spectrum Screening Questionnaire (ASSQ; Ehlers, Gillberg, & Wing, 1999) for ASD symptoms, the ADHD Rating Scale-IV (ADHD-RS-IV; Du Paul et al., 1998) for inattention/hyperactivity, the Sensory Profile (SP; Dunn, 1999) for sensory symptoms, the Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997) for anxiety/depression and conduct problems, the General Health Questionnaire (GHQ; Goldberg & Williams, 1970) for parent mental health, and the Positive and Negative Parenting Scale (PNPS; Ito, 2014) for parenting behaviors.

Results: Path analysis revealed that parent mental health was significantly predicted by child autistic symptoms, sensory symptoms, and anxiety/depression. Parent mental health, in turn, showed a negative relationship with positive parenting and a positive relationship with negative parenting. Thus, there is evidence that parent mental health serves as a mediating factor between child symptoms and parenting behaviors. In addition, some child symptoms had a direct effect on parenting behavior.

Conclusions:
First, the results suggest that parent mental health is more greatly affected by relatively passive symptoms, such as autistic symptoms, sensory symptoms, and anxiety/depression, in comparison to active symptoms, such as inattention/hyperactivity and conduct problems. This finding is not consistent with those of previous studies in Western countries that found externalized behaviors to be the central factor in the prediction of parental stress. This incongruence may be explained by cultural or ethnic differences. Second, the results provide evidence that parent mental health partially mediates the relationship between child symptoms and parenting behaviors. This may partly explain how negative spirals are created in families with children with ASD.

44   **122.044** Silver Linings: Optimism and Positivity As Buffers of Stress and Lower Well-Being in Mothers of Adolescents with ASD

J. Blacher[1] and B. L. Baker[2], (1)University of California - Riverside, Los Angeles, CA, (2)UCLA, Los Angeles, CA

Background:
There is considerable evidence that dispositional optimism is beneficial to one's health (Carver et al., 2010; Peterson, 2000) and helps maintain positive parenting and a positive outlook during adverse times (Taylor et al., 2010). Specific to mothers of children with ASD or disabilities, maternal optimism relates to increased positive affect, decreased negative affect, and more adaptive coping strategies (Blacher et al., 2013). However, little is known about how maternal optimism buffers the increased stress and lower sense of well-being experienced by mothers of adolescents with ASD and/or a mental disorder.

Objectives:
This paper explores the role of optimism and positive perceptions in mothers of teens: (1) Do mothers' optimism and/or positive perceptions relate to disability status (ASD, intellectual disability (ID) and typical development (TD)? (2) Do optimism and/or positivity buffer the increased stress and psychological difficulties experienced by mothers of youth presenting varying levels of risk?

Methods:
This research is drawn from the Collaborative Family Study, a 15-year longitudinal study of mental disorders in children with or without ID/ASD. We report findings from the age 13 assessments; the sample (N=195) contains youth with TD (IQ >84, n=100), ID (IQ <85, n=40), and ASD (n=58). The primary measure of behavior problems/mental disorders was the Child Behavior Checklist. Measures included the Family Impact Questionnaire (FIQ) Positive and Negative sub-scales; Symptom Checklist (SCL-36); and Life Orientation Test (LOT). A three-level risk index was determined from the presence of (a) ID and/or ASD, and (b) disruptive behavior diagnoses ADHD and/or ODD. Risk = 0/low (Neither a nor b); 1 (either a or b), or 2/high (both a and b).

Results:
Q1. While dispositional optimism is supposed to be independent of what life offers up, here, mothers' optimism was modestly (but significantly, *p*=.04) related to group status, even controlling for SES (TD>ID>ASD). On the other hand, perceived positive impact of the child on the family did not differ significantly by diagnostic group. Moreover, the presence or absence of co-morbid ADHD or ODD was not related to dispositional optimism. **Q2**. To study the personality trait of dispositional optimism as a buffer of the relationships between child challenges and maternal well-being, we divided optimism scores into high (optimistic), medium, and low (pessimistic) thirds. The figure (one example) illustrates that psychological symptoms increased dramatically with increasing child risk, but also were higher for mothers with lower optimism, especially at the high-risk levels. Optimism did not make a difference for at "low-risk" mothers, but at "high-risk" mothers with low optimism (pessimism) reported a greater than 2.5 times increase in psychological symptoms. Similar analyses with other well-being measures will be considered.

Conclusions:
Child disability status and child behavior problems/mental disorders take a psychological toll on mothers. However, the personality trait of dispositional optimism buffers these (child risk - parent adjustment) relationships. Perceived positive impact of the child has a similar buffering effect. In short, not all parents are impacted similarly by youth disability and/or problem behaviors. There is a silver lining for those who maintain more positive perceptions.

45   **122.045** Social Support As a Protective Factor for Typically-Developing Siblings in the Presence of

Parental Stress: A Moderated Mediation Model

T. S. Tomeny[1], T. D. Barry[2] and L. K. Baker[1], (1)Department of Psychology, The University of Alabama, Tuscaloosa, Tuscaloosa, AL, (2)Psychology, The University of Southern Mississippi, Hattiesburg, MS

Background: Typically-developing (TD) siblings of individuals with ASD may be at greater risk for negative outcomes due to a variety of factors, including symptom severity in siblings with ASD and elevated parental stress (Meadan et al., 2010). However, variability in sibling adjustment suggests that protective factors, such as social support, may improve TD sibling resilience (Armstong et al., 2005). Unfortunately, the ways in which these factors interact to predict TD sibling outcomes remain poorly understood.

Objectives: This study sought to examine social support as a possible buffer against TD sibling maladjustment within a moderated mediation model. It was predicted that the indirect effect of symptom severity in siblings with ASD on maladjustment in TD siblings through parental stress would be moderated by TD sibling perceptions of social support. Finally, exploratory analyses were conducted examining TD sibling maladjustment as predicted by social support subtypes.

Methods: Participants included 113 parents and TD siblings [ages 11 to 17 ($M = 13.34$, $SD = 1.81$)] of a child with ASD [ages 3 to 17 ($M = 12.03$, $SD = 3.28$)]. Parents completed two Strength and Difficulties Questionnaires (SDQ; one on each child) to assess general emotional and behavioral functioning, the Children's Social Behavior Questionnaire about the child with ASD to assess ASD symptom severity, and the Questionnaire on Resources and Stress – Short Form about themselves to assess parental stress. TD siblings self-reported via the SDQ to assess their own functioning and the Child and Adolescent Social Support Scale to assess their perceived social support.

Results: Conditional (based on TD sibling social support) indirect effects of ASD symptom severity on TD sibling maladjustment through parental stress were examined using bootstrapping analytical methods to estimate a bias-corrected asymmetric confidence interval of the indirect effects via "PROCESS," a computational tool for SPSS (Hayes, 2013). The plotted significant interaction between parental stress and TD sibling social support shows that TD sibling social support is a protective factor in the presence of high parental stress (Figure 1). Furthermore, parental stress was more likely to mediate the relation between ASD symptom severity in siblings with ASD and TD sibling maladjustment when TD sibling social support was high, specifically leading to lower maladjustment under the high social support condition (Table 1). Additionally, parent- and self-reported TD sibling maladjustment were separately regressed onto TD sibling social support subtypes as simultaneous predictors after controlling for ASD symptom severity and parental stress. Support from classmates ($\beta = -.35$, $p = .01$) and close friends ($\beta = -.21$, $p = .03$) uniquely predicted parent-reported TD sibling maladjustment, whereas support from parents ($\beta = -.24$, $p = .02$) and classmates ($\beta = -.36$, $p = .01$) uniquely predicted self-reported TD sibling maladjustment.

Conclusions: TD sibling social support moderated the mediational relation among ASD symptom severity, parental stress, and TD sibling maladjustment. Results show the importance of social support in reducing TD sibling maladjustment when ASD symptoms and elevated parental stress are present and underscore the importance of considering multiple raters when assessing social support subtypes.

46 **122.046** Stability and Change of Insightfulness Among Mothers of Children with Autism Spectrum Disorder

ABSTRACT WITHDRAWN

Background: A recent clinical trial of a parent-mediated intervention targeting responsive parental communication (Siller et al., 2013) revealed a conditional treatment effect, suggesting that baseline measures of maternal insightfulness moderate the intervention's efficacy. Mothers who were better able to discuss their child's thoughts and emotions in a complex, nuanced, and accepting way showed larger treatment-related gains in responsive parental behaviors than mothers who were less insightful at baseline.

Objectives: To investigate stability and change across two repeated measures of maternal insightfulness among mothers in the control group of a clinical trial.

Methods: The sample included 34 mothers of children with ASD (chronological age: $M = 56$ months, $SD = 12$; expressive language age: $M = 15$ months, $SD = 8$) enrolled in the control group of a clinical trial (Siller et al., 2013). Participants completed a series of baseline assessments to evaluate child characteristics (e.g., Mullen Scales of Early Learning, ADOS). Measures of maternal insightfulness were administered twice over a period of 5 months ($M = 141$ days, $SD = 43$ days). Maternal insightfulness was evaluated using the Insightfulness Assessment (IA, Oppenheim & Koren-Karie, 2002), a semi-structured interview that asks parents to discuss their child's thoughts and feelings during a previously recorded video vignette. Interviews are coded on ten 9-point rating scales, including insight into the child's motives, flexibility of thought, and complexity in description of the child. Profiles of scores on the ten scales indicate one of three primary classifications: Positively Insightful (PI), One-Sided (OS), or Disengaged (DE). A composite score was calculated by averaging six highly correlated subscales ($r > 0.6$). Inter-rater agreement between two coders was established on the composites ($ICC = 0.77$) and classifications ($kappa = 0.82$) on 12 transcripts.

Results: At time 1, the mean composite scores of mothers classified as PI ($n = 11$), OS ($n = 13$), and DE ($n = 9$) were 6.0 ($SD = 0.7$), 3.5 ($SD = 0.7$) and 2.7 ($SD = .5$), respectively. At time 2, the composite scores of mothers classified as PI ($n = 6$), OS ($n = 12$); and DE ($n = 12$) were 5.3 ($SD = $

1.6), 3.3 (*SD* = .7), and 3.1 (*SD* = 1.5), respectively. To evaluate the stability of individual differences in the insightfulness composite scores, we computed an Intraclass Correlation Coefficient (*ICC* = 0.72, *p* < 0.01). Although the percentage of mothers classified as PI decreased over time (33% and 20% at time 1 and 2), a chi-square test revealed that this change was not statistically significant, $x^2(1)$ = 3.54, ns. Similarly, paired sample t-tests revealed no significant difference in composite scores between time 1 and 2, *t* (25) = .79, ns.

Conclusions: Individual differences in maternal insightfulness appear to be relatively stable, with 72% of the variance in insightfulness composite scores at time 2 being predicted by baseline measures of insightfulness. We found no evidence to support that maternal insightfulness increases over time. There is a need to investigate the potential for responsiveness-based interventions to nurture maternal insightfulness.

47 **122.047** Stakeholder Perspectives on the Inclusion of Secondary Students with Autism Spectrum Disorder: Challenges and Support Needs

S. Hedges, UNC Chapel Hill, Chapel Hill, NC

Background: As the prevalence of Autism Spectrum Disorder (ASD) is increasing, some studies have found that the majority of individuals with ASD are without comorbid intellectual disability (ID; CDC, 2014; Kim et al., 2011). This means that high schools are serving a growing number of students with ASD in inclusion classrooms charged with preparing them for the postsecondary environment. Taylor and Seltzer (2011) described this subgroup of students with ASD without ID as "falling through the cracks" as they may not be eligible for the same transition services as their peers with ID who often participate in a more career and life skills focused curriculum. Consequentially many students with ASD are unprepared as they move from high school to the post-school environment (Chiang et al, 2012, Gerhardt & Lanier, 2011). The financial implications, according to a cost analysis for the United States, is $35 billion in direct and indirect costs across the lifespan for individuals with ASD who do not achieve independence (Ganz, 2007). The cost to families and the individuals themselves in terms of quality of life are more difficult to assess.

Objectives: Little is known about the experiences of adolescents with ASD in the inclusion classroom as they prepare for life after high school. Gathering and acknowledging the perspectives of stakeholders involved in the education of high school students with ASD is essential to implementing effective interventions to meet their needs and ultimately to provide more promising outcomes. This study explores stakeholder perspectives of the experiences of high school students with ASD in the inclusion classroom. It is guided by the following research question: How are high schools supporting students with ASD in the inclusion classroom to improve their outcomes?

Methods: This study uses focus group data gathered across multiple stakeholders (i.e. family members, adolescents and young adults with ASD, educators, administrators, community members, and, service providers). A total of 28 focus groups were held in 4 states (North Carolina, Tennessee, Texas, and Wisconsin) and included 152 participants. Parents and teachers represented the largest groups (n=47 and n=45 respectively), and individuals on the spectrum the smallest (n=6). Data was analyzed through a process of coding, categorizing, and theme development using NVivo 10 software.

Results: Three distinct themes emerged from the analysis of the data: (1) the need for whole school autism awareness (e.g. students, teachers, resource officers, bus drivers), (2) better implementation of the Individualized Education Program (IEP) in all classes, and, (3) more attention to the social and communication needs of students with ASD.

Conclusions: The successful transition to adulthood is particularly challenging for students with ASD without ID as they may not receive appropriate transition services during high school. Preparing students with ASD without ID to meet the academic requirements for post-secondary success may not be sufficient to meet all the challenges they will face once they leave high school. It is critical that social-communication needs be addressed not just in IEPs but also actively throughout the day in all classrooms and environments.

48 **122.048** The Cost of Autism Spectrum Disorders

T. Falkmer, Curtin University, Perth, WA, Australia

Background: A diagnosis of an autism spectrum disorders is usually associated with substantial lifetime costs to an individual, their family and the community. However, there remains an elusive factor in any cost-benefit analysis of ASD diagnosis, namely the cost of not obtaining a diagnosis. Given the infeasibility of estimating the costs of a population that, by its nature, is inaccessible.

Objectives: The current study compares expenses between families whose children received a formal ASD diagnosis immediately upon suspecting developmental atypicality and seeking advice, with families that experienced a delay between first suspicion and formal diagnosis.

Methods: A register based questionnaire study covering all families with a child with ASD in Western Australia. Families with one or more children diagnosed with an ASD, totalling 521 children diagnosed with an ASD; 317 records were able to be included in the final analysis.

Results: The median family cost of ASD was estimated to be AUD $34,900 per annum with almost 90% of the sum ($29,200) due to loss of income from employment. For each additional symptom reported, approximately $1,400 cost for the family per annum was added. While there was little direct influence on costs associated with a delay in the diagnosis, the delay was associated with a modest increase in

the number of ASD symptoms, indirectly impacting the cost of ASD.

Conclusions: A delay in diagnosis was associated with an indirect increased financial burden to families. Early and appropriate access to early intervention is known to improve a child's long-term outcomes and reduce lifetime costs to the individual, family and society. Consequently, a per symptom dollar value may assist in allocation of individualised funding amounts for interventions rather than a nominal amount allocated to all children below a certain age, regardless of symptom presentation, as is the case in Western Australia.

49   **122.049** The Impact of Children with and without Developmental Disabilities on Relationship Satisfaction and the Parenting Alliance

C. E. Walsh, *JFK Partners, University of Colorado, Denver, CO*

Background: Studies have shown that parents of children with ASD report greater negative impact of the child on family adaptation including financial stability, sibling relationships, and parents' social lives than parents of children with other chronic problems (e.g., Down syndrome, ADHD, ODD). Parents of children with ASD also report increased marital discord and parent stress. Currently there are no studies examining differences in parent perceptions of child impact and how this factor may influence parental relationships, particularly parents' spousal relationships and agreement on co-parenting.

Objectives: One goal was to determine whether there were differences in mothers' report of positive and negative impacts of children with an autism spectrum disorder (ASD), Down syndrome (DS), and Typically Developing (TD) children, as well as differences in parenting agreement and marital satisfaction. An additional goal was to determine whether there were differences between the three diagnostic groups in the relationship between child impact, mothers' marital relationship, and parental alliance.

Methods: The total sample included 157 mothers including, 54 mothers of children with Down syndrome, 56 mothers of children with ASD, and 47 mothers of typically developing children. The children ranged in age from 3-9 years old (DS Mean = 4.87, SD = 1.62; ASD Mean = 6.37, SD = 1.8; TD Mean = 5.31, SD = 1.9); 99 were male and 57 were female. Mothers completed measures online that assessed child impact on the family, marital satisfaction, co-parenting alliance, and child symptom severity. All parents completed the questionnaires online through SurveyMonkey. Only participants who completed 90% or more of the questionnaires received a $20 Amazon.com gift card.

Results: After controlling for child sex and parent education, results showed that mothers of children with ASD reported greater negative impact, lower marital satisfaction, decreased parent alliance, and higher child symptomatology compared to both other groups. Contrary to past research, the DS group did not differ from the TD group on measures of marital satisfaction and parent alliance. Further, child impact negatively predicted marital satisfaction and parent alliance for the ASD group only.

Conclusions: This is the first study to examine differences in parent perceptions of child impact on the family, the marital relationship, and the parenting alliance across parents of children with ASD, DS, and TD children. This study further supports the importance of including parents (and the family) in treatment for children with ASD. Specifically, targeting parents' negative cognitions about their child in family-based interventions may be important for increasing family adaptation and resilience. Treatment considerations also include a focus on improving parenting and marital relationships as well as child behavior in order to improve quality of life for families of children with ASD.

50   **122.050** The Relation Between Parent Stress and Children's Communication Skills Following a Theatre-Based Intervention for Children with Autism Spectrum Disorder

C. M. Herrington[1], C. R. Newsom[2] and B. A. Corbett[3], *(1)Department of Pediatrics, Vanderbilt University Medical Center, Nashville, TN, (2)Peabody Box 74, Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN*

Background: It is well established that parents of children with autism spectrum disorder experience more stress than those with typically developing children or another disability. Further, previous studies demonstrate an inverse relation between children's adaptive behaviors and parental stress. Impairments in social communication appear particularly stressful. In the current study, parents rated their stress before and after their child participated in a social skills intervention, and likewise also rated their child's adaptive functioning skills pre- and post-intervention.

Objectives: This study evaluates the impact of a theatre-based, social skills intervention for children with ASD. The 10-session program incorporates theatrical approaches, trained typically developing peers, and established behavioral strategies with the aim of increasing children's social functioning. A primary objective of this investigation was to examine the impact of a child-focused intervention on parental stress, and further, whether parental stress is related to their child's functional outcomes.Methods:

Methods: Participants included 30 youth with ASD between 8 to 16 years randomly assigned to the Experimental treatment group (EXP, N = 17) and Wait-list control group (WLC, N = 13). Parent stress was measured using the Parenting Stress Index- Short Form. This version of the PSI is comprised of 36 items divided into 3 subscales: Parental Distress, Parent-Child Dysfunctional Interaction, and Difficult Child. It also includes a total parental stress score. Children's adaptive behavior, including

social, communication, home living, and self-care skills, was measured with the Adaptive Behavior Assessment System-II. Nonparametric, Independent Samples Mann-Whitney U Test was used in which the post-intervention score served as the outcome variable and group (EXP or WLC) as the main independent variable.

Results: Significant differences were observed between the EXP and the WLC groups on the PSI Parent Distress (PD) scale (p = 0.039). Significant differences were also observed between the EXP and WLC groups for the ABAS-II Communication scale (p = 0.039). Pearson correlations indicated a significant relation between parents' post-intervention total stress (PSI Total Score) and children's post-intervention communication skills (ABAS-II Communication), r = -.381, p = .038.

Conclusions: This study extends previous findings about the relation of parent stress to child characteristics of ASD within a novel, theatre-based intervention design. Specifically, the distress parents experienced (in their parental role) was significantly less for the EXP group parents whose children received the theatre-based social skills intervention as compared to the WLC parents. At the same time, children who participated in the intervention demonstrated a significant increase in their adaptive communication skills compared to the wait-list controls. The findings further suggest that stronger child communication skills are related to less parental overall stress. The importance of child-focused interventions for parent well-being is discussed.

51   **122.051** Understanding Student-Teacher Relationships Among Children with Autism: The Role of Parental Involvement and Child Behavior

ABSTRACT WITHDRAWN

Background:
Parents who engage in reinforcing learning activities at home and regularly attend parent child conferences are more likely to have children with favorable school outcomes (e.g., Hoover-Dempsey & Sandler, 1997). However it is not clear whether parent involvement is also related to student-teacher relationships (STRs) which – when warm, close or positive in typically developing (TD) children – are predictive of positive school outcomes (Hamre & Pianta, 2001). This study qualitatively analyzed the STR from the parents', as opposed to the teachers' perspectives, and determined how parental involvement in the child's education may relate to the STR for young children with autism.

Objectives:
(1) To understand how parents describe the student-teacher-relationship (STR); (2) To examine the relationship between parents' involvement in their child's education and the STR; and (3) To understand how child behavior problems and social skills relate to both the parent-teacher relationship (PTR) and the STR.

Methods:
Interviews were conducted with parents (N = 116; 89% mothers) of children with autism (M age = 5.7; M IQ = 87, WPSSI). A subset of 30 interviews were qualitatively analyzed to examine how parents described the STR. Researchers iteratively coded interviews to look for broad codes related to the STR; a confirmatory phase followed. The 30 interviews were coded by two researchers; mean kappa indicated 80% reliability. Correlations among the quantitative Parent Teacher Involvement Scale (PTIS), the Parent Teacher Relationship Scale (PTRS), related child characteristics, and the Student-Teacher Relationship Scale (STRS) were examined.

Results:
Preliminary results indicated that: **Q1:** Qualitative parent reports of poor STRs matched quantitative teacher reports of a poor STRS. Qualitative parent reports of positive and warm student-teacher relationships matched quantitative teacher reports of a warm STRS. **Q2:** Correlation analyses revealed a significant negative correlation between STRS and PTIS scores (r = -.18, p <.05). **Q3:** Higher levels of child internalizing behaviors (CBCL), as reported by parents, were related to less positive STRs (r = -.24, p <.01); lower levels of child social skills were related to less positive PTRs (r = -.20, p <.01). Surprisingly, the PTRS and the STRS were not correlated significantly.

Conclusions:
Qualitative parent reports of the STR mapped onto teacher-ratings: parents and teachers agreed on the level of positivity/warmth in the relationship between the child and his/her teacher. Correlational analyses indicated that more parent involvement related to lower STRS scores. Perhaps parents of children with more behavioral/social problems are in more constant contact with the teacher regarding how to deal with these challenges. Conceivably, these meetings might be contentious (i.e., parents of children with more behavioral challenges and fewer social skills encountered less warm relationships with the child's teacher). Consistent with previous studies (Sutherland et al., 2008) parent reports of children's internalizing behaviors (e.g., anxiety) were significantly related to poorer STRs. Implications for interventions with teachers, parents and early schooling will be discussed.

52   **122.052** Understanding and Reducing Endorsement of Stereotypes of Autism: An Intervention Using Counterstereotypic Exemplars

M. Freeth and C. Wood, Psychology Department, University of Sheffield, Sheffield, United Kingdom

Background:
There is currently a paucity of knowledge around societal issues relevant to autism. In particular, stakeholder groups are extremely dissatisfied with the lack of research on improving societal attitudes towards individuals with autism (Pellicano et al., 2014). Examination of media

representations suggests that a negative and inaccurate characterisation of autism is perpetuated (Jones & Harwood, 2009; Huws & Jones, 2011) and this is likely to influence societal stereotypes of individuals with autism. However, before research can evaluate potential interventions for changing public perceptions of autism, a greater understanding of the nature and contents of societal stereotypes of autism is needed.

Objectives:
This research aimed to evaluate (Study 1) and subsequently reduce (Study 2) endorsement of negative stereotypic traits associated with individuals with Autism Spectrum Conditions (ASC) via exposure to video clips of individuals who display characteristics that counter negative aspects of the autism stereotype (i.e., who are counterstereotypic) autism stereotype.

Methods:
Study 1: 298 volunteers completed an online survey; 164 did not have a family member or close friend with ASC, did not have ASC themselves and had lived in the UK for five years or more. Responses of these 164 individuals were analysed.
Study 2: Sixty-six undergraduate and post-graduate students were randomly allocated to either the experimental group or the control group. Participants in the experimental group watched video clips of five individuals who were counterstereotypic on 4-key traits identified in Study 1 – poor social skills, introverted and withdrawn, poor communication, difficult personality or behaviour. Participants in the control group watched video clips of wildlife programmes. Participants then rated their endorsement of the 10 most frequently reported traits associated with ASC identified in Study 1. Demand characteristics were avoided by presenting this phase as an ostensibly separate study, which was validated via a funnel de-brief.

Results:
Study 1: found that the societal stereotype of ASC was predominantly negative. The 10 most frequently reported traits, in order, were poor social skills; being introverted and withdrawn; poor communication; difficult personality or behaviour; poor emotional intelligence; special abilities; high intelligence; awkward; obsessive; low intelligence.
Study 2: found that exposure to counterstereotypic exemplars successfully reduced endorsement of the frequently reported negative stereotypic traits tackled by the intervention compared to participants in the control condition, though stereotype endorsement was not reduced for all stereotypic traits assessed.

Conclusions:
This study reports the content of the societal stereotype of individuals with ASC in the UK. General knowledge of the characteristics of ASD was poor; the only characteristic that could be identified by over half of respondents was poor social skills. We demonstrated that it is possible to tackle endorsement of negative stereotypic traits via exposure to individuals with ASC displaying counterstereotypic behaviour. In future it will be important to tackle endorsement of the entire range of stereotypic characteristics of ASC in order to reduce prejudice and improve attitudes towards group members. This will likely improve the life chances of those with ASC.

53 **122.053** Understanding and Sharing an Autism Spectrum Disorder Diagnosis: Perspectives of Diverse Families Participating in a Family Navigation Program

*S. Rajabiun[1], **G. I. Orsmond**[1], X. Grossman[2], S. Blenner[2], I. Fernandez-Pastrana[2] and M. Augustyn[2], (1)Boston University, Boston, MA, (2)Boston Medical Center, Boston, MA*

Background: Caregivers express a range of responses and experiences following the diagnosis of autism spectrum disorder (ASD) in their child, including relief, stress, and perceived or enacted stigma. Few studies, however, have examined how families from immigrant, racial ethnic minority, or low-income backgrounds understand and disclose their child's diagnosis.
Objectives: The objectives of this analysis were to describe caregivers' understanding of their child's ASD diagnosis and what they told others about their child's difficulties. We explored patterns of understanding and disclosure in families participating in a Family Navigation program and a comparison usual care group, and across immigrant and U.S. born families.
Methods: This qualitative analysis included 155 families enrolled in a longitudinal, randomized controlled study of the impact of Family Navigation (R40 MC 19928-01, Augustyn, PI) on clinical (timeliness and adequacy of treatment received) and psychometric outcome. Participants were parents or legal guardians of the child and self-identified as the child's primary caregiver. Families were eligible if the child was younger than 8 years old and newly diagnosed with an ASD according to DSM-IV or DSM-5 criteria. Participants either received usual care or worked with a Family Navigator for 6 months. Data for this qualitative analysis included participant responses to two open ended questions at baseline and 6-month follow-up to *assess the understanding of the child's diagnosis*: (1) "When family or friends ask you what is the diagnosis your child has, what do you tell them?" and (2) "Can you explain what that word (s) means to you?" Qualitative content analysis using an inductive approach was used to analyze for emerging themes and patterns in the data, using open coding of the narrative responses and then using axial coding to identify patterns and relationships.
Results: Over half of the participant caregivers were immigrants (see Table 1). Across the entire sample, there was an increase in the number of caregivers who could report the clinical diagnosis between baseline and follow-up (65.1% ($n = 84$) vs. 85.3% ($n = 110$), $p < .000$). Among caregivers

born in the U.S., 77% could name their diagnosis at baseline compared to 95% at follow-up. Among caregivers born outside the U.S., 54% could name the diagnosis at baseline compared to 76% at follow-up. Four categories emerged in terms of to whom caregivers shared the ASD diagnosis: (1) Tell no-one, (2) Only close family and friends, (3) Very open to explaining the diagnosis, and (3) Never came up, no-one asks (see Table 2). Patterns of disclosure appeared to differ between immigrant and U.S. born caregivers, but not by participation in the Family Navigation program.
Conclusions: Family Navigator and other support programs at the time of diagnosis could provide training to support caregivers' understanding of the child's diagnosis and assist them with the disclosure process. The findings also have implications for culturally influenced perceptions of stigma in the disclosure process.

54 **122.054** Well-Being of Mothers of Preschoolers with Autism Is Mediated By Their Children's Treatment-Related Improvements in Every-Day Communication

Y. Ozturk[1], C. Dissanayake[2] and G. Vivanti[3], (1)Department of Psychology and Cognitive Science, University of Trento, Rovereto, Italy, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (3)Olga Tennison Autism Research Centre, Northcote, Australia

Background: Numerous studies have indicated that the behavior of children with autism poses unique challenges to parenting. As children's behavior and cognitive functioning are subject to change when suitable early intervention programs are put in place, it is plausible that positive treatment-related changes in the child will have a positive impact on parental well-being. To test this hypothesis we investigated whether maternal well-being is affected by the outcomes of children receiving intervention.
Objectives: Our aim was to evaluate whether treatment-related changes in children with autism (as well as other factors known to be linked to parental well-being) contribute to changes in maternal well-being from pre-intervention (baseline) to post intervention across three indexes – changes in Stress, Anxiety and Depression.
Methods: The participants comprised an Australian sample of 27 mothers (mean age = 36.11 years; SD = 5.65) of children diagnosed with ASD (confirmed with the Autism Diagnostic Observation Schedule; ADOS) who were enrolled at the Victorian Autism Specific Early Learning and Care Centre (ASELCC) in Melbourne, Australia. Mothers were asked to complete a demographic form and three questionnaires at pre- and post-intervention: the Depression Anxiety and Stress Scale to assess their well-being, the Parenting Sense of Competence to determine their satisfaction and self-efficacy in the parenting role and the Vineland Adaptive Behavior Scales II (VABS) to assess their children's adaptive behavior. Children were also administered the ADOS and the Mullen Scales of Early Learning (MSEL) pre- and post-intervention.
Results: We first determined which putative predictors at pre-intervention (VABS communication, daily living and social skills; MSEL verbal and non verbal developmental quotients (DQs); ADOS calibrated severity scores; mothers' age, SES, and parenting satisfaction and efficacy scores) moderate change by using repeated measure ANOVAs. Hierarchical multiple regression analyses were then conducted with the significant predictors to test their unique contribution to T2 well-being (controlling for T1 well-being). Different child and family factors including SES, mother's age, parental satisfaction and efficacy were linked to maternal well-being. However treatment-related changes in children's communication, as assessed on the VABS, contributed to variance in all maternal well-being variables (stress, anxiety and depression) above and beyond the other factors.
Conclusions: The findings highlight that rather than changes in cognitive functioning, it is improvements in everyday adaptive communication skills in children with ASD that impact on mothers' well-being.

55 **122.055** What Constitutes Autism Knowledge? Insights from Adults on the Autism Spectrum

K. Gillespie-Lynch[1], S. Kapp[2], J. T. Pickens[3], P. J. Brooks[4], B. Schwartzman[5] and K. Guardado[6], (1)College of Staten Island, Brooklyn, NY, (2)Department of Psychology, University of California, Los Angeles, Los Angeles, CA, (3)Psychology, The Graduate Center at the City University of New York, New York, NY, (4)Department of Psychology, The Graduate Center - CUNY, New York, NY, (5)Education, UCLA, Los Angeles, CA, (6)UCLA, Los Angeles, CA

Background:
Despite growing recognition that autism research is more likely to be useful if autistic people and their family members are empowered participants in the process (e.g. Parsons, 2014; Robertson, 2010), a recent online survey revealed that autistic adults continue to feel that their voices are not heard (Pellicano et al., 2014). A key area wherein autistic people's voices remain unheard is in defining what constitutes "knowledge" about autism. Although "autism knowledge" has been assessed among many different types of people around the world (e.g. Helps et al., 1999; Khatri et al., 2011), it has not previously been purposefully examined among those for whom it is most relevant—autistic people. Discrepancies between needed and received information about autism may contribute to lower Quality of Life (QoL) in autism (Renty and Roeyers, 2006).
Objectives:
(1) Compare knowledge of and stigma toward autism among autistic adults (N=219), their nuclear family members (N=137), and the public (N=115); (2) Examine associations between knowledge,

stigma and QoL; (3) Evaluate potential effects of an online-training on knowledge and stigma.
Methods:
Participants were classified as autistic if they self-identified as autistic *and* exceeded the autism cut-off on the RAADS-14 (Eriksson et al., 2013). The pre-test/post-test included an adapted version of Stone's (1987) Autism Awareness Survey, a social distance scale assessing stigma (Bogardus, 1933), and an opportunity to define ASD. Open-ended definitions of ASD were coded by independent coders after they achieved reliability. Non-parametric tests were used. Except where *p*-values are stated, all reported results are significant at $p \leq .001$.
Results:
Autistic people (*M* = 18.53, *SD* = 4.73) had higher autism knowledge than the public (*M* = 14.88, *SD* = 6.04). Family members exhibited a trend toward heightened knowledge (*M* = 17.45, *SD* = 5.40) relative to the public (*p* = .002). Autistic people were more likely than the public to agree with statements that autistic people show affection and have empathy, and disagree that autistic people do not have attachments, that they can outgrow autism, and that they are violent. Autistic people's definitions of ASD more often were internal, opposed to the medical model and/or described autism as a neutral difference relative to the public's definitions.
Autistic people (*M* = 7.20, *SD* = 2.10) endorsed lower stigma toward autism than the public (*M* = 8.71, *SD* = 3.27). Family members exhibited a trend toward reduced stigma (*M* = 7.47, *SD* = 2.17) relative to the public (*p* = .002). Knowledge about autism correlated negatively with stigma across groups but neither knowledge nor stigma was associated with QoL (which was lowest among autistic participants). Participation in the training was associated with increases in knowledge for all groups.
Conclusions:
This study suggests that autistic people should be considered "autism experts" and be involved as empowered collaborators in the research process. Although knowledge is not yet power for many autistic people, identifying how autistic people view autism is a crucial first step toward developing research that is relevant to the interests/needs of those whom the research is supposed to serve.

56   **123.056** A Telehealth Approach to Parent Coaching in ASD

L. Vismara, *Department of Psychology, York University, Toronto, ON, Canada*

Background: Many barriers exist to parents seeking early intervention for their child with ASD, including long waiting lists, costly services, and a shortage of specialist providers. The introduction and development of advanced technologies can provide supplements to current early intervention services. Telehealth is one mechanism that may support parents in their pursuit to help their child learn and access intervention resources sooner from home or other locations at any time of day.
Objectives: The study attempted to identify acceptable components of a telehealth parent coaching delivery model so as to better understand how this resource translates into viable practice for families with ASD. A randomized controlled trial of a telehealth coaching model to treatment-as-usual compared parents' intervention usage, program satisfaction, and online learning patterns. Children in both groups were expected to make gains so that the primary question remained about the feasibility and appropriateness of telehealth delivery to parents.
Methods: Parents received 12 weekly 1.5-hour video conferencing sessions and website access to self-guided learning resources of the parent coaching curriculum of the Early Start Denver Model (P-ESDM). The control group received monthly video conferencing sessions and website access to alternative intervention resources based on treatment-as-usual services. Parent-child interactions were recorded in real time across a six-month period to evaluate parents' fidelity with the P-ESDM, program satisfaction, and website engagement.
Results: Telehealth coaching facilitated greater fidelity gains, program satisfaction, and website usage for parents in the P-ESDM than control group at the end of 12 weeks and three-month follow-up. Increases in children's social-communication skills occurred for both groups.
Conclusions:
Findings suggest the feasibility of a telehealth approach to coaching parents with access to evidence-based intervention resources while waiting for other services to begin. However, not all technology options may be embraced by parents and/or lead to effective change in parent-child behaviors. Additional research must confirm the promise and utility of telehealth for increasing the availability and quality of parent-delivered interventions.

57   **123.057** Bayesian Meta-Analysis of Multiple Interventions and Outcomes for the Treatment of Autism Spectrum Disorder

*C. Fonnesbeck[1], A. S. Weitlauf[2], N. A. Sathe[3], M. McPheeters[4] and **Z. Warren**[5], (1)Biostatistics, Vanderbilt University, Nashville, TN, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)Vanderbilt Evidence-based Practice Center, Institute for Medicine and Public Health, Vanderbilt University, Nashville, TN, (4)Vanderbilt Universtiy, Nashville, TN, (5)Vanderbilt University, Nashville, TN*

Chris Fonnesbeck, Zachary Warren, Amy Weitlauf, Nila Sathe, Melissa McPheeters

Background: Applied early intervention practices for young children with ASD often involve multi-component interventions (*e.g.*, speech-language intervention, developmental preschools, occupational therapies, involvement with ABA programs, etc.). Providers and parents are often required to make recommendations and choices regarding which components of interventions should be included as part of intervention both based on resource availability and scientific understanding of studied interventions. Unfortunately, few studies have directly compared the effects of well-controlled treatment approaches, instead comparing interventions in isolation or to non-specific "treatments as usual." Such comparisons provide insufficient resolution of which components of intervention primarily drive developmental progress, and at what rate.

Objectives: In the current work, we present a novel meta-analytic approach for understanding ASD interventions with the potential for discriminating amongst the components of treatment response across the range of intervention classes. Specifically, we present a network (or mixed treatment comparison) meta-analysis of multicomponent ASD interventions. Network meta-analysis is a generalization of standard meta-analysis to allow for the simultaneous evaluation of a set of treatments, rather than a simple pairwise comparison. By constructing a network of studies, this approach considers both direct evidence from studies that compare the same interventions as well as indirect evidence from studies that have one intervention in common, but not all. Including indirect evidence can improve the precision of meta-estimates relative to using only direct evidence by borrowing strength from the indirect comparisons. Indirect evidence can also serve to mitigate biases that may exist in direct comparisons.

Methods: We implemented a Bayesian mixed-effects model that accounts for multi-component interventions and the reporting of multiple outcomes in a unified framework. Critically, this allows individual studies to contribute partial information, and for missing quantities to be readily imputed or predicted.

Results: The meta-analysis included 19 independent studies (extracted from 2014 AHRQ report on behavioral interventions for ASD) comprising 27 different interventions (classified into 7 multicomponent treatment categories) that reported one or more of three IQ scores (verbal, nonverbal, composite) as outcomes. We estimated the most effective intervention to be high-intensity applied behavior analysis (ABA), with a median posterior effect size of 5.0 (95% Bayesian credible interval = [1.0, 8.8]) points. In contrast, eclectic school programs had a posterior mean effect of -6.0 (95% BCI [-10.5, -1.6]), while the effects of the remaining classes were equivocal.

Conclusions: Our approach is general and flexible enough to provide comparative effectiveness inference on a range of disorders for which there is a heterogeneous mixture of interventions that warrant comparison. This suggests that Bayesian mixed-effects modelling may represent an important methodology for understanding the large and confusing body of ASD intervention research.

58   **123.058** Brief Background of Parent Training in ASD

ABSTRACT WITHDRAWN

Background: Parent Training (PT) is an evidenced-based intervention for children with disruptive behavior uncomplicated by ASD, but it has not been systematically tested in children with ASD.

Objectives: The purpose of this presentation is to illustrate the line of research conducted by our multisite network over the past decade.

Methods: We briefly describe the design and results of our feasibility trials and the randomized trial of medication alone versus medication plus parent training.

Results: PT is acceptable to parents with attrition of 5 /33 (15%), session attendance rate of 88% in the first two feasibility trials. Therapists trained in the intervention for these pilot studies maintained over 90% fidelity to the manual. In a randomized trial of 124 school-age children, we showed that PT in combination with medication was superior to medication alone.

Conclusions: Feasibility trials are prerequisites to large-scale randomized trials to show that the intervention is acceptable to parents and that trained therapists can reliably deliver the intervention.

59   **123.059** Children with Autism Spectrum Disorder Accessing Early Intervention in the Autism and Developmental Disabilities Monitoring (ADDM) Network

A. Messina[1], A. V. Bakian[1], W. Zahorodny[2], M. Kurzius-Spencer[3], S. A. Rosenberg[4], C. E. Rice[5], M. S. Durkin[6], S. Pettygrove[7], L. M. MacLeod[8], J. Shenouda[2], M. Rajan[9] and D. A. Bilder[1], (1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Pediatrics, Rutgers New Jersey Medical School, Newark, NJ, (3)Dept of Pediatrics, University of Arizona, College of Medicine, Tucson, AZ, (4)Department of Psychiatry, University of Colorado School of Medicine, Aurroa, CO, (5)National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA, (6)Population Health Sciences, University of Wisconsin-Madison, Madison, WI, (7)Epidemiology and Biostatistics, University of Arizona, Tucson, AZ, (8)Utah Department of Health, Salt Lake City, UT, (9)Department of Preventive Medicine and Community Health, Rutgers New Jersey Medical School, Newark, NJ

Background: Evidence-based treatments provided by Part C early intervention services, hereafter referred to as "EI," improve IQ, speech, and school performance for children with autism spectrum disorder (ASD). Best outcomes for these children are associated with early initiation of ASD-specific interventions. In the U.S., early ASD identification has been linked to sex, race/ethnicity,

developmental regression, and geographic location; however, little is known about characteristics of children with ASD receiving EI services. The CDC's Early Autism and Developmental Disabilities Monitoring Network (Early ADDM) identifies ASD among 4-year-old children. Two Early ADDM sites (New Jersey and Utah) collect information from EI, providing an opportunity to characterize children with ASD served by EI compared to those not.

Objectives: To describe the socioeconomic/demographic and diagnostic characteristics of children with ASD in two Early ADDM sites, comparing children who did and did not participate in EI services.

Methods: In surveillance year 2010, NJ and UT Early ADDM sites identified 4-year-old children with ASD using validated population-based, multi-source record review methods. Characteristics of children with ASD served by EI were compared with children with ASD not served by EI using chi-square and t-tests. Variables included sex, race/ethnicity, socioeconomic status (SES) indicators (parental ages and education duration at child's birth), presence of co-occurring intellectual disability (ID), attention deficit with hyperactivity disorder (ADHD), or seizures, regression history, previous ASD diagnosis by a qualified professional, and age at first ASD evaluation.

Results: NJ and UT Early ADDM sites identified 484 4-year-olds with ASD; 45% (N=218) participated in EI. A greater proportion of parents of children served by EI were >34 years old and had >13 years of education as compared with parents of children not served by EI (Table 1). Although no significant differences in race/ethnicity were detected between the two groups, a smaller proportion of children served by EI were White, non-Hispanic (36%) than those not served by EI (47%). No differences were detected in the frequency of co-occurring ID, ADHD, or seizures between children accessing and children not accessing EI. Children accessing EI were younger at first ASD evaluation (22.8 vs. 34.1 months, p<0.0001) and diagnosis (30.2 vs. 36.3 months, p<0.0001). Children served in EI were significantly more likely to have a final case status of autism (p<0.001).

Conclusions: Study findings suggest a link between higher SES and EI use; however, there appears to be some indication that the role of race and ethnicity should be further explored. Children accessing EI were not more likely to acquire a community-based ASD diagnosis by age four; however, as expected, they were more likely to have an evaluation and diagnosis at a significantly younger age than children without documented EI access. Toddlers with earlier evaluations and diagnoses have more time to qualify for and participate in birth-to-three EI programs. Although not a perfect severity metric, the co-occurrence of ID, ADHD, or seizures was not associated with EI participation. Additional exploration of the role of SES and other demographic factors in accessing universally-available EI programs for children with ASD is warranted.

60 **123.060** Comparing Two Parent-Implemented Interventions on Direct Observation of Joint Attention and Language of Preschool Children with Autism: A Pilot Study

M. E. Kerwin[1], M. E. Soreth[1] and C. Gangemi[2], (1)Psychology, Rowan University, Glassboro, NJ, (2)Family First, LLC, Haddonfield, NJ

Background: Acquiring joint attention (JA) and functional spoken language by the time a child with autism enters school around the age of 5 years old are critical. Involving parents in treatment maximizes the child's opportunities to learn. The efficacy and effectiveness of two popular approaches to autism treatment have not yet been evaluated as parent-implemented treatments. Relationship Development Intervention® (RDI) is a relationship-based intervention focusing on recreating developmental milestones through meaningful interactions with parents with a primary goal of increasing JA. In contrast, an Applied Behavior Analysis model based on Skinner's Analysis of Verbal Behavior (ABA/VB) increases spoken language directly when implemented by therapist and teachers; however, this approach has not been evaluated when implemented by parents. RDI and ABA/VB have different primary targets for intervention; however, both approaches assume that language and JA, respectively, will emerge as a corollary effect of the intervention.

Objectives: The purpose of this pilot study is to compare the efficacy of two parent-implemented adjunctive interventions, RDI and ABA/VB on JA and language in children 2-6 year old with ASD in preparation for a larger randomized clinical trial.

Methods: Participants were 12 children diagnosed with autism spectrum disorder (ASD) by community providers and the Autism Diagnostic Observation Schedule-2™. Participants were randomly assigned to parent-implemented RDI or ABA/VB. To control for services received in the community, parents reported weekly on the type and extent of services delivered. The intervention consisted of 16 sessions over 12 weeks delivered in the home. Assessments were conducted pre-treatment and end of treatment (3 months). The primary outcome measure was direct observation of parents and children interacting under different scenarios designed to implement conditions most likely to produce the behavior targeted by the interventions (e.g., joint attention, specific language skills) including prompts that involved having the child ask the parent for preferred items (PC5) and engaging the child in a conversation about family photographs (PC6). The direct observations were coded by research assistants blind to treatment condition and trained to interobserver reliability levels of 80% or above on a coding taxonomy that included an array of parent and child behavior related to joint attention, language, and problem behavior.

Results: Post-treatment direct observation assessment revealed that both the parent-implemented RDI and parent-implemented ABA/VB conditions were followed by gains in joint attention and verbal behavior, as well as decreased levels of problem behavior. Although greater improvements as measured by the direct observation coding system were observed in the ABA/VB condition compared to the RDI condition, there was variability in individual response.

Conclusions: Preliminary results from a pilot study comparing parent-implemented RDI and ABA/VB indicated that both interventions are able of producing gains in joint attention and verbal behavior, even though the two interventions differ in primary intervention targets. Further, these results support that parents can serve as effective agents of change in the implementation of empirically supported early interventions for ASD.

61 **123.061** Comparison of a Self-Directed and Therapist-Assisted Telehealth Parent Training Intervention for Children with ASD

B. Ingersoll, Psychology, Michigan State University, East Lansing, MI

Background: Although there has been growing interest in using telehealth interventions to provide parent training for children with ASD, empirical evaluations of such programs are limited, and little is known regarding the relative benefits of self-directed and therapist-assisted telehealth interventions for ASD. Self-directed programs have far greater dissemination potential as they do not require a trained professional and can typically be administered at a much reduced cost. At the same time, research on telehealth interventions for other disorders have found that therapist-assisted programs lead to better client outcomes than self-directed programs.
Objectives: The goal of this pilot RCT was to compare the effect of a self-directed (SD) and therapist-assisted (TA) telehealth intervention program on parent learning and self-efficacy and child language skills.
Methods: Children were matched with 3 months of expressive language age and then randomly assigned to the SD (n=14) or TA group (n=15). Parents were given up to 6 months to complete the program. Parent outcomes included parent intervention knowledge, parent intervention fidelity during a parent-child interaction in the home, and parent self-efficacy. Child outcomes included parent-report and observational measures of child language skills. In addition, program engagement data was monitored and treatment acceptability was measured at post-treatment.
Results: The program engagement data indicated high rates of program completion and treatment acceptability for both groups. Parents in both groups demonstrated significant improvements in parent knowledge of the intervention and parent self-efficacy from pre- to post treatment. Parents in both groups also demonstrated a significant improvement in parent fidelity; however, parents in the TA group made significantly greater gains in fidelity than parents in the SD group. Children in both groups demonstrated significant gains in expressive vocabulary on the MCDI, communication standard scores on the VABS, and rate of expressive language during a parent-child interaction, with a trend toward greater gains in child expressive language during the parent-child interaction for the TA group. Change in parent fidelity from pre- to post-treatment was significantly associated with improvements in child language during the parent-child interaction.
Conclusions: Both approaches show promise for increasing parents' use of evidence-based intervention techniques to promote their child's language skills. The self-directed program was effective for improving parent knowledge, self-efficacy, and fidelity of implementation. However, therapist assistance via remote coaching provided an added benefit for improving parent fidelity and child language. Additional research that can identify parents who are most likely to need remote coaching would assist in the development of a stepped care model that can increase parent access to evidence-based services in underserved communities.

62 **123.062** Conducting Assessment and Treatment of Problem Behavior for Children with Autism Via Telehealth

K. Pelzel[1], K. Schieltz[2], D. Wacker[3], A. Suess[4], S. Lindgren[5] and T. Kopelman[6], (1)Center for Disabilities and Development, University of Iowa Hospitals and Clinics, Iowa City, IA, (2)University of Missouri - Columbia, Columbia, MO, (3)Pediatrics, University of Iowa Hopsitals and Clinics, Iowa City, IA, (4)University of Iowa, Iowa City, IA, (5)Pediatrics, University of Iowa Children's Hospital, Iowa City, IA, (6)Psychiatry, University of Iowa Hospitals and Clinics, Iowa City, IA

Background: Problem behavior (e.g., aggression toward others, self-injurious behavior, property destruction) is recognized as a significant stressor for caregivers of children with autism. It can also be a barrier to early intervention efforts. Delivering evidence-based treatment for problem behavior via telehealth is a promising method for increasing access to these services, particularly for families who live in rural areas.
Objectives: The purpose of this investigation was to evaluate the efficacy of remotely training and coaching caregivers via telehealth to conduct functional analyses and implement functional communication training to address problem behaviors displayed by young children with an autism spectrum disorder in their homes. In addition to a summary of this project and its impact on problem behavior displayed by children with autism, a discussion of how telehealth was utilized and set up within the home environment will be presented.
Methods: Fifty-one children ages 1-6 were diagnosed with an autism spectrum disorder using the ADOS and the ADI-R; most of these participants continued with the behavior assessment and treatment phases of the study. Functional analyses and functional communication training were conducted by children's caregivers, who received remote training as well as "real time" remote coaching from a behavior therapist who was on average 123 miles from the families' homes. We evaluated these effects on three-levels: individual, group, and caregiver. At the individual level, we

evaluated the effects of functional analyses and functional communication training on problem behavior displayed in session by each child using single-case designs. At the group level, we will evaluate the effects of functional communication training for children participating in a randomized control trial. At the caregiver level, we evaluated changes in caregiver stress and self-efficacy ratings at pre- and post-treatment, as well as six months after treatment ended.

Results: Individual analyses to date show that 83% of children reached at least a 90% reduction in their identified problem behavior. Group results analyzed to date demonstrate that problem behavior decreases by an average of 91% following the implementation of functional communication training. Caregiver results suggest improved functioning following treatment, with caregivers reporting reduced stress and increased self-efficacy over time. The overall costs of providing six months of weekly behavioral services to the children averaged $1,440 per family whereas when the same procedures were conducted in vivo in a previous project, the average cost was $6,984.

Conclusions: Functional analysis and functional communication training can be successfully delivered to children with autism via telehealth. Caregivers are able to conduct the assessment and treatment sessions in their own homes with remote training and coaching from a behavior therapist.

---

63 **123.063** Cost-Effectiveness Analysis Comparing Pre-Diagnosis Autism Spectrum Disorder-Targeted Intervention with Ontario's Autism Intervention Program

*M. Rayar[1], **M. Penner**[2], N. Bashir[1], R. L. Hancock-Howard[3], W. Roberts[4] and P. Coyte[5], (1)Hospital for Sick Children, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Institute of Health Policy, Management and Evaluation, Unviersity of Toronto, Toronto, ON, Canada, (4)Integrated Services for Autism and Neurodevelopmental Disorders, Toronto, ON, Canada, (5)Institute of Health Policy, Managment and Evaluation, University of Toronto, Toronto, ON, Canada*

Background: Sequential wait times for diagnosis and intervention can negatively impact outcomes in autism spectrum disorder (ASD). New service delivery models propose providing ASD-targeted interventions to young children who show signs of ASD before a diagnosis. One such intervention is the Early Start Denver Model (ESDM), which has shown efficacy in children with ASD as young as 15 months. There are no studies examining the cost-effectiveness of pre-diagnosis ASD-targeted intervention models.

Objectives: We performed a cost-effectiveness analysis comparing the costs and dependency-free life years (DFLYs) generated by comparing pre-diagnosis intensive ESDM (ESDM-I) and pre-diagnosis parent-delivered ESDM (ESDM-PD) to the Ontario Status Quo (SQ).

Methods: The analysis took a time horizon to age 65 using both provincial government and societal perspectives. Published literature was used to derive estimates of effectiveness. The mean expected IQ was determined for each intervention profile. Probabilities of having an IQ in the typical (>70) or intellectual disability range (< 70) were calculated. Each IQ stratum was assigned a probability of achieving an Independent (60 DFLYs), Semi-Dependent (30 DFLYs) or Dependent (0 DFLYs) outcome. Costs were determined using the budget of an ESDM pilot project and government publications. A discount rate of 3% was applied to costs and effects occurring more than one year in the future. An incremental cost-effectiveness ratio (ICER) was calculated. One-way and probabilistic sensitivity analyses were performed to assess the impact of uncertainty in the model.

Results: From a provincial perspective, the ESDM-PD resulted in a savings of nearly $9,000 per person to age 65 compared to SQ, and generated 0.17 additional DFLYs. The ICER for ESDM-I compared to SQ was $23,000 per DFLY gained, and the ICER for ESDM-I compared to SQ was $58,000 per DFLY gained. One-way sensitivity analyses showed the model was most sensitive to uncertainty in predicting functional outcomes from IQ. From a societal perspective, the ESDM-I was the dominant strategy, producing more DFLYs for a lower cost than ESDM-PD or SQ. The societal model was most sensitive to uncertainty in predicted functional outcomes and caregiver costs. Probabilistic sensitivity analyses for both provincial and societal models showed considerable uncertainty in the effectiveness estimates of the interventions.

Conclusions: Pre-diagnosis ASD-targeted intervention may be associated with cost savings from both provincial and societal perspectives compared to current Ontario service models; however, predicted gains in independence based on increased IQ remain low with all programs. Caregiver costs were a significant driver in cost-effectiveness estimates. There was a high degree of uncertainty in the effectiveness of pre-diagnosis intervention, suggesting that further study on the effectiveness of these models is necessary to produce more accurate cost-effectiveness estimates.

---

64 **123.064** Developmental Trajectories of Response to Treatment for Toddlers with Autism: Findings from the Early Social Interaction Project

W. Guthrie[1], C. Lord[2] and A. M. Wetherby[1], (1)Florida State University Autism Institute, Tallahassee, FL, (2)Weill Cornell Medical College, White Plains, NY

Background: Early intervention for toddlers with ASD is critical, given increasing rates of early diagnosis and the potential for treatment to impact brain development. Early intervention programs have resulted in gains in cognitive, language, and/or social skills at the group level (Dawson et al, 2010; Kasari et al., 2008, 2010). However, these effects are often modest and variable across children, suggesting different patterns of response to treatments. A randomized controlled trial (RCT) of the Early Social Interaction (ESI) Project demonstrated group-level efficacy across measures of

language, social communication, and autism symptoms (Wetherby et al., 2014), but variability in degree of response was also observed. Despite promising findings at the group level, existing studies have not yet determined which children respond best to intervention.

Objectives: To identify patterns of response to intervention in children with ASD enrolled in ESI, using latent class growth analyses (LCGA).

Methods: 82 children diagnosed with ASD were enrolled in the ESI Project at 16-20 months of age. Children were randomly assigned to receive nine months of 1) individual-ESI offered in 2-3 weekly sessions to teach parents to support their child's social communication development or 2) group-ESI offered weekly. Children completed the ADOS and CSBS at baseline, bimonthly, and at the end of treatment, yielding 5-6 time points.

Results: Four LCGA models were conducted for CSBS Social, Speech, and Symbolic composites, and ADOS Social Affect severity scores. Three-trajectory-class solutions provided the best fit for the CSBS Social, Speech, and Symbolic models. For the Speech analyses, Class1 showed the highest scores at baseline and the highest rate of improvement, Class2 showed low baseline scores and significant growth during intervention, and Class3 also showed low baseline scores, but no change during treatment. For the CSBS Social and Symbolic analyses, Class1 showed the highest baseline scores with the highest rate of improvement, Class2 showed moderate baseline scores with significant but lower improvement than Class1, and Class3 had the lowest scores at baseline and no change during treatment. The two-trajectory-class solution provided the best fit for ADOS Social Affect scores: Class1 showed moderate social impairment and significant improvement while Class2 showed severe impairment and no change during treatment. Children in individual-ESI and group-ESI were relatively evenly distributed throughout trajectory classes. Significant predictors of treatment trajectory class membership validate these distinct patterns of response to treatment.

Conclusions: Findings support that group-level analyses, while important for RCTs documenting efficacy, can obscure individual-level variability in response to treatment. Significant variability in baseline skills and rate of improvement were observed and significantly related, with trajectory classes with the highest baseline scores showing the highest rate of improvement. Children in individual-ESI and group-ESI were represented across all trajectory classes, demonstrating that substantial variability in response exists across treatment type/intensity. LCGAs may help researchers identify which children respond best to which treatments, as well as those children who are not showing optimal response to treatment. This may ultimately improve our ability to identify which treatments work for which children and tailor treatments based on early pattern/rate of change.

---

65 **123.065** Dosage Effects of an Early and Intense Motor Skill Intervention in Young Children with ASD

L. R. Ketcheson[1] *and J. Hauck*[2], *(1)Sunfield Center for Autism, ADHD and Behavioral Health, Ann Arbor, MI, (2)Kinesiology, Michigan State University, East Lansing, MI*

Background: Despite evidence to suggest one of the earliest indicators of an ASD diagnoses is a delay in achieving early motor milestones, there remains very few evidence-based treatments targeting motor behavior as the primary outcome for young children with ASD.

Objectives: Therefore, the primary objective of this study was to investigate the effectiveness of an early and intensive motor skill intervention employing research supported strategies from Classroom Pivotal Response Teaching (CPRT) on motor skills (i.e. locomotor and object control skills) in young children with ASD aged 4-6.

Methods: Twenty young children with ASD aged 4-6 participated in this study. The experimental group (n=9) participated in an intense, 8-week intervention consisting of direct motor skill instruction in a 1:1 ratio for 4-hours/ day, 5-days/ week. The control group (n=11) did not receive the intervention. The environment modeled a youth sports camp, where participants received individual feedback followed by small group gross motor play using CPRT supported strategies. Fundamental motor skills (locomotor and object-control skills) were assessed in both groups using the Test of Gross Motor Development-2 at pre-intervention, post-intervention, and 4-weeks following the intervention (maintenance period). To investigate treatment dosage in the experimental group, bi-weekly assessment of motor outcomes occurred at weeks 2, 4, and 6 of the intervention. A general linear model analysis was conducted to examine differences in each group on motor skill performance. Pairwise t-tests were used to determine treatment dosage.

Results: Linear modeling demonstrated a statistically significant difference in motor performance following the intervention and after a 4-week maintenance period. For locomotor skills in the experimental group, there was a +16.82(SE=1.71) unit gain at post-intervention ($p<0.001$), and a -0.27 unit difference over the maintenance period. For object-control skills, there was a +18.27(SE=1.65) unit difference at post-intervention ($p<0.010$), and a -3.36(SE=1.18) unit difference over the maintenance period ($p<0.05$). The control group did not demonstrate significant gains in motor performance. Non-significant changes in motor skill performance at the post-intervention maintenance period demonstrated a preservation of skills in the absence of directed motor therapy. Pairwise t-tests were used to assess dosage response to the intervention. For locomotor skills, significant gains were observed from weeks 0-2 [$t(1,10)=+3.54, p<0.05$], weeks 2-4 [$t(1,10)=+2.48, p<0.05$], and weeks 6-8 [$t(1,10)=+2.82, p<0.05$], demonstrating continued locomotor gains throughout 8-weeks of intervention. For object-control skills, significant gains were observed from weeks 0-2 [$t(1,10)=+3.59, p<0.05$] and weeks 2-4 [$t(1,10)=+2.16, p<0.05$]. Although significant results continued through 8 weeks when compared to baseline [$t(1,10)=+11.57, p<0.05$], object-control gains plateaued after 4-weeks of intervention.

Conclusions: Following an 8-week motor skill intervention, children with ASD demonstrated and maintained improved motor skill performance. Significant locomotor gains continued throughout the study with minimal plateau. Significant object-control gains continued through 4-weeks of intervention then plateaued thereafter. Dosage response suggests motor performance can be modified in as few as 2-weeks of treatment with continued improvement with treatment duration of 8-weeks for locomotor skills and 4-weeks for object-control skills Findings should inform policy makers to include motor programming as part of the early intervention services delivered to young children with ASD.

66   **123.066**   Effect of Comorbid Psychopathology on Response to Pivotal Response Treatment

D. Oosting[1], H. E. Friedman[2], C. M. Keifer[2], A. J. Schneider[3], C. A. Paisley[3], A. Jack[2], N. M. McDonald[4], K. Pelphrey[2] and P. Ventola[2], (1)Yale Child Study Center, New Haven, CT, (2)Child Study Center, Yale University, New Haven, CT, (3)Center for Translational Developmental Neuroscience, Yale University, New Haven, CT, (4)Child Study Center, Yale School of Medicine, New Haven, CT

Background: Extant literature on response to behavioral treatments for autism spectrum disorder (ASD) primarily highlights cognitive, social, and adaptive skill gains, with relatively little examination of what predicts these gains. Studies examining predictors of Pivotal Response Treatment (PRT) in particular are few and focus on specific behaviors (i.e., toy play or self-stimulatory behaviors).
Objectives: Our study is one of the first to examine the predictive effects of symptoms of psychopathology on treatment response in young children with ASD.
Methods: Participants were ten 4- to 7-year-old children (2 girls) who participated in a 16-week PRT intervention. Inclusion criteria were a previous ASD diagnosis and full-scale IQ > 70 (measured by the Differential Abilities Scales-2nd Edition). Autism Diagnostic Observation Schedule (ADOS) and Vineland Adaptive Behavior Scales-2nd Edition (VABS-II) assessments were conducted pre- and post-treatment to measure autism symptom severity and adaptive skills. Parents also reported autism symptom severity on the Social Responsiveness Scale (SRS) and comorbid symptoms of psychopathology on the Child Behavior Checklist 1.5-5 or 6-18 (CBCL). Response to treatment was assessed by the change in total ADOS and SRS raw scores and VABS-II Adaptive Behavior Composite standard scores. Linear regression analyses examined the predictive value of pre-treatment CBCL subscale scores on these change scores, controlling for cognitive abilities.
Results: Pre-treatment scores on the aggression (β = -.79, p = .01), oppositional defiant disorder (β = -.64, p = .05), attention (β = -.79, p = .01), and attention deficit hyperactivity disorder (β = -.80, p = .02) CBCL subscales significantly predicted change in total ADOS scores. Scores on the withdrawn, affective, anxiety, and anxious-depressed CBCL subscales were unrelated to ADOS total score change. CBCL subscale scores at pre-treatment were unrelated to SRS and VABS-II change scores.
Conclusions: Our results suggest that externalizing behaviors contribute to the magnitude of effect of PRT on social communication skills, with greater behavioral dysregulation at pre-treatment predicting more improvement in symptom severity as measured by the ADOS. Behaviorally dysregulated children may demonstrate a greater effect from PRT because, in addition to gaining social communication skills, they may also develop a greater capacity for behavioral regulation. Further understanding of the factors impacting treatment response may assist in identifying which treatments work best for which children, towards the goal of individualized treatment design and implementation.

67   **123.067**   Effectiveness of Using a Mobile App Parent Training Program to Increase Language in Children with Autism

G. C. Law, M. F. Neihart and A. S. Dutt, Psychological Studies Academic Group, National Institute of Education, Singapore, Singapore

Background: Communication intervention in early life can significantly impact long term outcomes for children with autism spectrum disorder (ASD) (Howlin et al., 2004). Evidence-based practices such as naturalistic approaches (e.g. Koegel et al., 1987; Ingersoll & Schreibman, 2006) are found to be promising in improving communication in children with autism. However, limited resources and high costs have hindered children from receiving prompt and timely intervention. Parents of children with ASD can be vital and important intervention resources and, training them to be therapists can help reduce costs for intervention. The current study aims to evaluate the use of a mobile application as a training medium to disseminate intervention skills of naturalistic language intervention to parents in an effective and efficient way.
Objectives: The primary purpose of this project is to examine the effectiveness of using a mobile application (1) to train parents to implement naturalistic language intervention (Laski, Charlop, & Schreibman, 1988) with their young child with autism; and (2) to increase their child's spontaneous communication and requesting language skills.
Methods: A mobile app was developed with the instructional design of *behavioral modeling training* (BMT) (Bandura, 1976; key components include modeling, retention, behavioral rehearsal, feedback, and transfer of training) to deliver a curriculum of *naturalistic language intervention*. A multiple baseline single case experimental design was conducted across 3 parent-child dyads (i.e., children with ASD aged 2 to 5 years) to evaluate the impact of using iPad to teach parents on naturalistic

language intervention. Video recordings on parent's intervention with the child were collected via a one-push button on iPad and the network. Behaviors of both parents (10 parent behaviors) and children (5 child behaviors) were measured in 5 phases: *baseline, parent training, post-training intervention, generalizations and 1 month follow up*. Interrater reliability on target parent behaviors and child behaviors were collected for at least 33% of total sessions and an average agreement of over 85% was achieved. Procedural integrity of parents' intervention techniques were above 80% on average during post training intervention. Parents' acceptability of the mobile app and program satisfaction ratings were administered with survey forms.

Results: The current results indicate that (a) parents achieved an increase in knowledge on the principles of naturalistic language intervention via the mobile application during the course of parent training, (b) parents showed an increase in the application of intervention techniques in naturalistic settings, and (c) their respective children showed an increase in spontaneous word use.

Conclusions: The results show that mobile applications are a promising means for improving efficiency and effectiveness in disseminating evidence-based practices for autism intervention. Mobile platforms will close the research-practice gap, multiply intervention resources in both developed and developing countries for individuals with autism, and provide prompt intervention without delays. Further research on generalizations of the current intervention is expected to be completed by 2014 to assess parent and child behavioral gains in different home and community contexts.

68   **123.068** Effects of School-Based Interactive Book Reading on the Vocabulary and Emergent Literacy of Preschoolers with ASD

R. Hudson, I. S. Schwartz and R. M. Greenway, College of Education, University of Washington, Seattle, WA

Background:
Little is known about effective methods for preparing children with ASD to be competent readers. It is well-established that readers need to develop proficiency in word reading and general language comprehension to read with comprehension (Oakhill, Cain, & Bryant, 2003). Without both of these aspects, comprehension is limited. How these elements develop in young children with ASD is not well-understood.

This proposal presents preliminary findings from year 1 of a four-year project to examine the emergent literacy of preschoolers with ASD and the effectiveness of two school-based interventions. The intervention in year 1 was Dialogic Reading (DR), hypothesized to increase expressive and receptive vocabulary. Children build their emergent literacy skills and knowledge through interactions with print and literate behaviors from a young age. One common experience during this time is shared book reading which provides experiences with oral language, narrative structure, and conventions of print (Anderson et al., 1985). One method of providing good interactive storybook reading is DR (Whitehurst et al., 1988).

Objectives:
One of the project aims is to determine the immediate effects of school-based interventions for preschool children with ASD. Our Yr. 1 research question is: For which outcomes do children who received DR intervention significantly outperform their non-tutored peers?

Methods:
42 children diagnosed with ASD were randomly assigned to DR treatment (n = 21) or BAU control group (n=21). The inclusion criteria were (a) either a medical diagnosis of autism or an educational identification, (b) an active IEP and receive services for ASD, (c) be enrolled in their last year of preschool, (d) no known co-occurring neurological or genetic disorders, and (e) a minimum standard score of 55 on the OWEPVT. Children were in 24 classrooms across 13 schools.
 Children in the treatment condition had 1:1 interactive book reading sessions using DR methods 3-4 times per week, for 15-20 weeks in the children's preschool classrooms. Measures are outlined in the table of results and were pre-tested in November and post-tested in May.

Results:
Three-level Hierarchical Models were conducted. There were no group differences on pretests. Significant teacher and school variance was detected; therefore 3-Level models were retained. Raw score gain scores were computed to test treatment impact. All children made significant gains on all measures regardless of condition. As well, a significant treatment effect on EOWPVT was found along with a trend for treatment effects on PPVT and WJ Oral Communication. No other significant or trend differences were found. See the table for all of the results and treatment fidelity information.

Conclusions:
Improvements were found for the treatment group on the measures hypothesized to be affected. This finding is important given the applied nature of the research. School-based research is critical to learn what types of intervention are effective with this population given the specific ecological context. Due to the small sample size, there may be a lack of power. Given that the project has additional treatment groups in years 2 and 3, this will be avoided with the full sample.

69   **123.069** Enhancing the Social Interactions of Preschool Children with Autism: The Effectiveness of a Peer-Mediated Intervention

M. K. McCalla[1], S. E. Edwards Leger[2], A. R. Lemelman[2], E. P. Trinh[2], C. O. Leonczyk[2] and S. Mrug[2], (1)Kennedy Krieger Institute, Baltimore, MD, (2)University of Alabama at Birmingham, Birmingham, AL

Background: Deficits in social interactions are a defining feature of autism spectrum disorders (ASD) and a powerful predictor of individual outcomes (e.g., Carter, Davis, Klin, & Volkmar, 2005). Although a wide variety of methods for improving social skills has been examined, it is still unclear which approaches are most effective with very young children. Some of the techniques that have empirical support include ABA, peer training, and video modeling. However, each strategy has its limitations, especially when used in isolation (e.g., Ferraioli & Harris, 2011; Reichow & Volkmar, 2010).
Objectives: This pilot study examined the efficacy of a new manualized social skills treatment package for preschool children with ASD that combines several techniques with demonstrated efficacy in order to enhance intervention effects.
Methods: The participants were 19 children with ASD who were enrolled in an early intervention preschool program that also served typically developing peers. Children with ASD were assigned to either the treatment group (n = 11, M = 4.9 years, SD = 0.7) or the waitlist control group (n = 8, M = 4.6 years, SD = 1.1). Ten typically developing peers participated in 8 training sessions that consisted of explanations of strategies, modeling, role play, and reinforcement. The intervention itself was delivered across 10 weeks in natural social environments, including recess and classroom playtime. Each participant in the treatment group received approximately fifteen intervention sessions targeting parallel play, social initiation, imitation, shared positive affect, and turn taking. In addition to verbal and visual prompts, some sessions also included video modeling of targeted social skills. Participants and peers received immediate social praise and small tangible rewards for their efforts throughout treatment. Data were collected at three time points: pre-intervention, post-intervention, and at a ten week follow-up assessment. Parents and teachers completed the Autism Spectrum Rating Scale (ASRS) which produced Social/Communication and Unusual Behavior composite scores. Clinicians, who were blind to group assignment, rated participant's social and play skills using subscales of the Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP). Group differences post-intervention and at the 10-week follow-up were examined using univariate ANCOVAs.
Results: After adjusting for pre-intervention scores, parents reported that children in the treatment group demonstrated significantly fewer deficits in Social/Communication skills post-intervention compared to those in the control group, $F(1,16)$ = 4.64, p < .05, Cohen's d = -1.06. At the 10-week follow-up there were no significant group differences in parent reported Social/Communication skills, $F(1,16)$ = 1.51, p > .05, Cohen's d = -0.62. Results of clinician ratings revealed that at the 10-week follow-up, children in the treatment group demonstrated significantly more appropriate play skills compared to the control group, $F(1,16)$ = 4.69, p < .05, Cohen's d = 0.82.
Conclusions: Integrating evidence-based intervention techniques (e.g., ABA, peer training, video modeling) in a natural social environment may improve the social and play skills of preschoolers with ASD. Further examination of this intervention, potentially using more sensitive outcome measures and a larger, more diverse sample, is warranted.

70 **123.070** Evaluation of the PEERS Play Intervention for Preschoolers with Autism Spectrum Disorder (ASD)

K. Toth[1], G. L. Boulware[2], R. Leon-Guerrero[2], A. Wolken[3] and S. J. Webb[3], (1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)PEERS Play, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

Background:
Children with ASD have documented impairments in social communication skills that are related to concurrent language and predictive of later language abilities, adaptive functioning, and academic performance (Toth, Munson, Meltzoff, and Dawson, 2006; McGovern and Sigman, 2005; Sigman and Ruskin, 1999). Even before impairments in social interaction and communication are evident, however, parents of infants who later receive an autism diagnosis often describe their children as having difficulty controlling their attention, affect, and behavior (Dawson, 2008). Difficulties with self regulation in children with ASD can persist into adulthood, impacting relationships, attention, problem solving, and communication (Bradley & Isaacs, 2006; White, Oswald, Ollendick, & Scahill, 2009). Most of the interventions targeting social skills in children with ASD have focused on short term treatments (e.g., 8-12 weeks) and children older than 5 years (Ozonoff & Miller, 1995; Taras, Matson, & Leary, 1998). To our knowledge, only one published study has examined a social skills intervention for preschool aged children with ASD delivered in a group vs. one-to-one setting (Dykstra et al., 2012). Further, self regulation skills have not been the primary focus in prior studies of social skills group interventions for young children with ASD.
Objectives:
To evaluate the effectiveness of the PEERS Play intervention, assess change in self regulation skills and social functioning, and manualize the PEERS Play curriculum.
Methods:
The PEERS Play intervention targets social and self regulation skills in preschool aged children with ASD. The curriculum is based on extensive experience with this population, age, principles of applied behavior analysis, and self regulation techniques drawn from The Alert Program. The intervention follows a weekly group format consisting of structured (e.g., circle time, art) and unstructured (e.g., free play, choice time with a peer) activities. Pilot data were collected on 6 children with ASD ages 3 and 4 years. Pre-treatment baseline assessment included standardized cognitive and adaptive measures; parent, teacher, and clinician ratings; and videotaped behavioral observations. The

intervention phase consisted of 6 months of videotaped, weekly, 60-minute social groups using the PEERS Play curriculum. Post-treatment assessment duplicated the pre-treatment battery.
Results:
Two analytic plans are underway: 1) A multiple time point, single case design analyzing weekly behavioral codes from videotape across multiple domains (social initiation, joint attention, play level, cooperative play and emotion regulation); and 2) pre- and post-treatment parent, teacher, and clinician ratings on a variety of measures. Results from analytic plan 2, using paired difference t-tests, indicated significant positive change on measures of parent rating of social skills (t=2.755, p=0.04), teacher rating of social skills (t=4.284, p=0.05), and parent ratings on the Temperament and Atypical Behavior Scale (TABS; t=2.86, p=0.035), a measure of atypical self-regulatory behavior intended for use with infants and young children. Additionally, on the BRIEF-P, most children showed positive change on most domains.
Conclusions:
The present findings indicate that the PEERS Play intervention can effect change in multiple domains including self regulation in preschool age children with autism. Future research will include an RCT design and a parent-mediated adjunct to this intervention.

71   **123.071** Family Implemented Teacch for Toddlers (FITT) Reduces Parent Stress and Improves Toddler Social-Communication Skills: Results from a Small, Randomized Controlled Trial

L. Turner-Brown[1], K. Hume[2], B. A. Boyd[3], K. Kainz[4], S. Jennings[4], S. Zheng[5] and C. C. Arnold[4], (1)Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)University of North Carolina at Chapel HIll, Chapel Hill, NC, (3)Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)School of Education, University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: FITT was designed using core TEACCH principles of Structured TEACCHing and evidence based practices for toddlers with ASD. One core principle of TEACCH is the inclusion of parents as co-therapists, but the effects of this component on parent well-being have not yet been studied. In addition, there is limited research examining the effects of structured teaching on toddler skills.
Objectives: The objectives of this study were to examine the effects of FITT on child and parent factors, including child social-communication and developmental skills and parent stress.
Methods: Forty-nine toddlers with ASD (ages 17 mos – 35 mo at baseline) enrolled in a 6-month RCT comparing FITT (n = 32) to community services as usual (SAU; n = 15). Approximately 50% of participants lived in rural communities. A majority of the sample (88%) demonstrated moderate to high autism symptoms on the ADOS and 72% scored below 70 on the Mullen ELC, with 28% scoring at the floor (Early Learning Composite = 49). There were no baseline differences between FITT and SAU for key demographic variables. FITT included 20 90-minute in-home parent coaching sessions and 4 parent group sessions over 6 months. Child outcome measures included the Mullen Scales of Early Learning and Parent Interview for Autism-Clinical Version. Parent stress was measured using the Parental Stress Index-Short Form.
Results: Attrition was greater in the SAU group than the FITT group. The final sample included 42 participants (FITT n =30; SAU n = 12). To produce an ITT estimate of treatment effects for child and parent outcomes, we used ANCOVA models where the outcome at Time 2 was modeled as a function of the Time 1 pre-test, treatment status, gender, and age at Time 1. Treatment status, pre-tests, age, and gender were centered at zero before analysis so that the intercept of each model reflects the sample average performance on the modeled outcome at Time 2. Children in the FITT group had higher PIA Total scores at Time 2 than children in the SAU group (B =.26, p < .05). Parents in the FITT group had lower Total Stress scores at Time 2 than parents in the SAU group (B = -13.20, p = .05). While parent stress increased over time in the SAU group, it decreased over time for the FITT group (see Figure 1). There were no statistically significant treatment effects on Mullen Early Learning Composite.
Conclusions: Results supported the use of FITT for toddlers with ASD and their parents, with treatment effects found for social communication skills and parent stress. Treatment effects were not detected for developmental skills as measured by the Mullen ELC. The severity of the ASD symptoms and developmental delays in a majority of the sample may have contributed to these findings. The low intensity of the parent coaching intervention may have also played a role. The significant decrease in parent stress for these families new to a diagnosis of ASD was encouraging given that stress increased for SAU parents during this time.

72   **123.072** Gesture in Toddlers with Autism Spectrum Disorder: Before and after Intervention

E. S. LeBarton[1,2] and R. J. Landa[3], (1)Johns Hopkins School of Medicine, Baltimore, MD, (2)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD

Background: Young children with autism spectrum disorders (ASD) exhibit impaired gesture development (APA, 2013; Landa, 2007). Gesture is an essential component of social interaction. Also, gesture can be used to compensate for spoken language limitations (e.g., typically-developing toddlers, and children with language delay; Capone & McGregor, 2004) and can index and facilitate learning (Goldin-Meadow, 2009). For these reasons, gesture is an important aspect of communication

to target in early interventions for ASD.

Objectives: We investigated gesture production in toddlers who participated in a previously reported intervention for ASD (Landa et al., 2011). We predicted that across the entire sample gesture production would increase from pre-test to post-test. However, gains in mature gesture use, including pointing gestures, would only be observed for the treatment group.

Methods: Toddlers (mean age=31.06 months, SD=6.08) with ASD participated in a six-month randomized-controlled-trial targeting social and communication skills. In both groups, caregivers were coached in the implementation of evidence-based child-responsive strategies. In only one condition, however, this intervention was supplemented with nursery school classroom-based instruction (class) treatment condition where they received an interpersonal synchrony curriculum and instruction fostered peer-to-peer engagement. Here, we report on nine children in each condition. There were no significant differences between groups for age (p=.69), general developmental level on the Mullen Scales of Early Learning (MSEL) (p=.79), MSEL Expressive Language (p=.730), nor on any of our outcome measures (p's>.63) at baseline. The Autism Diagnostic Observation Schedule (ADOS, Lord et al., 2000) was administered to all children before and after the intervention. Coders blind to condition coded communicative gesture production during the sections of the ADOS that are included in the modules used here (T, 1, 2) (e.g., free-play). We derived three measures of gesture based on developmental maturity and importance in ASD (Iverson, et al., 1994; Kita, 2003, Wetherby et al., 2004). Measures included: (1) number of developmentally mature gestures produced (e.g., pointing gestures, waving goodbye, holding an object up to show to someone); (2) number of developmentally immature gestures produced (e.g., extending an object for someone to take); and (3) number of pointing gestures. Measures (1) and (2) are mutually-exclusive. Due to small sample size, we used non-parametric tests when possible, although results are unchanged when using parametric alternatives.

Results: We found significant increases in mature gestures (p=.016) and pointing gestures (p=.049), but not immature gestures (p=.399) from pre- to post-test in both groups (Figure 1). However, consistent with our predictions, effects varied with condition. Two-factor repeated-measure ANOVAs revealed a significant interaction between session (pre-test, post-test) and condition for mature gestures (F=5.36, p=.038) and pointing gestures (F=4.77, p=.048), but not immature gestures. At post-test, children in the treatment group produced more mature gestures and more pointing gestures than the control group (p=.024 and p=.019, respectively). In contrast, the control group produced relatively more immature gestures (p=.050) (Figure 2).

Conclusions: Intervention is associated with increased frequency and maturity of communicative gesture in toddlers with ASD. These effects may have cascading consequences for positively impacting and enriching social interactions for children with ASD.

73   **123.073** Impact of Parent Training on Parental Competence and Parental Stress
L. Lecavalier, Psychology, The Ohio State University, Columbus, OH

Background: We propose that serious behavioral problems in children with ASD erode parental confidence and increases parental stress. Thus, reducing disruptive behavior through PT should restore parental competence and decrease parental stress.

Objectives: This presentation reports on the measures of self-perceived parental competence and parental stress before and after six months of PT compared to six months of PEP.

Methods: The 17-item Parental Sense of Competence (PSC) asks parents to report on self-efficacy in the parenting role. Parental stress was measured by the 36-item Parent Stress Index (PSI) and the 21-item Caregiver Strain Questionnaire (CSQ). These measures were collected at baseline and endpoint (6 months).

Results: At baseline, mean PSI and CSQ total scores were elevated in the study sample as a whole (PSI = 104.5; CGS = 32.0). PSC total score was low (62.4 of possible 102). These results suggest that parenting a child with ASD and disruptive behavior is a major challenge. Compared to PEP, PT significantly reduced scores on the CSQ and increased scores on PSC (effect sizes 0.50; p < 0.5 for both). PSI scores improved in both PT and PEP groups (effect size 0.27 in favor of PT; p not significant). Within the PT-treated group, we had complete data on the CGI-I and parent measures for 80 of 89 subjects. Children rated as *much improved* or *very much improved* (n=61) on the CGI-I had significant reductions in parental stress on the PSI and CSQ when compared to children rated as non-responders (n=19) (effect sizes 0.63; p values 0.004 and 0.02, respectively). Parents of positive responders showed an increase on the PSC compared to non-responders (effect size 0.4; p value 0.06). Results of exploratory analyses on the correlations of the PSC and parental stress measures at baseline and endpoint will also be presented.

Conclusions: These results suggest that PT reduces parental stress and enhances self-perceived parental competence.

74   **123.074** Implementation and Impact of Focused Early Intervention Services
A. Stainbrook[1], C. G. Herrington[2], N. Broderick[3], Z. Warren[4] and A. P. Juárez[5], (1)Kennedy Center and Department of Pediatrics, Vanderbilt University, Nashville, TN, (2)Vanderbilt Kennedy Center, Vanderbilt University, Nashville, TN, (3)Kennedy Center, Vanderbilt University, Nashville, TN, (4)Vanderbilt University, Nashville, TN, (5)Pediatrics & Psychiatry, Vanderbilt Kennedy Center, Nashville, TN

Background:
Quality early intervention programs emphasize the role of the caregiver in supporting the child at home. However, support and education programs are often difficult to access. In an effort to better equip caregivers with the knowledge base and tools necessary to adequately address the needs of children with Autism Spectrum Disorder (ASD), a university-based institute on ASD and state department of education have collaborated to develop and implement two model early intervention programs for families of young children with ASD and related developmental delays.
Objectives:
This program evaluation study investigates the feasibility of implementing two different parent education-focused service models with fidelity. In addition, this study assessed parent satisfaction with each service as well as the impact of services on child functioning as perceived by both caregivers and clinicians.
Methods:
Approximately 60 families will be provided with services following participation in a psychological evaluation for ASD. All participating families receive 2 home-based evaluation support sessions which include an opportunity to discuss the evaluation report as well as focused consultation and training on evidence-based practices for children with ASD. Approximately half of these families will participate in a parent education series that includes 12 additional sessions guided by the Early Start Denver Model (ESDM). Professionals in the fields of early intervention and applied behavior analysis conduct all visits within both models of service. Procedural fidelity data, satisfaction ratings, and Clinician Global Impression ratings are collected on both services in an effort to evaluate program effectiveness.
Results:
Preliminary data on families that have completed each service at this time (N = 34; N = 8) suggest that clinicians were able to apply the training model with over 95% fidelity across families with varying needs. Additional data collected on the application of the ESDM curriculum suggest that clinicians were able to cover over 90% of the ESDM curriculum across the 12 visit model and that parents were able to demonstrate over 70% of those strategies covered within sessions. Preliminary data using a Clinician Global Impressions rating of improvement suggest that both clinicians and caregivers observed improvement following completion of the brief evaluation support service with average ratings of 3.2 and 2.4 respectively on a scale of 1 to 7 with 1 equaling "very much improved" and 4 equaling "no change". Caregivers and clinicians also observed improvement following completion of the extended parent education service with ratings of 2.1 and 2.4 respectively. In addition, caregivers assigned high ratings to their overall satisfaction with services as well as their own competence in implementing the strategies with overall ratings averaging 3.8 on a scale of 1 to 4.
Conclusions:
The preliminary results of this study suggest that early intervention programs emphasizing caregiver support and education can be implemented with high levels of fidelity. Additionally, the results suggest that even brief intervention services focused on providing caregivers with immediate support and education may result in improvements in child functioning and caregiver confidence in supporting their child.

75   **123.075** Improved Parent Interaction Style Associated with Improved Child-Parent Joint Engagement 3-Months after a Low-Cost, Group, Parent-Training Workshop

K. Houghton[1], A. Rattazzi[2], S. H. Cukier[2], P. Landolfi[2] and C. Lewis[3], (1)Lancaster University, Chatham, NY, (2)PANAACEA, Buenos Aires, Argentina, (3)Psychology, Lancaster University, Lancaster, United Kingdom

Background:
Parent-implemented interventions for young children with ASD have been found to be associated with improvements in child social engagement (e.g. Casenhiser and Shanker. 2011; Kasari et al.2010; Patterson, Elder, Gulsrud and Kasari, 2013) language (Coolican et al. 2010; Vismara et al. 2009), imitation (Ingersoll and Gergans, 2007), and play (Gillett and LeBlanc 2007). In countries with relatively few trained autism professionals, such as Argentina, parent-implemented interventions may be the only services available for young children with ASD. However, traditional parent training models emphasizing individual coaching sessions are not scalable in countries such as Argentina and very little research has focused on group parent training which has the potential to make training more accessible to families (Minjarez, Williams, Mercier and Hardan, 2011; Ingersoll and Dvortcsak, 2007). This study is a 3-month follow-up to a parent-training program delivered in Buenos Aires, Argentina.
Objectives:
To investigate the relationship between change in parental interaction style following a weekend, group parent-training workshop and changes in parent-child joint engagement 3 months post-training.
Methods:
The parent-training program was originally developed for a multi-cultural, low-income, group in the Bronx, NY (Houghton, 2012) then delivered to 24 families in Buenos Aires, Argentina (Hougthon et al, 2013). It teaches parents research-based techniques for encouraging joint engagement embedded in everyday activities at home. 22 families participated in the training program. Video of parent-child free play sessions were taking pre-training, post-training and 3-months post-training. Parent

interaction style was coded along the dimensions of Responsivity and Directiveness (Mahoney and Perales, 2003) and parent-child joint engagement coded following Baekman and Adamson (1984) and Kasari et al. (2010).

Results:

Results show a relationship between parent interaction style post-training and at 3-month follow up and between parent interaction style and parent-child joint engagement at 3-months.

Conclusions:

A brief, low-cost group parent-training program was shown to improve parent interaction style which was then associated with improved parent-child joint engagement at 3-month follow-up without further training.

---

76 **123.076** Joint Attention during an ABA Intervention Session Can Predict Progress of Preschoolers with Autism Spectrum Disorder

S. Van der Paelt, P. Warreyn and H. Roeyers, *Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: Although the positive effect of ABA has repeatedly been demonstrated, it remains unclear how variations in techniques affect the results. Moreover it is poorly understood why a substantial subgroup of children with ASD does not improve with ABA. Possibly features of the interaction between therapist and child during intervention account for part of the variability in outcome.

Objectives: This study performed a descriptive analysis of the variability in the joint attention interaction sequences between therapists and children. Second, the study focused on the extent to which these observational data predicted the progress which children made during 6 months of intervention.

Methods: 16 children with ASD participated. They were between 30 and 75 months old. The children received an ABA intervention. They were followed-up during a period of 6 months and their joint attention and language skills were tested both before and after this period. After three months we videotaped one intervention session of each child. Both the imperative and declarative joint attention behaviours of the children, as well as their antecedents (prompts) and consequences (rewards) provided by the therapist were coded. We calculated the frequency of imperative and declarative joint attention bids that were either prompted or spontaneous and rewarded or unrewarded.

Results: Children who showed more spontaneous imperative than declarative joint attention were 1.93 times more rewarded for imperative than declarative joint attention, while children who mainly showed spontaneous declarative joint attention were 1.62 times more rewarded for declarative compared to imperative joint attention The majority of the children showed more or less the same amount of prompted and spontaneous imperative joint attention.

We conducted four backward stepwise regression analyses with the joint attention interaction sequences as predictors and progress in imperative joint attention, declarative joint attention, receptive and expressive language as dependent variables. The first regression analysis showed that the progress in imperative joint attention could be predicted by the number of rewarded declarative joint attention bids, $\beta = .59$, $t(15) = 2.36$, $p = .04$. over and above the number of imperative joint attention bids and the number of unrewarded declarative joint attention bids. Progress in declarative joint attention on the other hand, was negatively related to the number of prompted unrewarded imperative joint attention bids, $\beta = -.55$, $t(15) = -2.43$, $p = .03$, which was the only significant predictor. Progress in receptive language was predicted by a model with spontaneous unrewarded declarative joint attention, $\beta = .54$, $t(15) = 2.84$, $p = .01$ and prompted rewarded imperative joint attention, $\beta = .48$, $t(15) = 2.52$, $p = .03$. Progress in expressive language could only be predicted by the number of spontaneous declarative joint attention bids, $\beta = .73$, $t(15) = 3.99$, $p = .001$.

Conclusions: Joint attention behaviours that are rewarded seem to occur more frequently, even within one session. Moreover the interaction between therapist and child within this session after three months of intervention can predict the amount of progress children make in a period of 6 months on joint attention and language.

---

77 **123.077** Lasting Effects of a 12-Week Group Parent Education Model for Pivotal Response Treatment

E. Salzman[1], S. Schapp[1], E. Solomon[2], K. L. Berquist[3], M. B. Minjarez[4], T. W. Frazier[5], J. M. Phillips[6], G. W. Gengoux[6] and A. Y. Hardan[6], (1)PGSP-Stanford Psy.D. Consortium, Palo Alto, CA, (2)PGSP-Stanford Psy.D. Consortium, Mountain View, CA, (3)Stanford University, Stanford, CA, (4)Psychiatry and Behavioral Sciences, Seattle Children's Hospital, Seattle, WA, (5)Cleveland Clinic, Center for Autism, Cleveland Clinic Children's, Cleveland, OH, (6)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA

Background: Preliminary studies of Pivotal Response Treatment (PRT) have shown that parents can successfully learn and implement PRT with high fidelity, indicating that parent-delivered treatment could be an efficacious treatment modality. While a recent randomized controlled trial of a 12-week parent education group treatment showed an increase in children's functional utterances and adaptive communication skills (Hardan et al., 2014), the lasting effects of a short-term parent-delivered PRT group intervention have not yet been sufficiently researched.

Objectives: The objective of this study was to assess maintenance of treatment effects, following a 12-week PRT parent education intervention at the follow-up assessment at 24-week. The primary goal was to measure improvement in children's language development between baseline, week 12 (treatment end), and week 24 (follow-up assessment), as well as changes in developmental functioning over this 6-month period.

Methods: Families who were randomized to the active treatment group and participated in the full 12-week PRT parent education group training (n=23; mean age=3.9 years, SD= 1.04) were followed over the course of 6 months with parent questionnaires and structured laboratory observations. At follow-up, participants were re-assessed for changes in communication, cognitive, adaptive, and social skills.

Results: Preliminary results from baseline, week 12 and week 24 measures suggest that a 12-week group-delivered parent education treatment model has enduring effects on language. Mean total number of child functional utterances during a 10-minute structured laboratory observation suggests a significant improvement from pre to post-treatment, with maintenance at 24 week follow-up (Baseline: 45.7 ± 23.1; Week 12: 64.5 ± 28.9; Week 24: 55.1 ± 23.2; F: 5.9, p=.009). Children also made significant gains on the Vineland Communication Domain Standard Score that continued to improve over time (Baseline: 69.9 ± 16.3; Week 12: 78.9 ± 18.9; Week 24: 83.1 ± 17.8; F:11.74, p=.001). In order to assess the effects of parent-implemented PRT on early developmental/cognitive skills, standard scores from week 24 on the Mullen Scales of Early Learning (MSEL) were compared with baseline levels. The MSEL early learning composite score was calculated and showed significant improvements beyond expected developmental gains (F= 5.43, p=.03).

Conclusions: Children randomized to PRT showed evidence that treatment gains were maintained 12 weeks after the active treatment ended. Overall improvements were noted on child communication measures, at post-treatment, as well as 12 weeks after that (24-week follow-up), indicating maintenance of treatment effects. Interestingly, gains in total number of child utterances appeared to decline after active treatment. Nevertheless, at 6 months, the children were still using significantly more functional utterances than at baseline. The preliminary results of this study suggest that a brief PRT parent group intervention can facilitate improvements in language skills and cognitive functioning that are maintained 12 weeks post treatment. These findings will be discussed in terms of the need for effective and efficient treatments that can be easily disseminated. Future research should continue to address questions about the maintenance of developmental gains from short-term parent education interventions.

78   **123.078** Long-Term Outcomes of Early Intervention in 6-Year-Old Children with Autism

A. M. Estes[1], S. J. Rogers[2], J. Greenson[1], J. Munson[3], J. Winter[4] and G. Dawson[5], (1)Speech and Hearing Sciences, University of Washington, Seattle, WA, (2)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)University of Washington, Seattle, WA, (4)Psychiatry, Weill Cornell Medical College, White Plains, NY, (5)Psychiatry and Behavioral Sciences, Duke University, Durham, NC

Background: There is a lack of long-term outcomes studies for comprehensive autism interventions conducted with very young children. The only long-term outcome study of comprehensive autism intervention of which we are aware was published over 20 years ago (McEachin et al., 1993) and this seminal study was conducted with older children. The Early Start Denver Model (ESDM) intervention, conducted for 2 years at 15 hours per week, begun when children were 18-30 months of age, showed evidence of efficacy immediately post-treatment in a randomized controlled trial (Dawson et al., 2010, 2012). The ESDM group significantly surpassed the community-intervention comparison group in IQ gain, adaptive behavior, and diagnostic changes. Furthermore, an EEG study revealed normalized patterns in the ESDM group involving stronger responses to social than nonsocial stimuli, a pattern opposite that of the comparison group.

Objectives: We prospectively examine evidence for the sustained effects of early autism intervention, begun at 18-30 months of age, when children are 6 years of age. We also examine patterns of group differences in the ESDM group as compared with the Community-intervention group at 6 years of age.

Methods: Forty-five children completed the original outcome study. Thirty-nine children were available for follow-up at 6 years of age (3 lost per group). During the two-year follow-up period the study no longer provided intervention to either group, so parents selected varying types and intensities of community-based interventions. Measures of IQ (Mullen, DAS), adaptive behavior (Vineland), autism symptoms (ADOS), and challenging behaviors (ABC) were gathered immediately post-intervention (age 4) and after the 2-year follow-up period (age 6). Peer relations were assessed at age 6 (ADI-R, selected items.)

Results: The ESDM group, on average, maintained or increased improvements during the follow-up period in intellectual ability, adaptive behavior, symptom severity, and challenging behavior. At follow-up the ESDM group demonstrated improved core autism symptoms compared with the Community group. In contrast, no significant differences in core autism symptoms as assessed by the ADOS were found immediately post-treatment (see Dawson et al., 2010.) In addition, the ESDM group had improved adaptive behavior and peer relations compared with the Community group at follow-up. The two groups did not differ in terms of intellectual functioning at age 6 follow-up.

Conclusions: These results indicate sustained and, in some domains, enhanced long-term effects of early ASD intervention. This is the first study to examine the role of early ESDM behavioral intervention initiated below 30 months of age in altering the longer term developmental course of autism.

79 **123.079** Parent-Mediated Intervention for Hispanic Families of Young Children with Autism

J. Kinard[1] *and L. R. Watson*[2], *(1)The University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Division of Speech and Hearing Sciences, University of North Carolina, Chapel Hill, NC*

Background: The US Hispanic population has grown rapidly over the past decade (Humes, Jones, & Ramirez, 2012) and has experienced one of the largest increases in ASD prevalence when compared to other populations (MMWR, 2014). A support system needs to be in place for this population, one that includes accessible, high-quality intervention. Unfortunately, US Hispanic families have poor access to ASD services (Harstad, Huntington, Bacic, & Barbaresi, 2013), diminished treatment quality (Magaña, Parish, Rose, Timberlake, & Swaine, 2012), and poorer outcomes when compared to White, non-Hispanic families (Fountain, Winter, & Bearman, 2012). Based on their negative experiences, Hispanic families report losing trust in the healthcare system (Zuckerman et al., 2014). These findings emphasize the importance of establishing supportive early interventions for Hispanic families of children with ASD. To date, however, no studies have examined early parent-mediated interventions for Hispanic families of children with ASD. To address this need, this study investigated a parent-mediated intervention called "Adapted Responsive Teaching" (ART; Wakeford et al., under revision) in primarily Spanish-speaking families.

Objectives: The purpose of the study was twofold: (1) to examine how ART impacts the social-communication skills of children with ASD from Hispanic families; and (2) to explore the acceptability & feasibility of ART among these families.

Methods: This study used a multiple baseline across participants and behaviors design. Three Hispanic children diagnosed with ASD participated in an initial assessment (age range in years;months was 2;9 – 4;4). Baseline data were collected on selected social-communication behaviors for each child. During the ART intervention, parents were taught responsiveness strategies, which were intended to improve the social-communication skills of their children. Measures of parent responsiveness and parent fidelity of implementation were also taken. At the conclusion of the intervention, caregivers participated in qualitative interviews about their perspectives of the ART intervention.

Results: Treatment effects were demonstrated in four out of seven opportunities, providing moderate evidence for the ART intervention's effectiveness at improving social-communication skills in Hispanic children with ASD. Two out of three children demonstrated improvements in social-interaction and requesting. For the two children who showed treatment effects, their parents also showed high levels of parent responsiveness and fidelity to intervention; the third parent demonstrated inconsistent responsiveness and fidelity to intervention. According to the interviews, parents perceived that the ART intervention was feasible and acceptable for their families overall, and felt that it would also be applicable to other Hispanic families of children with ASD. Families reported that they would continue implementing ART strategies after the program ended, but also provided suggestions for modifications.

Conclusions: ART appears to be a promising intervention option for US Hispanic, primarily-Spanish speaking families, particularly for families and children who share similar characteristics as the participants in this study. Explanations for the differences in parent and child outcomes are explored, providing guidance to professionals and families who are making decisions about early interventions, as well as to early intervention researchers conducting future studies with this population.

80 **123.080** Pilot Randomized Controlled Trial of the Effects of Reciprocal Imitation Training on Children with Autism

S. Malik[1], *C. Oliver*[1], *J. Moss*[1], *B. Ingersoll*[2], *C. Stefanidou*[1] *and J. McCleery*[3], *(1)School of Psychology, University of Birmingham, Birmingham, United Kingdom, (2)Psychology, Michigan State University, East Lansing, MI, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Children with autism exhibit pervasive social and communication difficulties, including particular deficits and delays in social imitation skills. Reciprocal Imitation Training (RIT) is a play-based behavioural intervention focused on increasing imitation skills and gesture use in individuals with autism. Previous research has demonstrated RIT to be effective for increasing spontaneous object and gesture-based imitation. However, a limitation in existing literature includes independent replication of effectiveness of intervention outside the parent lab.

Objectives: The current study is an attempted replication of the previous behavioural effects, as well as an examination of electroencephalographic (EEG) measures of brain activity as potential biomarkers for intervention effects.

Methods: Participants to date in this on-going Randomized Controlled Trial are 17 children with autism aged 2- to 6-years. Participants in the intervention group receive 20 sessions of RIT over a period of 12 weeks, relative to a Wait-List control group. Stratified randomization is conducted utilizing pre-defined chronological age and verbal ability criteria at intake. Pre- and post-intervention assessments include the verbal portion of the Mullen Scales of Early Learning, Autism Diagnostic Observation Schedule, and two experimental-behavioural change measures: Unstructured Imitation Assessment (UIA) and Structured Imitation Assessment (SIA), administered by experimenters who are blinded to intervention status. EEG assessments of auditory and visual human versus non-human action processing are also recorded at pre- and post-training.

Results: To date, we have analyzed data from the Unstructured Imitation Assessment. The effect of

the intervention was evaluated using repeated-measures ANOVA including Condition (Immediate Intervention, Wait-List) as a between-subjects factor and Time (Pre, Post) as a within-subjects factor. A significant Condition by Time interaction showed that children in the Immediate Intervention group (N = 9; pre-intervention M = 5.4, S.E. = 2.1; post-intervention M = 13.6, S.E. = 3.6) made significantly more gains in spontaneous imitation compared with children in the Wait-List group (N = 8; pre-intervention M = 7.9, S.E. = 3.1; post wait-list M = 6.8, S.E. = 3.8), F (1,15) = 8.47, p = .01, η_p^2 = .36. Follow-up t-tests on the intervention group data also supported this finding, where a significant difference between pre-intervention scores and post-intervention imitation was observed, t (9) = 3.73, p <.01. Preliminary results from an event-related potentials assessment of human versus non-human action sound processing will also be presented.

Conclusions: The current results suggest that children who received RIT showed significant improvements in spontaneous imitation during play with an unfamiliar adult, compared with children who were in a wait-list control group. Because reciprocal imitation of the actions of others in unstructured contexts is considered to be a core deficit that impacts negatively upon socialization and learning in this population, the results of this study are very encouraging. Although this study is on-going and the results preliminary at this point, these findings provide further support for RIT as an effective intervention for teaching critical social imitation skills to this population. Preliminary results from the ERP assessments of this study will provide an initial assessment of potential biomarkers for the observed intervention effects.

81 **123.081** Pivotal Response Treatment Alters Brain Function in Children with Autism
ABSTRACT WITHDRAWN

Background:
Autism Spectrum Disorder (ASD) is characterized by severe deficits in social information processing (Levy, Mandell, & Schultz, 2009), which are most visible in natural social settings (Volkmar et al., 2004). Pivotal response treatment (PRT) is a naturalistic behavioral intervention that promotes social communication development in children with ASD. Although PRT is an empirically validated treatment, the neural and behavioral mechanisms by which PRT is efficient are lacking.
Objectives:
We aim at identifying neural and behavioral mechanisms of PRT related improvements in the social functioning of children with ASD using well-validated eye-tracking and fMRI paradigms.
Methods:
We are randomly assigned 4- to 6-year-old children with ASD (N=20) to either a waitlist control group (WTC, n=10) or the PRT group (n=10). Additionally, we include typically developing children (TD, n=20, matched for age, sex and IQ) as a point of reference for the interpretation of changes in brain function and visual scan paths. All children are assessed twice, at time 1 (T1) and time 2 (T2) separated by a four-month interval, during which the PRT group receives treatment.
Results:
Preliminary eye-tracking data from 8 children with ASD (6 males) pre and post PRT indicates that at T2, the proportion of fixations on the mouth region significantly increases, relative to T1. FMRI analysis including 10 children with ASD (9 male) at T1 yields activity of the right fusiform gyrus, and the bilateral lateral occipital cortex for faces vs. houses. Analysis of treatment effects (T2 > T1) reveals significant increases in activity in the medial prefrontal cortex (MPFC) for social stimuli (faces vs. houses) in PRT (n=5) vs. WTC (n=5) group.
Conclusions:
Preliminary analyses of PRT-related effects indicate that the treatment modulates behavior and brain function. In particular, the MPFC has been closely linked to consciously engaging in social cognition (e.g., taking another's perspective into account (Amodio & Frith, 2006)). Increased activity in the MPFC after treatment might underlie the positive effects of PRT on social behavior.

82 **123.082** Pivotal Response Treatment Improves Neural Efficiency for Social Perception in Children with Autism Spectrum Disorder

M. Rolison[1], J. H. Foss-Feig[2], R. Tillman[3], H. S. Reuman[2], A. Naples[2], K. Pelphrey[2], P. Ventola[2] and J. C. McPartland[2], (1)Yale University, New Haven, CT, (2)Child Study Center, Yale University, New Haven, CT, (3)University of Maryland, College Park, MD

Background:
Individuals with autism spectrum disorder (ASD) demonstrate reduced social motivation, resulting in diminished attention to people and consequent dysfunction in the specialization of neural mechanisms associated with social behavior. This dysfunction has been reliably associated with a deficit in the neural response to face stimuli, indexed both functional neuroimaging and electrophysiological techniques. Pivotal Response Treatment (PRT) is an empirically validated behavioral treatment for ASD that focuses on improving key social and communication abilities by enhancing social motivation. Prior research from our group demonstrated that a 16-week PRT intervention results in meaningful improvements in pragmatic language, social engagement, and adaptive functioning (Ventola et al., 2014), with accompanying changes in regional brain activation (Voos et al., 2012). Effects of treatment on neural efficiency have not yet been studied. The current study utilizes electroencephalography (EEG), an imaging method with excellent temporal resolution,

to examine the temporal dynamics of brain responses associated with positive response to intervention.

Objectives:

To identify temporal changes in neural mechanisms associated with social perception following PRT treatment.

Methods:

Seven children with ASD between ages 4 and 6 years received PRT for 8 hours per week (child: 6 hours; parent: 2 hours) for 16 consecutive weeks. Participants completed an EEG session, recorded with a 128-channel Hydrocel Geodesic sensor net, both pre- and post-treatment. A waitlist control sample completed an EEG session 16 weeks prior to starting treatment to differentiate effects of treatment from those resulting from developmental changes over a four-month period. During the EEG sessions, participants viewed 73 distinct, computer-generated faces displaying neutral and fearful expressions. Data were segmented to onset of face stimuli and event-related potentials (ERPs) were extracted over the right occipitotemporal region. Changes in the amplitude and latency of early feature detection and face-sensitive ERP components (P100 and N170, respectively) were examined.

Results:

Results revealed a main effect of treatment [$F(1,6) = 11.34$, $p = .015$], indicating a change in the efficiency of face processing, indexed by N170 latency. Post-hoc paired samples t-tests revealed that the reduction in N170 latency was significant for both neutral ($p = .027$) and fearful ($p = .029$) face stimuli from pre-treatment to post-treatment assessments. There were no significant changes in N170 amplitude or in either P100 latency or amplitude ($p > .05$). There was no significant change in N170 latency across the 4-month period prior to treatment when participants were enrolled as waitlist controls [$F(1,2) = 2.45$, $p = .26$].

Conclusions:

A 4-month course of PRT for young children with ASD was associated with improved efficiency of neural indicators of social behavior. Effects of treatment were reflected in brain responses associated with social perception (N170), rather than low-level sensory processes (P100), suggesting focal treatment effects on social processing mechanisms. Preliminary data also revealed that a 4-month period of development without intervention does not result in similar changes in neural efficiency, indicating specific effects of treatment. These findings provide the first evidence of increased processing efficiency for social information resulting from PRT.

83   **123.083** Predicting Growth of Communication Skills of Preschoolers with Autism Spectrum Disorder during Treatment in a Community-Based Pivotal Response Treatment Program

*K. L. Fossum[1], L. Williams[2] and **I. M. Smith**[3], (1)Psychological Services, IWK Health Centre, Halifax, NS, Canada, (2)Psychology & Neuroscience, Dalhousie University, Halifax, NS, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, NS, Canada*

Background: Understanding the variable responses of children with ASD to current early intervention (EI) programs is a research priority (Vivanti et al., 2014). Attempts to understand this variability have examined global factors (e.g., IQ and age) and their relations to particular outcomes (e.g., IQ changes; Howlin et al., 2009). Increasingly, researchers are attempting to move beyond these immutable factors to examine empirically and theoretically informed predictors (baseline child characteristics). Such research aims to elucidate mechanisms of change, and ultimately to match interventions to individual profiles. A set of variables that together predicted response to Pivotal Response Treatment (PRT; Koegel & Koegel, 2006), in single-case design research (Scherer & Schreibman, 2005; Schreibman et al., 2009) were baseline levels of appropriate toy contact (ATC), social approach, social avoidance, stereotyped and repetitive vocalizations (SRV) and non-verbal behaviours. These variable have not yet been examined as group-level predictors of outcome among children with ASD. An additional variable, baseline positive child affect, is also of interest, given its role in early communication (Kasari et al., 1990) and negative association with emerging ASD (Garon et al., 2009).

Objectives: To determine whether variables identified by Scherer & Schreibman (2005), and child affect, predicted expressive language (EL) outcomes in an unselected sample of preschoolers with ASD in a PRT program.

Methods: Preschoolers with ASD (n=57) participated; mean baseline chronological age (CA) of 48.81 mo (SD = 8.97), mean baseline ratio IQ scores of 53.38 (SD = 20.35), and mean baseline severity of ASD symptoms (SRS T score) of 77.40 (SD = 9.99). Children were enrolled in a one-year community-based EI program (Bryson et al., 2007). The dependent variable, EL, was assessed by research examiners at baseline and after 12 months of EI, using the Preschool Language Scales, 4th ed. (Zimmerman, Steiner & Pond, 2002). Independent variables (i.e., ATC, Avoidance, SRV and affect) were coded blindly from baseline videos of children interacting with a therapist or a research examiner.

Relations between putative predictors and EL outcomes were examined using hierarchical linear regression. Baseline EL was entered as a predictor with IQ and chronological age. Based on the patterns of bivariate correlations, ATC, Avoidance, SRV and Affect were entered in a second step.

Results: The first step accounted for 84% ($p = .000$) of variability in 12-month EL outcomes. Higher baseline EL and IQ scores significantly predicted greater 12-month EL. Step two accounted for an additional 4% ($p = .005$) of outcome variability. Baseline EL remained a significant predictor. More

positive baseline child affect predicted greater 12-month EL outcomes; lower baseline ATC (p = .061) and avoidance (p = .056) were strong trends.
Conclusions: Positive affect emerged as a predictor of EL outcome in a PRT-based program for preschoolers with ASD, contributing variance in addition to that accounted for by previously established predictors such as baseline language and IQ. The predictor profile described by Sherer & Schreibman (2005) was not observed in this sample.

84 **123.084** Predictors of Successful Parent Training in Pivotal Response Treatment during the Jumpstart Program: Parent Mental Health and Self-Efficacy

N. L. Matthews[1], B. Conti[2], B. Harris[1] and C. J. Smith[3], (1)Southwest Autism Research and Resource Center, Phoenix, AZ, (2)Clinical Programs, Southwest Autism Research & Resource Center, Phoenix, AZ, (3)Research, Southwest Autism Research & Resource Center, Phoenix, AZ

Background: Many behavioral treatment models for autism spectrum disorder (ASD) include a parent training component. Theoretically, this allows the caregiver to implement intervention consistently and in multiple environments without the presence of a professional behavioral interventionist (Steiner et al., 2012). Many parents are able to successfully implement pivotal response treatment (PRT), a naturalistic therapy based on the principles of applied behavior analysis, with fidelity; however, there is considerable variability in parent fidelity of implementation (FOI) and the amount of time necessary for parents to learn how to implement PRT with acceptable FOI (Coolican et al., 2010). Little is known about parent characteristics associated with successful parent implementation of PRT. Parent mental health and parenting self-efficacy (SE) have been identified as potential correlates (Guimond et al., 2008; Steiner et al., 2012). JumpStart is a 20-hour education and empowerment program for parents of children recently diagnosed with ASD. JumpStart meets twice a week for four weeks, and parents receive 11.25 hours of PRT training (didactic, observation, and in-vivo coaching).
Objectives: To examine: (1) changes in depression, parenting SE, parent FOI, and child responsivity among families who completed the JumpStart program, and (2) whether initial levels of depression and parenting SE predict changes in parent FOI and child responsivity.
Methods: Participants were 65 parents (46 mothers; age M = 35.15 years, SD = 5.84) of 49 children (42 males; age M = 40.25 months, SD= 11.73) with a clinical diagnosis of ASD or an at-risk classification. Families were predominantly Caucasian and middle- to upper-middle class. Parents completed the Center for Epidemiological Studies Depression Scale (CES-D; Radloff, 1977) and the Early Intervention Parenting Self-Efficacy Scales (EIPSES; Guimond et al., 2008) pre- and post-JumpStart participation. Videotaped 10-minute probes pre- and post-JumpStart were coded for overall parent FOI and child responsivity.
Results: There were significant decreases in depression symptoms (F(1, 46) = 9.74, p = .003, h^2 = .18) and increases in parenting SE (F (1, 49) = 20.73, p < .001, h^2 = .30), FOI (F (1, 46) = 77.90, p < .001, h^2 = .63), and child responsivity (F (1, 46) = 36.38, p < .001, h^2 = .44) pre- to post- JumpStart participation. These effects did not differ between mothers and fathers. Time 1 depression levels were not associated with pre-post changes in FOI (ρ = -.20, p= .19) or child responsivity (ρ = -.03, p = .87); nor were parent age, level of education, or household income. Time 1 parenting SE was positively associated with pre-post change in FOI and child responsivity (Table 1).
Conclusions: Findings indicate that participation in JumpStart reduces depression symptoms and increases parenting SE. From a family systems perspective, improvements in these domains may translate to improved outcomes and quality of life for children with ASD. Initial parenting SE predicted positive change in parent FOI and child responsivity. Thus, it may be useful to implement interventions targeting parenting SE prior to parent training in PRT in order to maximize parent FOI and improve child outcomes.

85 **123.085** Prevalence and Correlates of Use of Complementary and Alternative Medicine in Children with Autism Spectrum Disorder in Europe

E. Salomone[1], T. Charman[1], H. McConachie[2] and P. Warreyn[3], (1)Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (2)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom, (3)Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium

Background: Complementary and alternative medicine (CAM) comprises diverse health care systems, practices, and products not considered to be part of conventional medicine, including potentially unsafe or definitively disproven approaches. Children with ASD are treated with CAM at higher rates than the general population. In US samples, high parental educational level, lower level of functioning and high levels of use of conventional treatment increase the likelihood of CAM use.
Objectives: To report on prevalence and correlates of use of different categories of CAM among a sample of young children with ASD in Europe. Specifically, the following characteristics in relation to the likelihood of CAM use were examined: child's age, gender, verbal ability, use of prescription medication, level of use of conventional treatment, parental educational level.
Methods: Parents of children with ASD < 7 years completed an online survey on use of conventional, pharmacological and CAM treatments. The survey, translated in 19 languages, was distributed via national support associations in 20 countries.
Results: The survey yielded 1,680 responses. Forty seven percent of parents reported having used

one or more CAM approaches in the past 6 months; for these, the total number of different CAM approaches used ranged from 1 to 12 with a mean of 2.15 (SD=1.55; IQR: 1-3). Diets and other supplements were used by 25% of the sample, mind and body practices by 24% and other unconventional approaches by 25%. A minority of parents reported having tried an invasive or potentially harmful approach (2%). Children over 5 years and children with lower verbal ability were more likely to have used CAM. Use of any prescription medication was associated with using any CAM, particularly diets and supplements (two-fold increase). Concurrent high levels of use of conventional psychosocial interventions were associated with a three-fold increase in use of any CAM; the effect was four-fold for mind-and-body practices. Higher parental educational level also increased the likelihood of CAM use; both of diets and supplements and mind-body practices.
Conclusions: This was the first study to report on factors associated to use of CAM in a large sample of young children with autism in Europe. The study replicates the findings of high prevalence of CAM use among young children with ASD in non-EU samples. Use of CAM was positively associated with concurrent use of high number of conventional treatment, which is an indication that parents need to be supported in the choice of appropriate treatments early on in the assessment and diagnostic process.

86 **123.086** Receipt of Early Childhood Special Education and Therapeutic Services Prior to Autism Diagnostic Evaluations in Children Referred to a Regional Autism Clinic

S. Monteiro[1], L. Berry[2], A. Spinks-Franklin[3], D. Treadwell-Deering[4], S. Broton[4], J. Dempsey[5], R. P. Goin-Kochel[6] and R. G. Voigt[3], (1)Pediatrics, Baylor College of Medicine/Texas Childrens Hospital, Houston, TX, (2)Suite 180, Baylor College of Medicine, Houston, TX, (3)Pediatrics, Baylor College of Medicine, Houston, TX, (4)Pediatrics, Baylor College of Medicine/Texas Children's Hospital, Houston, TX, (5)Baylor College of Medicine, houston, TX, (6)Autism Center, Texas Children's Hospital, Houston, TX

Background: The estimated lifetime cost to care for all individuals in the US with autism spectrum disorder (ASD) is $35 billion or $3.2 million per person. However, when early interventions are implemented, studies have shown potential savings of up to $208,500 per child across 18 years of education. Increasing recognition of ASD behaviors by families and primary pediatric health care providers has led to long wait lists at tertiary ASD diagnostic clinics and delays in formal ASD diagnoses. Whether such wait lists for ASD diagnostic evaluations delay referral to early interventions has not been previously investigated.
Objectives: To determine the prevalence of receipt of early intervention and therapeutic services in children prior to their diagnostic ASD evaluations and whether prior receipt of such services predicts an ASD diagnosis.
Methods: The electronic medical records of all children ≤ 5 years of age evaluated at a single regional ASD clinic between September 2012 and June 2014 were reviewed. Information regarding type of services, clinical diagnoses, and demographic information was abstracted for each patient.
Results: 561 children (mean age = 44 months [SD 10 months]; 80% [N=450] male; 20% [N=111] female) completed a diagnostic ASD evaluation. Of these children, 498 (89%) were already receiving early intervention services and only 63 (11%) were not receiving any services. Receipt of services did not vary based on race, ethnicity, insurance type, or primary language. Children who were already receiving services were more likely to receive an ASD diagnosis (67% [N=333]) than those not receiving services (43% [N=27]; p = .0002).
Conclusions: Despite concerns that long wait lists for diagnostic ASD evaluations may delay initiation of critical early interventions, our data indicate that a majority of children are receiving early intervention services prior to their diagnostic ASD evaluations, particularly if an ASD diagnosis is confirmed. This may be attributable to increased awareness among primary care providers and families of the importance of early interventions. Further investigation into access to more intensive and costly interventions (such as Applied Behavioral Analysis) once an ASD diagnosis is established is warranted.

87 **123.087** Reliability of Retrospective Parent Report: Hours and Type of Intervention

L. D. Haisley, M. L. Barton and D. A. Fein, Psychology, University of Connecticut, Storrs, CT

Background: Research on ASD frequently relies on retrospective parent report to gather information about the child's behavioral profile as well as any interventions employed. Many intervention studies have utilized retrospective report to detail the type and intensity of interventions used by children in early development. Previous research has called into question the reliability of retrospective report in general; therefore it is important to understand whether we can rely on retrospective parent report to inform intervention practices.
Objectives:
The current study examines the agreement between parent's report of intervention at the time the child was receiving those services, and their retrospective report of those same services 5 years later.
Methods:
In a longitudinal study, 24 parents reported on the services their child had received during the past year when the child was approximately 4 years of age (M = 52.33, SD = 9.83; Time 1). The child returned for a follow-up evaluation at 9 years of age (M = 116.76, SD = 9.91; Time 2) and parents

were asked to recall the services their child received from 3-4 years of age.
Results:
Children most frequently received occupational therapy, speech therapy or ABA therapy. Correlation coefficients between therapy hours recalled at Time 1 and Time 2 were significant for all three types of therapy (OT: r = 0.46, p = .02; ST: r = 0.74, p < .001; ABA: r = 0.90, p < .001). Reliability between Time 1 and Time 2 reports was calculated using Cronbach's alpha and demonstrated good agreement across therapies: OT, α = 0.61; ST, α = 0.85; ABA, α = 0.94. Further types of interventions will be discussed.
Conclusions:
Although there was not perfect agreement between intervention hours reported at Time 1 and Time 2, the agreement between current and retrospective report was significant. The current study supports the validity of parent retrospective report to examine the effects of types and intensity of interventions on child outcomes.

88   **123.088** Sensory Treatment for Autism to Alleviate Tactile Abnormalities Reduces Severity of Autism and Improves Self-Regulation: A Randomized Controlled Trial in 100 Pre-School Children

L. Silva and M. Schalock, Teaching Research Institute, Western Oregon University, Monmouth, OR

Background:
Two recent studies in pre-school children with autism showed the universal prevalence of tactile/oral abnormalities (pain and numbness) suggestive of tactile impairment. Severity of tactile abnormalities was linearly associated with self-regulatory delay and severity of autism. Concurrently, two small randomized controlled trials (n=47, n=46) evaluating treatment of tactile abnormalities showed a mean 25% decrease in severity of autism, providing initial evidence that tactile abnormalities may be a contributing cause of autism. Treatment was with a Chinese medicine-based massage protocol for autism given daily by parents and weekly by therapists for five-months. Treatment was effective in low and high-functioning children. This was important as there are currently few treatment options for low-functioning children.
Objectives: To replicate and extend earlier studies with a larger controlled study and determine whether sensory treatment for autism directed at tactile abnormalities decreases severity of autism.
Methods: 104 pre-school children with ASD were recruited, underwent confirmation of autism diagnosis by DSMIV criteria, and were randomly assigned to treatment and wait-list control groups. Pre-testing was accomplished by experienced autism examiners who were blind to group, and parents. The treatment group received 5 months of treatment, and post-testing was accomplished with the same examiners. Treatment was given at multiple sites by multiple trained therapists. No additional research-based autism treatments were initiated during the study period. Autism severity was measured by the CARS and Autism Behavior Checklist; sensory and self-regulatory abnormalities were measured with the Sense and Self-Regulation Checklist; language was measured with the PLS-5; parenting stress was measured with the Autism Parenting Stress Index.
Results: Repeat-measure multivariate analyses showed medium-to-large effect size on improvement of severity of autism (F(2,81)=5.71, p=.008, Partial η2=.113); large effect size on improvement tactile/oral and self-regulation abnormalities (F(3,80)=6.74, p<.0001, Partial η2=.202); and medium effect size on improvement of receptive language (F(1,83)=4.81, p=.031, Partial η2=.055). Univariate analysis showed large effect size on reduction of parenting stress (F(1,82)=15.69, p<.0001, Partial η2=.161). Treatment was effective in low and high functioning groups, indicating that language was not required for treatment to be effective.

Conclusions: Five months of sensory treatment for autism was effective in reducing tactile/oral and self-regulatory abnormalities, as well as in considerably reducing the severity of autism. With parent training and support, the program was readily implemented in the home. This treatment is the first to be effective in reducing severity of autism in low and high-functioning children, and can be helpful to families at the time of autism diagnosis. More improvement can be expected with longer-term treatment, and additional treatment and evaluation is underway.

89   **123.089** Student Change in Response to Early Achievements Intervention Translated for Public Preschool Classrooms

K. P. Wilson[1], R. J. Landa[2] and E. Stripling[3], (1)8000 York Road, Towson University, Towson, MD, (2)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD, (3)Kennedy Krieger Institute, Baltimore, MD

Background: The substantial increase in students with autism spectrum disorder (ASD), combined with a decline in educational funding, makes the availability of cost-effective, evidence-based classroom intervention options vital to both student outcomes and special education costs. However, there is a troubling research-to-practice gap in educational settings for young children with ASD. Empirically-proven interventions for young students with ASD are often too complex, costly, or impractical for use in authentic educational settings. With these barriers in mind, intervention researchers must take into account the needs and characteristics of educators, their classrooms, and their students with ASD when developing and evaluating potential interventions.
Funded by an Institute for Education Science (IES) Goal 2 Development and Innovation grant, this

ongoing study's overall aims are to translate an existing evidence-based intervention (i.e., the Early Achievements model) for implementation in public preschool classrooms, thereby improving the outcomes of preschoolers with ASD. This presentation reports on data reflecting student change in response to the translated intervention, collected across the first two years of the study. These data are vital in guiding the final year of the study, which involves a small efficacy trial of the intervention and its associated professional development model.

Objectives: The objectives of this presentation are: (1) to describe the translated Early Achievements model and the associated professional development program provided to educators in participating classrooms; and (2) to share pilot data evidencing the promise of the intervention through reporting of student change.

Methods: The pilot data presented herein were obtained through a quasi-experimental pre-post design (treatment group only) with data captured at the start and end of the school year. Results across two years of study are presented. Demographic and baseline information will also be presented to describe the sample of students, their families, and the participating educators.

Results: Combined data across two years of pre-post comparisons of preschool student participants' (n=49) standardized assessment results showed a significant decrease in their *Autism Diagnostic Observation Schedule-2* calibrated severity scores ($p=.004$), significant gains in their *Mullen Scales of Early Learning* age equivalent scores across all subtests (p<.001 for all), and significant gains in their *Peabody Picture Vocabulary Test* standard scores ($p=.019$) and age equivalent scores ($p=.003$). Logistic regression results showed *Mullen* expressive language gains of 5 or more months from pre- to post-test were predicted by *Mullen* visual reception age equivalent scores at pre-test, as well as by sex of the participants.

Conclusions: This study's intent is to assess the promise and impact of an evidence-based clinical intervention program specifically translated for use in public preschool classrooms serving children with ASD. Results showing educators' successful uptake of the intervention were presented previously. Student gains presented here add to those results as further evidence of the effectiveness of both the professional development *and* intervention models. Language and visual reception gains indicate parallel gains in student attention and learning based on educators' increased understanding of development and increased use of strategies to enhance engagement. Further implications, discussion of regression results, and future directions will be included.

90 **123.090** Telehealth Delivery of Cognitive-Behavioral Intervention for Anxiety in Youth with ASD: Perspectives of Parents in Rural Communities

S. L. Hepburn[1], J. Reaven[2] and A. Blakeley-Smith[2], (1)Psychiatry & Pediatrics, JFK Partners/University of Colorado School of Medicine, Aurora, CO, (2)Psychiatry, JFK Partners/University of Colorado School of Medicine, Aurora, CO

Background: A comparative effectiveness review by AHRQ (2014) determined that there is now a "strong body of evidence" supporting cognitive-behavioral interventions targeting anxiety and mood symptoms in youth with ASD who are verbally fluent. For families living in rural communities, access to specialists who have been trained to deliver evidence-based treatments, such as CBT, is severely limited. Telehealth delivery of evidence-based interventions has the potential to improve access to services for rural families.   However, little is known about how to modify evidence-based protocols for delivery of psychosocial interventions through telehealth in a manner that is acceptable and feasible for families.

Objectives: To examine parent perceptions of credibility, feasibility and impact of a short-term telehealth intervention designed to reduce interference and severity of anxiety symptoms in youth with ASD. Results will inform revisions of the model in planning for a large, multi-site trial.

 Methods: Twenty-six parents participated in a pilot study of telehealth delivery of Facing Your Fears (FYF; Reaven et al., 2011), which is an empirically supported, manualized, multi-family group CBT for anxiety for youth with ASD. Parents completed several questionnaires focused on acceptability and feasibility of delivering mental health interventions directly to youth with ASD through videoconferencing before and after engaging in the intervention. Parents also completed a structured exit interview that probed for feedback regarding intervention content, delivery and impact. Efficacy data (published elsewhere) will be reviewed briefly and long-term follow-up measures of anxiety symptoms are being collected to assess sustainability of effects.

Results: Credibility and acceptability ratings by parents were consistently high before, during and after the intervention. Qualitative data from the exit interviews are being analyzed through Atlas, a software program that identifies emerging themes and associations amongst themes. Thus far, the majority of parents perceive telehealth as a viable option for improving access to specialty mental health care. Many cite the ease of engaging their son or daughter in a treatment session that occurs via the home computer as a benefit and several reported knowing of no local alternative to the services provided through this telehealth program. Few parents expressed any concerns about risks to confidentiality. The majority of families identified the need for ongoing support from project therapists, suggesting the importance of long-term sustainability.

Conclusions:

Parents who participated in a short-term, multi-family CBT intervention with their son/daughter with ASD via telehealth report that the approach is credible, acceptable and feasible. Analysis of their feedback regarding ways to improve the program are ongoing. Many parents have expressed interest in building sustainable models wherein clinicians can be accessed as needed by project

91   **123.091** The Effect of an Outdoor Adventure Program on Functioning of Children with Autism Spectrum Disorder

D. A. Zachor[1], S. Vardi[2], I. Brodai-Meir[3], S. Eitan[3] and E. Ben Itzchak[4], (1)Pediatrics, Assaf Harofeh Medical Center, Tel Aviv University, Zerifin, Israel, (2)Etgarim non-profit organization, Tel Aviv, Israel, (3)Ariel University, Ariel, Israel, (4)Ariel University/ Assaf Harofeh Medical Center, Ariel, Israel

Background:
Challenge in the outdoors is important for people with and without disabilities. The outdoor environment intensifies group interaction and development. Individuals with cognitive and/or motor disabilities benefit from participation in outdoor adventure programs and show increased outdoor recreation skills, enhanced self-concept, self-esteem, social adjustment, positive behavior changes, increased interpersonal relationships, and sensitivity to the needs of others. The effect of outdoor adventure programs (OAP) on the functioning of children with autism spectrum disorder (ASD) has not yet been examined.
Objectives:
The aim of the current study was to examine the effect of OAP for children with ASD on autism severity, adaptive skills, and the kindergarten (KG) teacher's perception of the child's 'future competence'.
Methods:
Fifty-one participants recruited from seven special education KGs for ASD using the same educational curriculum in Tel Aviv, with an age range of 3:4-7:4 years (M=5:4, SD=.9) were enrolled in this study. Four KGs including 31 participants were randomly selected to participate in an OAP (research group). The other three KGs included 20 participants who did not participate in this program (the control group). The groups did not differ in age and sex. The OAP included 13 weekly sessions of 30 minutes each provided by professional recreation specialists from "ETGARIM", a non-profit organization. Activities included: climbing and descending a ladder; a rope elevator requiring group collaboration by pulling a child tied to a harness; walking on ropes tied to trees requiring a request for the instructors' help, and swinging on a hanging hammock. Pre-and post-evaluation of autism severity (Social Responsiveness Scale-SRS), adaptive skills (Vineland Adaptive Behavior Scales- VABS) and perception of the KG teacher on 'future competence' (a questionnaire based on several sources and modified by the authors) were conducted.
Results:
Outcome in autism severity revealed a significant TimeXGroup interaction. At post-intervention time, the research group showed a significant reduction in autism severity on the SRS composite and specific subdomains (cognition, motivation and repetitive behaviors scores), while the control group showed an increase in autism severity in these measures. Further analyzing the differences between the groups using T tests revealed that only the research group showed significant improvements in SRS communication, $p<0.05$) and motivation ($p<0.05$) subdomains. At post-intervention time, only the control group had more severe SRS composite, $p<0.05$) and repetitive behaviors ($p<0.05$) scores. The two groups showed significant improvements over time in VABS communication and daily living skills scores. No significant TimeXGroup interaction was found for VABS scores nor for the 'future competence' questionnaire scores. Dividing the groups at baseline into two autism severity subgroups based on the SRS scores revealed that only the low autism severity subgroup that received intervention showed significant improvements on the VABS DLS scores ($p<0.05$) and on 'future competence' questionnaire scores ($p<0.05$).
Conclusions:
Outdoor adventure programs for children with ASD improve measures of autism severity and prevent deterioration in socio-communication skills and repetitive behaviors. Children with less severe autism symptoms benefit from this program and improve in adaptive skills. Including an outdoor adventure program in the intervention plan in ASD is recommended.

92   **123.092** The Effects of Teacher Perceptions on Fostering Engagement during Dyadic Play Interactions with Students with ASD

J. Panganiban[1], H. Gould[2], Y. C. Chang[3], S. Y. Shire[4] and C. Kasari[5], (1)University of California, Los Angeles, Arcadia, CA, (2)UCLA, Los Angeles, CA, (3)Semel Institute, UCLA, Los Angeles, CA, (4)University of California Los Angeles, Los Angeles, CA, (5)UCLA Center for Autism Research & Treatment, Westwood, CA

Background: Children with an autism spectrum disorder (ASD) are less likely to be jointly engaged with a play partner than typically developing children (Adamson, Bakeman, Deckner, & Romski 2009). Being in a joint engaged state during play provides educators an optimal environment to target social communication skills, such as joint attention. It is especially important then for teachers to use strategies that promote engagement for students with ASD.
Objectives: The aim of this study was to investigate how teachers' perceptions about their students with ASD influenced their use of strategies to engage with their students during dyadic play interactions. Specifically, we examined how teachers perceived their students' ability to control of

their ASD related behaviors, and how this perception relates to strategies that foster engagement.
Methods:
Participants: We included preschool aged students with ASD (mean = 48 months), 82% male, and from diverse ethnic backgrounds (12.1% African American, 30.3% Caucasian, 18.2% Latino, 15.2% Asian, and 18.2% other). Twelve teachers from six ASD preschool classrooms (two teachers from each class) located around the greater Los Angeles area participated.
Measures: Teachers completed questionnaires rating their students' ability to control behaviors associated with ASD: social interaction, non-verbal communication, repetitive interests/behaviors, and sensory seeking behavior. For these four domains, teachers were given a brief description of behaviors associated with ASD, and asked to rate each child on their ability to control those behaviors. Scores across all four domains were totaled to create a composite score representing teachers' perceptions of each student's ability to control ASD related behaviors. Teachers and students were filmed during a ten minute dyadic play interaction in the classroom. Videotapes were scored for teachers' appropriate use of strategies to promote engagement during the play interaction, resulting in an overall teacher strategies score. Strategies included appropriate matching of affect, response to dysregulation, providing opportunities for students to initiate play, responding to student initiation of play and communication, and modeling language matched to verbal ability. Students were administered the Mullen Scales for Early Learning (Mullen, 1989) to assess expressive language.
Results: Multiple regression analysis revealed that teachers' perceptions of a student's ability to control ASD behavior predicted overall teacher strategies scores during dyadic play interactions, while accounting for students' expressive language ability ($\beta = .015$, $p < .05$). Teachers' perceptions of a student's ability to control ASD behavior accounted for an additional 14% of variance in teacher strategies scores ($DR^2 = .147$). Correlation analysis of specific strategies showed that teachers' perception was positively correlated with appropriate responding to child initiated social communication ($r(45) = .35$, $p < .05$) and appropriate language strategies ($r(45) = .31$, $p < .05$).
Conclusions: These findings indicate that teachers' perception of students' ability to control ASD behavior is associated with strategies used during play interactions. Teachers tended to more appropriately use strategies promoting engagement when students were perceived to be better able to control their ASD behavior. Specifically, teachers scored better in actively responding to the student's initiations and using language that matches the student's abilities.

93 **123.093** Toddlers and Families Together: Caregiver Implementation and Perceptions of Strategies to Facilitate Joint Engagement

C. Wong[1,2], K. C. Gallagher[1], J. Page[1], K. Wong[1], G. Arellano[1] and S. Arbiv[1], (1)UNC Frank Porter Graham Child Development Institute, Chapel Hill, NC, (2)UCSD Child & Adolescent Services Research Center, San Diego, CA

Background:
Research on early intervention programs targeting toddlers with or at risk for autism spectrum disorder (ASD) primarily involve individual sessions with the caregiver and child in the home which may be isolating or impractical for some families. In Toddlers and Families Together (*Together*), toddlers and their families participate in eight weekly group sessions that take place during the weekend and focus on increasing joint engagement with their child. Specifically, families have an opportunity to practice strategies and receive feedback within a context of everyday routines and activities for toddlers (e.g., play, snack, art, gross motor, music) within 3-hour long group sessions that also include a family education/support segment to learn and discuss strategies with a facilitator and other caregivers while the toddlers are engaged in various learning activities.
Objectives:
With an overarching goal of promoting joint engagement for children with ASD through the *Together* program, the specific questions of this study include:

1. Does participation in the program result in changes in caregiver implementation of strategies to facilitate joint engagement with their children?
2. After participating, what are caregiver perceptions of the strategies and the program?

Methods:
The study utilized a multiple baseline design across four toddlers (24-31 months) with or at risk for ASD and their families that included an initial baseline period (of 4, 6, 8, or 10 weeks) followed by participation in the 8-week *Together* program. The weekly sessions included a 10-minutes video-recorded interaction between the child and the primary caregiver that was rated on eight items that were scored on a three-point Likert scale for implementation of strategies to promote joint engagement. In addition, at the end of treatment, caregivers completed a brief questionnaire reporting their ability (e.g., time, comfort, confidence) to implement and perceptions (acceptability) of the treatment strategies. Families also participated in a semi-structured interview to provide their opinions about the intervention.
Results:
Results show increased caregiver implementation of strategies during intervention and demonstrated family acceptability of the intervention. Visual analysis indicates a functional relationship between the intervention and caregiver implementation of the strategies with increased level changes observed

during the intervention phases for all caregivers. Furthermore caregiver responses to the questionnaire and interview indicated overall acceptability of the strategies and program. Most family members felt comfortable and confident with the strategies but did note that it did take a little effort and time to implement the strategies. They also reported that the family support/education sessions were the most helpful aspect of the intervention.

Conclusions:
The results from this SCD provide preliminary efficacy and social validity data supporting the *Together* program. However, further study needs to test the program with a larger sample of children and families in randomized controlled trial. Furthermore, additional analysis is required to examine caregiver outcomes of stress and coping as well as child outcomes of joint engagement. Overall, it may be beneficial to both toddlers and families to use a group-based model of intervention for families of young children with or at risk for ASD.

94 **123.094** Using EEG to Target GABA-a for the Treatment of Social Disability in Young Adults with Autism Spectrum Disorders

S. Loo[1], S. J. Webb[2], I. Mohammad-Rezazadeh[3], G. Frishkoff[4], R. T. Amoss[5], B. H. King[6], L. Scahill[7] and J. T. McCracken[8], (1)Psychiatry and Biobehavioral Sciences, UCLA David Geffen School of Medicine, Los Angeles, CA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA, (4)Cognitive Sciences Program, Georgia State University, Atlanta, GA, (5)Marcus Autism Center, Emory University School of Medicine, Atlanta, GA, (6)Psychiatry and behavioral sciences, University of Washington, Seattle, WA, (7)Pediatrics, Marcus Autism Center, Atlanta, GA, (8)Psychiatry and Biobehavioral Sciences, UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA

Background:
Identification of biological targets could represent opportunities to intervene and ameliorate core pathophysiology in ASD. Changes in resting and activated neuronal network oscillatory activity across various frequency bands are evident in ASD. To this end, NIMH Fast Fail Trial in AS Network evaluated one compound, AZ7325 (a $GABA_{a2/a3}$ partial agonist), by examining its target engagement, safety and tolerability, and preliminary efficacy indices. The GABA system shows strong evidence of disruption in ASD and EEG has been investigated as translational biomarkers for examining putative decreased GABA signaling. Most models of temporally organized oscillatory activity interpret the activity as the output of network interactions between interconnected glutamatergic pyramidal cells and GABAergic inhibitory interneurons (Bartos et al 2007), wherein GABAA signaling mediates phasic inhibitory control of excitatory pyramidal firing, the source of the EEG signal.

Objectives:
Our hypothesis is that administration of a selective $GABA_{a2/a3}$ receptor partial agonist in an adult ASD sample is expected to result in specific EEG signatures of drug action consistent with selective target engagement.

Methods:
In Phase 1 (EEG Biomarker Validation): a battery of 4 EEG paradigms consisting of resting state, face perception, sensory perception, and frontal functioning were developed. Pilot data were collected on 39 controls and 12 adults with ASD from 3 sites. All data were collected using high density EEG under standardized settings. Each data file was artifact detected using Independent Component Analysis, and key features included the presence of posterior alpha activity in eyes closed and a N170 component to face stimuli. Analyses compared the ASD and Controls for identification of a biomarker that differentiated group functioning. In Phase 2 (Double Blind Placebo Control Study), 24 adults with ASD from 3 sites were screened on the EEG paradigm and assessed for inclusion based on the identified biomarker.

Results:
Although there were few significant differences between ASD and Controls on a specific variable (e.g., non significant delta, theta, alpha ps>.10), a linear discriminant analysis consisting of 3 metrics (from resting state eyes closed and faces) were combined to provide a sensitivity of .8 and specificity of .7 for separation between groups. Using this combined marker as an inclusion criteria, we are currently completing Phase 2. Upon completion in Dec, the blind will be broken and analysis of baseline vs week 4 and week 6 EEG will be conducted for the active vs. placebo group.

Conclusions:
Fast Fail AS is the first trial to develop a targeted EEG biomarker for use in investigating a GABA deficit in ASD. This study of AZD7325 may provide insight into the relevance of GABAergic medications in ASD and the role of EEG as a marker of treatment response.

95 **123.095** Why High-Risk Families Decline Early Treatment: Barriers to Treating at-Risk Siblings

K. K. Powell[1], E. Schoen Simmons[1] and K. Chawarska[2], (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT

Background: Prospective studies of infant siblings that later develop autism show the emergence of symptoms within the first year of life (Ozonoff, et al., 2010, Macari et al., 2012). A small body of literature explores the treatment of very young children at high risk for ASD (Bradshaw et al., 2014).

The subset of studies that examine the feasibility of intervention for very young infants, 12 months of age or younger, have small sample sizes suggesting parents may decline these types of services. Little research has been conducted on the factors that influence parents' decisions to enroll their infant, who does not yet have a clinical diagnosis, in very early intervention.

Objectives: The purpose of this study was to examine factors influencing decision making of high risk families to participate in early social communicative treatments for their at-risk infant.

Methods: Twenty eight participants, 12-18 months, were evaluated from a prospective study examining infant siblings at risk for developing ASD. Infants exhibiting delays in social communication were invited to participate in a 12-week adapted Pivotal Response Treatment (PRT). Questionnaires measuring degree of parental concern for their infant's development were collected. An interview was conducted with families who declined participation or discontinued treatment.

Results: Of the 28 HR infants who were evaluated, 17 (61%) met inclusion criteria. Twelve families (71%) declined participation. Five families (29%) elected to enroll in treatment. Of these five, three (60%) discontinued participation within the first four sessions. The following factors were reported by the 15 families (88%) who declined participation or discontinued treatment. Five families (33%) reported more than one factor impeding participation.

Factor 1: Distance to the Clinic. Seven families (47%) reported distance as a factor. All of these families lived >50 miles round trip from the Clinic.

Factor 2: Early Intervention. Two families (11%) enrolled in state provided home based early intervention instead of our clinic-based treatment.

Factor 3: Family Commitments. Three families (13%) reported significant commitments at home related to the older siblings with Autism and other disabilities.

Factor 4: Parental Concern. Five families (33%) reported little to no concern regarding their child's development despite clinicians concerns.

Factor 5: Unknown. Three families (20%) did not provide a reason for declining treatment.

Conclusions: Results from this pilot study indicated that few families expressed interest in treatment. Although many families reported distance to the clinic as a barrier, for others, home based intervention was more practical. Others declined treatment because of family commitments involving older siblings with disabilities in the home. A proportion of families did not express the same level of concern for their child's development as the clinicians. One interpretation of this mismatch is that parents may be comparing the development of their younger child with the older sibling who has autism, often minimizing the developmental concerns of the younger child. While treating high risk infants who demonstrate developmental delays may seem intuitive, this preliminary study suggests continued research is needed regarding the feasibility of these types of very early treatments.

96 **123.096** Efficacy of Adapted Responsive Teaching in a Community Sample of One-Year-Olds at-Risk for ASD

L. R. Watson[1], E. R. Crais[1], G. T. Baranek[2], L. Turner-Brown[3], J. Sideris[4], J. S. Reznick[5], L. Wakeford[2], J. Kinard[6] and K. L. Martin[7], (1)Division of Speech and Hearing Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Division of Occupational Science and Occupational Therapy, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)TEACCH Division, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Frank Porter Graham Child Development Institute, Chapel Hill, NC, (5)Psychology, The University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)The University of North Carolina at Chapel Hill, Chapel Hill, NC, (7)Carolina Institute for Developmental Disabilities, The University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: Contemporary theories emphasize the transactional influences of biology and environment on neurodevelopment (Beauchaine et al. 2008). Infants at-risk for ASD are vulnerable to disrupted neural connectivity (e.g., Dinstein et al., 2011; Righi et al., 2014); thus, introducing behavioral intervention soon after the first birthday, when neural shaping processes become prevalent (Webb et al., 2001), may be key timing to promote more typical neural development and, subsequently, more typical child-environment transactions. The efficacy of interventions for infants at-risk for ASD before all ASD diagnostic symptoms emerge has been examined previously only in small samples.

Objectives: To determine whether (1) a parent-mediated intervention, Adapted Responsive Teaching (ART; adapted from Mahoney & MacDonald 2007) impacts expressive communication (ExpCom) outcomes of one-year-olds at-risk for ASD; (2) ART is differentially efficacious as a function of parental stress or infant nonverbal cognitive skills at pretest; (3) ART impacts caregiver interaction styles.

Methods: 87 infants scoring at-risk for ASD on the First Year Inventory (Baranek et al., 2003) were enrolled in a randomized controlled trial at 13 to 15 months, along with a primary caregiver of each. Staff provided all families with information about community early intervention services, and monitored participants through monthly phone calls. Families randomized to the control group received no further services from project staff. Families randomized to ART participated in a manualized intervention entailing ~30 one-hour home sessions over 6 to 8 months. ART uses a variety of responsive strategies to promote pivotal behaviors in the social-communication and sensory-regulatory domains, with planned individualization. The interventionist provides caregivers with a rationale for each session's focus, demonstrates and coaches new responsive strategies, and discusses caregivers' observations of their infants' behaviors and responses. Assessors, blind to group assignment, completed assessments with the infants and caregivers immediately before and

after the intervention phase.

Results: Analyses are preliminary. All models covaried for child gender and caregiver education, as well as the pretest scores corresponding to posttest outcomes. There were no significant group differences on posttest ExpCom. Parental Stress Scale (Berry & Jones, 1995) scores did not moderate the effects of ART. However, pretest Visual Reception (VR) T-scores (Mullen, 1995) interacted with treatment group in that infants with low VR scores assigned to ART showed fewer gains on ExpCom than infants in the control group, whereas infants with high VR scores assigned to ART showed greater gains, $t = 2.57$, $p = .012$ (Figure 1). No group effect was apparent on the Maternal Behavior Responsiveness Scale (Mahoney et al. 1986) for Responsiveness, Achievement or Directiveness, but parents in the ART group had higher posttest ratings on Affect, Cohen's $d = .71$, $p < .01$.

Conclusions: The moderating effect of VR on ExpCom outcomes of infants assigned to ART reinforces the importance of determining how to best fit interventions to child and family characteristics. The impact of ART on parent affect raises the possibility of more distal effects on child outcomes due to changes in parent interaction style. Future research should be directed at both issues.

---

Background: Younger siblings of children with Autism Spectrum Disorder (ASD) are at high risk (HR) for developing ASD, as well as features of the broader autism phenotype. While this complicates early diagnostic considerations in this cohort, it also provides an opportunity to examine patterns of behavior associated specifically with ASD as compared to other developmental outcomes.

Objectives: We examined (1) combinations of behavioral features at 18 months that are associated with ASD diagnosis at 3 years, and (2) the factors that affect accurate identification at 18 months of HR siblings who receive a diagnosis of ASD at 3 years of age.

Methods: We applied a nonparametric decision-tree learning algorithm, Classification and Regression Trees (CART) analysis, to individual items of the Module 1 Autism Diagnostic Observation Schedule in 719 HR siblings to identify behavioral features at 18 months that are predictive of diagnostic outcomes at 36 months. CART analysis allows for selection of the most predictive features from a multiplicity of behavioral symptoms *and* their interactions, resulting in a parsimonious mapping of different sets of predictors of later outcomes.

Results: Three combinations of features at 18 months were predictive of ASD outcome: 1) poor eye contact and lack of communicative gestures and giving; 2) poor eye contact and a lack of imitative or spontaneous imaginative play; and 3) lack of giving and presence of repetitive stereotyped behaviors despite intact eye contact (**Figure 1**). These behavioral profiles predicted ASD versus non-ASD status at 36 months with 82.7% accuracy in the initial test sample and 77.3% accuracy in a validation sample. Clinical features at age 3 years among children with ASD varied as a function of their 18-month symptom profiles (**Figure 2**). Cases with ASD who were missed at 18 months were higher functioning and their autism symptoms increased over time.

Conclusions: A large minority of HR siblings with ASD display marked symptoms at 18 months, whereas in others, symptoms become pronounced after 18 months, suggesting at least two windows of opportunity for identification of the affected cases in clinical settings. Several combinations of clinical features at 18 months were predictive of ASD outcome, each associated with a different developmental course and clinical profile by the 3 years of age. Combined, these findings suggest the presence of different developmental pathways to the common diagnostic ASD outcome, pathways characterized by distinct combinations of early markers, reinforcing the need for repeated screening in the first three years of life to identify individual cases of ASD as their behavioral symptoms appear.

124.098 A Comparison of Live Versus Video Modalities for Measurement of Eye Contact in Infants at Age 6 Months As 'Red Flags' for ASD

*A. Townsend[1], J. A. Chevallier[2], **P. A. Filipek[1]**, C. Laufer[1], M. M. Abdullah[3], P. Horner[3], J. T. Phan[3], K. Pham[3], K. Jung[1] and J. M. Williams[1], (1)University of Texas Health Science Center at Houston, Houston, TX, (2)UT Houston, Houston, TX, (3)University of California, Irvine, Irvine, CA*

Background: Considerable research in infants-at-risk for ASD (IAR) has focused on eye-tracking devices to measure the degree of eye contact, with variable results at age 6-months (mos). Many studies of eye fixation show abnormalities developing between 6- to 12-mos of age, often reporting no differences from typical infants at 6-mos but significant differences in eye gaze patterns by 12-mos. However, Jones and Klin showed that at-risk infants had a mean decline in eye fixations from 2- to 6-mos that continued to decline to ~50% of typical infants by 24-mos, while object fixations nearly doubled.[1] By 6-mos, Chawarska *et al.* showed that IAR spend more time engaged in abstract stimuli and disengaged from pertinent social stimuli, and gaze less at the inner features of the face compared to low risk infants.[2,3] These findings suggest that IAR already do not attend to the salient facial features necessary for social communication in very early infancy.[4]

Objectives: To compare two eye gaze modalities in 6-month-old infants who were later classified as either ADOS-Toddler Module (ADOS-T) positive (ASD+) or Non-Spectrum (N/S) as toddlers: conventional eye-tracking with caregiver's face presented on a monitor (FTM) *versus* face-to-face (FTF).

Methods: Twenty-three 6-mos old infants interacted with their caregiver during traditional Still-Face (SF) paradigms while eye contact was recorded under two conditions:

- with a conventional Tobii eye-tracking device (FTM), and
- FTF recorded with a fiber-optic eyeglass camera.

Each infant had psychometric testing including the ADOS-T in the second year of life. ADOS-T classification was used to divide the subjects *post-hoc* into ASD+ (n=10) and N/S (n=13) groups. Trained blinded researchers coded eye contact data using Tobii 1.73 and Noldus X10. Fixation length (FL), fixation count (FC), and mean duration (MD) of eye contact were subjected to ANOVAs to compare the two groups; only effect sizes greater than 0.5 were considered to be meaningful differences between the two groups.

Results:

- Both groups generally had higher FL and MD of eye contact in FTF-SF than in FTM-SF interactions.
- However, during FTF-SF, the ASD+ group had significantly lower FL and MD of eye contact than the N/S group (p≤ 0.001).
- The ASD+ group also surprisingly had a longer FL in FTF than FTM interactions, but had a greater FC in FTM than FTF interactions.

Conclusions: As noted by several other studies, ASD+ infants displayed eye contact behaviors similar to that of N/S infants during FTM video interactions at 6-mos. In contrast, in FTF interactions ASD+ infants had fewer fixations with shorter durations than did the N/S infants. Live social interactions may be a more sensitive experimental tool than computerized eye-tracking technology in detecting anomalous eye contact in ASD+ infants as young as 6-mos.

124.099 A Computational Approach to Eye-Tracking Analysis Reveals Slower Orienting to Movements in Social Scenes in Toddlers with ASD

***Q. Wang**, S. Macari, K. Chawarska and F. Shic, Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Complex, naturalistic, dynamic scenes are becoming increasingly prevalent in eye-tracking research on autism spectrum disorder (ASD). However, conventional analyses with predefined Areas of Interests (AOI) have limitations: they are created subjectively, are hard to apply to dynamic stimuli, and have a binary definition ("in" or "out"). Computational approaches may provide alternative analytical quantitative frameworks that are more automated, less arbitrary, and that highlight more nuanced features of atypical scanning strategies in ASD.

Objectives: To develop a framework for examining motion-driven visual scanning during observation of naturalistic scenes. We use this framework to compare the visual scanning patterns of toddlers with ASD and typically developing (TD) controls.

Methods: Participants included 20 month-old toddlers with ASD (n=99), developmental delays (DD, n=56), and TD (n=111). Toddlers freely viewed a dynamic 3-minute scene with four probes (Dyadic Speech, Sandwich-Making, Joint Attention, and Animated Toys), which was broken down into contiguous 100 ms segments for analysis. We first conducted a Cohesion Analysis of TD scanning

patterns (Shic et al., 2012). We used three-fold cross validation to compute a 'cohesive score,' calculated by the sum of the inverse distances between each participants' gaze position and that of a subset of TD toddlers for each segment. Next, we computed the optical flow (Horn and Schunck, 1981; Sun et al., 2010), i.e. the relative motion at pixel level between frames in scene. We conducted a Latency Analysis to find the temporal lag between gaze orienting and motion in scene that maximized the average optical flow indexed by the participant's gaze orienting positions (Maximal Optical Flow). Correlations were computed between cohesive scores, maximal optical flow magnitudes, and behavioral characteristics of toddlers with ASD.

Results: Cohesion Analysis: ASD scanning patterns deviated from both DD and TD groups on cohesive scores (p< .01, p<.001) in all four probes, with no significant differences between DD and TD groups. Latency Analysis: The ASD group responded more slowly to motion than the TD group (p<.05), but not the DD group. This effect was driven by the Joint Attention (p<.05) and Sandwich-Making (p<.05) probes. Maximal Optical Flow: On average, toddlers with ASD looked less at motion than TD and DD groups (p<.05, p<.05), particularly in the Sandwich-Making probe (p<.001, p<.001). Correlations: Strong correlations between cohesion and the optical flow magnitude for all groups (r>.76, p<.001) suggest that motion has a strong organizing influence on looking behavior. Toddlers with ASD with higher cohesion scores presented with higher verbal (r=.21, p<0.05) and non-verbal (r=.22, p<0.05) DQ and lower ADOS autism severity (r=-.21, p<.05); those with longer lags had higher ADOS autism severity (r=.22, p<.05).

Conclusions: Our results suggest that, as a group, toddlers with ASD react slower toward movement in social scenes, and that this behavior is associated with developmental level and social deficits. These techniques may help characterize the nature of atypical scanning patterns in ASD and lead to new, automated instruments for identifying early symptoms of ASD.

100 **124.100** A Dynamic Eye-Tracking Paradigm: Eye Gaze Patterns in Typically Developing and Infants at-Risk for Autism

C. Parikh and A. M. Mastergeorge, Family Studies and Human Development, University of Arizona, Tucson, AZ

Background: The ability to follow the gaze of others is an essential advancement in the development of social attention. Eye gaze sets the foundation for the initiation of joint visual attention and understanding the intentions, mental states, and goals of others (Gredeback et al., 2008; Jones & Klin, 2013). Deficits in eye contact and gaze have been hallmarks of autism spectrum disorders (ASD; Chawarska et al., 2012; Swanson et al., 2013). A recent focus on comparisons between typical (TD) and at-risk development of visual fixation patterns using eye-tracking paradigms may be a proxy for early indicators of gaze discontinuity and may classify the phenotypic behaviors of infants' visual attention patterns for early identification and intervention purposes (Frank et al., 2014; Merin et al., 2007).

Objectives: To examine preliminary individual differences in eye gaze patterns in TD and infants at-risk for autism.

Methods: Participants include 37 males and 31 females consisting of ($N = 60$) TD and ($N = 8$) infants at-risk for autism with chronological ages ranging from 3 to 12 months ($M = 7.59$, $SD = 3.35$). Participants were considered to be at-risk if they had an older sibling diagnosed with ASD. A Tobii Studio eye-tracking model captured the visual fixation patterns during a dynamic clip of *Peter Pan*. The total on-screen area was divided into areas of interests (AOIs) including eyes of the characters, mouth and chin region, and a salient object (ball) region. Gaze fixation counts and duration were calculated by measuring the frequency and duration of each individual fixation made within an AOI.

Results: Table 1 displays results of a 2-way ANOVA that examined the effect of developmental status (TD or at-risk) and age (3, 6, 9, and 12 months) on total gaze fixation. There was a significant effect of developmental status on total gaze fixation counts within the AOIs, $F(1, 60) = 5.57$, $p < 0.05$, $\omega = 0.13$. There was a non-significant effect of age ($p = 0.32$) and an interaction term between age and developmental status ($p = 0.67$). Independent samples T-tests were conducted to compare average gaze duration within AOIs (eyes, mouth, and object) in TD and at-risk groups. There was a significant difference in gaze duration towards the mouth between TD ($M = 5.46$, $SD = 5.38$) and at-risk groups ($M = 1.94$, $SD = 2.12$); $t(66) = 1.82$, $p < 0.05$. A significant difference was also found for gaze duration on the eyes between TD ($M = 6.80$, $SD = 6.16$) and at-risk groups ($M = 2.44$, $SD = 1.62$); $t(66) = 1.98$, $p< 0.01$ (see Figure 1).

Conclusions: This study was designed to understand the differences that exist in TD and infants at-risk for ASD for gaze patterns as they relate to social attention within the first year of life. Few studies focus on eye gaze trajectories during dynamic social paradigms in young infants. This study contributes to understanding early neurodevelopmental and endophenotypic mechanisms that could inform later atypical development.

101 **124.101** A Novel Parent Report Questionnaire of Early Behavioral Signs Between 6 and 24 Months of Age: The Autism Parent Screen for Infants

S. E. Bryson[1], L. A. Sacrey[2], L. Zwaigenbaum[2], J. A. Brian[3], I. M. Smith[4], W. Roberts[5], P. Szatmari[6], T. Vaillancourt[7], C. Roncadin[8] and N. Garon[9], (1)Autism Research Centre, Dalhousie/IWK Health Centre, Halifax, NS, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital/ U of Toronto, Toronto, ON, Canada, (4)Dalhousie

University / IWK Health Centre, Halifax, NS, Canada, (5)University of Toronto, Bracebridge, ON, Canada, (6)University of Toronto, Toronto, ON, Canada, (7)University of Ottawa, Ottawa, ON, Canada, (8)Kinark Child and Family Services, Markham, ON, Canada, (9)Psychology, Mount Allison University, Sackville, NB, Canada

Background: Identifying early impairments in children who will subsequently be diagnosed with Autism Spectrum Disorder (ASD) is crucial to ensure that they gain timely access to interventions that will improve functional outcomes. Although prospective studies of high-risk infants have increasingly focused on direct observation of infants' behavior during interactive assessments, prospective parent reports may provide valuable and complementary information. Parents are familiar with the infant's naturally occurring behaviors across varied contexts. This study reports on a novel parent-report questionnaire, the 'Autism Parent Screen for Infants' (APSI), which was developed as a parent-report analogue of the Autism Observation Scale for Infants (AOSI), an observational assessment designed to elicit ASD-related behaviors (Bryson et al., 2008).

Objectives: Our primary objective was to examine whether APSI scores distinguish high-risk infants ('HR'; older sibling diagnosed with ASD) who were diagnosed with ASD at 36 months from other HR and low-risk infants ('LR'; no family history of ASD) on repeat assessments from ages 6 to 24 months.

Methods: *Participants*: Three groups of children: (1) HR siblings who did not receive an ASD diagnosis at 36 months (HR-N; n = 138), (2) HR siblings who did receive a diagnosis of ASD at 36 months (HR-ASD; n = 66), and (3) infants without a family history of ASD (LR; n = 79). ASD diagnoses were based on an independent expert clinical assessment using the ADOS and ADI-R.

Parent Report Questionnaire: The APSI is a 26-item forced-choice questionnaire modeled in content from the AOSI (Bryson et al., 2008), thus including items enquiring about atypical patterns of eye contact, visual tracking, responding to name, imitation, language, social development, joint attention, gestures, play, visual examination of objects, and emotional regulation. Parents of LR and HR infants completed the APSI at 6, 9, 12, 15, 18 and 24 months.

Statistical Analyses: Performance on the APSI was compared using linear mixed modeling with Group (HR-ASD, HR-N, LR) and Age as Independent measures and APSI scores as the Dependent measure. Total scale score and groupings of questions by developmental domain (social-communication, sensory stimulation, temperament, and motor skills) were compared and group by age interactions were explored using Benjamini & Hochberg (1995) corrections.

Results: Total score on the APSI differentiated the HR-ASD group from HR-N and LR beginning at 6 months and at each subsequent age ($q < .036$). Subgroupings of questions also differentiated the HR-ASD group from the other two groups; social-communication at each time-point between 6 and 24 months ($q < .039$), temperament/reactivity from 12 to 24 months ($q < .025$), and sensory stimulation and motor skills from 9 to 24 months ($q < .031$; $q < .025$. respectively). Estimates of sensitivity and specificity at 12 months were 0.61 and 0.70, respectively.

Conclusions: The APSI shows promise as a simple, low-cost parent-report monitoring tool, which may lead to earlier identification of risk and implementation of interventions to remediate problematic behavior in children at-risk for ASD.

---

102 **124.102** A Preliminary Investigation of Child, Caregiver and Sociocultural Factors Influencing Caregiver-Reported Autistic Trait Scores on the Quantitative – Checklist for Autism in Toddlers (Q-CHAT) in an Unselected Sample of Asian Toddlers

I. Magiati[1], *D. A. Goh*[2], *D. Gan*[3], *J. Kung*[3], *B. F. Broekman*[4], *A. Rifkin-Graboi*[5], *P. K. Agarwal*[6], *H. Y. Chen*[7], *S. M. Saw*[8], *Y. S. Chong*[9], *K. Y. Kwek*[10], *P. ---

Background: There is increasing research evidence that individuals with a diagnosis of ASD lie at the extreme end of a continuum of quantifiable autistic traits and that there is moderate to high heritability of these traits in child, adolescent and adult community samples. Given this shift towards a dimensional conceptualization of ASD, a range of measures have been developed to dimensionally measure and quantify autistic traits, but to our knowledge only the Q-CHAT is available to measure autistic traits and related symptoms in toddlers. Autistic traits research has largely, if not exclusively, relied on informant report of sub-threshold symptoms, without considering whether other individual, informant or sociocultural factors may affect the reporting of autistic traits.

Objectives: This study aimed to explore the relationship between caregiver-reported autistic traits and a range of individual child (gender, IQ, birth order, verbal skills), maternal and socio-cultural

variables (maternal age, education, depressive symptoms and ethnicity). Specifically, the relationship of these variables with Q-CHAT Total as well as Factor scores (social/ communication; repetitive behavior; and language/ speech subscales derived following exploratory factor analysis) was examined.

Methods: Participants were 396 2-year old toddlers (205 males) from a sample of caregivers and their children recruited into an ongoing large longitudinal birth cohort study in Singapore (GUSTO – Growing Up in Singapore Towards Healthy Outcomes) who had completed the Q-CHAT at the 2-year old follow-up of this study. Demographic information was collected in earlier stages of the study and mothers also completed a measure of depressive symptoms at various time-points throughout the study.

Results: In preliminary regression analyses, children's higher verbal/ language scores predicted lower (i.e. less severe) Q-CHAT total, social-communicative factor and language factor scores. Increased maternal depressive symptoms also predicted higher Q-CHAT total and factor scores. When all child and maternal characteristics were considered together, maternal education, maternal depressive symptoms, children's birth order and verbal/ language scores were significant predictors of Q-CHAT total and behavioural trait scores. Child gender and IQ and ethnicity were not predictive of any autistic trait scores.

Conclusions: The findings from this study are discussed in relation to existing literature examining the potential influence of child and caregiver characteristics in reporting autistic traits and symptoms. The potential limitations of relying exclusively on informant-based measures of autistic traits for research examining autistic traits and the broader autism phenotype in unselected samples or families of individuals with ASD respectively is also discussed.

---

103   **124.103** Acoustic Properties of Affective Vocalizations Produced By Six-Month-Old High- and Low-Risk Infants

L. DiNicola[1], E. Schoen Simmons[1], F. Shic[2], R. Paul[3] and K. Chawarska[2], (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Sacred Heart University, Fairfield, CT

Background:
Intonation emerges in infancy, at approximately six months, in response to physiological changes to the vocal tract, perceptual biases and linguistic influences within the infant's environment (Stark et al., 1993). While nuclear intonation provides linguistic information, affective intonation conveys emotion (Cruttenden, 1997). Atypical cry intonation may emerge as young as six months in high-risk infants and may be a precursor of later affective intonation deficits associated with ASD (Sheinkopf et al., 2012). Despite recent literature regarding the vocalizations of high-risk infants, little is known about the acoustic properties of affective vocalizations in this population.
Objectives:
To examine the acoustic properties of affective vocalizations produced by six-month-old high- and low-risk infants.
Methods:
Thirty high-risk (HR) and twenty low-risk (LR) six-month-old infants were recruited from a larger study examining ASD symptoms in the first three years of life**.** A subset of the sample was coded for this abstract ($n = 7$), including four high-risk and three low-risk infants. At age three, all HR infants in this subset received an ASD diagnosis, and all LR infants were typically developing (TD). Five-minute speech samples were collected during quasi-naturalistic parent-child interactions (Paul et al., 2010). A research assistant blind to risk status acousticaly coded vocalizations for pitch range and mean fundamental frequency using Praat (Boersma, 2014). Vocalizations were also assigned a perceptual rating of either affective (i.e. positive or negative) or neutral (not conveying affect). Volubility of vocalizations was computed.
Results:
Both groups produced similar proportions of affective ($M_{hr} = 0.69$, $M_{lr} = 0.58$) and neutral ($M_{hr} = 0.31$, $M_{lr} = 0.42$) vocalizations. Independent t-tests revealed no significant effect of risk status on volubility for affective ($t(5) = -1.35$, $p = 0.24$) or neutral ($t(5) = -1.06$, $p = 0.34$) vocalizations. A linear mixed model analysis showed a main effect of affect ($F(1, 173.93) = 6.38$, $p < 0.05$; affective > neutral) and a trend toward an effect of risk status ($F(1,5.88) = 4.13$, $p = 0.09$; HR > LR) on pitch range. Planned comparisons also suggested trends toward between-group differences in pitch range for affective vocalizations ($F(1, 7.45) = 4.67$, $p = 0.07$; $HR_{affective} > LR_{affective}$). An additional linear mixed model revealed a main effect of affect ($F(1,158.23) = 19.38$, $p < 0.001$; affective > neutral) and a trend toward an effect of risk status ($F(1,5.22) = 3.09$, $p = 0.14$; HR > LR) on mean fundamental frequency.
Conclusions:
These preliminary results reveal intonation trends in the affective vocalizations produced by six-month-old HR infants later diagnosed with ASD. In this subset, HR infants produced higher- and more variably-pitched affective vocalizations. Analyses of the total sample will ascertain whether the observed trends translate into reliable effects. If so, as early as six months, HR infants' vocalizations may be shown to exhibit acoustic differences that are not evident perceptually (Paul et al., 2010). Ongoing full-sample analyses will include comparisons between 1) affective categories (positive and negative) and 2) diagnostic groups (HR-ASD, HR-BAP (broader autism phenotype), and LR-TD). We will

present the full sample at IMFAR.

104 **124.104** Adaptive Behavior Profiles in Toddlers with Autism Spectrum Disorders

R. E. Nevill[1], D. Hedley[2], N. Fields[3], Y. Monroy Moreno[4], J. Wilkins[5], J. A. Mulick[6] and E. Butter[5], (1)The Ohio State University, Columbus, OH, (2)LaTrobe University, Melbourne, Australia, (3)Kent State University, Kent, OH, (4)National Autonomous University of Mexico, Iztacala, Mexico, (5)Nationwide Children's Hospital, Westerville, OH, (6)Pediatrics, The Ohio State University, Westerville, OH

Background: Efforts have been made to lower the age at which ASD is first diagnosed. Additional diagnostic information, such as cognitive and adaptive behavior testing, can supplement results from an autism assessment to help improve clinical decision making. Several studies have explored the differences in adaptive behavior between children with autism spectrum disorder (ASD) and other developmental disabilities. An "autism profile" of adaptive behavior has been identified that ranks Vineland Adaptive Behavior Scale domain scores, from highest to lowest, as motor, daily living, communication, and socialization scales. Perry, Flanagan, Geier, et al. (2009) confirmed this profile in a large sample of children under 6 years, finding that children with ASD scored lower than children with ID on communication and socialization scores. Of interest is whether the same adaptive behavior profile is also found in toddlers aged 12 to 36 months since the introduction of the Vineland – II (VABS-II), the DSM-5 revised diagnostic criteria, and tools allowing for the earlier identification of ASD, such as the ADOS-Toddler Module.
Objectives: To identify and compare adaptive behavior profiles of toddlers diagnosed with ASD versus global developmental delay (GDD) based on DSM-5 criteria in a sample of toddlers referred to the developmental assessment center of a pediatric hospital.
Methods: A retrospective chart review was conducted to review clinical assessment records of children presenting for a diagnostic evaluation at the developmental disabilities clinic of a large Midwestern pediatric hospital. Children who presented with concerns of ASD or a developmental delay were evaluated using DSM-5 criteria, cognitive assessments, the VABS-II, and the appropriate ADOS module (Toddler, 1, or 2 few to no words) if concerns of ASD were presented. A final sample of toddlers with ASD (n=54) and global developmental delay (n=54) was used.
Results: VABS-II communication and daily living skills scores were significantly correlated with Mullen Early Learning Composite scores for toddlers with ASD. For the ASD sample administered with ADOS-Toddler module, a moderate negative correlation was found between VABS-II communication, socialization, and daily living skills scores and ADOS scores. VABS-II subdomain scores confirmed a pattern similar to that found by other studies of the "autism profile" in toddlers diagnosed with ASD using DSM-5 criteria. Additionally, toddlers with ASD were found to have comparable scores on the daily living and motor scales to toddlers with global developmental delay. Toddlers with ASD had significantly lower communication and socialization scores than toddlers with global developmental delay.
Conclusions: The "autism profile" of adaptive behavior is relevant for toddlers aged 12-36 months, and remains relevant for use with newer assessment tools and systems, specifically the VABS-II, and the DSM-5 criteria for ASD. This profile should be considered to supplement clinical decision making when required to make a differential diagnosis between ASD and another disorder in toddlers.
References: Perry, A., Flanagan, H. E., Geier, J. D., & Freeman, N. L. (2009). Brief Report: The Vineland Adaptive Behavior Scales in Young Children with Autism Spectrum Disorders at Different Cognitive Levels. Journal of Autism and Developmental Disorders, 39(7), 1066–1078.

105 **124.105** An Autism Screening Tool for Underserved Young Children: Preliminary Findings

Y. Janvier[1], J. Harris[2], D. S. Mandell[3], M. Xie[3] and M. Zuniga[2], (1)Medicine, Children's Specialized Hospital, Toms River, NJ, (2)Children's Specialized Hospital, Mountainside, NJ, (3)Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA

Background: Significant disparities have been identified among poor and minority children in the identification and treatment of ASD. Late diagnosis leads to later enrollment in intervention and potentially poorer outcomes. Multiple barriers to early diagnosis of underserved children may include reduced utility of existing ASD screening tools which require reading comprehension and parental recognition of behaviors that may be red flags for ASD.
Objectives: The objective of this study is to improve the identification of young children with ASD from traditionally underserved populations by refining and testing the utility of a new, visual ASD screening tool, the Developmental Check- In (DCI).
Methods: Items for the DCI were selected based on behaviors or skills noted to have the highest item discrimination on the ADOS and other measures, as well as based on clinical experience. Both photographs and line drawings were created to depict each item. In order to determine if the visual images were identified by parents from underserved populations as depicting the behavior or skill intended, cognitive interviews were conducted with parents of children with ASD or typically developing children from low income, racial or ethnic minorities or those with Spanish as the primary language.   Parents were also questioned regarding preference for line drawings or photographs.
  The target population of this study was children at risk for ASD between the ages of 24-60 months from minority groups, and/or with Medicaid as insurance, and/or whose parents speak Spanish as a primary language. Subjects were drawn from hospital-based developmental clinics and from Federally

Qualified Health Centers. At risk for ASD status was based on parent/caregiver or healthcare provider concern about child's language, social, and/or behavioral development. Parents of subjects completed the DCI, M-CHAT-R, Social Communication Questionnaire, a medical history form, adaptive behavior measure (ABAS) and demographic information.   The children were evaluated using the Mullen Scales of Early Learning and the ADOS-2. Hypothesis: The DCI will more accurately predict ASD diagnosis in this underserved population in comparison to MCHAT-R or SCQ.

Results: Photographs of the DCI items were better accepted and understood than were line drawings. For several of the items, direct translation of item labels into Spanish was confusing to parents who required more descriptive labels in order to adequately identify intent of the visual depiction. To date,   87 subjects have been evaluated with approximately 280 subjects expected by time of presentation.   Demographic data to date confirms representation of an underserved population with 55% of subjects reporting Hispanic/Latino ethnicity, 43% had a primary language other English and 97% of subjects had Medicaid coverage. Further analyses including comparison of the DCI to other ASD screening tools will be conducted by the time of presentation.

Conclusions: The results of this study will provide important information about the utility of a pictorial screening tool in a population in which English comprehension and literacy preclude the use of more text intensive screening strategies.

106   **124.106** Anogenital Distance (AGD): A Novel Biomarker of Elevated Fetal Androgen Activity in Toddlers with Autism?

A. L. Pohl[1], L. Ruta[2,3], A. Gagliano[4], M. L. Eisenberg[5], M. Hsieh[6] and S. Baron-Cohen[1,7], (1)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (2)Stella Maris Scientific Institute, Calambrone (Pisa), Italy, (3)Institute of Clinical Physiology, National Research Council of Italy, Messina, Italy, (4)Department of Paediatrics, University of Messina, Messina, Italy, (5)Department of Urology, Stanford University, Stanford, CA, (6)Department of Urology, Children's National Health System, Washington, DC, (7)CLASS Clinic, Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom

Background: During a critical period of prenatal brain development, fetal steroid hormones, particularly fetal testosterone (fT), may contribute to the etiology of autism, as fT is elevated in children who go on to develop autism spectrum conditions (ASC) and is positively correlated to autistic traits in typically developing (TD) children. Direct measure of fetal steroids is only possible in convenience samples of women undergoing amniocentesis. Thus, a robust biomarker of fT exposure is needed to assess the contribution of fT to the autism phenotype in wider studies. Right hand 2nd digit to 4th digit (R2D:4D) ratio, a biomarker of fT activity, has been previously shown to be masculinized in ASC. However, R2D:4D is also influenced by postnatal steroid levels, and the effect size of sex upon fT is weak, especially in early development, limiting its utility as a biomarker of fT activity. Anogenital distance (AGD), which is determined by fT in the prenatal male programming window (gestational weeks 8-14), has been suggested as a superior biomarker of fT activity.

Objectives: To test whether toddlers with ASC have increased AGD, indicative of increased fetal androgen activity, compared to controls.

Methods: Anopenile distance was measured in male toddlers with ASC (n=29) and in male controls (n=24) using electronic callipers. Groups were frequency matched on age and BMI (ASC n=28, control n=12).

Results: Groups did not differ on age or BMI (p>0.05). Males with ASC had a longer AGD than controls. (Mean ± SD; ASC 80.6 ± 7.4, CTR 74.8 ± 8.9, p = 0.017, Cohen's d=0.71).

Conclusions: Consistent with the predicted role of fT in the development of autism, children with ASC had significantly greater AGD, indicating increased fT activity during gestational weeks 8-14. With further research, AGD may be a useful biomarker, measurable at birth, for risk of ASC linked to elevated prenatal testosterone activity in autism.

107   **124.107** Associations Between Behavior Problems and Dopaminergic Variants in High- and Low-Risk Siblings

D. N. Gangi[1], D. S. Messinger[2], L. V. Ibanez[3], W. L. Stone[3], M. L. Cuccaro[4] and E. R. Martin[4], (1)5665 Ponce de Leon Blvd, University of Miami, Coral Gables, FL, (2)University of Miami, Coral Gables, FL, (3)Psychology, University of Washington, Seattle, WA, (4)Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL

Background: Children with autism spectrum disorder (ASD), as well as their younger siblings (high-risk siblings), exhibit substantial heterogeneity in behaviors. Children's behavior problems have important implications both for children with ASD and their families. High levels of internalizing and externalizing behavior problems have been reported in both children with ASD (Mahan & Matson, 2011; Maskey, Warnell, Parr, Couteur, & McConachie, 2013) and in their high-risk siblings (Fisman et al., 1996; Rodrigue, Geffken, & Morgan, 1993; Verte, Roeyers, & Buysse, 2003). In children with ASD, behavior problems are also associated with the severity of ASD symptomatology (Pearson et al., 2006), as well as broader family factors such parent stress and depression (Davis & Carter, 2008; Ekas & Whitman, 2010). In typically developing children and children with ASD, dopaminergic variants have been associated with behavioral difficulties. As behavior problems may be particularly relevant to ASD symptomatology and family emotional factors in high-risk siblings, identifying common genetic variants

associated with behavior problems would enable potential early identification of behavioral targets for early intervention.

Objectives: Examine the role of dopaminergic variants associated with behavior problems, *DRD4* and *DRD2*, in externalizing and internalizing problems at three years in siblings at high and low risk for ASD.

Methods: High-risk (*n*=37) and low-risk (*n*=27) siblings were genotyped for *DRD4* and *DRD2*. A dopamine gene score was created for each child, ranging from 0-2, indicating the number of alleles associated with lower dopaminergic functioning (7-repeat allele of *DRD4* and A allele of *DRD2*). At 36 months, parents reported behavior problems (Externalizing and Internalizing Problems) using the Child Behavior Checklist (CBCL).

Results: Regression models were constructed for CBCL Externalizing and Internalizing Problems to assess effects of the dopamine score, risk group status, and their interaction. For Externalizing Problems (see **Figure 1**), neither status, b=-0.55, *t*=-1.37, *p*=.89, nor dopamine score, b=-3.95, *t*=-1.20, *p*=.24, were significant predictors. There was a dopamine score*status interaction effect, b=8.97, *t*=2.06, *p*=.045, suggesting a moderating role for status. For Internalizing Problems (see **Figure 2**), neither status, b=-2.71, *t*=-0.79, *p*=.43, nor dopamine score, b=-4.35, *t*=-1.55, *p*=.13, were significant predictors. There was a dopamine score*status interaction effect, b=11.73, *t*=3.17, *p*=.003, again suggesting a moderating role for status.

Conclusions: Associations between dopaminergic functioning and behavior problems were moderated by risk group. Lower dopaminergic functioning (indexed by higher dopamine gene scores) was associated with higher levels of behavior problems (externalizing and internalizing) at three years in high-risk siblings. Low-risk siblings exhibited the opposite pattern, suggesting differential susceptibility. In the presence of familial risk for ASD, lower dopaminergic function was associated with increased behavior problems. Knowledge of common genetic variants associated with ASD-relevant behaviors may aid in identifying those high-risk siblings at greatest risk for difficulties relevant to ASD-related outcomes and family functioning. Those high-risk siblings at greatest genetic risk represent an appropriate target for prophylactic early intervention.

108 **124.108** Attention Shifting from Emotional Faces in High-Risk Infants and Relations with Later Social-Communicative Behavior

J. B. Wagner[1], B. Keehn[2], H. Tager-Flusberg[3] and C. A. Nelson[4], (1)Department of Psychology, College of Staten Island, CUNY, Staten Island, NY, (2)Purdue University, West Lafayette, IN, (3)Boston University, Boston, MA, (4)Division of Developmental Medicine, Boston Children's Hospital, Harvard Medical School, Boston, MA

Background: Studies with individuals with ASD and their first-degree relatives have found difficulties in face processing as well as more general atypicalities in visual attention. Prospective studies of infants at high-risk for autism (HRA; defined as having an older sibling with ASD) allow researchers to examine the origins of these difficulties to help understand how these domains could be linked to later developmental difficulties.

Objectives: The present study examined attention disengagement from emotional faces in HRA and low-risk control (LRC) infants. Attention shifting was then analyzed alongside prospective social-communicative behavior with the aim of using early visual attention to predict later development within the broader autism phenotype.

Methods: Attention disengagement in HRA and LRC was tested in 6- (HRA: 30; LRC: 34), 9- (HRA: 34; LRC: 25), and 12-month-olds (HRA: 29; LRC: 28). Infants receiving a subsequent clinical judgment of ASD were not included in the present sample. Each trial presented one of three emotional faces (happy, fearful, neutral) in the center of the screen for 1s, then the face remained present while a distracter appeared on the left or right. A Tobii T60 eye-tracker recorded gaze, and for each emotion, latency to shift from face to distracter and percentage of no-shift trials were calculated. Parents completed the Communication and Symbolic Behavior Scales (CSBS) at 18 months.

Results: For latency to shift from faces, infants showed a main effect of emotion ($p = .012$), with slower shifting from fearful as compared with happy and neutral faces ($ps < .015$). A significant age*group interaction was also found ($p = .025$), with LRC showing decreasing shift latency with age, while HRA show the opposite pattern (Figure 1). Analysis of no-shift percentage revealed a main effect of emotion ($p < .001$), with a greater percentage of no-shifts found for fearful faces compared with happy and neutral ($ps < .05$), and happy greater than neutral ($p = .027$). A significant age*group interaction ($p = .033$) revealed that HRA show increasing no-shift percentage with age, while LRC show no age-related differences. Correlations were run at each age between eye-tracking measures and CSBS 18-month social and total scores. At 6 months, HRA showed a positive association between disengagement latency from fearful faces and CSBS total scores ($p = .044$; Figure 2). At 9 months, HRA showed a positive association between no-shift percentage to fearful faces and CSBS social scores ($p = .05$). No other correlations were significant.

Conclusions: Similar to past work, we found slower shifting and increased no-shifts for fearful faces, and this emotion-specific pattern was comparable for LRC and HRA. HRA infants with more normative responses to fearful faces also showed better social-communicative outcomes. Across emotions, our results show diverging trajectories of increasing and decreasing disengagement efficiency during the first year of life in low-risk and high-risk infants, respectively. These findings are representative of the broader autism phenotype, as this sample excluded infants with an ASD diagnosis. Future work will examine whether infants later diagnosed with ASD differ on these emotion and attentional measures.

124.109 Attention and Proximity to Threat Among Toddlers with Autism Spectrum Disorders

G. Greco[1], S. Macari[2], L. DiNicola[1], L. Flink[2], S. S. Lansiquot[2] and K. Chawarska[2], (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT

Background: Among children with autism spectrum disorders (ASD), comorbidity with anxiety disorders later in life is common, affecting up to 40% of youth with ASD (van Steensel, Bogels, & Perrin, 2011). In non-ASD populations, social inhibition and anxiety have been linked to individual differences in attention and proximity to a threatening stimulus during early childhood (Crockenberg & Leerkes, 2004, 2006). Little is known about proximity and attention to threat or their relationship to negative affectivity, a precursor to later anxiety, among toddlers with ASD.
Objectives: The first goal was to investigate differences between toddlers with ASD and TD in terms of attention and proximity to threat. The second goal was to investigate the associations between these variables and parent-reported negative affectivity.
Methods: Participants were 20 toddlers from 13.9 to 28.3 months of age (M=20.6 months) with ASD (n=12) and typical development (TD; n=8). Behavioral samples were taken from the Spider Episode portion of the Laboratory Temperament Assessment Battery (LabTAB; Goldsmith, et al., 1987), during which children sat next to their parents as a large, realistic remote-controlled spider crawled toward them. Proximity variables included proportion of the episode the participant spent approaching the spider, staying in place/not moving, or escaping. Attention was measured using the proportion of the episode spent looking at or away from the spider. Negative Affectivity was derived from the Early Childhood Behavior Questionnaire (ECBQ; Putnam, Gartstein, & Rothbart, 2006) with subscales including Fear, Discomfort, Frustration, Motor Activation, Perceptual Sensitivity, Sadness, Shyness, and Soothability.
Results: Groups differed in proximity to the spider, with toddlers with ASD approaching for a larger proportion of the episode compared to toddlers with TD, $t(18) = -2.01$, $p = .06$. The TD group stayed in place for a larger proportion compared to the group with ASD, $t(18) = 2.18$, $p = .04$. Effect sizes were large: approach, $d = .95$; staying in place, $d = 1.03$. Groups did not differ in the time spent escaping from, looking at, or looking away from the spider. Within both groups, the Negative Affectivity composite was moderately positively correlated with proportion of time spent escaping ($r = .38$, $p = .12$).
Conclusions: Our findings show that toddlers with ASD are more likely to approach a threatening stimulus than toddlers with TD, who are more likely to stay in place compared to the ASD group. Higher levels of approach suggest an atypical response to threat in very young children with ASD. Additionally, longer escape behavior was observed in those toddlers with greater parent-reported negative affectivity, highlighting the relationship between a fear response (escape) and a precursor of anxiety (negative affectivity). By May, we expect to have results for approximately 35 children in each group (N= 70). With these greater numbers we will be able to evaluate correlations within both the ASD and TD groups.

124.110 Attention to Conspecific Auditory Information in Infants at-Risk for Autism

J. D. Ference[1], A. Sorcinelli[2], S. Curtin[1] and A. Vouloumanos[2], (1)University of Calgary, Calgary, AB, Canada, (2)New York University, New York, NY

Background: In typical development, infants demonstrate perceptual biases that direct their attention to socially relevant, conspecific information (e.g., voices and faces of the same species; Johnson, Dziurawiec, Ellis, & Morton, 1991; Vouloumanos & Werker, 2004, 2007), which may facilitate infants' ability to become competent linguistic and social beings (e.g., Tomasello, 2008; Werker & Curtin, 2005). For example, 3-month-olds prefer looking at human faces over gorilla and monkey faces (Heron-Delaney, Wirth, & Pascalis, 2011) and they prefer listening to human speech over nonspeech and rhesus monkey vocalizations (Shultz & Vouloumanos, 2010, Vouloumanos, et al., 2010). However, children diagnosed with Autism Spectrum Disorder (ASD) process auditory and visual information from conspecifics differently (Kuhl, et al., 2005; Chawarska, Volkmar, & Klin, 2010). Differences in these early biases could have cascading effects in development, suggesting that atypical conspecific biases in infancy may form the basis of the social communication difficulties characteristic of ASD (Surian & Siegal, 2008; Volkmar, Chawarska, & Klin, 2005).
Objectives: To examine whether 7 to 9-month-old infant siblings of children diagnosed with ASD (SIBS-A) attend to auditory conspecific information in the same way as infant siblings of typically developing children (SIBS-TD). Approximately 19% of SIBS-A will also be diagnosed with ASD by 3 years of age, thus representing a high-risk population of interest to researchers examining the early development of ASD (Ozonoff, et al., 2011).
Methods: Infants were tested using the Infant-controlled Sequential Looking Preference Procedure (*see* Cooper & Aslin, 1990, 1994). The infants viewed 6 test trials consisting of 3 human speech ('keev', 'ploo', 'boola', etc.) and 3 monkey call (coos, girneys, warbles) trials paired with the static image of a bullseye on a monitor. Stimulus presentation was contingent on infants looking toward the monitor. We hypothesized that SIBS-TD would look longer to the human speech test trials and that SIBS-A would not differentially attend to either trial type.
Results: We found a significant interaction between risk group status and attention to the human speech versus monkey calls, $F(1, 63) = 4.16$, $p = .046$. Follow-up comparisons revealed that SIBS-TD

($n = 41$) looked significantly longer during the monkey call trials ($M = 19.75$s, $SD = 9.01$) versus the human speech trials ($M = 16.49$s, $SD = 9.16$; $t(1, 40)=2.77$, $p = .009$); whereas SIBS-A ($n = 24$) did not demonstrate a clear preference for either stimulus (human: $M = 17.71$s, $SD = 9.01$; monkey: $M = 17.27$s, $SD = 8.45$; $p = .729$).

Conclusions: Our hypothesis was partially supported in that SIBS-A did not demonstrate a clear preference for either trial type, whereas SIBS-TD preferred the monkey calls. Stimulus preferences may shift during development such that younger infants prefer familiarity whereas older infants prefer novelty (Hunter & Ames, 1988). Compared with younger infants who prefer human speech over monkey calls (Vouloumanos et al., 2010), our results suggest a possible shift toward preferences for novelty by 7 to 9 months in TD infants in favour of monkey calls. These findings may have implications for the development of social communication.

111   **124.111** Attentional Protective Factors in Typically-Developing 6-Month-Old Girls at High-Risk for Autism

F. Shic[1], S. Macari[2] and K. Chawarska[2], (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT

Attentional Protective Factors in Typically-Developing 6-month-old Girls at High-Risk for Autism

Background: Recent studies have highlighted potential neuroprotective factors against the development of ASD that are associated with being of female gender (Robinson et al., 2013). Prospective longitudinal studies of the infant siblings of children with ASD offer the possibility of examining how these gender-specific neuroprotective factors manifest developmentally in those siblings who go on to show typical development. Given recent evidence that infant siblings who go on to develop ASD show atypical patterns of visual scanning of social scenes in the first year of life (Chawarksa et al., 2013; Klin et al., 2013; Shic et al., 2014), it is possible that gender differences in visual exploration may manifest early in development in the attentional patterns in unaffected siblings.

Objectives: To use eye tracking to examine gender differences in looking patterns towards social scenes in the first two years of life in high-risk (HR) infant siblings who receive a later diagnosis of typical development.

Methods: Participants were high- and low-risk (LR) infant siblings of children with ASD enrolled in a prospective, longitudinal study of social attention and who were judged by a multidisciplinary diagnostic team to have typically developing (TYP) outcomes at 24 or 36 months of age: HR-TYP F (n=23), HR-TYP M (n=25), LR-TYP F (n=30), LR-TYP M (n=29). All groups were comparable and in the typical range for: chronological age, verbal and nonverbal ability, and presence of autism symptoms. Participants were presented with videos of an actress emulating a bid for dyadic engagement (Spontaneous Social Monitoring Task; Chawarska et al., 2013,2014) at 6, 12, 18, and 24 months of age while their scanning patterns were recording using eye tracking. Outcome measures included longitudinal changes percentage of time looking at the scene (%Valid), the actress (%Person), and her mouth (%Mouth).

Results: Longitudinal mixed effects modeling with quadratic effects of age and fixed effect of group showed increasing %Valid and %Mouth with age in all groups (p<.05). In the LR-TYP group no gender effects were observed at any time point on any outcome measure. Relative to the LR group, the HR-TYP boys showed diminished %Valid at 12 and 18 months (p<.05) and trends for diminished %Mouth before from 6 to 18 months (p~.10). The HR-TYP girls showed increased %Valid relative to HR-TYP boys and LR-TYP girls (p<.05), and greater %Person and %Mouth compared to all other groups (p<.05).

Conclusions: High-risk infant sibling girls who develop typically show heightened attentional responses to social and communicative information early in development relative to both high-risk typically developing boys and low-risk infants. These results contrast with observed viewing strategies in high-risk TD boys, who show some evidence of residual scanning strategies more similar to HR-boys who develop ASD. Given positive predictive relationships between mouth looking and later language acquisition, and the importance of attending to people in social motivation frameworks of ASD, our results are consistent with increased risk in HR boys and attentional protective factors in HR girls.

112   **124.112** Can ASD and ADHD Symptoms in Children with Autism Predict Early Attentional Disengagement in Their Infant Siblings?

C. H. Cheung[1], E. Jones[2], T. Gliga[2], G. Pasco[1], M. H. Johnson[2] and T. Charman[1], (1)Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom

Background: Studies with infants with older siblings with autism spectrum disorder (ASD) (probands) suggest that difficulties in visual disengagement may be one of the earliest emerging features of ASD (Zwaigenbaum et al., 2005; Elsabbagh et al., 2009; Elsabbagh et al., 2013). At 9-10 months, infant siblings of children with ASD took significantly longer to disengage from a central fixation and orient to peripheral stimuli compared to low-risk controls (Elsabbagh et al, 2009). To date, no studies have investigated whether ASD or attention-deficit/hyperactivity disorder (ADHD) symptoms in the proband predict attentional disengagement in their infant siblings. As ASD co-occurs frequently with ADHD, a

condition in part characterized by attentional difficulties, there is a need to consider the role of ADHD symptoms in early attentional markers of ASD.

Objectives: To examine the relation between ASD and ADHD symptoms in probands and attentional disengagement in their infant siblings at 8 and 14 months.

Methods: A cohort of 108 infants with an older sibling with ASD completed the gap-overlap task (Elsabbagh et al, 2009) at 8 months and 14 months. In a series of trials, infants were presented with a central stimulus (CS) followed by a peripheral stimulus (PS); reaction time (RT) to saccade to the PS was measured using eye-tracking technology. There were three conditions: Baseline (CS disappeared as PS onset), Gap (CS disappeared 200ms prior to PS onset) and Overlap (CS and PS on screen at the same time). Key dependent variables at 8 month and 14 months were the number of trials in which the infant failed to saccade to the PS within 1.2 seconds of onset, and mean RT in the Overlap condition. Proband ASD symptoms were measured with the Social Communication Questionnaire (SCQ), and ADHD symptoms with the hyperactivity and inattention symptom subscale of the Strengths and Difficulties Questionnaire (SDQ) reported by the parents on the children with ASD (mean age = 7.05 years, S.D.=2.46; 91% male).

Results: More severe proband ASD symptoms predicted more frequent disengagement failure (rho = 0.29, p<0.01), and slower disengagement times at 8 months (t=-2.61, p=0.01); but not at 14 months (rho = 0.03, p=0.73; t=-0.58, p=0.56; respectively). Proband ADHD symptoms did not relate to disengagement failure in infant siblings at either time points (all ps>0.30). However, more severe proband ADHD symptoms significantly predicted faster disengagement speed in the infant siblings at 8 months (t=-2.61, p=0.01) but not at 14 months (t=-0.58, p=0.56).

Conclusions: Proband ASD and ADHD symptoms predicted infant sibling attentional disengagement at 8 months, but this effect was not observed at 14 months. While greater levels of ASD symptoms in probands related to greater difficulty with disengaging from the central stimulus, proband ADHD symptoms predicted faster orienting in overlap conditions. Our findings highlight the importance of taking into account ADHD symptoms when studying infants with familial risks for ASD.

---

113   **124.113**   Catching up Vs. Falling behind: Longitudinal Investigation of Developmental and Adaptive Skills in Toddlers with ASD

J. Lorenzi[1,2], *C. Klaiman*[2], *C. A. Saulnier*[2] *and S. Hoffenberg*[2], *(1)Virginia Tech, Blacksburg, VA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA*

Background: Previous research has demonstrated deficits in adaptive skills in toddlers with ASD, particularly socialization skills (Ventola et al., 2014). Likewise, high-risk samples have characterized various trajectories of developmental skills in ASD between infancy and toddlerhood, with a recent study identifying stable-average and declining trajectories as those most common (Brian et al., 2014). However, the trajectory of adaptive skills and their relation to overall development in early toddlerhood (i.e., age 3 and earlier) is less clear.

Objectives: This study seeks to examine longitudinal changes in developmental and adaptive skills among toddlers with ASD.

Methods: Participants included 24 toddlers (20 males) from a community-referred sample whose families expressed developmental concerns and enrolled in a longitudinal study on social engagement. Two separate visits spanned an average of 15 months (mean age in months at initial visit = 22.89, SD = 4.38), and first-time ASD diagnoses were provided by a multidisciplinary team. Families were offered recommendations regarding interventions that they might choose to pursue (87.5% of families reported subsequent involvement in intervention, with speech therapy, occupational therapy, and special education most commonly endorsed). In addition to the Autism Diagnostic Observation Schedule, Second Edition, toddlers completed a developmental assessment (Mullen Scales of Early Learning) and parents completed an interview on their child's adaptive behavior (Vineland Adaptive Behavior Scales, Second Edition) at both visits. Analyses compared standardized scores across time points.

Results: Paired-samples t-tests indicated that Mullen t-scores improved significantly between the two visits on the scales of Receptive Language, $t(23)$ = -3.86, p < .01, and Expressive Language, $t(23)$ = -2.35, p = .03, with a trend in the direction of scores on Visual Reception having improved significantly, $t(23)$ = -1.98, p = .06 (Table 1). However, Fine Motor t-scores became significantly worse between visits, $t(23)$ = 2.47, p = .02. Paired-samples t-tests with Vineland Standard Scores indicated that Communication skills improved significantly between visits, $t(23)$ = -2.72, p = .01, while Daily Living Skills remained statistically unchanged, $t(23)$ = 1.56, p = .13. However, adaptive skills of both Socialization, $t(23)$ = 2.86, p = .01, and Motor Skills, $t(23)$ = 2.90, p = .01, became significantly worse.

Conclusions: Across most scales/domains of the Mullen and Vineland, community-referred toddlers with ASD evidenced developmental progress between their second year of life and approximately age three, as represented by significantly improved standard scores (Receptive Language, Expressive Language, Communication), or standard scores that remained comparable across time points (Visual Reception, Daily Living Skills). Standard scores in the area of Motor Skills became significantly worse on both measures. Interestingly, despite improved scores in the areas of Receptive and Expressive Language, and also Communication, toddlers evidenced significantly worse Vineland scores in the domain of Socialization. Results highlight the need for interventions that target not only increasing speech/communication, but also improving social interaction, play, and motor skills, which in spite of

treatment continue to fall rapidly behind relative to peers. Future research should seek to identify interventions that embed socially-oriented goals into all treatments for young children with ASD.

114 **124.114** Cerebellum Enlargement in 4-6-Month-Old Infants at High Familial Risk of Autism Spectrum Disorders

I. Pote[1], *S. Wang*[2], *A. Blasi*[3], *T. Charman*[4], *E. Daly*[1], *M. H. Johnson*[3], *M. Kuklisova-Murgasova*[5], *S. Lloyd-Fox*[3], *E. Mercure*[6], *V. Sethna*[1], *S. Williams*[7], *D. G. Murphy*[1] and *G. M. McAlonan*[1], (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (2)Department of Engineering Science, Institute of Biomedical Engineering, University of Oxford, Oxford, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (4)Department of Psychology, Henry Wellcome Building, King's College London, London, United Kingdom, (5)Division of Imaging Sciences and Biomedical Engineering, King's College London, London, United Kingdom, (6)University College London, Institute of Cognitive Neuroscience, London, United Kingdom, (7)Department of Neuroimaging, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom*

Background: Imaging studies of typical brain development highlight that the first two years of life are a time of dynamic growth. However, very little is known about early brain development in infants at high familial risk of autism spectrum disorder (ASD), prior to the age of two. At present, only two other groups have studied high-risk infants at 6-months of age, with one group finding no significant differences in intracranial, cerebrum, cerebellum or lateral ventricular volume (Hazlett et al., 2012), and the other finding significant enlargements in total brain volume and extra-axial fluid (Shen et al., 2013).

Objectives: In this study, magnetic resonance imaging (MRI) was used to investigate the differences in regional brain volumes from a sample of 4-6-month-old infants at high-risk of ASD, relative to a group of infants at low-risk. Infants were considered to be at 'high-risk' if they had an older sibling with a diagnosis of ASD, and at 'low-risk' if they had an older sibling who was typically-developing.

Methods: 31 (n=22 'high-risk', n=9 'low-risk') infants were scanned in natural sleep at 4-6-months of age on a 1.5T scanner. T2-weighted structural MRI images were acquired. The images were volumetrically segmented following an in-house automated protocol, which was based on the intensity distributions of the regions of interest, and made use of a probabilistic atlas. Following this, manual editing was carried out 'blind' to participant group. The intracranial, subcortical grey, total cerebrospinal fluid, cerebellum, midbrain, and lateral ventricular volumes were compared between groups, using a General Linear Model. The analysis was conducted on SPSS v.21, and the model controlled for age and gender.

Results: We found a significant group difference in the cerebellar volume [$F_{(1,23)}=4.420$, $p=0.047$], with the infants at high-risk of ASD showing a significantly greater volume than those at low-risk. In addition, we also found a significant group by age interaction [$F_{(1,23)}=4.307$, $p=0.049$], which was explained by a distinct relationship between age and cerebellar volume in infants at high-risk of ASD ($r=0.807$, $p=0.0001$), relative to those at low-risk ($r=0.771$, $p=0.015$). Between the ages of 120-150 days, infants at high-risk of ASD show larger cerebellar volumes that those at low-risk. However, by the age of 160 days, this pattern seems to be reversed (Figure 1). No other significant results were found.

Conclusions: We emphasize that these results are preliminary and that data acquisition is still in progress. Nevertheless, this data suggests that within the first 6 months of life there are differences in the trajectory of cerebellar growth in infants at high-risk of ASD, relative to those at low-risk. Besides continuing with data acquisition, we are following up our participants until at least 3-4 years of age. We hope, eventually, to identify patterns of brain development before 6 months of age which signpost the future diagnosis of ASD in those infants at high familial risk.

115 **124.115** Characterising 'other Developmental Concerns (ODC)' at 36 Months in Infants at Familial High-Risk for Autism Spectrum Disorder: A Bsrc Study

ABSTRACT WITHDRAWN

Background: Approximately 20% of HR infant siblings are diagnosed with ASD at 36 months of age and a further 20% show other sub-optimal developmental profiles (Messinger et al., 2013). However, the pattern of these ODC and whether they are associated with early development or sex has not been determined.

Objectives: N/A

Methods: 1,931 infant siblings (1,330 HR; 601 LR) from 15 different BSRC sites were recruited. The N=330 siblings with an ASD diagnosis at 36m were excluded (321 HR, 9 LR) leaving 1,601 siblings (1,009 HR, 592 LR). 36 month outcomes were defined as: Broader Autism Phenotype (BAP): ADOS severity score > 4 regardless of Mullen scores; Subthreshold ASD (Sub): ADOS severity score = 3 no Mullen subtest t score < 30 and at most 1 Mullen subtest t score < 35; Developmental Delay (DD): ADOS severity score < 3 combined with 2 or more Mullen subtest t scores < 35 or 1 or more subtest t scores < 30; or Typical Development (TD).

Results:
Multinomial logistic regression was used to test whether risk status (HR vs. LR) and sex (male vs.

female) was associated with ODC outcome group (Table 1). Compared to TD children those categorised as BAP were more likely to be HR (relative risk ratio (RRR): 1.84 (95% CIs: 1.33 to 2.53), p<.001) and male (RRR: 1.52 (1.13 to 2.04), p<.01). Those who were categorised as Sub were more likely to be HR (RRR: 2.52 (1.51 to 4.18), p<.001) and those who were DD were more likely to be HR (RRR: 3.03 (1.55 to 5.90), p=.001) and male (RRR: 3.43 (1.86 to 6.32), p<.001).

In order to examine whether developmental abilities at earlier timepoints (6, 12, 18, 24 months) was associated with ODC outcomes the Mullen ELC was added to the model (Figure 1). Lower ELC at 6m was marginally associated with an increased likelihood of being in the BAP group (RRR: 0.99 (0.97 to 1.00), p=.06). Lower ELC at 12m was significantly associated with an increased likelihood of being in the DD group (RRR: 0.97 (0.95 to 0.99), p<.01). Lower ELC at 18m was associated with an increased likelihood of being in the BAP group (RRR: 0.98 (0.96 to 1.00, p<.05) and the DD outcome category (RRR: 0.96 (0.93 to 0.99), p<.01). Lower 24m ELC was associated with being in the DD group (RRR: 0.93 (0.91 to 0.95), p<.001).

Conclusions: One quarter of HR siblings fell into one of the ODC groups. Each of these outcomes was also seen in the LR siblings, albeit at around half the rate. Boys were more likely than girls to be in these ODC groups. Earlier developmental abilities only weakly predicted outcomes, with the exception of DD where Mullen scores were low from 6 months onwards. Further analysis will explore the clinical utility of these outcome groupings to help establish if they should be used when reporting HR infant sibling studies.

---

116   **124.116** Clinical Correlates of Social Affect in Early Infancy: Implications for Early Identification of Autism Spectrum Disorder

J. Bradshaw[1], L. K. Koegel[2] and R. L. Koegel[2], (1)Clinical, Counseling, and School Psychology, University of California Santa Barbara, Santa Barbara, CA, (2)Koegel Autism Center, University of California Santa Barbara, Santa Barbara, CA

Background: Earlier intervention for infants and toddlers with autism spectrum disorder (ASD) enhances developmental gains (Rogers, et al. 2012) and necessitates ascertainment of early, reliable indicators of ASD. Diminished positive social affect, also termed social smiling, has been among the leading hypothesized risk factors for ASD in the prelinguistic period, between 6-12 months of age. However, research has resulted in mixed findings for the predictive value of social engagement in 6-9-month-old infants for the development of ASD. If abnormalities in infant social affect contribute to the early phenotypic expression of ASD, it is important to determine whether diminished social affect is a unique construct associated exclusively with social impairments or if it is, alternatively, an expression of normal variation in individual development better explained by temperamental style.

Objectives: The current study sought to enhance the understanding of atypical social development in early infancy by investigating individual differences in social engagement. Positive social affect exhibited by 6-8-month-old infants during naturalistic parent-infant interactions was correlated with four dimensions of behavior relevant to early identification of ASD: social-communication, vocal production, and autism symptomology. Temperament was included as a control measure of individual behavioral style, often considered to be independent of developmental psychopathology.

Methods: Participants included 33 dyads of 6-8-month-old infants and their mother. Each dyad participated in a videotaped semi-structured face-to-face interaction that was later coded for infant expression of directed positive affect. Positive social affect was coded in ten-second intervals using a previously developed affect rating scale (Koegel et al., 2014). Time spent engaging in positive social affect was then correlated with clinical measures of social-communication (CSBS Social Composite and Mullen Receptive Language), vocal production (CSBS Speech Composite), autism symptomology (Autism Observation Scale for Infants), and temperament (Infant Behavior Questionnaire).

Results: Overall, the proportion of time infants spent exhibiting positive social affect ranged from .00 to .60 with an overall mean of .32 (SD=.18). Analyses revealed a positive association between positive social affect and receptive language (r=.428, p=.007). No significant relations were observed between positive social affect and other clinical measures, including vocal production (r=-.118, ns), autism symptomology (r=-.166, ns), or the three dimensions of temperament (Surgency: r=.042; Negative Affect: r=.098; Effortful Control: r=-.125). Age and gender were not significantly associated with the primary measure of positive social affect. Further, overall attention the caregiver's face regardless of affect revealed no significant associations with clinical measures.

Conclusions: These results suggest that positive social affect in early infancy may be a uniquely meaningful indicator of social responsivity and perhaps social motivation. The lack of association between positive social affect and other clinical measures, including temperament, may suggest that this is a specific behavioral marker for low social responsivity and possibly ASD. Additionally, the lack of relation between total time looking to the caregiver's face and clinical measures suggests that overall social attention at this age is not indicative of social-communicative skills. Further research is needed to understand how diminished positive social affect in early infancy may impact later developmental outcomes, including development of ASD.

---

117   **124.117** Cognitive and Adaptive Functioning of Children Who Lose Their ASD Diagnosis

E. Moulton[1], M. L. Barton[1] and D. A. Fein[2], (1)Psychology, University of Connecticut, Storrs, CT, (2)University of Connecticut, Storrs, CT

Background:
Emerging literature has indicated that a subset of children with a documented Autism Spectrum Disorder (ASD) lose their diagnosis and function in the average range of cognition and behavior. Following an early ASD diagnosis, these children experience significant improvements in ASD symptoms, cognitive abilities and adaptive skills during their toddler years. Children who lose an ASD diagnosis might be expected to display residual difficulties in social or language functioning. This study aims to characterize children who lose the diagnosis at an early age.
Objectives:
To compare the cognitive and adaptive functioning of toddlers who demonstrate highly positive outcomes from an early ASD diagnosis to peers with high functioning autism and to typically developing (TD) peers.
Methods:
Developmental and diagnostic evaluations were conducted at approximately 26 months following positive screening on an autism-specific screener (MCHAT(-R)). The Autism Diagnostic Observation Schedule (ADOS), Mullen Scales of Early Learning (Mullen), Vineland Adaptive Behavior Scales (VABS II), and Childhood Autism Rating Scale (CARS) were completed. Diagnosis was assigned based on the clinical judgment of experienced clinicians. At approximately 50 months, children were re-evaluated. The current study utilizes three groups of children (Optimal Progress (OP), HFA, TD). The OP group includes children who initially met criteria for an ASD, no longer meet criteria for any ASD, and demonstrate functioning in the average range (within 1.5SD of the mean) on standardized measures of cognition, language, social and communicative skills. Children in the HFA group met criteria for an ASD at both evaluations and are functioning within 1.5SD of the mean on cognitive measures. Children in the TD group did not meet criteria for any clinical diagnosis and are functioning within 1.5SD of the mean on cognitive and adaptive measures.
Results:
Children in the OP group (N=19) were matched to HFA (N=19) and TD peers (N=19) on gender and age at re-evaluation. The groups did not differ in median household income (p=.870) or ethnicity (p=.203). ANOVAs were utilized to compare the cognitive and adaptive functioning of the groups at re-evaluation (mean age = 50.92 months). No group differences were found in visual receptive, fine motor or receptive language abilities. In the domain of expressive language, the OP group demonstrated weaker skills than their TD peers (p=.031) and comparable skills to their HFA peers (p=.937). In terms of adaptive abilities, the OP group demonstrated stronger skills than their peers with HFA across domains (Communication, p=.008; Daily Living, p=.003; Motor, p=.006; Socialization, p<.001), and comparable skills to their TD peers (p>.05 across domains).
Conclusions:
By age four, children who demonstrate Optimal Progress from an early ASD diagnosis are functioning comparably to TD peers cognitively and adaptively. These children continue to demonstrate weakness in expressive language skills. This supports existing research with older children with Optimal Outcomes who continue to show mild deficits in pragmatic language. In sum, in addition to losing the symptoms associated with ASD, children who demonstrate Optimal Progress in their toddler years are largely indistinguishable from TD peers in the areas of cognitive and adaptive skills.

118   **124.118** Contingent Maternal Vocal Responses to 9-Month-Old Infant Siblings of Children with Autism

M. R. Talbott[1], C. A. Nelson[2] and H. Tager-Flusberg[3], (1)University of California, Davis, MIND Insitute, Sacramento, CA, (2)Education, Harvard Univesity, cambridge, MA, (3)Boston University, Boston, MA

Background: As a group, infant siblings of children with autism demonstrate difficulties in language and communication that appear towards the end of the first year of life (Mitchell et al., 2006; Ozonoff et al., 2014; Paul, Fuerst, Ramsay, Chawarska, & Klin, 2011). These difficulties are presumed to reflect an increased familial risk, but the extent to which this familial risk includes environmental influences remains poorly understood. An extensive literature documenting the role of maternal input in shaping the language development of typically developing infants and toddlers, toddlers with autism, and other high risk infant populations (e.g. infants of depressed mothers), but no studies have examined maternal linguistic input to infant siblings of children with autism in the first year of life.
Objectives: The goal of the current study was to investigate the linguistic input provided to high risk infants by their mothers during the first year of life.
Methods: The vowel (VV) and consonant-vowel (CV) production of 30 infant siblings of children with autism and 30 low risk infants were scored from video diaries filmed in the home when infants were 9 months of age. Maternal contingent responses to these early vocalizations were also scored and classified as either language promoting or non-promoting responses.
Results: A 3 (Diagnostic Group) by 2 (Vocalization Type) repeated measures ANOVA revealed no significant main effects of Group or a Vocalization Type x Group Interaction. There was a significant main effect of Vocalization Type, $F(1, 57) = 62.11$, p <.001, indicating that infants in all groups produced significantly more Vowel than Consonant-Vowel Vocalizations.
A 2 (Infant Vocalization Type) x 2 (Maternal Response Type) x 2 (Group) repeated measures ANOVA revealed significant main effects of both infant vocalization type, $F(1,44) = 9.61$, p < .01 and maternal response type, $F(1,44) = 61.51$, p < .01, with infants overall producing more Vowel than Consonant-Vowel utterances, and mothers overall producing more Language Promoting that Non-Promoting

Responses. These main effects were modulated by a significant Infant Vocal Type X Maternal Response Type interaction, $F(1,44) = 22.45$, $p < .01$. There were no significant main or interaction effects involving group. Simple main effects analyses conducted to determine the source of this significant interaction revealed that Language Promoting responses occurred significantly more frequently in response to Consonant-Vowel than Vowel vocalizations ($F (1, 46) = 21.57$, $p = .000$), while the opposite pattern was observed for Non-Promoting responses, which occurred significantly more in response to Vowels than Consonant-Vowels ($F (1,46) = 10.43$, $p = .002$).

Conclusions: These results indicate that as a group, mothers of high risk infants provide equally high quality linguistic input to their infants in the first year of life and suggest that impoverished maternal linguistic input does not contribute to high risk infants' initial language difficulties. Implications for intervention strategies will be discussed.

119 **124.119** Contingent Smiling Behavior in 2-to 5-Month-Old Infants with and without ASD during Dyadic Interactions

R. Sandercock[1], W. Jones[1], A. Klin[1] and S. Shultz[2], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Department of Pediatrics, Marcus Autism Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA

Background: Social smiling, smiling that is closely linked to vocalizations and affective changes in one's communicative partner, is one of the most visible forms of early social engagement, emerging by the second month of life in typical development. By contrast, individuals with autism spectrum disorders (ASD) have impaired social interaction abilities, displaying reduced social smiling relative to their TD peers (e.g., Zwaigenbaum et al., 2005). In typical development, the emergence of social smiling marks a pivotal milestone, as early success in reciprocal social interaction likely plays a role in shaping social and communicative outcomes. In ASD, reduced social smiling in later life may reflect the cascading impact of disruptions in reciprocal social interaction from the first months of life. Consequently, examining early smiling behavior may provide an early diagnostic marker of ASD and inform how deviation from the normative course of development impacts the unfolding of social deficits characteristic of ASD.

Objectives: Investigate whether infants at low-risk for ASD with typical outcomes (LR-TD), and infants at high-risk for ASD with and without later diagnoses of ASD (HR-ASD and HR-unaffected) differ in: (1) frequency of smiles; and (2) whether their smiles are time-locked to the behavior of their communicative partner.

Methods: Two-to-five-month-old LR-TD (n = 25; mean age = 4.06 months), HR-unaffected (n = 5 ; mean age = 3.6 months), and HR-ASD (n=9; mean age = 4.36 months) infants were recorded monthly during 30-second face-to-face interactions with their caregivers. Infant facial expressions (including smiling) and gaze direction, and caregiver facial expressions and vocalizations were coded as in Lavelli & Fogel (2005).

Results: One-way ANOVAs revealed no differences in frequency of smiling between LR-TD, HR-ASD, and HR-unaffected infants (p's > .05). Infants also displayed similar levels of looking towards versus away from their caregiver, and caregivers showed no between-group differences in frequency of infant-directed behaviors (all p's > .05). Peristimulus time histograms were created to examine the temporal relationship between infant smiling and specific caregiver behaviors. LR-TD infants showed a significant *decrease* in smiling rate when caregivers displayed neutral expressions, both with and without vocalization (74.46% and 67.39%, respectively; p's < .05), but showed a significant *increase* in smiling rate when caregivers were smiling, both with and without vocalization (37.68% and 29.31%, respectively; p's < .05). Smiling rate of HR-unaffected infants was only time-locked to moments when caregivers were vocalizing while smiling, increasing by 24.05%. Finally, smiling in HR-ASD infants was not modulated in relation to any caregiver behavior (p's > .05).

Conclusions: The temporal relationship between infant smiles and caregiver behaviors differed significantly between LR-TD, HR-unaffected, and HR-ASD groups, though infants in all groups displayed comparable frequency of smiling. While LR-TD infants showed changes in smiling rate that were time-locked to affective changes in their caregivers, smiling in HR-ASD infants was not contingent upon caregiver behavior. These results highlight a very early disruption to social smiling and sensitivity to social contingencies in ASD, skills that serve as an essential means of pre-verbal communication and social learning in typical development.

120 **124.120** Decreased Neural Response to Touch As a Marker of Autism Risk Across the First Year of Life

H. M. Fichtenholtz[1], N. M. McDonald[2], L. C. Anderson[3], C. M. Keifer[4], H. E. Friedman[5], J. A. Eilbott[6] and K. Pelphrey[4], (1)Yale School of Medicine, West Haven, CT, (2)Yale School of Medicine, Fairfield, CT, (3)Psychology, University of Maryland, College Park, MD, (4)Child Study Center, Yale University, New Haven, CT, (5)Yale Child Study Center, New Haven, CT, (6)Yale University, New Haven, CT

Background:
Touch is an important means of social communication between parents and infants and facilitates social interactions throughout the lifespan. Neuroimaging studies have revealed that slow (affective) touch selectively activates areas of the brain also involved in social perception of visual stimuli (e.g., posterior superior temporal sulcus, medial prefrontal cortex); the level of activation in these areas

negatively correlates with levels of autistic traits in typical adults. Additionally, individuals with autism spectrum disorder (ASD) and infants at risk for ASD show diminished responses in these brain regions during visual social perception tasks. It is not clear whether similar deficits are apparent in the neural responses to tactile social perception tasks in infants who are at elevated risk for ASD.
Objectives:
To investigate neural responses to affective (slow) versus non-affective (fast) touch using functional near infrared spectroscopy (fNIRS) in infants at high- and normal-risk for ASD across the first year of life.
Methods:
Participants were 40 infants at high-risk (*n*=17) or normal-risk (*n*=23) for ASD. High-risk children had at least one older sibling with ASD, while normal-risk children had no known family history of the disorder. Infants visited the laboratory with their parent at approximately 3 (n=13), 6 (n=9), 9 (n=8) or 12 (n=10) months of age. Prior to the experimental procedures, infants were outfitted with the fNIRS optode headgear and were seated on their parent's lap. The tactile perception task consisted of 8 periods each of slower (0.5 Hz) and faster-paced (2.5 Hz) brushing to the skin of the infant's leg, which alternated with periods of no tactile contact. Both oxygenated and deoxygenated hemoglobin responses were recorded with a Hitachi ETG4000 fNIRS transcranial optical topography system.
Results:
Epochs of fNIRS data were extracted from each optode around the stimulus presentation (-1 sec – 7 sec) and averaged by brushing type (fast, slow) for each participant. At optode sites over left superior temporal cortex, high-risk infants, in comparison to normal-risk infants, showed decreased responses to fast brushing 1-5 seconds after the beginning of the stimulation. This response was seen in infants at 3, 6, and 12 months of age. No consistent differences were seen in response to slow brushing across the first year of life.
Conclusions:
This is the first known study to examine neural responses to a tactile social perception task in infants at-risk for ASD across the first year of life. We found that infants at high- and normal-risk of developing ASD have differential sensitivity to tactile stimuli. Our results suggest that (1) areas of the temporal cortex (superior temporal cortex), which is known to respond to visual social cues, also play a role in the processing of tactile social information. (2) Differences in response to tactile stimulation evident in the first year of life are a potential biomarker for elevated risk of ASD.

121 **124.121** Developmental Plateaus in Gaze Following in 24-Month-Old Toddlers with ASD: An Eye-Tracking Study

L. DiNicola[1], E. S. Kim[1], C. A. Wall[1], G. Greco[2], S. S. Lansiquot[2], L. Flink[2], Q. Wang[1], S. Macari[2], F. Shic[1] and K. Chawarska[2], (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT

Background:
Recent work has highlighted eye tracking's potential to catalogue a range of critical social and communication skills in individuals with ASD (Guillon et al., 2014). Gaze-following skills are particularly interesting given their fundamental connection to joint attention and social monitoring. Although recent eye-tracking studies have examined gaze following in older children and adolescents (Freeth et al., 2010; Swanson & Siller, 2013), no reports have used eye tracking to analyze the developmental processes underlying gaze following in toddlers with ASD.
Objectives:
To use eye tracking to examine developmental changes in gaze following during emulated joint attention in toddlers with ASD between the ages of 18- and 24-months.
Methods:
Participants included 18- and 24-month-old toddlers with ASD (ASD-18, *n*=77, Age: M=19.3 (SD=1.5) months; ASD-24, *n*=80, Age: 24.0 (0.9) months), non-ASD developmental delays (DD-18, *n*=11, Age: 18.4 (1.1) months; DD-24, *n*=12, Age: 23.5 (1.3) months), and typical development (TD-18, *n*=87, Age: 18.3 (0.9) months; TD-24, *n*=89, Age: 23.9 (1.0) months). Participants were administered an eye-tracking task testing spontaneous social attention to discrete probes, including a Joint Attention (JA) probe, in which an actress repeatedly looked at the camera and then at one of four toys (see Chawarksa et al., 2012). Outcome variables included percentages of valid scene-viewing time spent attending to the actress's head (%Head), any toy (%Toys), and the toy at which the actress looked (%Target). Looking patterns within a circuit of targets, including Toys-cued (TargetRatio), Toys-not-cued (DistractorRatio), and the actress's head (HeadRatio), were also calculated.
Results:
Linear mixed effects modeling was employed to examine the fixed effects of diagnostic group, age group, and their interaction. Effects for %Head were not significant. %Toys revealed an age x diagnosis interaction ($p<.05$; toy-looking increased with age in the TD ($p<.001$) and DD (trend; $p=.10$) groups but not the ASD group ($p=.73$)). For %Target, a diagnosis effect (ASD<DD,TD: $p=.06$, $p<.001$; DD=TD: $p=.94$) and an age effect ($p<.01$; target-looking increased with age) were observed. Circuit analyses confirmed conversion of attentional focus from the actress's head to the cued toy in the transition between 18- and 24-months in the TD (increasing TargetRatio, $p<.01$; decreasing HeadRatio, $p<.05$) and DD (increasing TargetRatio, $p=.09$) groups but not in the ASD group. For the ASD-24 group, %Toy correlated with Mullen verbal age equivalent scores ($r=.31$, $p<.05$), and DistractorRatio correlated with ADOS severity scores ($r=.31$, $p<.05$).

Conclusions:
Our results reveal developmental gains in gaze following from 18- to 24-months of age in non-ASD toddlers but not in toddlers with ASD. Although time spent attending to the cued toy increased for all groups over time, toddlers with ASD consistently attended less to the cued toy and did not demonstrate developmental improvement in gaze following. This, combined with relationships between gaze following and characterization variables in ASD, suggests that scanning patterns in response to JA probes may provide clinically meaningful indices of social ability. More broadly, these results indicate that eye tracking may help quantify atypical social information processing in toddlers with ASD and monitor changes due to development or intervention.

122 **124.122** Differences in Means-End Exploration Between Infants at Risk for Autism and Typically Developing Infants in the First 15 Months of Life

S. Srinivasan[1], M. Kaur[1] and A. N. Bhat[1,2], (1)Department of Physical Therapy, University of Delaware, Newark, DE, (2)Center for Health, Intervention & Prevention, Department of Psychology, University of Connecticut, Storrs, CT

Background: Means-end exploration has been well studied in typically developing infants between the first and second year of life. Infants are able to efficiently retrieve small toys from nested boxes through the use of advanced strategies that reflect improved bilateral hand use (transition from unilateral to bilateral hand use) as well as motor planning (the ability to perform movement sequences) (Goubet et al., 2006). Infants who later develop autism often show fine and gross motor delays within the first few years of life (Landa & Garrett-Mayer, 2005; Bhat et al., 2012). However, there has been no research to date that has examined means-end exploration tasks as early tools to determine autism-risk.
Objectives: Therefore, the purpose of this study was to compare the means-end exploration abilities of infants at-risk (AR) for autism and typically developing (TD) infants between 9 and 15 months of age.
Methods: 16 AR infants and 16 TD infants were observed during a means-end exploration task at 9, 12, and 15 months with developmental follow-up and autism screening at 18 and 24 months. During each visit we collected video data on three tasks that involved retrieving a small toy sheep by – a) opening an opaque box, b) opening a transparent box, and c) opening two nested boxes. Dependent variables included time taken to complete each task, bilateral hand use, the number and variety of strategies used, number of attempts made, the amount of tester assistance provided, and the number of prompts provided.
Results: Our preliminary findings from a subset of infants suggest that TD infants dramatically reduced the amount of time taken to complete the task between 9 and 15 months. They also reduced the amount of assistance and prompts required to complete the task. They showed greater asymmetrical hand use and more advanced strategies to retrieve the toy. In contrast, AR infants showed greater task failure, longer times to complete the task, and immature exploration strategies such as greater unilateral hand use.
Conclusions: Our results suggest that means-end exploration tasks provide a window into the bilateral coordination and motor planning abilities of young infants, including those at-risk for autism. These contexts may provide an early marker for future risk of ASDs by the end of the first year of life. Moreover, these early bilateral coordination and motor planning delays may contribute to the social communication and cognitive delays of infants at risk for ASDs, specifically, in gestural communication, functional play, and problem solving abilities. Facilitating early means-end exploration would be an important learning context for infants at risk for ASDs.

123 **124.123** Does Functional Gaze Following of Children with an Autism Spectrum Disorder Really Rely on Gaze Direction? an Eye-Tracking Study

L. Van Schuerbeeck[1], M. A. Braeken[1], R. Meesen[2], J. Steyaert[3] and M. Vanvuchelen[4], (1)Hasselt University, Diepenbeek, Belgium, (2)Faculty of Medicine and Life Sciences, Hasselt University, Diepenbeek, Belgium, (3)Leuven Autism Research (LAuRes), University of Leuven (KU Leuven), Leuven, Belgium, (4)Hasselt University Faculty of Medicine and Life Sciences, Diepenbeek, Belgium

Background:
Children with autism spectrum disorders (ASD) show abnormalities in functional gaze following. Although their gaze shifts towards attended objects are accurate, the duration of their first fixation at these objects is shorter suggesting weaker initial processing bias for attended objects (Falck-Yttter, Thorup, & Bölte, 2014). However, it is not clear whether they rely exclusively on other's gaze direction or use other's head direction to govern functional gaze following.
Objectives:
The experimental manipulation in this eye tracking study is whether or not an adult could see the objects by using an open and closed eyes paradigm (Brooks & Meltzoff, 2002) while objects were present or absent (Caron, Butler, & Brooks, 2001).
Methods:
Seven children with ASD (mean chronological age of 64 months; mean mental age of 36 months) and 7 mental age-matched typically developing younger children (TD) were involved in this study. Children saw video clips of an adult turning her head to the right or left in 2 different conditions (eyes open or

closed) and with 2 different stimuli (with or without objects). This resulted in four different situations: open-eyes with object, open-eyes without object, closed-eyes with object, closed-eyes without object. Gaze was measured with a Tobii T120. The outcome parameters were the accuracy (amount of congruent gaze shifts minus amount of incongruent gaze shifts) and the duration of the first fixation to the attended target.
Results:
A three-way ANOVA (2groups*2conditions*2stimuli) revealed no significant effect for the accuracy (F=1.07; p=.32) whereas a significant effect was present for the duration of the first fixation to the attended target (F=11.64; p=.005). Post hoc testing showed that TD demonstrate a longer first fixation duration to the attended target in the open compared to the closed eyes conditions if objects were present (p=.04) in contrast to children with ASD (p=0.10).
Conclusions:
Consistent with Falck-Ytter et al. (2014), children with ASD followed the adult's gaze in terms of accuracy as much as mental aged-matched younger children but showed an aberrant pattern of first fixation duration to the attended target. In line with findings of Brooks and Meltzoff (2002), gaze following of TD seems to be influenced by the open or closed status of the eyes, directing a higher initial object processing to the attended object when the eyes of the adult are open. In contrast, children with ASD showed no difference in initial object processing between open and closed eyes conditions. Findings suggest that gaze following of children with ASD may rely on the adult's moving head and less on the status of the adult's eyes. Since in naturalistic settings gaze shifts towards an object may indicate an upcoming goal-directed action with an object, an altered gaze following pattern and initial object processing can interfere with action understanding. To investigate action understanding in children with ASD the above mentioned aberrant gaze following pattern should be taken in account.

124 **124.124** Early Gross and Fine Motor Abilities in Infants at Heightened Vs. Low Risk for ASD: A Bsrc Study

J. M. Iverson[1], F. Shic[2], C. A. Wall[3], Y. Bensinger-Brody[4], S. Curtin[5], A. M. Estes[6], J. M. Gardner[7], T. Hutman[8], S. Johnson[9], B. Z. Karmel[7], R. J. Landa[10], A. R. Levin[11], K. Yirmiya[22] and G. S. Young[23], (1)University of Pittsburgh, Pittsburgh, PA, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Yale University, New Haven, CT, (4)Physical Therapy, Touro College, Bay Shore, NY, (5)University of Calgary, Calgary, AB, Canada, (6)Speech and Hearing Sciences, University of Washington, Seattle, WA, (7)Infant Development, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY, (8)Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (9)University of California Los Angeles, Los Angeles, CA, (10)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD, (11)Neurology, Boston Children's Hospital, Boston, MA, (12)University of Miami, Coral Gables, FL, (13)Division of Developmental Medicine, Boston Children's Hospital, Harvard Medical School, Boston, MA, (14)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis Medical Center, Sacramento, CA, (15)*Shared Senior Author, ., NC, (16)University of California at Davis, Sacramento, CA, (17)University of Alberta, Edmonton, AB, Canada, (18)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (19)Psychology, University of Washington, Seattle, WA, (20)Boston University, Boston, MA, (21)Department of Educational Psychology, University of Minnesota, Minneapolis, MN, (22)Psychology Department, Hebrew University, Jerusalem, Israel, (23)MIND Institute, University California Davis, Sacramento, CA

Background: A growing body of research has pointed to the presence of early-appearing delays in gross motor (GM) and fine motor (FM) development in infants at heightened risk (HR) for ASD (e.g., Libertus et al., 2014; Nickel et al., 2013). In addition, relative to HR infants who are not later diagnosed with ASD and to infants with low ASD risk (LR), HR infants later diagnosed with ASD exhibit poorer gross and fine motor skills by 6 months of age (e.g., Leonard et al., 2013). However, much of this work has involved comparison of overall scores on standardized assessments and relatively small sample sizes.
Objectives: To examine GM and FM skills at an item level at 6 months in relation to outcome classification at 36 months in a large sample of HR and LR infants.
Methods: This study utilized data from the GM and FM subscales of the Mullen Scales of Early Learning (MSEL) administered at 6 months of age at 7 Baby Siblings Research Consortium (BSRC) sites. The total sample included 530 infants (363 HR, 167 LR). Thirty-six month outcome classification followed procedures outlined by Chawarska et al. (2014), with HR infants categorized as ASD, Atypically-Developing (ATYP), or Typically-Developing (HR-TD). A comparison sample of typically-developing low risk infants (LR-TD) was also included.
Results:
General linear mixed model logistic regressions with outcome classification and item as fixed effects and random intercepts for participants were carried out separately on the GM and FM subscale data (Figure 1). Results were generally similar across subscales, with group item performance for GM: (ASD=ATYP)<LR-TD (p<.01) and (ASD=ATYP)<HR-TD(p~.06); and for FM (ASD=ATYP)<LR-TD

(p<.05,.01) and HR-TD<LR-TD (p<.01).

To examine motor milestones specific to age 6 months, we focused on subsets of 4 items on each subscale tapping sitting and grasping skills respectively and identified infants who were low performers (≥3 items failed; Figure 2).

For sitting items, significantly more ASD and ATYP infants were low performers relative to both the HR-TD and LR-TD groups, who did not differ from one another. A similar pattern of differences was evident for grasping items, but in addition, significantly more HR-TD infants fell into the low performing group relative to the LR-TD group (all ps < .05). Within the ASD group, significantly more females (44%) than males (22%) failed 3 or more grasping items (p = .04).

Conclusions: Delays in gross and fine motor development were evident among ASD infants at 6 months of age, but similar delays were also apparent among HR-ATYP infants. In addition, HR-TD infants also demonstrated delays relative to LR-TD infants in fine motor skills. These findings have implications for early identification and intervention efforts and for the understanding of the pathways from genetic risk for ASD to social and cognitive impairments associated with ASD and the broader autism phenotype.

125 **124.125** Early Social Communication Predictors of Clinical Diagnosis from 18 to 24 Months

T. N. Day[1], W. Guthrie[1], C. Schatschneider[2] and A. M. Wetherby[1], (1)Florida State University Autism Institute, Tallahassee, FL, (2)Florida State University, Tallahassee, FL

Background: Social communication deficits are often the first noticeable 'red flags' of autism spectrum disorder (ASD), as typically developing (TD) children demonstrate robust intentional modes of social communication (i.e., to engage another person in their requesting and expressing interest) by one year of age. Previous studies have identified differences in social communication in children with ASD (Chawarska et al., 2014; Clifford et al., 2007; Wetherby et al., 2007), but some of these studies have not had the power to detect potential differences between children with ASD and developmental delay (DD). Given the average age of diagnosis at 4-5 years (CDC, 2014), it is important to identify early indicators that can reliably differentiate TD, DD, and ASD. Since communication delays are usually present by the second year of life and may be more readily identified by parents and professionals than other red flags (e.g., repetitive behaviors), these social communication skills represent an important measure for early screening.

Objectives: (1) Examine differences in social communication at 18-24 months between children diagnosed with ASD, DD, and TD and (2) Identify significant predictors of diagnosis of ASD compared to DD or TD.

Methods: Children participated in the FIRST WORDS® Project at Florida State University and were administered the Communication and Symbolic Behavior Scales (CSBS; Wetherby & Prizant, 2002) Behavior Sample between 18-24 months. They also received a concurrent diagnostic battery to determine best-estimate diagnosis of ASD (n=275), DD (n=93), or TD (n=99).

Results: An ANCOVA, controlling for age and nonverbal skills, revealed that the ASD group had lower CSBS Cluster scores, which measure seven distinct dimensions of social communication, than the TD group (p<.001). All Cluster scores were significantly lower in ASD than DD (p<.05), except for Word Use. Logistic regressions examined z-scored CSBS Clusters to identify significant predictors of clinical diagnosis. In comparing ASD and TD, four significant predictors emerged (p<.05): Emotion & Eye Gaze (*odds ratio* [*OR*]=.30), Gestures (*OR*=.38), Sounds (*OR*=.40), and Understanding (*OR*=.57). Overall, 88% of children were accurately classified as either ASD or TD (sensitivity: 93%, specificity: 77%). In the model comparing ASD and DD, Emotion & Eye Gaze (*OR*=.32) and Gestures (*OR*=.55) were significant predictors (p<.05) of clinical diagnosis. In total, 80% of the children were accurately classified as either ASD or DD (sensitivity: 92%, specificity: 53%).

Conclusions: Results indicate that social communication deficits measured by the CSBS discriminate children with ASD from both DD and TD. Four of the seven clusters differentiated ASD from TD, resulting in 88% correct classification. Impressively, just two clusters (Emotion & Eye Gaze and Gestures) resulted in 80% correct classification of ASD and DD. This suggests that screening should focus on gaze, facial expressions, and gestures to most efficiently identify children with ASD. Given the high sensitivity rates found, the CSBS may serve as a useful ASD screening tool to identify children in need of ASD-specific testing. Higher specificity in the TD than DD analyses suggests that many "false positives for ASD" may indicate non-ASD delays requiring intervention services.

126 **124.126** Early Social Development in Preschoolers with Autism Spectrum Disorders: A Comparison of DSM-5 Profiles

T. A. Bennett[1], P. Szatmari[2], E. K. Duku[1], S. Georgiades[3], S. E. Bryson[4], E. J. Fombonne[5], I. M. Smith[6], P. Mirenda[7], J. Volden[8], C. Waddell[9], L. Zwaigenbaum[8], W. Roberts[10], T. Vaillancourt[11], M. Elsabbagh[12], A. Zaidman-Zait[13] and A. Thompson[1], (1)Offord Centre for Child Studies & McMaster University, Hamilton, ON, Canada, (2)University of Toronto, Toronto, ON, Canada, (3)McMaster University, Hamilton, ON, Canada, (4)Autism Research Centre, Dalhousie/IWK Health Centre, Halifax, NS, Canada, (5)Oregon Health & Science University, Portland, OR, (6)Dalhousie University / IWK Health Centre, Halifax, NS, Canada, (7)University of British Columbia, Vancouver, BC, Canada, (8)University of Alberta, Edmonton, AB, Canada, (9)Faculty of Health Sciences, Simon Fraser University, Vancouver, BC, Canada, (10)Pediatrics, University of Toronto, Toronto, ON, Canada, (11)University of Ottawa, Ottawa,

ON, Canada, (12)Department of Psychiatry, McGill University, Montreal, QC, Canada, (13)Tel-Aviv University, Tel-Aviv, Israel

Background: The new diagnostic criteria for autism spectrum disorders (ASD) in the 5th edition of the Diagnostic and Statistical Manual (DSM-5; American Psychiatric Association, 2013) represent an attempt to capture the heterogeneity of symptoms and impairment among children with ASD in a dimensional manner. In DSM-5, associated clinical specifiers describe co-morbid developmental challenges experienced by children with ASD, including structural language impairment (LI) and intellectual disability (ID). Children with ASD plus LI (ASD/LI) and ASD plus ID (ASD/ID) may be at greater risk of adverse social-developmental outcomes than those with ASD alone (ASD/alone).

Objectives: We aimed to compare the trajectories of social competence in young children recently diagnosed with ASD/alone, ASD/LI and ASD/ID.

Methods: Data were provided by 332 children and their families participating in the Canadian *Pathways in ASD* study, a multi-site longitudinal inception cohort study of children aged 2-4 years with a recent DSM-IV diagnosis of ASD (278 boys, 54 girls). Children who scored below 70 standard score (SS) points on the Merrill-Palmer-Revised Developmental Index (MPR-DI) were described as ASD/ID (n=249, 75.0% of sample). Among those with baseline MPR-DI scores above 70 SS points, children who scored 1.5 standard deviations below population mean scores on the Preschool Language Scale-4 (PLS-4; Auditory Comprehension or Expressive Communication subscales) were classified as language impaired (ASD/LI; n=32, 9.64%). Children in the ASD/alone subgroup (n=51, 15.36%) scored in the unimpaired range on language and cognitive testing. Participants were assessed at baseline (within 4 months of diagnosis) and 6 and 12 months later. We examined latent growth curve trajectories of early social competence (as measured by the Vineland Adaptive Behavior Scales-II [VABS-II Socialization domain]), and compared parameters of growth (intercept and slopes) of social competence trajectories between the ASD/alone, ASD/LI and ASD/ID subgroups.

Results: Twelve months after diagnosis, 74% of children in the ASD/LI group no longer met criteria for language impairment; however, by contrast 69% of the ASD/ID group continued to score as impaired on cognitive testing. On average, children with ASD made significant gains in social competence over 12 months (slope = 7.15 raw points [SE=0.36, p<0.01], equivalent to 3 SS points on VABS-II). There was significant variability within the group with respect to initial levels (intercepts) and rates of change (slopes). Growth parameters were significantly associated with family income (intercept) and child age at diagnosis (intercept and slope), but not child sex or years of primary caregiver education. Children with ASD/LI were significantly more socially impaired at baseline than the ASD/alone subgroup, and less impaired than those with ASD/ID. Rates of change in social competence did not differ between the ASD/alone and ASD/LI subgroups, however children with ASD/ID made significantly fewer social gains during the year after diagnosis.

Conclusions: Clinicians should describe DSM-5 diagnoses of ASD/LI as provisional when assessing preschoolers, given the significant language gains made by many children. The ASD/ID classification appeared to be more stable in the first year after diagnosis. Children with ASD/ID were most severely impaired and lagged further behind in their early social development.

127   **124.127** Effects of Race, Ethnicity, and Maternal Education on Reported Regression in Children with Autism Spectrum Disorder (ASD)

J. B. Swanson[1], A. Spinks-Franklin[1], L. Berry[2], D. Guffey[3], C. G. Minard[3], R. G. Voigt[1] and R. P. Goin-Kochel[1], (1)Pediatrics, Baylor College of Medicine, Houston, TX, (2)Texas Children's Hospital, Autism Center, Baylor College of Medicine, Houston, TX, (3)Dan L. Duncan Institute for Clinical and Translational Research, Baylor College of Medicine, Houston, TX

Background: According to parent report, about one-quarter to one-third of children with ASD experience developmental regression. Previous studies have noted that gender and socioeconomic status have no associations with reported regression among children with ASD. However, information about the effects of race, ethnicity, and maternal education on the prevalence of regression in children with ASD is limited.

Objectives: To determine the effects of race, ethnicity, and maternal education on reported regression in children with ASD in the Simons Simplex Collection (SSC) and Autism Genetic Resource Exchange (AGRE) databases.

Methods: Data were analyzed for children with ASD in the SSC (N=2695; mean age at study participation=9.0 years (SD = 3.6); 87% male). Regression status was ascertained via the *Autism Diagnostic Interview-Revised* (ADI-R) and operationalized for this study as any loss of language and/or social engagement at or before 36 months of age. Logistic regression was used to explore possible associations with regression by race/ethnicity, maternal education, annual household income, and age at first concern.

Results: The overall prevalence of language and/or social regression in the SSC sample was 28%. Prevalence of regression by race/ethnicity was: non-Hispanic white 26%, non-Hispanic black 42%, Hispanic 37%, and non-Hispanic other 30% (p<0.001). In unadjusted analyses, regression was associated with race/ethnicity (p<0.001), age at first concern (p<0.001), and maternal education (p=0.013), but not annual household income (p=0.818). When controlling for age at first concern and maternal education, race/ethnicity was significantly associated with language and/or social regression (p=0.0002). Non-Hispanic black children were twice as likely to experience regression than non-Hispanic white children (95% CI 1.1, 3.5; p=0.011). Hispanic children were 1.6 times more likely to

experience regression than non-Hispanic white children (95% CI 1.1, 2.2; p=0.004). When controlling for age at first concern and race/ethnicity, children with mothers with an associate's degree or higher were 20% less likely to reportedly experience regression (p=0.019), although the difference in reported regression between maternal education groups was small (32% for mothers with no degree and 27% for mothers with a degree). Comparable analyses in the AGRE dataset are currently underway.

Conclusions: In the SSC sample, non-Hispanic black and Hispanic children with ASD were at increased risk of parent-reported regression compared to non-Hispanic white children, when controlling for maternal education and age at first concern. Further studies are needed to evaluate whether these differences in race/ethnicity among children with ASD and regression are related to cultural and/or genetic differences possibly resulting in different phenotypes of ASD.

128   **124.128** Emotional Reactivity in Toddlers with ASD: Diminished Response to Threatening Stimuli during the Laboratory Temperament Assessment Battery (Lab-TAB)

S. Macari[1], L. DiNicola[1], A. C. Dowd[2], L. Flink[1], E. B. Gisin[1], G. Greco[1], S. S. Lansiquot[1], E. Prince[1], S. H. Kim[1], F. Shic[1] and K. Chawarska[1], (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Department of Psychology, University of Texas at Austin, Austin, TX

Background:
Temperament, biologically-based aspects of behavior in the domains of emotional reactivity, attention, and regulation (Rothbart, 1981), is relatively unexplored in very young children with ASD. Existing research in this population focuses largely on parent questionnaires (del Rosario et al., 2014, Clifford, 2013; Garon, 2009) but laboratory-based methods hold additional promise. The Laboratory Temperament Assessment Battery (Lab-TAB) is an in-vivo behavioral assessment for infants and toddlers that examines temperamental characteristics based on standardized naturalistic probes (Goldsmith & Rothbart, 1999). The Lab-TAB has been used extensively to study temperament in typically-developing children (Gagne et al., 2011), but little is known about emotional reactivity in very young children with ASD in response to a range of challenges.

Objectives:
To examine emotional reactivity in very young children with ASD compared to their non-ASD peers in response to behavioral probes aimed at eliciting fear, joy, and anger.

Methods:
We adapted the Laboratory Temperament Assessment Battery (Lab-TAB; Goldsmith & Rothbart, 1999) for use with toddlers with developmental disabilities, including a period of extensive piloting and reliability coding (across 5 coders, ICC>0.85). Nine episodes of the Lab-TAB were administered to toddlers with ASD (n=15) and age-matched peers without ASD (Non-ASD (n=10); 6 with typical development and 4 with non-ASD developmental delays) at age 20 months (SD=2.5). Three episodes per emotion were administered: Fear (Spider, Masks, Dinosaur); Anger (Carseat, End of the Line, Restraint); and Joy (Bubbles, Puppet Show, and Penguin Race). Each episode consisted of three to four trials lasting 10 seconds each. Videotaped sessions were coded offline by blinded coders for intensity of emotional responses during each trial on a four-to-six-point Likert scale. Responses were averaged across trials, and composites computed for Negative Affect (facial fear, facial sadness, distress vocalizations, escape, bodily fear); Joy (facial joy, positive vocalizations, bodily joy); and Anger (facial anger, distress vocalizations, bodily struggle).

Results:
A linear mixed models analysis examining group, episode type and their interaction indicated that toddlers with ASD exhibited less intense Negative Affect only during the Fear episodes ($F(1, 23)=9.42$, $p<.01$) than Non-ASD peers ($p<.01$, $d =1.17$). Joy and Anger were expressed at similar levels of intensity during the Joy and Anger episodes ($p=.51$, $p=.25$, respectively) across both groups of toddlers.

Conclusions: Preliminary findings suggest that 20-month-old toddlers with ASD exhibited less intense observable negative affect than their non-ASD peers in response to novel and potentially frightening stimuli. Diminished affect was specific to the Fear probe, as both groups responded similarly to joy- and anger-inducing situations. The factors underlying diminished emotional reactivity in threatening situations in ASD, including basic attentional, physiological, affective, and cognitive processes require further examination. Deficits in emotion processing are likely to impair the use of affective communication channels to form social bonds, develop empathy, and learn about the world. Data collection is ongoing and further analysis with a larger sample will enable examination of the specificity of these findings to the ASD group.

129   **124.129** Empathy Emerges: Attention and Affective Responses to Maternal and Experimenter Distress in Infants at Risk for Autism at 12- and 15-Months

A. C. Dowd[1], B. G. Davidson[2], J. G. Hixon[1] and A. R. Neal-Beevers[1], (1)Department of Psychology, University of Texas at Austin, Austin, TX, (2)Dept of Psychology, University of Texas at Austin, Austin, TX

Background:
Emerging at 12 months, empathy appears to be relatively stable over time, consistent across contexts, and predictive of prosocial behaviors. Empathy consists of both attending to a person in distress (attention) and displaying concern (affect; Knafo et al., 2008). High-risk infants (by virtue of

having a sibling with ASD; HR) later diagnosed with autism spectrum disorder (ASD) were less attentive and displayed fewer affective responses to an experimenter in distress than non-ASD infants (Hutman et al., 2010). Interestingly, infants may be more responsive to mother's distress versus a stranger's (Young et al, 1999), but when these differences emerge and if such differences occur in HR infants have yet to be explored.

Objectives:
Identify changes in attention and affect: (1) toward other's distress between 12 and 15 months across risk groups, and (2) toward experimenter versus maternal distress within risk groups.

Methods:
Nineteen HR infants and 21 low-risk (LR) infants were administered a standard empathy paradigm by both an experimenter and their mother at 12 and 15 months. Attention and affective response to distress were coded from video using an existing coding scheme (Hutman et al., 2010). Linear mixed-effects (LME) models were conducted separately for attention and affect scores as outcome variables, with age and risk as the independent variables for (1) maternal distress (MomDistress) and (2) experimenter distress (ExpDistress; Table 1). Additional LME models were conducted separately for each risk group, with age and condition (MomDistress/ExpDistress) as the independent variables (Table 2).

Results:
Affect was significantly different between risk groups, such that the HR group displayed less affect in both conditions. Additionally, there was a significant increase in affect over time for ExpDistress, but not for MomDistress. Within the HR group, no significant main effects of age or condition were found. In contrast, within the LR group, there was a significant age by condition interaction, such that affect increased over time for ExpDistress. Attention toward ExpDistress was significantly different between risk groups, such that the HR group paid less attention. For MomDistress, there was a significant age by condition interaction, which indicated attention decreased over time for the HR group and increased for the LR group. Within the LR group, there was a significant difference in their attention between conditions, such that they attended less to MomDistress.

Conclusions:
Results of this study suggest differences in empathic responses to others' distress are present as early as 12 and 15 months, when comparing HR and LR infants. The HR infants displayed weaker affect and attended less to others' distress than their LR peers. Furthermore, while LR infants' affect increased between 12 and 15 months, HR infants' affect did not change (ExpDistress) or decreased (MomDistress). The HR infants also did not differ in their affect and attention to experimenter versus maternal distress, while their LR peers showed increased affect to experimenter distress and increased attention responses to maternal distress over time. These deficits may be an early marker of social cognitive impairment and may be an important target for early intervention.

130 **124.130** Examining the Structure of Temperament Traits in Toddlers with and without ASD

C. A. Wall[1], L. Flink[2], S. S. Lansiquot[2], S. H. Kim[1], F. Shic[2], J. Koller[3], K. Chawarska[2] and S. Macari[2], (1)Child Study Center, Yale University, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)The School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel

Background: Temperament is defined as constitutionally based individual differences in reactivity and regulation (Rothbart & Bates, 2006). Research has highlighted the importance of this construct to social and behavioral outcomes in typically developing (TD) children. One important measurement of temperament is the Toddler Behavior Questionnaire-Supplemental (TBAQ-S; Goldsmith, 1996). The TBAQ-S includes 13 subscales subsumed by three composites: Attention (including Perceptual Sensitivity, Attention Focusing, Attention Shifting, Inhibitory Control, and Low Intensity Pleasure), Negative Emotionality (consisting of Discomfort, Sadness, Soothability (negatively), Anger, and Social Fear), and Surgency (comprising Social Fear (negatively), High Intensity Pleasure, Activity Level, and Approach/Positive Anticipation; Becken-Jones, Gartstein, Rothbart, & Chasman, 1999). Now scholars have turned to examining temperament in children with autism spectrum disorder (ASD). The TBAQ-S was only validated for use in TD populations, and no study to date has explored the composite trait structure of this measure in toddlers with ASD. Improving our understanding of temperament in special populations may elucidate the relationship between temperamental characteristics and later outcomes and help us identify subgroups of ASD for diagnostic and treatment purposes.

Objectives: To examine the structure of temperament traits as measured by the TBAQ-S in toddlers with ASD compared to their TD peers.

Methods: Participants included 146 toddlers with a diagnosis of ASD, derived from a clinically-referred sample (Mean age = 26.01 months) and a control group of TD toddlers ($n = 118$; Mean age = 24.16 months). All participants underwent a comprehensive developmental and clinical assessment to confirm diagnostic status. Measures included the Mullen Scales of Early Learning and ADOS-G. Parents completed the TBAQ-S prior to developmental testing. An exploratory factor analysis (EFA) was performed for both groups using principal axis factoring with direct oblimin rotation. Factor scores in ASD were correlated with Mullen and ADOS scores.

Results: EFA revealed three-factor models for both groups. The TD model appeared similar to Becken-Jones and colleagues' (1999). Loadings were also similar in the ASD model, but some notable exceptions emerged. Perceptual Sensitivity loaded on Negative Emotionality, and Social Fear only loaded on this factor. In addition, Activity Level, High Intensity Pleasure, and Approach/Positive

Anticipation loaded together negatively, resulting in an Introversion factor. The Introversion composite was positively correlated with ADOS Severity ($r = .289$, $p < .001$) and negatively correlated with nonverbal DQ ($r = -.208$, $p < .05$).

Conclusions: The traits measured by the TBAQ-S in toddlers with ASD appear slightly different from those in TD toddlers. Perceptual Sensitivity and Social Fear are both more associated with Negative Emotionality in ASD. Additionally, the most socially relevant scales loaded negatively, suggesting that they represent a more withdrawn pattern of behavior in ASD. This Introversion factor is associated with greater ASD severity and poorer nonverbal functioning. These results suggest that temperament may be organized differently in toddlers with ASD, and these differences may be related to autism symptomatology. Future work should explore how this trait structure may improve our characterization of children with ASD, identify possible subpopulations, and identify other ASD outcomes that may be influenced by temperament.

131 **124.131** Exploring the Relationships Between Visual Preference for Biological Motion, Joint Attention Behaviors and Language Development in Young Children with Autism Spectrum Disorders

M. Franchini[1], H. Wood de Wilde[1], B. Glaser[2], E. Gentaz[3], S. Eliez[2] and M. Schaer[1,4], (1)Office Médico-Pédagogique, University of Geneva, Geneva, Switzerland, (2)University of Geneva Medical School, Geneva, Switzerland, (3)Faculty of Psychology and Educational Sciences, University of Geneva, Geneva, Switzerland, (4)Stanford Cognitive & Systems Neuroscience Laboratory, Stanford University, Palo Alto, CA

Background:
According to the social motivation theory in autism (reviewed in Chevallier et al., 2012), social-communication deficits observable in autism are partly explained by a lack of social orienting. Eye-tracking studies show promise to quantify social orienting, with reduced preference for biological motion being already observed in toddlers with autism from 14 months of age (Pierce et al., 2011). It is typically assumed that reduced social orienting reduces opportunity for learning. For instance, decreased attention to people is thought to impair joint attention behaviors, and may represent a barrier to further language development (e.g. Charman et al., 2003). The formal relationship between social orienting, following joint attention behaviors and language skills have however not been extensively examined to date.

Objectives:
We sought to explore the relationship between lack on biological motion in ASD, joint attention behaviors and language development in young children with autism.

Methods:
We recruited 25 children with ASD (mean age= 3.2 ± 1.2 years old), and 20 typically developing children (TD, mean age= 3.0 ± 1.5 years old). Measures of initiation and response to joint attention were collected using the Early Social Communication Scale (ESCS, Mundy et al., 2003). Language development was quantified using the Psychoeducational Profile, 3rd version (PEP-3, Lansing et al., 2010) and the Vineland Adaptive Behavior Scales, Second Edition (Vineland-II, Sparrow et al., 2005). Finally, we quantified social orienting using an eye-tracking paradigm inspired from the one by Pierce and colleagues (2011), using a split screen with simultaneous biological motion and geometrical motion.

Results:
Replicating results by Pierce et al, we found that, as a group, children with autism orient less on biological motion compared to TD (t=3.48, p=0.0012). Important heterogeneity was however observed in the ASD group. Part of this variance related with social communication. Indeed, orientation on biological motion in ASD correlated with initiation and response of joint attention behaviors in the ESCS (R=0.508, p=0.022; R=0.438, p=0.04). Response to joint attention further correlated with expressive language standard scores at the PEP-3 and at the Vineland-II (R=0.501, p=0.009; R=0.452, p=0.012).

Conclusions:
Our results support the view that reduced orientation on biological motion has consequences on joint attention behaviors in children with ASD. The correlation between lack of response to joint attention and language outcome in children with ASD confirms the crucial role of joint attention in the development of communication in children with ASD. Future longitudinal studies are required to further understand whether social orienting and joint attention behaviors can serve as predictor of social and clinical outcome in autism.

132 **124.132** Frequencies of Vaccine Uptake in Children with Autism Spectrum Disorder and Type of Onset Described By Parents

R. P. Goin-Kochel[1,2], S. S. Mire[3], R. H. Fein[4], A. G. Dempsey[5], D. Guffey[6], C. G. Minard[7], R. M. Cunningham[8], L. C. Sahni[9] and J. A. Boom[8], (1)Pediatrics, Baylor College of Medicine, Houston, TX, (2)Autism Center, Texas Children's Hospital, Houston, TX, (3)Educational Psychology, University of Houston, Houston, TX, (4)University of Houston, Houston, TX, (5)Pediatrics, University of Texas Health Sciences Center, Houston, TX, (6)Baylor College of Medicine, Houston, TX, (7)Dan L. Duncan Institute for Clinical and Translational Research, Baylor College of Medicine, Houston, TX, (8)Texas Children's Hospital, Houston, TX, (9)Immunization Project, Texas Children's Hospital, Houston, TX

Background: A highly controversial theory for ASD is that regressive-onset ASD is triggered by vaccines. If vaccines are associated specifically with developmental regression in ASD, then it follows that vaccination rates should be significantly higher among children with ASD plus regression. Two studies conducted outside the U.S. found no association between the MMR vaccine and regression in ASD; however, these works only focused on one type of vaccine and did not examine ASD onset more broadly. The current study extended this line of work to examine potential associations between different types of ASD onset—not just regression—and a variety of vaccines that children routinely receive between birth and age 3 years. Focus was on both proportion of vaccine uptake and proportion of non-delay (i.e., accepting the vaccine at the time it was offered) for each vaccine.
Objectives: To examine whether vaccine-uptake and non-delay rates were equivalent among in a large sample of children with confirmed ASD diagnoses who had different types of autism onset (early onset, plateau, delays + regression, regression).
Methods: Data were analyzed for children with ASD (N = 2755; 86.4% male; M age = 9 years, SD = 3.6 years, range = 4—17.9 years; 78.5% White, 88.8% non-Hispanic) who participated in the Simons Simplex Collection (SSC). Onset categories for ASD were created using various combinations of responses to select items from the *Autism Diagnostic Interview—Revised* (ADI-R) to group children into one of the following four ASD-onset types: early onset, plateau, delay + regression, or regression. Vaccination history was obtained as part of an extensive Medical History Interview (MHI) conducted with children's parents; families were permitted to send in shot records for these data. Focus was on the following vaccines queried during the MHI: DPT/DTaP, HepB, HiB, poliovirus oral/injected, MMR, chicken pox/varicella. Equivalence for uptake and non-delay for each type of vaccine was assessed by deriving the risk difference of the percentage of vaccine uptake between all pairwise comparisons for ASD-onset groups using a two-sided 90% confidence interval.
Results: Proportions of children in each ASD-onset group were 33.5% for early onset, 36.5% for plateau, 10% for delay + regression, and 20% for regression. Vaccine-uptake rates ranged from 79% to 99%; non-delay rates ranged from 92% to 98%. All pairwise group comparisons for vaccine uptake and non-delayed administration were statistically significantly equivalent (adj p < .05), with the exception of varicella, for which the early onset/delay + regression comparison and the delay + regression/regression comparison were not equivalent for uptake (adj p = .07). The early-onset (85%) and regression (83%) groups each had higher rates of uptake than the delay + regression group (79%).
Conclusions: Equivalence was demonstrated between all ASD-onset types for each vaccine except varicella; however, differences between groups were not considered clinically meaningful (4—6% difference). Moreover, uptake proportions for early-onset and regression were equivalent. This, in conjunction with equivalent uptake across onset groups for all other vaccines, does not support the theory of an association between vaccines and regressive-onset ASD.

133 **124.133** Gaze Following in Infants at Risk for Autism: The Role of Eye Information, Head Turns and Salient Objects

E. Thorup[1], P. Nystrom[1], G. Gredebäck[1], S. Bolte[2] and T. Falck-Ytter[3], (1)Department of Psychology, Uppsala University, Uppsala, Sweden, (2)Division of Child and Adolescent Psychiatry, Stockholm County Council, Stockholm, Sweden, (3)Dept. of Women's & Children's Health, Karolinska Institute, Stockholm, Sweden

Background: The ability to follow other people's gaze is a key component of joint attention (JA), and Autism Spectrum Disorders (ASD) are associated with poor JA skills. Surprisingly, a recent eye-tracking study (Bedford et. al., 2012) found that infants with later emerging ASD were as accurate in gaze following as control children. In contrast, Elsabbagh et. al. (2012) found different ERP responses to dynamic gaze shifts in infants who were later diagnosed with an ASD as compared to typically developing infants. Thus, despite processing eye-related information differently, infants with later autism seem to be able to follow gaze. No study of infants at risk has investigated the tendency to follow eye direction alone, without an accompanying head turn.
Objectives: The aim of the present study was to investigate gaze following in 10-month olds at risk for autism (due to having an older sibling with ASD), with and without head turns.
Methods: The study included a group of children at high risk (HR) for ASD (n=24) as well as a group of children at low risk (LR, n=11). Using live eye tracking technology, we recorded the infants' gaze patterns when they observed a model who gazed at one of two objects in front of her. The primary measure was a difference score (DS) with the number of incongruent gaze shifts subtracted from the number of congruent gaze shifts made by the child, aggregated over several trials. The design included three conditions; one in which the model turned his/her head towards the toys (eyes and head condition), one in which the model shifted his/her gaze towards the toys without turning the head (eyes only condition) and one where the model turned his/her head towards empty spaces with no objects present (empty condition).
Results: The analysis revealed a group x condition interaction (p < 0.05). The HR group showed significantly higher gaze following accuracy in the eyes and head condition than in the eyes only and empty conditions (p:s < 0.05, bonferroni corrected). The gaze following accuracy in the LR group did not differ between conditions. The effect could not be explained by a general group difference in number of gaze shifts. Both groups were able to follow gaze accurately (DS > 0) in the eyes and head and empty conditions, but only the LR group followed gaze accurately in the eyes only condition.

Conclusions: While performance was modulated by condition in the HR group, no such modulation was found in the controls. This could suggest that infants in the HR group rely more on features such as head turns towards target objects, and fail to follow gaze when such cues are absent (i.e. in the eyes only condition). Lack of modulation in the LR group could indicate that these infants are more sensitive to the communicative meaning of the gaze cue, and less reliant on salient features such as head turns and objects.

134 **124.134** Growth Trajectories in Initiating Joint Attention during the First Three Years of Life in Siblings of Children with Autism Spectrum Disorder

M. Dereu, H. Roeyers, S. Van der Paelt, P. Warreyn and I. Schietecatte, *Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: Since initiating joint attention (IJA) is impaired in children with autism spectrum disorder (ASD), many researchers are currently studying the development of IJA and its relations to outcome in children who have an older sibling with ASD. This could lead to insight into differential pathways in the early development of these children: younger siblings who also have ASD themselves, siblings on the broader autism phenotype, and non-affected siblings.
Objectives: To explore differences in growth trajectories in IJA: a) between siblings of children with ASD compared to typically developing children and b) within the group of siblings according to their autism symptomatology at 36 months and their diagnostic outcome.
Methods: The Early Social Communication Scales (ESCS) were administered to siblings of children with ASD (SIBS; $n = 36$) and to typically developing children (TD; $n = 32$) at 9, 12, 18, 24, and 36 months of age. Rates per minute were calculated for IJA bids. The proportion of higher level IJA bids (i.e., pointing or showing) to the total number of IJA bids was used as a measure of the quality of nonverbal IJA bids. In addition, the Dutch version of the MacArthur-Bates Communication Development Inventories (N-CDI's) was administered at the ages of 18 and 24 months to assess the acquisition of spoken words. Finally, the Autism Diagnostic Observation Schedule (ADOS) was administered at 36 months as a measure of ASD symptomatology by means of the ASD severity scores (see Gotham, Pickles, & Lord, 2009). Currently, all children are being contacted to collect information about community clinical diagnosis. The Autism Diagnostic Interview-Revised (ADI-R) will be administered to children with a community clinical diagnosis and to children who scored above the ASD cut-off on the ADOS at 36 months. A clinical best estimate diagnosis will be given by a team of licensed clinical psychologists.
Results: At the conference, results of hierarchical linear modeling (HLM) will be presented to examine initial status of IJA at 9 months and growth in IJA between 9 and 36 months in relation to language acquisition between 18 and 24 months, autism symptom severity at 36 months, and diagnostic outcome. Since data collection on diagnostic outcome is still ongoing, only preliminary results comparing TD children and SIBS are summarized here. A decline was noted in the total frequency of IJA for TD children between 12 and 18 months, whereas in SIBS this was observed between 18 and 24 months. SIBS show an increase in the proportion of higher level IJA bids until 18 months, whereas TD show a growth until 24 months (see Figures). Also, the total frequency of IJA at 18 months was related to autism symptom severity at 36 months in both groups.
Conclusions: Differences in IJA trajectories between SIBS and TD children were most apparent between 18 and 24 months. Further analysis with HLM and complete outcome data will be presented and considered in the light of possible relations between these IJA trajectories, concurrent language acquisition, and autism symptom severity at a later age.

135 **124.135** Infants and the Emerging Autism Phenotype

A. Gulsrud[1], T. Carr[2], L. Huynh[3], K. Berry[3], T. Paparella[2] and C. Kasari[4], (1)UCLA, Los Angeles, CA, (2)University of California Los Angeles, Los Angeles, CA, (3)University of California, Los Angeles, Los Angeles, CA, (4)UCLA Center for Autism Research & Treatment, Westwood, CA

Background:
While ASDs can reliably be diagnosed in children starting around 18-24 months of age, symptoms present much earlier. Converging evidence has pointed to a constellation of developmental differences in infants as young as 12 months, including limited eye contact, imitation, social smiling, receptive language, and affective sharing. This study enrolled infants and toddlers between the ages of 12 and 22 months who were exhibiting early behavioral features consistent with a diagnosis of ASD.
Objectives:
This study aimed to characterize symptoms of ASD emerging in infants evaluated as a part of a larger randomized control trial. Specifically, we aimed to understand whether chronological age and sibling status would predict differences in standardized measures of functioning and diagnosis.
Methods:
36 infants (M=17.81 months old, 83% male) were asked to participate in a series of assessments including the ADOS- Toddler Module, Mullen Scales of Early Learning and the clinician's best estimate of diagnosis. Overall, infants demonstrated significant developmental delays with an average Mullen Early Learning Composite standard score of 67.58 (SD=13.36). Four scored "mild to moderate risk" classification on the ADOS- Toddler, with the remainder scoring with "moderate to severe risk". The clinicians also rated their certainty that the infant met DSM criteria for ASD using the Diagnosis Data

Form (Adapted from Cathy Lord, Personal Communication). A score of 15 reflects the highest score and the most diagnostic certainty. The scores of this sample ranged from 6-15 with an average score of 12.28 (SD=2.8).

Results:

Of the 36 infants who participated, 16 were first born and 20 had older siblings, 7 of whom had a diagnosis of ASD. Therefore, 19% of the total sample was infant siblings of children with ASD who were also showing early signs of the disorder. The child's chronological age was not a significant predictor of overall developmental quotient score, ADOS total algorithm score or clinician's diagnostic certainty. Infants with an older sibling with a diagnosis of ASD had significantly higher cognitive scores (M=77.86, SD=16.10) than children without a sibling (M=66.50, SD=11.63) with a diagnosis; t(33)=-2.33, p=.026). There were also trends toward infants with older siblings with confirmed diagnoses having lower ADOS total algorithm scores (M=15.57, SD=4.93) than those without (M=18.93, SD=4.29). Clinicians reported having more diagnostic certainty in those infants who did not have an affected older sibling (M=12.68, SD=2.28) compared to those who did (M=10.57, SD=4.28).

Conclusions:

This study examined the age related and sibling status differences in development amongst those children with the earliest signs of ASD. Although chronological age did not relate to the developmental or diagnostic outcomes, it may be that sibling status does play a role although larger samples are needed. Infants who belonged to the high risk group of infant siblings presented with less significant developmental delays, lower scores on the ADOS and clinicians rated less certainty in their overall diagnosis. These findings suggest that this subset of children may present with subtle delays early on but due to their sibling status parents may be more vigilant about monitoring these behaviors.

136 **124.136** Inhibited Toddlers and ASD Screening

A. Ben-Sasson, *University of Haifa, Haifa, Israel*

Background: A child's inhibited temperament greatly influences social engagement and exploration particularly in unfamiliar situations. Hence, inhibition can be confused with social-communication delays. Inhibition, defined by shyness, withdrawal, and under-activity, is rarely considered a mediator of ASD screening results.

Objectives: (1) Examine reliability and validity of inhibition observation. (2) Describe early ASD markers unique to those who were inhibited at one-year of age. (3) Determine whether inhibition increases false clinical referral for a developmental evaluation.

Methods: Parents of 84 12-month-old toddlers completed the First Year Inventory (FYI) an ASD screener. At 13 months toddlers participated in an in-home assessment including the Autism Observation Schedule for Infant (AOSI) and Mullen Scales of Early Learning (MSEL). The AOSI includes a reactivity item that captures both under- and over-reactivity. At 30 months parents completed the Infant Toddler Social Emotional Assessment (ITSEA) and toddlers participated in an in-home assessment including the MSEL and Autism Diagnostic Observation Schedule – Generic (ADOS-G). At 13 and 30 months toddlers were referred for a diagnostic evaluation if warranted by assessment results (n=18, 16, respectively). Inhibition was rated during the AOSI by experienced clinicians blind to the child's risk status. Five children were excluded from the non-inhibited group due to their rating as over-active.

Results: Twelve infants were rated as inhibited, 7 of which were also captured by the AOSI reactivity item. Inter-rater agreement for inhibition observation was significant, *PABAK* = 0.79. Parents of all infants in this group stated that the toddler behaved as usual during the observation. Inhibited infants received a significantly higher risk on the FYI social-communication score but not on the sensory-regulatory score; 58.3% met FYI risk cutoff versus 10.4% in the non-inhibited group. Inhibited infants showed significantly higher risk rates on the following five AOSI items: visual tracking, social babbling, response to name, reciprocal social smile, and social interest and shared affect. The inhibited versus control group had significantly lower early learning composite scores at 13 months, and marginally lower at 30 months. At 30 months this group had a significantly higher clinical referral rate of 54.5% versus the non-inhibited children (16.7%). However, there was no difference in rates of false (positive or negative) referrals at 13 versus 30 months referral; or based on risk on the FYI relative to 13 month referral. At 30 months, the inhibited versus the non-inhibited group had significantly ($p < .05$) higher rates of meeting ITSEA 90th percentile for inhibition to novelty (45.5%, 15.5% respectively) and depression/withdrawal scores (36.4%, 8.5% respectively).

Conclusions: Inhibition was reliably measured and persisted over time for about half of the children. An inhibited, withdrawn and difficult to engage infant has a higher likelihood of falling at risk on both parent and clinician based ASD screening measures. Nonetheless, inhibition did not inflate false screening results.

137 **124.137** Jealousy and Social Engagement in Very Young Children with Autism Spectrum Disorders

N. Bauminger-Zviely, *Bar-Ilan University, Ramat Gan, Israel*

Background: Jealousy is expereinced in a triadic context, where a potential threat exists that a valued relationship will be lost to a rival. Thus, expression of jealousy requires children to intersubjectively share with others. Intersubjective sharing is a core deficits in ASD—leading to speculation concerning

their ability to express jealousy. Recent data presented evidence of jealousy indices in some high-functioning preadolescents and preschoolers with ASD (IQ>75) (Bauinger, 2004; Bauminger, Chomsky-Smolkin, Orbach-Caspi, Zachor, & Levy-Shiff, 2008), and in half of low-functioning preschoolers with autism (IQ<75) (Bauminger et al., 2008), but no data was presented yet regarding children with ASD who are younger than three years. Also the link between jelaousy and social engagement was not yet examined.

Objectives: In an attempt to illuminate the nature of autism's affective deficit, the present study aimed to conduct assessment of jealousy in very young children with ASD (personal–mother and nonpersonal–stranger) and to identify jealousy's linkage with experimenter-child's social egngagement.

Methods: Participants included 19 toddlers with ASD (*CA*=23.16, months). To provok jealousy we manipulated two triadic conditions (personal mother-child-baby doll scenario and nonpersonal stranger-child-baby doll scenario), consisting of the mother/stranger putting a "life-like newborn-baby doll" on her lap, and cuddling the newborn-baby doll (e.g., Hart, Aaron, Jones, & Field, 2003). Social engagament was tested through 3 interactive social tasks based on the ADOS (Lord et al., 2000) including bubble play; peek-a-boo and playing with a Balloon.

Results: Repeated measure ANOVA conducted to examine differences in protest behaviors between the two situations (personal/non-personal) revealed a significant main effect for situation**,** $F(1,18) = 7.30$, $p < .05$, η2 = .29. Young children with ASD showed more protest behaviors in the jealousy personal situation (mother-holding the baby-doll) versus the non-personal situation (stranger holding the baby-doll). Furthermore, eye gazes, physical proximity behaviors and verbal gestures were directed more towards the mother in both the personal and non-personal situations versus the stranger. Higher levels of social engagement were linked with more eye gazes, physical proximity behaviors and verbal gestures in the jealousy personal situation.

Conclusions: The fact that jealousy expressions were higher in the personal-mother condition than the nonpersonal - stranger situation and the link between jealousy and social engagement in very young children with ASD holds significant implications for understanding ASD children's intersubjective capabilities.

138   **124.138** Joint Attention and Language Development in Infants at Risk for Autism

B. G. Davidson[1], *A. R. Neal-Beevers*[2] *and J. Cartwright*[3], *(1)Dept of Psychology, University of Texas at Austin, Austin, TX, (2)Department of Psychology, University of Texas at Austin, Austin, TX, (3)UT Southwestern, Dallas, TX*

Background:
Few studies have prospectively examined joint attention and language development in infants with an older sibling with ASD (Sibs-ASD), who have a higher risk of ASD and/or language delay than infants with an older sibling without ASD (Sibs-TD; see Rogers, 2009). We hypothesized that Sibs-ASD would have lower RJA, receptive language, and expressive language scores than Sibs-TD. We also expected to replicate the findings of Hudry and colleagues (2013) that Sibs-ASD would have a smaller gap between receptive and expressive language scores than Sibs-TD. Moreover, we expected RJA at 9, 12, or 15 months of age would positively predict 24-month language scores across groups.

Objectives: This study examined associations between joint attention across 9, 12, and 15 months and multiple measures of language development across 9, 12, 15, 21, and 24 months in Sibs-TD versus Sibs-ASD.

Methods:
Twenty-one Sibs-TD (11 female; 10 male), 20 Sibs-ASD (10 female; 10 male), and their mothers participated as part of a larger longitudinal study of Sibs-ASD. The Early Social Communication Scales were administered to infants, and later coded for Initiating and Responding to Joint Attention (IJA and RJA; Mundy et al., 2003). We assessed infants' receptive and expressive language using the MacArthur Communication Development Inventories (MCDI; Fenson et al., 1993), Vineland Adaptive Behavior Scales (Vineland-II, Sparrow et al., 2005), and the Bayley Scales of Infant Development (Bayley-III, 2006). See Table 1.

Results:
A one-way ANOVA between groups revealed that Sibs-ASD had significantly less growth in IJA from 9 to 15 months compared to the Sibs-TD ($F(1, 30) = 10.107$, $p = .004$). However, there were no significant differences in RJA scores between groups. Sibs-ASD had significantly lower receptive vocabulary at 15 months on the MCDI ($F(1, 30) = 7.25$, $p = .011$) and 21 months on the Vineland ($F(1, 30) = 4.310$, $p = .047$). Sibs-ASD also had significantly lower Bayley expressive language scores than Sibs-TD at 12 months ($F(1, 30) = 4.079$, $p = .053$). Also, the advantage of receptive over expressive language skills on the MCDI at 15 months was significantly lower in Sibs-ASD than Sibs-TD ($F(1, 30) = 11.64$, $p = .002$). Across groups, 15-month RJA was positively correlated with 15-month MCDI expressive ($r = .476$, $p = .004$) and 24-month MCDI expressive scores ($r = .456$, $p= .022$).

Conclusions:
These findings suggest that Sibs-ASD, as a broader group, may not exhibit joint attention deficits when compared to Sibs-TD at one time point. However, Sibs-ASD did exhibit less growth in IJA than Sibs-TD. Our results also indicated that Sibs-ASD appear to have (a) significantly lower receptive language abilities at 15 and 21 months and (b) a significantly lower receptive over expressive language advantage at 15 months compared to Sibs-TD. Across groups, RJA at 15 months predicted expressive language at 15 and 24 months. One key implication of this study is that given the link

between early RJA and language development, facilitation of the early ability to respond to joint attention bids could mediate language deficits in Sibs-ASD.

139   **124.139**   Latency to Share Interest at 12 Months Is Associated with Joint Attention Trajectories in Infants at High and Low Risk for ASD
C. Ponting, M. La-Vu, C. Dull and T. Hutman, Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA

Background: Low-level initiation of joint attention (IJA-low; looking to the examiner and alternating gaze between toy and examiner) does not differ between 12-month olds who are later diagnosed with ASD and those who develop typically. However, IJA is impaired in older children with ASD. We explored individual differences in time to orient to an examiner after viewing an interesting event in 12-month olds at high (HR) and low risk (LR) for ASD to examine reaction time or speed to convert a solitary experience into a shared social experience. We hypothesized that social motivation would be greater and therefore latencies would be shorter in LR infants than in HR infants later diagnosed with ASD. There is limited research on social reaction time in ASD, but older children with ASD do not differ from neurotypical controls in inspection time on computerized nonsocial tasks. Investigation of skills that are intact in infancy but impaired in childhood is expected to reveal useful targets for early intervention.
Objectives: (1) Evaluate latency to share interest in HR and LR 12-month olds; (2) Evaluate relations between latency to orient and frequency of IJA concurrently and longitudinally.
Methods: Participants were 105 infants at high and low risk for ASD. Evaluations at 36 months indicate that 50 were developing typically (TD); 30 showed signs of social and/or language delays; and 25 met criteria for ASD. We administered the Early Social Communication Scales (ESCS; Mundy et al., 2003) at 12 and 18 months. During the wind-up toy portion of the ESCS, the time between presentation of the wind-up toy and first look to the examiner was measured. Latency times were averaged across trials for each participant. IJA-low at 12 and 18 months was coded according to the ESCS manual.
Results: Preliminary results show no difference in average latency time between groups (Mean (Standard Deviation) in seconds: ASD = 6.4 (5.3); Atypical outcome = 6.3 (4.3); TD = 7.9 (5.7)). However, latency to orient across groups was negatively correlated with frequency of IJA-low (r=-.59, p<.01). Additionally, the relation between latency to orient at 12 months and growth in IJA-low from 12 to 18 months was moderated by outcome classification (F(3,52)=5.41, p<.01): the TD group showed a positive relation between latency and IJA growth, and the ASD group showed a negative relation.
Conclusions: Latency to convert one's own enjoyment of an event to a shared social experience did not differ between 12-month olds later diagnosed with ASD and those with other atypical or TD outcomes. Longer latency to disengage from the non-social stimulus and orient toward the examiner appears beneficial among TD infants whereas infants who take longer to orient to the examiner and who are later diagnosed with ASD show decreases in IJA-low from 12-18 months. Social orienting is present in all outcome groups and occurs at comparable speeds. Mechanisms of experience-sharing are evident but function differently among groups, arguing for interventions that focus on transforming social glances into opportunities for shared enjoyment in infants at heightened risk for ASD.

140   **124.140**   Longitudinal Development of Preferential Attention to Biological Motion in Infants at Low and High Risk for Developing ASD
L. Olson[1], R. D. Sifre[2], S. Shultz[3], W. Jones[4] and A. Klin[4], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, Atlanta, GA, (2)Marcus Autism Center, Emory University School of Medicine, Children's Healthcare of Atlanta, Atlanta, GA, (3)Department of Pediatrics, Marcus Autism Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA, (4)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA

Background: Preferential attention to biological motion is typically present in human infants shortly after birth and plays a key role in facilitating filial attachment and guiding social interaction (Simion et al., 2007). In contrast, absence of preferential attention to biological motion in 24-month-olds with ASD (Klin et al., 2009) suggests a disruption of normative social engagement. Little is known, however, about the longitudinal development of preferential attention to biological motion in either TD or ASD populations. Knowledge thereof would be critical in understanding *when* deviations are first observed in ASD and what their developmental consequences may be.
Objectives: To measure the development of preferential attention to biological motion from 2-24 months in infants at high-risk (HR) and low-risk (LR) for ASD.
Methods: 88 LR (49 male) and 95 HR (67 male, 50%>12 months) infants were shown point-light biological motion animations as in Klin et al. (2009). An upright point-light animation was presented on one half of the screen, with the inverted version playing on the other half in reverse order. Piloting revealed that trials lasting <30sec failed to elicit interstimulus shifting in young infants; as a result, we increased trial time by playing two unique animations in succession (referred to as part 1 and part 2). Eye-tracking data, collected at months 2, 3, 4, 5, 9, 15, and 24, were used to calculate percentage of fixation time during the whole trial, part 1, and part 2.

Results: Analyses of percent fixation during the whole trial revealed that at 15 months both LR (M(SD) = 55.8(9.4)%, $t(16) = 2.55$, $p<0.05$) and HR infants (M(SD) = 58.2(9.2)%, $t(24) = 4.52$, $p<0.05$) have a preference for the upright figure that increases at 24 months, (M(SD) = 63.0(9.5)%, $t(28) = 7.33$, $p<0.05$) (M(SD) = 62.6(7.4)%, $t(22) = 7.96$ $p<0.05$). Analyses of percent fixation during part 2 of the trial revealed that LR and HR infants have a preference for the upright figure beginning at 3 months (M(SD) = 57.9(19.4)%, $t(31)= 2.32$, $p<0.05$) (M(SD) = 57.6(19.5)%, $t(34) = 2.32$, $p<0.05$), an effect that remains robust at 4, 5, 9, 15, and 24 months (all p's <0.05) in TD infants. An absence of preferential attention to biological motion was observed at 2 months in LR and HR infants. Conclusions: Our results replicate earlier findings of preferential attention to biological motion in 24-month-old TD infants and map the trajectory of this preference during the first two years of life. The absence of preferential attention to biological motion at 2 months, followed by preference at 3 months and thereafter, matches the existing literature regarding preferential attention to faces, which is present at birth but declines at 4-6 weeks of age before re-emerging at 2-3 months. The current findings provide evidence of a similar transition in orienting to biological motion, and highlight this developmental period as a critical focus for future research into the unfolding of social disability in ASD (Klin, Shultz, Jones, 2014). Future analyses will examine early departures from normative trajectories in infants later diagnosed ASD.

141 **124.141** M-CHAT-R with Follow-up Phone Interview (M-CHAT-R/F): Analysis of Changed Responses

K. R. Bradbury[1], D. L. Robins[2], M. L. Barton[1] and D. A. Fein[1], (1)Psychology, University of Connecticut, Storrs, CT, (2)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA

Background:
The M-CHAT-R is a screening instrument developed for the detection of autism spectrum disorder (ASD) in children ranging from 16 to 30 months of age. It is a parent-completed measure consisting of 20 yes/no items. When a child screens positive on the M-CHAT-R, a more comprehensive follow-up phone interview can be conducted to confirm a parent's answers and rule out potential false positives. A recent validation study suggests that the completion of the follow-up phone interview is most critical for children who fall in a medium risk category, failing between three and seven items on the M-CHAT-R. Despite the importance of the follow-up phone interview, the performance of individual items has not yet been examined. As the American Academy of Pediatrics recommends screening for ASD at 18- and 24-month well-child visits, the current study proposes to compare item performance on the follow-up phone interview (PI) for children who screen positive on the M-CHAT-R at 18- and 24-months.
Objectives:
To examine item performance on the M-CHAT-R Follow-up phone interview at 18 and 24 months.
Methods:
Parents completed the M-CHAT-R at their child's 18- or 24- month well-child visit. The parents of children who screened positive on the M-CHAT-R were contacted, and PIs were conducted. The demographics of the 18-month (n = 400) and 24-month (n = 213) samples that screened positive on the M-CHAT-R were compared using Chi Square or t-tests, as appropriate. The percentage of times each item was asked on the PI (i.e., failed on the M-CHAT-R) was compared between the 18- and 24-month samples using Chi Square. The percentage of answers changed when each item was asked (i.e., fail on M-CHAT-R to pass on PI) was also compared using Chi Square.
Results:
Although samples differed on gender, they did not differ on ethnicity or informant characteristics, such as relationship to child and maternal education. PIs were conducted with over 80% of each sample, and were completed approximately a month and a half after the M-CHAT-R, on average. Items reflecting early development, such as imitation, were asked more often in the 18- than 24-month sample. Responses to twelve of twenty items changed (i.e., Fail to Pass) more than 60% of the time when asked on the PI. The most frequently changed items included encouraging parents to watch him/her, making unusual finger movements, and engaging in pretend play. Three items, pointing to direct attention, interest in peers, and response to name, were significantly more likely to change in the 24- than 18-month sample.
Conclusions:
Results suggest that the performance of individual M-CHAT-R and PI items may differ depending upon the age at completion. High frequency of change in response for more than half of the items reinforces the importance of the PI in the screening process. Parents may be cued to look for certain behaviors after completing M-CHAT-R leading to changed responses on the PI. Alternatively, parents may not understand the question as intended. Further research examining the predictive nature of change in item response for diagnosis is warranted.

142 **124.142** Measuring the Importance of Fyi Screener Items in Predicting Adost Totals at 12 and 18 Months: A Machine Learning Approach

E. S. Kim[1], S. H. Kim[2], S. Macari[3], K. Chawarska[3] and F. Shic[3], (1)Yale University, New Haven, CT, (2)40 Temple St., Suite 7D, Yale University, New Haven, CT, (3)Child Study Center, Yale University School of Medicine, New Haven, CT

Background: The First-Year Inventory (FYI) parent questionnaire is designed to screen for autism

(Reznick et al., 2007). Given the potential benefits of early intervention (Filipek et al., 1999), it is important to identify those active ingredients most informative of later outcome.

Objectives: To identify FYI items from 12 months that predict levels of autism symptoms at 12 and 18 months measured by the ADOST algorithmic total, among high-risk (HR) infant siblings.

Methods: Parents of HR siblings (N=76) completed the FYI at 12 months. Those children received ADOST evaluations at 12 and 18 months. We used random forest machine learning (#trees=500, #tries=35; similar to Wu et al. 2003) to measure the importance of individual FYI items, predicting ADOST algorithm totals at 12 and 18 months. Random forests measure the importance of each training variable in terms of resultant change in sample variance when moving that training item's position within the step-wise predictive model. Items with larger changes are more important. We selected as important those variables whose scores affected variance at a higher rate.

Results: Random forest variable selection isolated three FYI questions, important in predicting ADOST totals at both 12 and 18 months: Q37 (restricted interest in parts of toys, Sensory-Regulatory Functions—SRF—domain), Q49 (social interactive play, social communication—SC—domain), and Q24 (vocal imitation, SC). Two items were important for predicting 18 but not 12 month ADOST totals: Q57 (reactivity, SRF) and Q12 (attention to others, SC). Six items were important for predicting 12 but not 18 month ADOST totals: Q43 (stuck postures, SRF), Q48 (fixated interest in certain toys, SRF), Q6 (avoiding eye contact, SRF), Q11 (isolated play, SRF), Q45 (kicking, SRF), Q41 (feeding, SRF).

Conclusions: We have applied machine learning to identify early screening questions that are most predictive of later autism symptom levels. In predicting ADOST total scores, the importance of an FYI item may reflect three properties: [1] prevalence of the behavior at 12 months, [2] good operationalization in the FYI and ease of evaluation of the behavior by parents, and [3] developmental stability of the behavior. Items that were important in either prediction may be prevalent and easily detectable at 12 months. Items Q37, Q49, and Q24 were important for predicting both 12 and 18 month ADOST totals, suggesting developmental stability, especially because these are closely related to core symptoms of ASD. Items Q57 and Q12 were important for predicting 18- but not 12-month ADOST totals, possibly indicating association with the development of more refined and advanced social communication behaviors (Q12), and with impairments in sensory-regulatory functions (Q57), that emerge between 12 and 18 months. These items may represent early, recognizable precursors of greater impairments that develop between 12 and 18 months. The six items that were important for predicting ADOST totals at 12 but not 18 months all fall within the sensory-regulatory function domain. These may be easier for parents to evaluate at 12 months than social communication behaviors. Their decline in importance at 18 months may reflect the specificity of those behaviors to an earlier developmental epoch.

143 **124.143** Motor Development, Autism Symptoms, and Emerging Executive Functioning in Infants and Toddlers at High and Low Risk for ASD

*T. St. John[1], A. M. Estes[2], S. L. Alvarez[3], S. Dager[3], S. J. Paterson[4], J. Pandey[5], R. T. Schultz[4], J. R. Pruett[6], K. N. Botteron[7], H. C. Hazlett[8] and J. Piven[6], (1)University of Washington Autism Center, Seattle, WA, (2)Speech and Hearing Sciences, University of Washington, Seattle, WA, (3)University of Washington, Seattle, WA, (4)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (5)The Children's Hospital of Philadelphia, Philadelphia, PA, (6)*Shared Senior Author, ., NC, (7)Washington University School of Medicine in St. Louis, St. Louis, MO, (8)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: The A-not-B task, developed by Piaget, is one of the classic tests of human cognitive development and has been used widely in developmental research. This task is based on the theory of object permanence and is purported to measure working memory, response inhibition, and goal-directed behavior. Ability to perform the A-not-B task requires acquisition of specific motor milestones (e.g., reaching and grasping). Furthermore, research suggests that motor abilities and executive functioning are associated. However, relationships between abnormal early motor ability, impaired performance on the A-not-B task, and later development of autism symptoms in a high-risk (HR) sample having an affected older sibling are not well understood.

Objectives: To assess whether performance on the A-not-B task at 12 and 24months is associated with motor development and autism symptoms. We hypothesize that 1) better motor skills will be associated with better performance on the A-not-B at both 12 and 24months and 2) toddlers who develop autism symptoms at 24months (HR-ASD-Positive) will perform worse on the A-not-B at 12 and 24months than those without autism symptoms (HR-ASD-Negative, LR-ASD-Negative).

Methods: Participants are part of a multi-site, longitudinal study of brain and behavioral development in infants at high-risk (HR) and low-risk (LR) for ASD followed from 6months and assessed for autism symptoms at 24 months (HR-ASD-Positive, n=34; HR-ASD-Negative, n=133; LR-ASD-Negative, n=69). A-not-B data was collected at 12months (n=291) and 24months (n=226). In the A-not-B task, the infant watched as a toy was hidden to the left or right of midline. The infant was encouraged to find the toy after a delay of either 5s or 12s. Once the infant found the hidden toy on two consecutive trials, the side of hiding was switched. A maximum of 24 trials were administered. Performance was measured by the percentage of accurate reaches/errors at each delay interval. Motor skills were assessed with the Mullen Scales and Vineland. Autism symptoms were assessed using the ADOS and DSM at 24months.

Results: Preliminary results revealed that nearly one-third of HR and LR 12-month-olds had unusable

A-not-B data and one-quarter had unusable data at 24months. These children had lower fine motor skills at 12 months and lower fine and gross motor skills at 24 months as compared with children with useable A-not-B data. The groups (HR-ASD-Positive, HR-ASD-Negative, LR-ASD-Negative) did not differ on A-not-B performance at 12 months. At 24months, the HR-ASD-Positive group demonstrated significantly lower total percent correct than the LR-ASD-Negative group. The HR-ASD-Negative group demonstrated significantly decreased performance (percent correct reversal at 5s, total reversal errors, and total percent correct) as compared with the LR-ASD-Negative group. Further analyses will investigate the interaction between group, motor ability, and A-not-B performance and the role of overall cognitive ability in A-not-B performance.

Conclusions: Preliminary evidence suggests that difficulties on the A-not-B task at 12 and 24months may be associated with motor ability at 12 and 24 months, with autism symptoms at 24months, and with autism risk status. Future studies should evaluate possible causal pathways between early motor deficits and later outcomes in ASD.

144 **124.144** Online Queries of Parents Suspecting Their Child Has ASD: A Clinician Mediated Machine Learning Prediction of ASD Risk

*E. Yom-Tov[1] and **A. Ben-Sasson**[2], (1)Microsoft Research Israel, Herzeliya, Israel, (2)University of Haifa, Haifa, Israel*

Background: The increasing rates of autism spectrum disorders (ASD) and the growing awareness of them lead more parents to suspect ASD in their child. These early concerns can precede their referal of a professional by months. Parents are increasingly approaching online communities for information about their child's development expecting to verify/dispute their concerns by a largely non-professional community. Online queries are a testimony to the signs alarming parents. Machine learning tools may offer a way to facilitate an estimate of the degree of ASD risk of the child in an online query.

Objectives: (1) Identify signs that differentiate online queries of children with low, medium, versus high ASD risk as rated by clinicians; (2) Test the efficacy of machine learning tools in classifying a child for ASD risk.

Methods: Yahoo Answers, a social question and answering site, was mined for queries of parents asking the community whether their child has ASD. The 194 questions from the resulting corpus were sampled for this study (Mean age = 39.59 months; 72% < 3 years; 86.32% boys). Domain expert clinicians performed a content analysis of the types of signs described in the question. The child's risk level for ASD in the question was rated as low, medium, and high by a different clinician. Machine learning tools were applied for predicting risk from text or coded signs.

Results: Of the 194 questions, 31 were rated as low risk, 55 medium risk, and 108 high risk. There was no difference in gender distribution between risk groups. Chi square tests showed that questions rated as high risk contained a significantly ($p < .05$) higher rate of social, communication, language, and cognitive problems as well as repetitive and restricted behaviors in text. Of the 55% of parents that mentioned a language problem there was a 95.3% chance of high or medium risk compared to 70.4% for the rest of the sample. 20.6% of the sample did not mention language problems and no repetitive and restricted behaviors. For them the chance of high or medium risk was 55%. 24.7% of parents did not report language problems but reported repetitive and restricted behaviors. For them the chance of high or medium risk was 83.3%. When predicting if a question was medium or high risk using the text of the question, an automatic classifier (decision tree) reached an Area Under the Curve (AUC) of 0.63, compared to 0.78 when the classifier used coded signs.

Conclusions: Most children for which parents suspect they have ASD are judged by a clinician as in need for a clinical evaluation. Parents report signs in all core ASD diagnostic domains as well as concerns related to cognitive functioning. Accurately predicting ASD risk from a question requires a mediating step of classifying text into symptom domains. Findings support the need for a computerized tool to assist parents in tagging their concerns in order to obtain a risk estimate.

145 **124.145** Optimizing Stimulus Selection for Early Detection of ASD Based on Preferential Attention to Audiovisual Synchrony in Toddlers

A. Abraham[1], A. Trubanova[2], J. B. Northrup[3], D. Lin[4], P. Lewis[5], A. Klin[1], W. Jones[1] and G. J. Ramsay[1], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, (3)University of Pittsburgh, Pittsburgh, PA, (4)Department of Neurology, Massachusetts General Hospital, Boston, MA, (5)Marcus Autism Center, Atlanta, GA

Background: Our previous studies of two-year-olds with ASD demonstrated increased orientation to physical contingencies relative to social contingencies in a preferential looking paradigm when physical contingencies were defined by audiovisual synchrony between sound and light while social contingencies contrasted faces and voices with moving objects. Typically developing (TD) toddlers preferentially attended to social contingencies. We previously demonstrated a likelihood-ratio-based classifier discriminating between ASD and TD toddlers using eye-tracking measures of behavioral response to social and physical contingencies based on a variety of stimulus types but did not test for the effect of clip type.

Objectives: This study uses a permutation-based stimulus selection technique to optimize the

performance of eye-tracking measures of behavioral responses to social and physical contingencies to discriminate between ASD and TD toddlers.

Methods: Using a preferential looking task, TD and ASD toddlers (Table 1) were presented with videos of audiovisual stimuli that paired faces and geometric shapes with tones or speech. A second cohort of TD and ASD toddlers were presented with naturalistic videos of a caregiver paired with one of four toys – rocking horse, light-up toy, mobile, or train – exhibiting different types of motion synchronized with the caregiver's speech. Using eye-tracking measures of fixation on regions of interest, the optimal classifier for discriminating ASD from TD participants was created using a likelihood ratio test. Receiver Operating Characteristics with leave-one-out cross-validation (LOOCV) evaluated the performance of the classifier. To optimize the stimulus set for maximizing the classifier performance, each possible permutation of the stimulus clips was used to train the classifier and the corresponding area under the curve (AUC) was used to identify the combination of clips with the best classification performance.

Results: We obtained a maximum AUC = 0.968 and sensitivity and specificity of 91% using the classifier to distinguish between TD and ASD toddlers for the preferential looking task. The top ten clip combinations had an AUC value centered on 0.967 ± 0.0001. After LOOCV, the best clip combination yielded an AUC = 0.967 ± 0.004, sensitivity = $90.8 \pm 0.9\%$, and specificity = $90.4 \pm 0.9\%$. Using the naturalistic stimuli, we obtained a maximum AUC = 0.944 with sensitivity and specificity of 88% (Figure 1). Furthermore, the mobile toy clip comprised 50% of the clips in the best clip combination with the highest AUC indicating that the rotational motion of the mobile toy exhibited the greatest difference in perceptual salience between ASD and TD groups.

Conclusions: Unlike traditional strategies of pooling stimuli for classification analysis, this study used a permutation based stimulus selection strategy to select the video clips that maximized the AUC. This significantly improved the discrimination between ASD and TD toddlers and inherently sorted the stimuli based on clip features. In addition to maximizing classifier performance, the permutation based clip selection also revealed which type of toy motion showed the greatest difference in salience between groups.

146 **124.146** Parent Education Level and Developmental Progress in Toddlers with ASD

T. Aronson[1], *J. Lorenzi*[1,2] *and S. Hoffenberg*[1], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Virginia Tech, Blacksburg, VA

Background: Given disparities regarding age of diagnosis and access to services amongst underserved populations, (Liptak et al., 2008) it is vital to examine factors associated with developmental gains in toddlers with ASD. Previous research has demonstrated an association between parental education level and earlier diagnosis as well as family's income level and risk for ASD (Fountain et al., 2010; Rai et al., 2012). Additionally, maternal education level has shown to predict developmental gains following intervention (Ben Itzchak et al., 2011). Impact of paternal education in relation to developmental gains in early toddlerhood is less clear.

Objectives: The purpose of this study is to examine whether parent education level is associated with developmental progress in toddlers with ASD.

Methods: The current sample included 24 community-referred toddlers with ASD (20 males) who participated in a longitudinal study on social engagement. The study consisted of two separate visits (about 15 months apart), both of which included the Autism Diagnostic Observation Schedule, Second Edition, and Mullen Scales of Early Learning (Mullen). Families received ASD diagnoses and recommendations from a multidisciplinary team. In order to consider developmental progress on the Mullen between visits (mean age Time 1 (T1)=22.89 months; mean age Time 2 (T2)=38.30 months), a ratio was computed for each scale [(T2 age equivalent–T1 age equivalent)/(T2 chronological age–T1 chronological age)]. A ratio of greater than 1 indicated that for the given scale, the participant gained more in age equivalent (months) than he or she aged chronologically. Parents self-reported on educational attainment; this was coded into two categories: below bachelor's degree (47.83% of mothers, 52.17% of fathers) and bachelor's degree or beyond. Analyses considered toddlers' developmental progress by determining whether parental education level was associated with aforementioned Mullen ratios.

Results: Given that Mullen Fine Motor scores decreased significantly between visits, $t(23)=2.47$, $p=.02$, toddlers' developmental progress was considered in terms of the remaining three Mullen scales (Visual Reception, Receptive Language, Expressive Language). One subgroup of participants consisted of those who made gains in all three areas, ("more progress"; 48.7% of participants). The other subgroup consisted of those with gains on two or fewer scales ("less progress"; 58.3% of participants). Fisher's exact tests (rather than chi-square tests of independence, due to low expected cell counts) were conducted to examine the association between developmental progress and maternal/paternal education level. The association between maternal education and developmental progress was not significant, Fisher's exact test $p=.68$. Conversely, there was a significant association between paternal education and developmental progress, Fisher's exact test $p=.01$, whereby higher paternal education (i.e., bachelor's degree or beyond) was associated with "more progress."

Conclusions: When analyzing toddler outcomes between visits in three areas on the Mullen (Visual Reception, Expressive and Receptive Language), there was a significant association between paternal education level and developmental progress. There was no significant association with maternal education. Future research should examine the relevance of socioeconomic status and

parental education level to ASD prognosis as well as how interventions can be adapted to better address needs of families from varying backgrounds.

147 **124.147** Parent Prediction of ASD in Infants at Risk

C. Wang[1], M. Feldman[2], R. A. Ward[3], M. L. Hudson[4] and X. Liu[5], (1)Centre for Applied Disability Studies, Brock University, New Westminster, BC, Canada, (2)Centre for Applied Disability Studies, Brock University, St. Catharines, ON, Canada, (3)Applied Disability Studies, Brock University, St. Catharines, ON, Canada, (4)Psychiatry, Queen's University, Kingston, ON, Canada, (5)Psychiatry, Queen's University, Kingston, ON, Canada

Background: Infants with older siblings with ASD are at biological risk for ASD or the broader phenotype. Early identification could lead to earlier treatment and prevention.
Objectives: This study compared three groups of 1 to 36 month children ($N = 108$) at-risk (because they had an older biological sibling with ASD) on the Parent Observation of Early Markers Scale (POEMS, Feldman et al., 2012). The POEMS has 61 items completed prospectively by parents. Parents rate each item as 1 (no problem) to 4 (severe problem) with ½ scores allowed; scores range from 61-244. Elevated items are those with scores of 3, 3.5 or 4.
Methods: The groups were: (1) 13 children who were eventually diagnosed with ASD by 13 years; (2) 5 children who lost their ASD diagnosis by 6 years; and (3) 89 children never diagnosed. A mixed ANOVA determined the differences between the three groups on the POEMS total scores and elevated items.
Results: Using all available POEMS scores at 9, 12, 18, 24 and 36 months, total POEMS scores differed between groups, $F(2, 69) = 11.78$, $p < .001$, partial eta-squared (h^2) = .025, and group X age was significant, $F(8, 276) = 3.76$, $p < .001$, (h^2) = .098. Post hoc comparisons using the Tukey HSD test showed that the diagnosed group ($M = 87.76$, $SD = 28.68$) had significantly higher scores than the undiagnosed group ($M = 67.83$, $SD = 8.33$). The lost diagnosis group ($M = 74.70$, $SD = 8.63$) did not differ significantly from the diagnosed and undiagnosed groups. The groups differed on the number of elevated items, $F (2, 70) = 9.34$, $p < .001$, $h^2 = .21$, and group X age was significant, $F (8, 280) = 3.16$, $p < .001$, (h^2) = .083. Post hoc comparisons using the Tukey HSD test showed that the diagnosed group ($M = 7.3$ $SD = 9.78$) had significantly more elevated items than the undiagnosed group ($M = 1.10$, $SD = 2.34$), but not the lost diagnosis group ($M = 1.93$, $SD = 1.64$) that also did not differ from the undiagnosed group. (3) Repeated measures analyses revealed a significant age effect as the children got older on total POEMS scores $F (4, 276) = 4.55$, $p < .001$, $h^2 = .062$, but not for elevated items $F (4, 280) = 2.28$, $p = .061$, $h^2 = .032$. Significant differences in total scores and elevated items between the undiagnosed and diagnosed groups began emerging as early as 12 months. Across ages, imitation, verbal communication, pointing in response to a question, tolerance for waiting and acceptance of food most differentiated the at risk infants eventually diagnosed from those who had not been diagnosed by age 13 years.
Conclusions: The findings suggest that by completing the POEMS prospectively, parents of at-risk infants may be able to predict which infants will or not be diagnosed, or lose their ASD diagnosis, as early as 12 months of age, with prediction increasing the closer the child is to 36 months.

148 **124.148** Parental Concerns and Their Relation to Early Intervention and Social-Communicative Functioning within the First Two Years of Life

L. V. Ibanez[1], E. A. Karp[2], Z. Warren[3], D. S. Messinger[4] and W. L. Stone[2], (1)University of Washington, Seattle, WA, (2)Psychology, University of Washington, Seattle, WA, (3)Pediatrics, Vanderbilt University, Nashville, TN, (4)University of Miami, Coral Gables, FL

Background:
Parental concerns about a toddler's development may serve as a catalyst for seeking guidance, diagnostic evaluations, and/or early intervention services. For children diagnosed with ASD, on average, parents report becoming concerned about their child's development by 18 months. However, little is known about how these concerns develop, whether they prompt parents to seek early intervention services for their toddlers, and the extent to which they predict toddlers' later social-communicative functioning. The current study examined the presence of parental concerns in infants at risk for ASD with an ASD diagnosis (Sibs-HR/ASD), at risk but without an ASD diagnosis (Sibs-HR/ND), and low risk controls (Sibs-LR).
Objectives:
Examine: 1) change in parental concerns between 12 and 18 months, 2) the extent to which parental concerns at 18 months increase the likelihood that toddlers are enrolled in intervention services at 18 months, and 3) the extent to which parental concerns at 18 months predict childrens' language and social-communication at 24 months.
Methods:
Sibs-HR/ASD ($n=21$), Sibs-HR/ND ($n=39$), and LR-sibs ($n=41$) were examined at 12, 15, 18, and 24 months. At 12-18 months, parental concerns were calculated by summing parent's responses indicating level of concern (i.e., 0=no, 1=a little, 2=yes) across the 7 items on the Parent Concern Form, which focuses on motor, language, and social behaviors. At 18 months, toddlers were identified as receiving early intervention; 12 Sibs-HR/ASD, 4 Sibs-HR/ND, and 3 LR-sibs were receiving services

per the Child Treatment Questionnaire. At 24 months, expressive and receptive language were measured via T-scores on the Mullen, and social-communication was measured via Vineland standardized Communication and Socialization scores.
Results:
For parental concerns, a repeated-measures ANOVA yielded significant main effects for Age and Diagnostic Group, and their interaction, $ps<.01$ (see Table 1). Post-hoc analyses indicated that: (1) at 12 months, parental concerns were significantly higher for Sibs-HR/ASD and Sibs-HR/ND than Sibs-LR, $ps<.03$; (2) at 15 and 18 months, parental concerns were significantly higher for Sibs-HR/ASD than Sibs-HR/ND and Sibs-LR, $ps<.01$; and (3) for Sibs-HR/ASD only, parental concerns significantly increased between 12 and 18 months, $p<.02$. A logistic regression indicated that, across all toddlers, higher levels of parental concerns at 18 months increased the likelihood that early intervention services were being received, $OR=1.51$, $p<.01$.
For Sibs-HR/ASD, higher levels of parental concerns at 18 months predicted lower levels of receptive language ($r=-.49$), communication ($r=-.65$), and socialization ($r=-.59$) at 24 months. For Sibs-LR, higher levels of parental concerns at 18 months predicted lower levels of expressive language, $r=-.31$.
Conclusions:
At 1 year of age, parents of Sibs-HR were more concerned about their infant's development than Sibs-LR parents; however, concerns significantly increased over the following 6 months only for those Sibs-HR who received an ASD diagnosis at age 2. The presence of concerns increased the likelihood that toddlers would be receiving intervention by 18 months. While parental concerns predicted lower levels of expressive language for Sibs-LR, they predicted both language and *social* outcomes for HR-sibs/ASD, suggesting that early developmental concerns may map on more closely to later ASD-specific deficits for these toddlers.

149 **124.149** Patterns of Repetitive Behavior with Objects in Infants Developing ASD

M. Miller[1], G. S. Young[2], A. Belding[3], A. M. Hill[1], A. Tubbs[1] and S. Ozonoff[4], (1)UC Davis MIND Institute, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Psychiatry, UC Davis MIND Institute, Sacramento, CA, (4)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis Medical Center, Sacramento, CA

Background: Prior studies examining early manifestations of ASD have largely focused on social communication. However, it is increasingly recognized that repetitive behaviors also emerge early. Studies of infant siblings indicate that, at 12 months of age, infants who later developed ASD showed significantly more repetitive behaviors with objects (Ozonoff et al., 2008) and stereotyped motor mannerisms (Elison et al., 2014). However, it is unknown whether such behaviors are evident prior to the first birthday nor how they develop over the first years of life.
Objectives: We evaluated infant behaviors with objects from 9 through 36 months to determine whether infants later diagnosed with ASD show distinct early patterns.
Methods: Infant siblings of children with ASD (high-risk) or typical development (low-risk) were administered a task designed to elicit repetitive object use (Ozonoff et al., 2008) at 9, 12, 15, 18, 24, and 36 months of age. Of 151 infants, 59 were classified as low-risk typically developing (LR-TD), 76 as high-risk non-ASD (HR-Non-ASD), and 16 as high-risk ASD (ASD) at 36 months. Behavior was coded using seven codes, four of which were hypothesized to be developmentally typical (bang, drop/throw, shake, functional/symbolic play), and three hypothesized to be atypical (spin, rotate, unusual visual inspection). Employing a Generalized Estimating Equations approach using a negative binomial distribution with log link, we evaluated group differences in repetitive behavior frequencies between 9 and 36 months.
Results: The interaction between type of repetitive behavior, visit, and outcome was significant (Wald $\chi^2=308.29$, $df=60$, $p<.001$). The groups showed few persistent differences in typical behaviors (Figure 1). The ASD and HR-Non-ASD groups displayed significantly less shaking at 9 months and more banging at 12 months relative to the LR-TD group, and the ASD group displayed significantly less dropping/throwing at 24 months relative to the LR-TD group. From 12-18 months, the LR-TD and HR-Non-ASD groups engaged in significantly more functional/symbolic play than the ASD group. Regarding atypical behaviors (Figure 2), at 9 months, the ASD group engaged in significantly more unusual visual inspection than the LR-TD and HR-Non-ASD groups, persisting through 36 months. The ASD group also engaged in significantly less spinning than the LR-TD and HR-Non-ASD groups at 9 months. There were no differences in rotating, although trends for the ASD group being higher were evident at 15 and 18 months.
Conclusions: Unusual visual inspection of objects is present and stable as early as 9 months of age in infants developing ASD. This replicates and extends, in an independent sample, prior findings from 12-month-olds developing ASD (Ozonoff et al., 2008), demonstrating that unusual visual inspection is present earlier than previously thought and is one of the earliest behavioral predictors of ASD outcome yet documented. The groups showed few persistent differences in developmentally typical repetitive behaviors, suggesting that those developing ASD are not broadly repetitive overall, but display specific atypical repetitive behaviors with objects. These results suggest that close monitoring of unusual visual inspection may be an important aspect of early detection efforts and could be incorporated into screening and diagnostic tools.

124.150 Perception of Biological Motion and Integration of Audio-Visual Stimuli in Infants at Risk for Autism

H. S. Reuman[1], R. Tillman[2], T. Kim[3], E. J. Levy[1], K. Law[1], A. Naples[1], K. K. Stavropoulos[1], A. T. Odonkor[3], S. H. Kim[1], E. Schoen Simmons[1], K. K. Powell[1], S. Macari[4], F. Shic[1,4], K. Chawarska[4] and J. C. McPartland[1], (1)Child Study Center, Yale University, New Haven, CT, (2)Clinical Psychology, University of Maryland, College Park, MD, (3)Yale University, New Haven, CT, (4)Child Study Center, Yale University School of Medicine, New Haven, CT

Background: Biological motion (BM) perception and multisensory integration (audio-visual synchrony; AVS) are critical processes in typical development that are implicated as potential mechanisms of dysfunction in ASD. In typical development, preferential attention to biological motion and successful detection of temporal contingency between auditory and visual events develop early in life and facilitate interpersonal interactions. Behavioral research indicates that these abilities are impaired in toddlers diagnosed with autism spectrum disorder (ASD). However, the developmental emergence and neural underpinnings of these abilities are poorly understood.

Objectives: Neural responses to BM and AVS were compared in infants at high-risk (HR; having an older sibling with ASD) and infants at normal risk (NR; no family history of ASD) for ASD. Through investigation of electrophysiological markers of BM and AVS, we aimed to (a) compare sensitivity to BM, (b) evaluate the degree of neural facilitation when processing multisensory stimuli, and (c) track the emergence of BM sensitivity and AVS facilitation to define typical vs. atypical trajectories.

Methods: Through a longitudinal design, HR (n=36), and NR (n= 42) infants were assessed at three-month intervals between three and twenty-four months. EEG was recorded with a 128-channel Hydrocel Geodesic Sensor net while infants viewed point-light displays illustrating BM and scrambled motion (SM; Experiment 1) or unimodal/bimodal auditory (tone) and visual (blue circle) stimuli (Experiment 2). In Experiment 1, two event-related potentials (ERPs) indexing BM perception (N200, negative deflection over right occipitotemporal scalp between 200-300ms; PSW, late anterior positive slow wave between 900-1500ms) were examined. In Experiment 2, two ERPs indexing multisensory integration (N100, negative deflection over fronto-central scalp between 90-145ms; N200, negative deflection over occipitotemporal scalp between 150-200ms) were assessed.

Results: Preliminary analyses from Experiment 1 found that neither HR nor NR infants exhibited significant differentiation between BM and SM (p>.05) at the six and nine-month time points. Descriptively, both groups exhibited attenuated N200 to BM, relative to SM, at six months, but this differentiation did not reach significance. NR infants, but not HR infants, continued to demonstrate this N200 attenuation to BM at nine months. In Experiment 2, 9 to 12 month NR infants exhibited a significantly enhanced N200 in response to AVS, (p=.01), whereas HR infants did not.

Conclusions: HR and NR infants elicited differential neural responses to BM at six months of age, and 9-12 month old HR infants exhibited neural atypicalities for AVS. These characteristic changes in neural response to BM and AVS over the first two years of life have the potential to serve as early indicators of ASD and to guide development of individually-tailored early interventions.

124.151 Predictors of Functioning in Preschool and School Age Children with ASD

M. C. Lyons[1], R. Paul[2], K. D. Tsatsanis[3] and F. Shic[4], (1)Yale University, New Haven, CT, (2)Sacred Heart University, Fairfield, CT, (3)Child Study Center, Yale University School of Medicine, New Haven, CT, (4)Child Study Center, Yale University, New Haven, CT

Background:
Many longitudinal studies thus have examined the stability of the ASD diagnosis over time, yet occurred at a 1 to 2 year period, at preschool age, when the symptomology is most prototypical (Thurm, Lord, Lee & Newschaffer 2006). There is a need for longitudinal research on the trajectories of development and predictors of functioning for school age children that explore the core developmental factors involved. Smaller studies have looked at measured outcome for three time points (Charmen, 2005); however, most have focused on outcome rather than level of functioning across time.

Objectives:
To examine what degree measures of early communication, language, cognitive and social competence predict later outcomes in nonverbal functioning and autism severity in a cohort of children with ASD.

Methods:
Participants included 74 children with ASD who were initially derived from a sample of children who were evaluated at ages two (toddler), and four (preschool), as part of participation in the NAAR/CPEA and STAART funded Yale projects. These participants were seen again at age eight (school age) as part of their participation in the NICHD funded study on the Developmental Processes, Trajectories, and Predictors of Outcome in a Longitudinal Cohort. The assessments at ages two and four included measures of autism, adaptive, cognitive and language functioning and were used to examine the predictability across time of autism severity and nonverbal functioningfor this cohort.

Results:
Pearson's correlations were conducted to assess the cross-time association between a variety measures. All characterization measures demonstrated strong correlations from 1st to 2nd visits and from 2nd to 3rd visits. Multiple linear stepwise regressions were further run to identify significant

relationships over time among autism severity and cognitive development with measures of language, social, adaptive and cognitive functioning.

Preliminary results show a shift in predictors based on point of assessment. 30% of the variance in ADOS calibrated severity score (CSS) measured at age four was predicted by the CSS at age two (R^2=.296, $F(1,67)$=28.11, p<.000) whereas a shift to 38% of the variance in calibrated severity scores at age eight was predicted by socialization and functional communication (Vineland) in combination with CSS at age four (R^2=.381, $F(3,57)$=11.68, p<.000).

47% of the variance in nonverbal performance at age four was predicted by, non-verbal developmental quotient (Mullen), functional communication (Vineland), and autism severity (CSS) at age two (R^2=.473, $F(3,63)$=18.82, p<.000). By age eight, however, VDQ (Mullen) is most strongly predictive of nonverbal performance with 57% of the variance. (R^2=.570, $F(1,64)$=84.82, p<.000).

Conclusions:

The combinations of multiple source of information including direct assessment and parent interview lead to more stable prediction of functioning, particularly in the transition from preschool to school age. The identification of early mediators will also inform research on the predictive power of various measures and may contribute to establishing goals for early intervention services.

152   **124.152**   Reduced Attention to Fearful Faces in 10 Month Old Infants at Risk for Autism

J. L. Kleberg[1], P. Nyström[1], G. Gredebäck[1], S. Bolte[2,3] and T. Falck-Ytter[1,4], (1)Department of Psychology, Uppsala University, Uppsala, Sweden, (2)Division of Child and Adolescent Psychiatry, Stockholm County Council, Stockholm, Sweden, (3)Center of neurodevelopmental disorders, Karolinska Institutet, Stockholm, Sweden, (4)Dept. of Women's & Children's Health, Karolinska Institute, Stockholm, Sweden

Background: Autism spectrum disorder (ASD) is associated with atypical face perception. Studies with children and adults have found that people with ASD are less sensitive to configural information in faces than controls. ASD is also commonly associated with impaired attention to emotional faces. These impairments may be most pronounced for negative and threat related emotions such as fear. Although atypical face scanning patterns may be one of the earliest signs of ASD in infants, little is known about the underlying mechanisms.

Objectives: Here we assessed sensitivity to emotional expression and configural information in infants with typical development and infants at risk for ASD (HR-siblings) HR-siblings have an increased risk of developing ASD compared to the general population. Given the high risk for ASD and related developmental concerns in HR-siblings, we predicted that they would show reduced attention to fearful faces than typically developed infants. Secondly, we predicted HR-infants to be less sensitive to spatial inversion of faces, which disrupts configural processing.

Methods: 26 HR-infants (22 female) and 12 Low-risk infants (LR-infants; 6 female) were included in the final sample. The infants were 10 month old (M=10.23 months; sd = 0.45). There were no group differences in age or verbal and nonverbal cognitive development as measured with the Mullen Scales of early learning (MSEL), (all *ps* >.05). Gaze data was recorded using a corneal reflection eye tracker. The dependent variable was looking time to the whole face. 4 static images of happy or fearful adult faces were presented one at a time in random order (5 seconds duration). Faces were presented either upright or inverted. All trials were preceded by a central moving animation in order to attract the infant's attention. Trials were included if the infant looked at the center of the screen at trial onset.

Results: A group (HR/LR) x Emotion (Fearful/Happy) interaction effect was found (*p* < .05). Follow up comparisons revealed that this was driven by longer looking time to fearful faces in the LR- as compared to the HR-group (*p* <.05). The LR-group looked longer at fearful than happy faces (*p* <.05) whereas the HR-group did not differentiate reliably between emotions. No main or interaction effect of orientation was found

Conclusions: We found evidence of reduced attention towards fearful faces in infants at risk for ASD. Moreover, LR- but not HR- infants looked longer at fearful than at happy faces. These results are consistent with the theory that altered processing of fearful faces is an early marker of the ASD phenotype. These results are consistent with studies in older populations with ASD. Follow up of the infants studied here will determine if the performance of the HR-siblings as a group is particularly pronounced among those later being diagnosed with ASD. In contrast, no effect of spatial orientation was found. This means that no evidence of configural face processing was found in any of the groups

153   **124.153**   Referral Patterns and Early Signs of Possible ASD Among Children Referred for Generic Developmental Early Intervention

N. Rasuratnam[1], M. Penner[2], C. Saul[3], J. A. Brian[4], L. Vismara[5] and W. Roberts[1], (1)Integrated Services for Autism and Neurodevelopmental Disorders, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)York Region Early Intervention Services, Newmarket, ON, Canada, (4)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital/ U of Toronto, Toronto, ON, Canada, (5)Department of Psychology, York University, Toronto, ON, Canada

Background: Early identification of autism spectrum disorders (ASD) is essential to providing intervention during a time when neural plasticity allows for optimal social learning. Few studies have

looked at the early signs of ASD in high-risk community samples, such as children referred to generic developmental early intervention (EI) programs.

Objectives: The objective of this study was to describe a developmentally high-risk, community-based cohort of children referred to EI with regard to their demographic characteristics, reasons for referral, source of referral, as well as the prevalence of early signs of ASD in this population. An additional aim was to assess the implications of these findings for EI intake processes and service delivery for children showing early signs of ASD.

Methods: A retrospective chart review was conducted using EI electronic records from York Region, an urban regional municipality in the Greater Toronto Area, Ontario, Canada. All referrals and intake interviews conducted between January 2014 and April 2014 were screened for inclusion. Children with conditions that would automatically generate a referral were excluded (those referred through prematurity pathways, ASD-sibling monitoring pathways and those with established diagnoses that generate referrals, such as Trisomy 21). Data were extracted from the referral form and from the intake interview conducted by York Region EI staff. Descriptive statistics were calculated for referral data and early signs of ASD. ANOVA was used to evaluate the differences in the referral ages based on the referral source.

Results: During the four month period, there were 759 referrals to York Region EI, of which 81 were excluded due to being automatically generated referrals. The remaining 678 referrals were included in the analysis. The mean age at referral to EI was 27 months (95% confidence interval 12 to 47 months). The source of referral was available for 559 charts. Caregivers were the source of referral in the majority of cases (54%, n=302), compared with physicians (33%, n=185) and others (13%, n=72). There was a significant difference in the age at referral between the three sources, with physicians making the earliest referrals (F=3.5, p=0.015). Screening tools were noted in only 20% of referrals. Delayed domains of development were indicated in 126 cases. Speech and language delays were identified in 86% of these cases, and social/emotional delays (which may be indicative of ASD) were identified in 44%. In the intake interviews, the proportion of the sample showing specific early signs of ASD varied from 1-59%.

Conclusions: Our results were disappointing in both the age at referral to EI and the reported use of developmental screening tools, given recent local efforts to implement routine eighteen month developmental screening. The number of children with potential early signs of ASD varied greatly, and further characterization of ASD risk in this population was limited by the lack of standardization in the intake process. The inclusion of validated, standardized developmental screening tools in the intake process, including screening tools for ASD, would provide better information on the early signs of ASD at a population level.

154 **124.154** Response to Name: Increasing the Sensitivity of This Very Specific Sign of ASD

J. Miller[1], J. Shamash[2], J. E. Norry[3] and T. P. Gabrielsen[4], (1)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Center for Autism Research, Children's Hospital of Philadlephia, Philadelphia, PA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)CPSE, Brigham Young University, Provo, UT

Background: Response to name (or rather, the failure to respond to one's name) is one of the most consistently documented behaviors that distinguishes autism at a young age. However, despite its very high specificity to ASD, and its clinical relevance, it has not yet been a useful measure of autism, severity, or response to treatment. This is likely because we have misconceptualized it as a dichotomous variable; as if children either always respond or always fail to respond, when a closer look at the evidence suggests that children with autism show a decrease in, not an absence of, responding. Measured as a quantitative variable, or as a *rate* of responding rather than a dichotomous summary judgment, response to name may be a powerful indicator of ASD and perhaps a clinical measure that could be sensitive to change.

Objectives: To characterize and measure both the child's behavior and adult's behavior around Response to Name, including determining the different kinds of "bids" adults use during a clinical interaction, and the child's rate of responding to each type of bid. Secondary objectives were to compare results to the more categorical measures of Response to Name currently used (ADOS, ADI-R, M-CHAT, ITC, Mullen, and Vineland).

Methods: We rated children's responses to their own name during 20 minutes of free play and structured activities (two 10-minutes segments from the ADOS). Participants (11 with ASD; 12 with speech or other delays, and 11 typically developing controls) included children who had been screened as part of a highly comprehensive screening study within a large community practice, and thus are highly representative of the types of children presenting to pediatricians for screening. Ratings were conducted by two blind raters, and percent exact agreement was 90%.

Results:

Adults used three types of name calls (Name, Name with Command, and Name within a social game). Children who responded less than 50% of the time were considered to show weak responding. In the ASD group, 63% of children showed weak responding to Name, compared to 25% of children with delays, and 36% of typically developing children. In contrast, only 18% of children with ASD were weak responders to Name with Command, with 8% and 0% weak responders in the other groups (respectively). Our quantitative measures showed almost no correspondence with ADOS, ADI-R or questionnaire items completed by parents. On questionnaires and interviews, parents virtually always rated their children as good responders. On the ADOS, only 36% of children with ASD obtained a

score of 2 or 3 on the Response to Name activity, and of those, half were good responders otherwise.
Conclusions:
Among children screened in pediatric practice, actual rates of responding to name showed little correspondence to current clinical and research measures. As a simple behavior with high specificity to ASD and high ecological validity, Response to Name may have more clinical and research utility as a quantitative variable, rather than a categorical judgment.

155   **124.155** Sensory Responsiveness in Infants at-Risk for Autism Spectrum Disorders within the First Two Years of Life

M. Kaur[1], S. Srinivasan[1] and A. N. Bhat[1,2,3], (1)Department of Physical Therapy, University of Delaware, Newark, DE, (2)Department of Kinesiology, University of Connecticut, Storrs, CT, (3)Center for Health, Intervention & Prevention, Department of Psychology, University of Connecticut, Storrs, CT

Background: Autism Spectrum Disorders (ASDs) are multisystem neurological disorders with primary impairments in the social communication skills as well as the presence of stereotyped/repetitive behaviors (American Psychiatric Association, 2013). Additional comorbidities such as sensory processing dysfunction are reported in more than 90% of the children diagnosed with ASDs (Tomcheck & Dunn, 2007). Parents of infants later diagnosed with ASDs reported early atypicalities in sensory responsiveness to auditory, tactile, and visual stimuli as well as excessive oral exploration of objects (Hoshino et al., 1982; Baranek, 1999; Tomcheck & Dunn, 2007). Early identification of sensory processing issues in infants at-risk for ASDs could help in developing appropriate early interventions. However, few studies have prospectively examined the presence of sensory processing deficits in the at-risk infants.
Objectives: The current project examined the sensory processing abilities of infant siblings of children diagnosed with ASDs (AU sibs) within the first 2 years of life by using a parent questionnaire, the Infant/Toddler Sensory Profile (ITSP).
Methods: This study was part of a larger ongoing longitudinal study comparing the development of AU sibs and typically developing infants within the first 2 years of life. Parents of 13 AU sibs were asked to complete the ITSP at 6,9,12,15,18, and 24 months of age. ITSP assesses the sensory processing abilities from birth to 3 years and its effects on the infant's daily performance (Dunn, 2002). ITSP scoring was done for 2 sections: (i) response to various sensations, i.e. auditory, visual, tactile, vestibular, and oral sensation and (ii) the neurological threshold of the infant for various sensory behavior such as sensation threshold, seeking behaviors, sensitivity, and avoidance.
Results: 8-54% of the AU sibs showed atypical response - over or under responsiveness to various sensations as well as atypical neurological thresholds between 6 to 24 months. Specifically, 30-50% of the AU sibs showed auditory, oral, and tactile processing deficits early on at 9 months whereas vestibular and visual processing deficits were evident from 12 and 15 months respectively in 30-38% of the group. In terms of neurological thresholds, 50% of AU sibs showed atypical low threshold behaviors early on at 6 months whereas sensation seeking and sensory sensitivity were seen at 12 months and sensation avoiding at 9 months. Currently, we are relating infancy performance to future outcomes and conducting individual item analyses to better understand the sensory processing issues of the AU sibs.
Conclusions: Parent questionnaires such as the ITSP are a quick and easy tool for evaluating the sensory processing issues of infants at-risk for ASDs. Our study suggested that almost half of the at-risk infants showed sensory difficulties. However, the incidence is lower than that reported in the previous literature indicating that some of the parents might have over or under estimated the performance of their infants.

156   **124.156** Sex Differences Do Not Distinguish High-Risk ASD, High-Risk No ASD, and Low-Risk Children through Three Years: A Bsrc Study

D. S. Messinger[1], G. S. Young[2], S. J. Webb[3], S. Ozonoff[4], L. Zwaigenbaum[5], K. Chawarska[6], R. J. Landa[7], K. R. Dobkins[8], W. L. Stone[9], A. Klin[10], M. C. Lai[11], S. Baron-Cohen[12] and A. S. Carter[13], (1)University of Miami, Coral Gables, FL, (2)MIND Institute, University California Davis, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis Medical Center, Sacramento, CA, (5)University of Alberta, Edmonton, AB, Canada, (6)Child Study Center, Yale University School of Medicine, New Haven, CT, (7)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD, (8)Psychology, University of California, San Diego, La Jolla, CA, (9)Psychology, University of Washington, Seattle, WA, (10)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (11)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (12)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (13)Department of Psychology, University of Massachusetts Boston, Boston, MA

Background: Autism spectrum disorders are more common in males than females, but the relative risk of ASD among high-risk siblings (younger siblings of ASD probands) requires large-scale characterization. It is also currently not clear whether there are sex differences in symptom presentation and cognitive functioning among children with ASD; nor is it clear whether potential sex

differences are unique to ASD or characterize high-risk siblings without ASD and low-risk children. Finally, there has been little opportunity to investigate the longitudinal development of symptom presentation and cognitive functioning for children with and without ASD.

Objectives:
Obj1. Compare the relative risk of ASD outcomes for males and female high-risk siblings.
Obj2. Examine sex differences in the longitudinal development of ASD symptom presentation and cognitive functioning among high-risk siblings with and without an ASD outcome and among low-risk children.

Methods: Participants were 1,830 infants (1,241 high-risk siblings, 583 low-risk) from 15 consortium-contributing sites who were recruited prior to 18 months of age (M=7.28, SD=3.36) with outcome diagnosis at 33 months or older. ASD at outcome involved both outcome diagnosis and meeting ASD cut-off criteria on the ADOS. Hierarchical generalized linear models (HGLM) in which site was included as a random variable were used to determine factors affecting ASD incidence among high-risk siblings (**Obj 1**) and factors affecting Mullen Scales of Early Learning (MSEL) subtest and ADOS domain scores longitudinally among high-risk ASD, high-risk non-ASD, and low-risk children (**Obj 2**).

Results:
Obj. 1.
Of 1,241 high-risk siblings, 252 had ASD outcomes. The sex effect was significant ($X2$=55.35, df=1, p<.001) with a 3.18 odds ratio (95% CI = 2.31 to 4.39) of male to female recurrence. Male recurrence was 26.7% and female recurrence 10.3%.

Obj. 2.
MSEL (see **Figure 1**). All main and interaction effects of Group (High-risk ASD, High-Risk Non-ASD, Low-Risk Non-ASD), Age (18, 24, & 36 months) and MSEL Subtest (a repeated measure: Expressive & Receptive, Fine Motor, Visual Reception) on MSEL scores were significant (*p<.001).* There was no main effect of Sex (p=.20) and Sex did not interact with Group either alone (*p*=.23) or in combination with other variables (*p*>.69). There was a Sex by Subtest interaction (*p<.001).*
ADOS (see **Figure 2**). Group (High-risk ASD, High-Risk Non-ASD, Low-Risk Non-ASD), Domain (Restricted & Repetitive Behaviors, RRB, and Social Affect, SA) and their interaction were significant (*p<.001*). Age (24, & 36 months) was not significant (p=.41). Sex was not significant (p=.41), nor were its interactions with any variables (*p>.07),* except Domain (p<.05).

Conclusions: In prospectively followed high-risk siblings, males had a 3.18-fold greater chance of ASD outcomes. However, we found no ASD-specific sex differences in symptoms and cognitive functioning. Sex differences in repetitive behaviors and social affect were apparent in children with ASD, but also in high-risk and low-risk children without ASD,. Likewise, sex differences in particular areas of cognitive performance (e.g., language and visual reception) characterized the total sample and were not unique to ASD. Sex differences that appear in children with ASD may not be ASD-specific.

---

157   **124.157**   Sex Differences in Adaptive Skill Trajectories from 12 to 36 Months in Infants at High and Low Risk for ASD

T. Hutman, L. Gomez, B. E. McCarthy and M. Del Rosario, *Psychiatry & Biobehavioral Sciences, UCLA, Los Angeles, CA*

Background: Children with ASD appear to have a distinct profile of adaptive behaviors even when compared to children with non-ASD developmental delays. ASD-specific trajectories of adaptive skills have been reported with cross-sectional differences evident as early as 12 months. Here we investigate ASD-specific sex differences in trajectories of adaptive skill development. This study seeks to determine whether parent report regarding adaptive behaviors may provide insight into the apparent discrepancy between the high male:female diagnostic ratio in ASD and null results with respect to ASD-specific sex differences on measures of ASD symptomatology (ADOS) and cognitive development (Mullen).

Objectives: To evaluate ASD-specific sex differences in trajectories of adaptive skill development among high- and low-risk infants from 12-36 months of age.

Methods: Parents completed the Vineland Adaptive Behavior Scales (VABS) interview or questionnaire when their infants/toddlers at high and low risk for ASD were 12, 18, 24, and 36 months of age. Diagnostic classifications were made at 36 months. Children with atypical non-ASD outcomes were excluded from these analyses. 42 children were diagnosed with ASD (gender ratio 5:1). 200 children were judged to be developing typically (gender ratio 1.2:1). Hierarchical linear models evaluated trajectories of each VABS subscale using age equivalencies. Predictors were sex, diagnostic outcome (ASD or TD), and sex*diagnosis. A second set of models included baseline verbal mental age based on observed sex differences in that measure and its association with the development of adaptive skills.

Results: Linear, but not quadratic, effects of time were observed for the Communication (Com), Daily Living (DLS), Socialization (Soc), and Motor (Mot) scales of the VABS (ps<.001). Significant sex-by-diagnosis interactions were observed with respect to growth in Com (p=.007), DLS (p=.034), and Soc (p<.001), but not Mot (p=.85). Parent ratings of adaptive skills in boys and girls with ASD were similar at 12 months and skills of girls with ASD improved more rapidly than skills of boys with ASD between 24-36 months. Main effects of sex were observed with respect to COM, DLS, and SOC. Main effects of ASD were observed with respect to DLS and SOC, but not COM. Baseline language skills were associated with trajectories of Com, DLS, and Soc. When language skills were included in models, a

robust sex-by-diagnosis interaction was observed on Com and Soc, but not DLS.

Conclusions: Parent-reported adaptive behavior trajectories during the time frame when overt symptoms of ASD first emerge indicate that girls differ from boys within the group of toddlers who are diagnosed with ASD and between diagnostic groups. Developmental trajectories reflect an improvement of adaptive behaviors among girls with ASD relative to boys with ASD across infant-toddler development. Further investigation is necessary to confirm that infant siblings are representative of non-familial autism phenotypes. Viewed longitudinally, these results are not consistent with the Carter Effect, which suggests that in conditions with uneven sex ratios, genetic loading should be significantly greater in the sex with lower prevalence. Other factors that may contribute to parents' differential reporting about ASD-related behavioral trajectories between girls and boys will be discussed.

158   **124.158**   Sex Differences in Visual Attention to the Mouth in Infancy: Implications for Language Development and ASD

R. Burger-Caplan[1,2], W. Jones[1] and A. Klin[1], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Psychology, Emory University, Atlanta, GA

Background: Development of pre-linguistic communication skills, like gesture, predicts acquisition of language in typically developing infants and toddlers (Iverson & Goldin-Meadow, 2005). Prior to, and concurrent with, such communicative development, infants are attuned to social auditory and visual input, such that their visual behavior serves to index interest in, and predict later proficiency with, social-cognitive abilities (Jones & Klin, 2013). Analysis of social-visual engagement in infants suggests that the degree to which infants visually fixate on eyes of others successfully differentiates between typically-developing (TD) infants and infants subsequently diagnosed with Autism Spectrum Disorder (ASD; Jones & Klin, 2013). Irrespective of diagnosis, a global increase is evident in the second year of life in visual attention to the mouth (mouth-fixation), immediately preceding a period of known vocabulary growth, and a sex difference is evident in the chronology of this increase. The present study suggests mouth-fixation as potentially facilitative of language acquisition, delay of which is a hallmark of ASD.

Objectives: The current study seeks to elucidate the importance of increased mouth-fixation for language development, and to explore apparent sex differences among TD infants for their importance to the male-bias in ASD diagnosis. In keeping with these goals, this study tests the extent to which increased mouth-fixation correlates with increases in communicative abilities and in specific indices of language acquisition.

Methods: Eye-tracking data were collected longitudinally at 10 time-points from 2 to 24 months of life in TD-infants (26 male, 24 female), and high-risk infants later diagnosed with ASD (13 male). The Mullen Scales of Early Learning (Mullen) and the MacArthur-Bates Communicative Development Inventory (CDI) were administered longitudinally, assessing cognitive and communicative functioning.

Results: Results indicate a phase-shift in mouth-fixation, from increasing with age to decreasing with age, early in the second year of life. The mouth-fixation shift is evident in TD-females at 13.5 months of age, in TD-males at 15 months, and in ASD-males between 15 and 16 months. Concurrent sex differences in trajectories of scores on clinical measures of expressive vocabulary ($F_{(2,47)}=7.214$, $p<0.01$), gesture ($F_{(2,47)}=5.230$, $p<0.01$), and language-related cognitive abilities ($F_{(3,46)}=9.452$, $p<0.01$), indicate that TD-females are precocious in these areas, and support a relationship between mouth-fixation and language development. Spearman's rho was used to quantify the relationship between mouth-fixation and measures of communicative development before and after mouth-fixation phase-shift, for each sex and for ASD-males (Table 1).

Conclusions: Measures of communicative development were correlated with age and not with mouth-fixation *prior* to mouth-fixation phase-shift. *After* the phase-shift, vocabulary measures and mouth-fixation were negatively correlated in females, during their period of decline in mouth-fixation. As such, vocabulary growth was greatest just *after* the peak in mouth-fixation. Similar relationships existed for TD-males and ASD-males. Results suggest that sex-dimorphic chronologies of developmental events in typical-development are present in both language and in an apparent behavioral correlate, and can inform our understanding of developmental trajectories that deviate from those of TD-infants in ASD, as TD-females appear chronologically advanced.

159   **124.159**   Sex and ASD Risk Status Predict Both 3-Year Expressive Language and Expressive Language Growth from 1 to 3 Years in Children at High and Low Risk for ASD

S. R. Edmunds[1], L. V. Ibanez[2], C. Harker[2], E. A. Karp[3] and W. L. Stone[3], (1)UW Mailbox 357920, University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Psychology, University of Washington, Seattle, WA

Background: Sex differences have been found in both language development and ASD severity; relative to males, typically developing females show slightly better expressive language from 12-24 months (Eriksson et al., 2012), and females with ASD may show more severe ASD symptoms (Frazier et al., 2014). The purpose of this study was to examine early expressive language development in males and females at high and low risk for an ASD diagnosis. The potential importance of this question is twofold: (1) to characterize the developmental trajectories of expressive language of toddlers who have an older sibling with ASD (high-risk, HR-sibs) and toddlers without a sibling with

ASD (low-risk, LR-sibs); and (2) to understand the extent to which a child's sex, in addition to risk status, contributes to language development. Results may have implications for developmental monitoring as well as understanding genetic underpinnings of ASD.

Objectives: To examine the effect of sex and risk status for ASD on children's expressive language (EL) development from 12-36 months and EL outcome at 36 months.

Methods: Expressive language was measured for HR-sibs (n=69; male=36) and LR-sibs (n=42; male=23) at 12, 24, and 36 months as age equivalency scores (in months) using the expressive language (EL) subscale from the Mullen Scales of Early Learning (MSEL; Mullen, 1995). Hierarchical linear modeling was used to examine both growth from 12 to 36 months in EL and 36-month level of EL

Results: The overall trajectory of EL from 12 to 36 months was best characterized by significant positive, linear growth, $p<.01$. EL at 12 months showed little variability across individuals; therefore, the intercept was set at 36 months. EL growth and 36-month EL level were both modeled as random effects. Sex significantly predicted EL growth and 36-month EL, with males showing decreased growth and lower EL compared to females at 36 months. Males gained 0.85 years of EL growth for every year that females gained, $b=-.15$, $p=.01$, and at 36 months, their EL was almost 4 months lower, $b=-3.61$, $p<.01$. Risk status also significantly predicted EL growth and 36-month EL level, with HR-sibs showing decreased growth and lower EL compared to LR-sibs at 36 months. HR-sibs gained 0.85 years of EL growth for every year that LR-sibs gained, $b=.15$, $p=.02$, and at 36 months had an age equivalent EL almost 5 months lower than that of LR children, ($b=4.75$, $p<.01$). Sex and risk status did not interact to predict growth in language between 12 and 36 months or level of EL at 36 months.

Conclusions: Although sex and risk status independently affect children's expressive language, no interaction was found. Males and HR-sibs each showed slower EL growth and lower EL at 36 months relative to their counterparts. The lack of an interaction suggests that HR-sibs males are not at multiplicative risk for slower language growth and deficits by 3 years.

160 **124.160** Stability of Temperament in Toddlers with Autism Spectrum Disorders

S. S. Lansiquot[1], L. Flink[1], C. A. Wall[2], S. H. Kim[2], F. Shic[1], J. Koller[3], K. Chawarska[1] and S. Macari[1], (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale University, New Haven, CT, (3)The School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel

Background: Temperament has been defined as individual differences in behavioral styles relating to emotional reactivity, attention, and self-regulation (Rothbart and Bates, 1998). Previous studies have shown that three major domains of temperament, surgency/extraversion, negative affectivity, and attentional control, are stable in typically-developing children from toddlerhood to preschool age (Putnam et al., 2006). However, little is known about the stability of temperament over time in toddlers with ASD. Given the complex and variable patterns of development in ASD, particularly in the toddler and preschool years, understanding whether temperament is a stable construct may provide support for the use of temperament as an additional tool for exploring the heterogeneity of ASD and for understanding variation in individual children.

Objectives: To examine the stability of toddlers' temperamental traits from age 2 to age 3.

Methods: Participants included 64 toddlers with ASD who were derived from a clinic- referred sample and assessed by a multidisciplinary team. Measures includes the Toddler Behavior Assessment Questionnaire-Supplemental (TBAQ-S; Goldsmith, 1996). Parents completed the temperament scale prior to their child's first visit at the mean age of 23 months (range 16.4- 30.8 months) and before their child's second visit at the mean age of 37 months (range 31.0-48.0 months). The TBAQ consists of 3 composite scales: Surgency, Negative Affectivity, and Attention. Surgency is demonstrated through approach behaviors such as smiling, laughter, and body movements. Negative Affectivity behaviors relate to anger, fear and frustration. Attention is defined by the ability to regulate attention and exercise inhibitory control over behaviors.

Results: Pearson's r correlations were computed to assess the association between each composite scale across the first and second visits. All composite scales demonstrated strong associations over time: Surgency ($r=.481$, $p<.001$), Negative Affectivity ($r=.559$, $p<.001$), and Attention ($r=.561$, $p<.001$). In addition, paired-samples t-tests were conducted to compare changes over time. Results showed a significant positive increase in the Attention composite scale across the two time points ($p<.001$, $d=0.583$) with a moderately large effect size ($d=0.583$). This improvement in attention regulation appears to be driven by the subscale Inhibitory Control ($p<.001$, $d=0.78$).

Conclusions: These findings indicate that, similar to typically developing children, the three major domains of temperament are stable from age 2 to age 3 in toddlers with ASD. Furthermore, like very young children developing typically, their peers with ASD demonstrate significant improvements in attention over this period of time. These results suggest that temperamental factors in young children with ASD behave in a similar manner to those in TD children over the early preschool years, and can be viewed as separate axes for understanding intrinsic characteristics of individual children with ASD.

161 **124.161** Temperamental Features in Toddlers with ASD Are Independent of Symptom Severity

L. Flink[1], S. S. Lansiquot[1], C. A. Wall[2], S. H. Kim[2], F. Shic[1], J. Koller[3], K. Chawarska[1] and S. Macari[1], (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale

University, New Haven, CT, (3)The School of Education, The Hebrew University of Jerusalem, Jerusalem, Israel

Background: Temperament is defined as constitutionally-based aspects of behavior in the domains of reactivity and regulation (Rothbart and Bates, 1998). Temperament in toddlers with Autism Spectrum Disorder (ASD) remains largely unexplored, and information on the temperamental profiles of this cohort may shed light on their developmental patterns, heterogeneity of presentation, and treatment options. While research in this area has begun, it mainly focuses on the affective and attentional differences between toddlers with ASD and their typically developing and developmentally delayed peers (Garon, 2009; Koller, 2014). To complement previous work, this study examined the associations between temperament and autism symptom severity in a large sample of toddlers with ASD.

Objectives: The main goal was to examine the relationship between temperamental domains of the Toddler Behavior Assessment Questionnaire-Supplemental (TBAQ-S) and the severity of autism symptoms (ADOS-G) in toddlers with ASD, thereby determining whether the TBAQ-S captures a construct independent of social features in toddlers with ASD.

Methods: 182 toddlers with ASD (149 males) between 16 and 48 months of age (mean age = 28 months) were derived from a clinic-referred sample and received a comprehensive developmental and diagnostic assessment of cognitive, language, and social-communication skills. Prior to the testing, parents completed the TBAQ-S, which includes three composite scales: Attention— Attentional Focusing, Attentional Shifting, Inhibitory Control, Low Pleasure, Perceptual Sensitivity; Negative Emotion—Discomfort, Sadness, Soothability/Falling Reactivity, Anger, and Social Fear; and Surgency— Positive Anticipation, High-Intensity Pleasure, Activity Level, and Social Fear (Goldsmith, 1996; Jones, 1999). Associations between the TBAQ-S and ADOS-G severity were determined.

Results: Partial Pearson's r correlations, accounting for chronological age, were performed between the ADOS calibrated severity scores (CSS) and the thirteen TBAQ-S subscale scores as well as the three TBAQ-S composite scale scores. No significant correlations were found between any subscale or composite scale and ADOS severity. The three composite scales were modestly negatively correlated with CSS (Attention: r = -.12; Negative Emotion: r = -.16; Surgency: r= -.18).

Conclusions: The findings indicate that temperamental dimensions of behavior are largely independent of autism symptomatology, indicating the unique contribution of temperament to an individual's behavioral profile and strengthening the independent value of both the ADOS and the TBAQ-S. These results are perhaps not surprising, given that temperament captures vastly different aspects of behavior than that measured by the ADOS. Dimensions of temperament may further expand our understanding of the heterogeneity in functioning and development within the autism spectrum.

162 **124.162** The Role of Audiovisual Synchrony in Modulating Attention to Biological Motion in Infancy

R. D. Sifre[1], W. Jones[2], A. Klin[2] and S. Shultz[3], (1)Marcus Autism Center, Emory University School of Medicine, Children's Healthcare of Atlanta, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (3)Department of Pediatrics, Marcus Autism Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA

Background: Preferential attention to biological motion is present in human infants from the first days of life and plays a critical role in facilitating filial attachment and in guiding social interaction (Simion et al., 2007). In humans, biological motion includes gesture, gait, and facial expressions, actions that contain both rich social information and non-social audio-visual synchronies (AVS). By 24-months, these two features hold different significance for TD and ASD toddlers: while TD toddlers show a preference for biological motion regardless of underlying AVS, ASD toddlers preferentially attend to AVS, suggesting a disruption to normative processes of social development (Klin et al., 2009). Mapping the trajectory of how AVS influences preferential attention in typical development will establish a much needed framework for examining *when* deviations from this normative trajectory are first observed in ASD and *how* such deviations may impact developmental outcomes.
Objectives: The goal of this study is to measure longitudinal change in the association between AVS and preferential attention to biological motion in children at low-risk (LR) and high-risk (HR) for ASD.
Methods: 88 LR (49 male) and 95 HR (67 male, 50%>12 months) were shown point-light biological motion animations as in Klin et al. (2009). An upright point-light animation was presented on one half of the screen, with the inverted version playing on the opposite side in reverse order. Presentation was counterbalanced to control for side bias. Eye-tracking data, collected at months 2, 3, 4, 5, 9, 15, and 24, were used to calculate percentage of fixation time during each trial. Levels of AVS were quantified in all animations by measuring synchronous change in motion and sound.
Results: Spearman correlations revealed that preferential attention to audiovisual synchrony was developmentally modulated in LR infants: no association between preferential attention and AVS was seen at months 2, 3, 4, or 24, with the latter time point replicating the cross-sectional results of Klin et al (2009). Significant associations were observed at months 5 (r=.26, p<.001), 9 (r=.23, p<.05), and 15 (r=.36, p<.001). Data from HR infants showed increased variability at all time points.
Conclusions: The present findings reveal a period in typical development when preferential attention is associated with AVS. Previous studies have identified strong effects of AVS on selective attention to inanimate objects during early infancy (Bahrick, Lickliter & Flom, 2004), but in the context of socially-rich biological motion, the present study shows a peak in preferential attention to AVS at 15 months.

Intriguingly, this time point coincides in typical development with a period of increased visual attention to the mouth (Jones & Klin, 2013), an area of high AVS, and also to the onset of the oft-cited "vocabulary spurt" (Benedict, 1979), consistent with accounts of how language learning affects attention to faces (Lewkowicz & Hansen-Tift, 2012). Future analyses will examine associations between attention to AVS and to the mouth in the current cohort, and will focus on parsing the heterogeneity of HR infants to better understand the increased variability in their looking patterns.

163 **124.163** The Role of Early Gesture on Expressive and Receptive Vocabulary in Infants at High and Low Risk for Autism Spectrum Disorder

S. R. Edmunds[1], L. V. Ibanez[2] and W. L. Stone[3], (1)UW Mailbox 357920, University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Psychology, University of Washington, Seattle, WA

Background: Gesture use has been found to predict infant's later language abilities (Iverson & Goldin-Meadow, 2005). Infants who have an older sibling with ASD (HR-sibs) have been found to produce fewer gestures (Stone, McMahon, Yoder, & Walden, 2007), understand fewer words (Mitchell et al., 2006) and produce fewer words (Zwaigenbaum et al., 2005) in their second year of life than low-risk controls (LR-sibs). However, less is known about the developmental trajectories of expressive and receptive vocabulary and the extent to which gesture use and language interact during this pivotal period for communication development.
Objectives: To assess the extent to which early gesture use and ASD risk status predict: (1) growth in expressive (EV) and receptive vocabulary (RV) from 12 to 18 months and (2) the level of EV and RV at 18 months.
Methods: Gesture use, EV, and RV were examined in HR-sibs (n=69; male=36) and LR-sibs (n=42; male=23) at 12, 15, and 18 months using the MacArthur-Bates Communicative Development Inventory (MCDI; Fenson et al., 2007). Gesture use was measured via the Total Gestures summary score. EV and RV were measured using the "Words Produced" and "Words Understood" total scores, respectively. Hierarchical linear modeling was employed to examine the contributions of infants' 12-month gesture use and ASD risk on receptive and expressive growth and levels.
Results: The overall trajectory of EV and RV from 12 to 18 months was best characterized by significant positive, linear growth, $ps<.01$. EV and RV showed little variability across individuals at 12 months; therefore, the intercept was set at 18 months. Gesture use at 12 months did not predict growth in EV or RV from 12 to 18 months,,$ps > .05$, but significantly predicted 18-month levels of EV and RV. For every additional type of gesture infants produced at 12 months, they produced 1 more word at 18 months, $b=1.25$, $p=.002$, and understood 4 more words at 18 months, $b=4.15$, $p<.001$. Risk status significantly predicted growth in EV from 12 to 18 months, $b = 5.31$, $p = .003$, and levels of EV at 18 months, such that HR-sibs demonstrated slower growth and lower levels of EV at 18 months than LR-sibs. HR-sibs produced on average 5 fewer words per month between 12 and 18 months and 28 fewer words at 18 months than LR-sibs, $b=28.37$, $p<.01$. In contrast, risk status did not predict growth in RV, $p>.05$, but did significantly predict RV at 18 months. HR-sibs understood 40 fewer vocabulary words at 18 months than LR-sibs, $b=40.12$, $p<.001$. Infants' use of gestures did not interact with their risk group status to predict either growth of EV or RV or 18-month levels, $ps>.05$.
Conclusions: Although gesture use and risk status independently predicted 18-month levels of expressive and receptive vocabulary, no interactions were found. Implications of these findings will be discussed.

164 **124.164** Visual Attention Patterns of Toddlers with ASD: Comparison of Performance on the Visual Exploration Task (VET) and the VET-Toddler

S. Zheng[1], L. Turner-Brown[2], K. Hume[3] and B. A. Boyd[4], (1)School of Education, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)University of North Carolina at Chapel HIll, Chapel Hill, NC, (4)Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: The presence of restricted interests is one of the core characteristics in individuals with Autism Spectrum Disorders (ASD). Eye-tracking is an effective tool to capture visual patterns of individuals when presented certain visual stimuli. Previous eye-tracking studies found that children with ASD showed unique patterns of exploration, detail orientation, and perseveration in the Visual Exploration Task (VET). The VET was mainly used with school-age children or older individuals with ASD previously. However, as the VET was designed with images appealing to an older population, it may not be as reliable and valid a task for toddlers. We developed a toddler adaption of the VET (VET_T) using developmentally appropriate images and arrays, with fewer and bigger stimuli per slide and compared the visual attention patterns of toddlers using the VET and VET_T.
Objectives: This study compared the visual attention patterns of toddlers with ASD on the VET and VET_T in an effort to determine the utility of each eye tracking measure with. The goal was to compare visual exploration patterns across the VET and VET_T.
Methods: 40 toddlers with a diagnosis of ASD (17-35 months of age) participated in this study. Each participant completed the VET and VET_T, which includes a total of 19 visual arrays (12 VET and 7 VET_T). Randomized Arrays were organized to include high autism interest (HAI) items, low autism interest (LAI) items and social items. Four major outcome variables representing visual exploration

patterns were calculated: 1) Percentage of time onscreen, 2) Exploration: Number of images viewed per second onscreen, 3) Perseveration: Duration of fixation per image explored, and 4) Detail Orientation (DO): Number of discrete fixations per image explored. A series of repeated measures ANOVA were conducted to test the differences in visual patterns of toddlers on the VET and VET_T.
Results: No significant difference was found in percentage of time onscreen between the two tasks. However, toddlers with ASD showed different visual exploration patterns in the two tasks: 1) Toddlers with ASD were significantly more detail oriented in the VET_T ($p<.05$). Toddlers with ASD also showed significantly higher DO towards HAI items ($p<.05$), especially in the VET_T (significant interaction effect, $p=.001$);
2) No significant differences in exploration were found between tasks. However, in LAI and social arrays, the significant interaction effect indicated that toddlers with ASD showed more exploration for social items than LAI items in the VET_T
3) Toddlers with ASD showed significantly higher perseveration in VET_T ($p<.05$). No significant difference was found in stimulus types.
Conclusions: The use of the VET_T task did not increase the percentage of time on screen for toddlers with ASD when compared to the VET. However, toddlers with ASD did have higher exploration, detail orientation and perseveration when using the VET_T in comparison to the VET. With more developmentally appropriate stimulus, visual exploration patterns of toddlers with ASD are more manifested in the VET_T. Therefore, the VET_T might be a better tool in examining visual patterns of younger children with ASD.

165   **124.165** Visual-Motor Integration Associated with Familial Liability for Autism

M. B. Nebel[1,2], *J. L. Haworth*[3,4], *C. Hess*[3], *S. H. Mostofsky*[1,2,4] *and R. J. Landa*[3,4], *(1)Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD, (2)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (3)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (4)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD*

Background: School-age children with Autism Spectrum Disorder (ASD) exhibit particular difficulty with tasks that rely heavily on hand-eye coordination. In addition, these children show what appears to be an ASD-specific bias against using visual feedback during motor learning that is a robust predictor of their motor and social impairments (Haswell et al., 2009). Compelling evidence also suggests motor deficits are observable as early as 6 months of age in children who later develop ASD (Flanagan, Landa, Bhat, & Bauman, 2012). However, the interplay of early motor, visual and social skill development in ASD is not well understood. Because integration of visual input with motor output is vital for the formation of internal models of action necessary not only to develop a wide range of motor skills, but also to imitate and interpret the actions of others, closer examination of motor, and specifically visual-motor, deficits is of critical importance in understanding the pathophysiology of ASD.
Objectives: The goal of this study was to examine for behavioral markers of motor development, with a focus on visual-motor integration, in infants identified as at high risk for ASD (e.g., infants who have at least one sibling with an ASD diagnosis) using the ball-catching component of the Autism Observation Scale for Infants (AOSI; Bryson, Zwaigenbaum, McDermott, Rombough, & Brian, 2007). We hypothesized that infants at high risk for ASD would be delayed in developing a visually guided, open-handed reach strategy of catching.
Methods: Thirty-six 6-month-olds were tested (18 high-risk for ASD because they had an older sibling with ASD; 18 low risk, having no family history of ASD). The AOSI was video-recorded and the ball-catching component was scored offline by two trained raters, blind to risk group. The coding schema characterized the maturity of five behaviors during ball-catching: 1) anticipation of the examiner's action of rolling the ball toward the child; 2) visual tracking of the ball during the roll; 3) anticipatory grasping behavior during the roll; 4) maturity of lifting the ball after contact; and 5) visual-motor integration during object exploration. The first three rolls of the ball-catching task for each child were scored, and scores were averaged across trials.
Results: An independent samples Mann-Whitney U test indicated that the distributions of anticipation scores were different across groups, with high-risk infants showing less anticipatory grasping compared to low-risk infants (p = .022). High-risk infants also displayed less mature lifting (p = .024). No other significant group differences were observed, with the majority of children in both groups immediately looking at the ball or the examiner prior to the roll, tracking the ball for most of its trajectory, and simultaneously exploring the ball with their eyes and hands.
Conclusions: Results suggest that early motor delays are more common in high-risk infants compared to low-risk infants and that high-risk infants less rapidly interpret the action intentions of others. Findings preliminarily support our hypothesis that high-risk infants do not use visual information to guide their movements as effectively as their low-risk age peers.

166   **124.166** When an Early Diagnosis of ASD Resolves, What Remains?

L. H. Shulman[1,2], *E. D'Agostino*[1], *M. D. Valicenti-McDermott*[1,2], *R. M. Seijo*[1,2], *E. Tulloch*[1,2], *D. J. Meringolo*[1,2], *N. L. Tarshis*[1,2] *and S. J. Lee*[1], *(1)Pediatrics/CERC, Albert Einstein College of Medicine, Bronx, NY, (2)Children's Hospital at Montefiore, Bronx, NY*

Background: It has been documented that some children with an early diagnosis of Autism Spectrum

Disorder (ASD) do not meet criteria for the diagnosis at a later age. It is unclear, however, if deficits remain overtime when ASD symptomatology resolves.

Objectives: To characterize the residual learning, cognitive, and emotional/behavioral diagnoses and educational needs of a group of school-age children with a history of an early diagnosis of ASD that resolved.

Methods: A chart review of 38 children diagnosed with ASD at a University-affiliated inner-city diagnostic early intervention program between 2003 and 2013 who had follow up evaluations indicating resolution of the original ASD diagnosis. This group represents 7% of the 569 children diagnosed with ASD by the program during this period. Original and follow up diagnoses were made by an experienced multidisciplinary team (consisting of developmental pediatrician, psychologist, and speech and language pathologist) based on the DSM-IV criteria, Childhood Autism Rating Scale (CARS) and/or the Autism Diagnostic Observation Schedule (ADOS). All children had follow up visits and repeat evaluations for diagnostic clarification and/or educational planning an average of 4 years after the original diagnosis. The initial cognitive assessment was based on the Bayley Scales, and at follow up on the WPPSI, WISC, or Stanford Binet. Data collected included: demographics, age, cognitive level, CARS, developmental diagnoses and services at original and follow up evaluations.

Results: The mean age at initial diagnosis was 2.6y± 0.9y and at follow up 6.4y± 2.8y. The sample was 80% male; 44% Hispanic, 36% Caucasian, 10% African American; 46% had Medicaid; and 42% were bilingual. The mean initial CARS was 32±3 and at follow up 25±4. The initial ADOS (21/38) categorized 29% as having autism and 67% as ASD and it was negative at follow up when available (23/38). Initial cognitive testing (29/38) found 33% with intellectual disability, 23% in the borderline range and 44% in the average range and at follow up (33/38) revealed 6% in the borderline range and the rest in the average range. At follow up, 68% had language or learning disability, 49% were diagnosed with externalizing behavior problems (Attention Deficit Hyperactivity Disorder, Oppositional Defiant Disorder, Disruptive Behavior Disorder), 24% with internalizing problems (mood disorder, anxiety, OCD, selective mutism), 5% with a significant mental health diagnosis (psychosis.nos), and 8% warranted no diagnoses. Twenty six % of the group was in a mainstream academic setting without support, 13% in a mainstream class with paraprofessional support, 29% in an integrated setting/resource room, and 21% in a self-contained class.

Conclusions: When an early ASD diagnosis resolves, at least in the early elementary years, there are often other learning and emotional/behavioral diagnoses that remain. Understanding the full range of possible positive outcomes in this scenario is important information for parents, clinicians, and the educational system.

167   **125.167** A Comparison of Gene Expression in Inflamed Ileocolonic Tissue and Peripheral Blood from GI Symptomatic ASD Children

S. J. Walker[1] *and A. Krigsman*[2], *(1)Wake Forest Health Sciences, Winston-Salem, NC, (2)Pediatric Gastroenterology Resources of New York and Texas, Far Rockaway, NY*

Background: Gastrointestinal symptoms are common in children with autism spectrum disorder (ASD) and are often associated with mucosal inflammatory infiltrates of the small and large intestine. Whole transcriptome analysis of biopsy tissue from ASD[IC] (ASD with ileocolitis) and non-ASD IBD (Crohn's disease and ulcerative colitis) patients has provided molecular evidence for an overlapping, yet unique, IBD-like condition in ASD children. In this analysis we examined data from two separate cohorts: one from an earlier study that measured gene expression in GI tissue only and the other from the current study where we evaluated gene expression in GI tissue and peripheral blood from the same ASD[IC] individuals.

Objectives: The purpose of these analyses was: (1) to evaluate the reproducibility of transcriptome results derived from an earlier analysis of gastrointestinal tissue from ASD[IC] samples in a second cohort and, (2) to compare gene expression in inflamed tissue to gene expression in peripheral blood from the same patients to identify a peripheral biomarker for GI inflammation.

Methods: Study tissue, collected under appropriate IRB approval, consisted of ileocolonic biopsies (Study 1 and 2) and whole blood (Study 2 only) from two groups of children undergoing ileocolonoscopy for active gastrointestinal symptoms: (1) those with an ASD diagnosis and, (2) typically developing children.

In the initial study ("Study 1"), for each ASD individual a biopsy from either the terminal ileum (N=21) or colon (N=21) that demonstrated the histologic presence of either ileal infiltrates (ileitis), colonic infiltrates (colitis) were used. Histopathologically normal tissues from the identical locations were obtained from 14 control individuals for comparison.

The second study consisted of inflamed ileum or colon biopsy tissue and whole blood from ASD[IC] children (12 in each group) and the same number of (histopathologically normal) tissues and blood samples from a total of 24 typically developing children.

Total RNA was isolated from the tissue biopsy specimens and whole blood and used to query whole

genome DNA microarrays. Pair-wise comparisons of gene expression were made between ASD[IC] and control groups for each of the two tissues. Next, the list of genes that were uniquely expressed in inflamed GI tissues from ASD[IC] was compared to the list of genes differentially expressed in the peripheral blood from those same individuals.

Results: In Study 1, pair-wise analyses between inflamed ileal mucosa from ASD[IC] and non-inflamed control samples resulted in 3497 differentially-expressed genes (DEGs), versus 2949 DEGs in the comparison of colonic tissue gene expression. In Study 2, the numbers were comparable: 2451 DEGs in the TI comparison and 2821 DEGs between inflamed and non-inflamed colonic tissues. A comparison of the whole blood samples from ASD (with GI inflammation) versus TD samples (without GI inflammation) yielded 3183 DETs. The overlap between all genes that were differentially expressed both in ASD ileocoloinc tissue *and* blood revealed a biomarker consisting of 9 candidate genes.

Conclusions: We have shown overlapping gene expression uniquely found in inflamed gastrointestinal tissue (in two distinct locations) and blood from two separate cohorts of ASD[IC] children that my represent a diagnostic biomarker.

168   **125.168** A Comprehensive Meta-Analysis of Common Genetic Variants in Autism Spectrum Conditions

V. Warrier[1], V. Chee[2], P. L. Smith[3], B. Chakrabarti[4] and S. Baron-Cohen[5], (1)University of Cambridge, Cambridge, England, United Kingdom, (2)Autism Research Centre, Cambridge, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (4)Centre for Integrative Neuroscience and Neurodynamics, School of Psychology and Clinical Language Sciences, University of Reading, Reading, United Kingdom, (5)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom

Background: Autism Spectrum Conditions (ASC) are a group of neurodevelopmental conditions characterized by difficulties in social interaction and communication alongside repetitive and stereotyped behaviours. ASC is heritable, and common genetic variants contribute to substantial phenotypic variability. More than 600 genes have been implicated in ASC to date. Nevertheless, a comprehensive investigation of candidate gene association studies in ASC is lacking.

Objectives: To systematically review candidate gene association studies in ASC, and perform a meta-analyses of common genetic variants investigated in three or more independent cohorts.

Methods: We systematically reviewed the literature for association studies for 553 genes associated with ASC. We identified 58 common genetic variants in 27 genes that have been investigated in three or more independent cohorts and conducted a meta-analysis for 55 of these variants. Additionally, we investigated publication bias and sensitivity, and performed stratified analyses based on ethnicity or study methodology for a subset of these variants.

Results: We identified 16 variants nominally significant for the mean effect size, nine of which had P-values < 0.01. The top nine variants were located in seven genes: *DRD3*, CNTNAP2, *EN2, RELN*, *OXTR*, *SLC25A12,* and *MTHFR*. The most significant SNP was rs167771 in *DRD3* (OR = 1.822, P-value = 9.08×10^{-6}). The mean effect sizes for the variants investigated were modest and lay between 0.781 (0.446 - 1.368) for *MAOA* uVNTR and 1.822 (1.398-2.375) for *DRD3* rs167771. In the stratified analyses, seven variants had P-values below 0.05. These seven variants were in five genes (*EN2, OXTR, RELN, SLC6A4*, and *SLC25A12*). Publication bias was significant for two variants in *OXTR*. Sensitivity was an issue for five of the variants investigated. Finally, heterogeneity in effect sizes was significant for a large fraction of the variants tested and was positively correlated with a number of independent datasets investigated per common variant. We were able to remove some of the heterogeneity after stratifying for ethnicity and study methodology.

Conclusions: This is the first study to comprehensively examine common variants in candidate genes for ASC through meta-analysis. It supports the role of common genetic variation in the aetiology of ASC and prioritizes specific variants for further investigation.

169   **125.169** A Genetic Multi-Mutation Model of Autism Spectrum Disorder

I. Kramer[1], A. R. Marvin[2], P. H. Lipkin[3], J. K. Law[4] and P. A. Law[5,6], (1)Physics Department, University of Maryland Baltimore Country, Baltimore, MD, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (3)Pediatrics/Neurology and Developmental Medicine, Kennedy Krieger Institute/Johns Hopkins School of Medicine, Baltimore, MD, (4)Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD, (5)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (6)School of Medicine, Congo Protestant University, Kinshasa, Congo-Kinshasa

Background: The degree of genetic vs environmental determination as it relates to the cause(s) of autism is paramount to our understanding of the disorder. Until now, concordance of twin pairs has varied significantly in published literature. In this analysis we use a novel mathematical model for evaluating the genetic component for twins that takes into account the varied ages of twin sets in autism research. We present a method novel to autism research for evaluating autism concordance. Objectives: To evaluate how well ASD concordance data fits a multi-mutation model. Methods: The design of this study is cross-sectional. Data for this study was provided by parents of child with autism spectrum disorder through their online participation in the Interactive Autism Network (IAN) based in the United States. The IAN project is an online, voluntary research registry

that collects data from families using a set of standardized psychometric instruments and questionnaires. To be included in this analysis, participants must be from twin sets in IAN with at least one twin affected by ASD and for all affected twins must have provided their zygosity and date of diagnosis. A total of 320 twin sets were included (60 identical and 260 fraternal).

Results: The multi-mutation genetic model fits ASD age-of-onset data from IAN very closely (R>0.99). For an ASD susceptible cohort of twins with the same age of 120 months (10.3 years), for example, the modeling predicts that the monozygote concordance will reach 94% and the dizygotic concordance will reach 19%.

Conclusions: The multi-mutation model for autism fits the monozygotic twin data in the IAN data set very well suggesting that the vast majority of autism cases have a genetic susceptibility to acquire autism. Additional research should be performed on cohorts of twins that can be followed over time to see if the model concordance pattern over time is consistent with the actual experience of the discordant twins.

---

170   **125.170** A Peripheral Blood-Based Biomarker for Gastrointestinal Inflammation in ASD GI-Symptomatic Children

S. J. Walker[1] *and A. Krigsman*[2]*, (1)Neuroscience Graduate Program, Wake Forest University Health Sciences, Winston-Salem, NC, (2)Pediatric Gastroenterology Resources of New York and Texas, Far Rockaway, NY*

Background: Gastrointestinal symptoms are a common co-occurring medical issue in ASD children. GI mucosal inflammatory infiltrates of both the small and large intestine have been noted in the setting of GI-symptomatic ASD and may represent a potential etiology for many of the observed GI symptoms. Anecdotal and published reports of behavioral and cognitive improvement upon treatment of ASD-associated GI inflammatory disease supports the plausibility of a GI association for at least some of ASD behavioral and cognitive symptoms. We have previously described unique GI mucosal biomarkers specific for ASD-associated ileocolitis. It is not yet known whether these unique biomarkers are also present in the blood of these children. Identification of a blood based biomarker for ASD-associated enterocolitis could potentially allow for earlier identification of co-morbid GI disease, earlier GI intervention for affected patients, GI prognostic biologic markers, methods of non-invasive monitoring of response to GI treatment, and correlations between GI disease activity and ASD core symptomatology.

Objectives: The goal of these studies is to develop a non-invasive (blood-based) biomarker for GI inflammation in ASD children. In this talk I will outline our strategy and early results towards this objective.

Methods: The initial study cohort was comprised of tissue (GI biopsy and whole blood) from 24 ASD children undergoing clinically-indicated ileocolonoscopy for chronic GI symptoms, and 24 non-ASD (typically developing, TD) children also undergoing ileocolonoscopy. Differential gene expression between inflamed GI tissue from ASD children and non-inflamed tissue from TD children was examined and compared to differential gene expression in peripheral blood from the same individuals to identify co-differentially expressed transcripts that can serve as a biomarker for GI inflammation.

Results: We reported in an earlier study (Walker *et al.*, PlosOne, 2013) that inflamed ileocolonic biopsy tissue from GI-symptomatic ASD children has a gene expression profile that overlaps with known inflammatory bowel disease (i.e. Crohn's disease and ulcerative colitis) yet has distinctive features that may suggest a novel IBD variant in this population. These earlier findings were apparent in this second cohort as well. In addition, we found that there is significant differential gene expression in peripheral blood derived from children with ASD and ileocolonic inflammation compared to TD children without evidence of GI inflammation. Some of the key biological pathways that are coordinately down-regulated in the blood of the ASD (with inflammation) group are oxidative phosphorylation glutathione metabolism, and NOD-like receptor signaling. The overlap between co-differential gene expression in GI tissue and peripheral blood consisted of 40 potential candidate biomarkers.

Conclusions: The search for biomarkers of disease 'pre-disposition' and disease 'in-progress' through the molecular analysis of peripheral blood is gaining favor due to several obvious advantages: (1) tissue accessibility, (2) the ability to sample longitudinally, over time, and (3) the ability to sample pre- and post-treatment. We have identified a number of potential biomarkers that may be diagnostic for ileocolonic inflammation in ASD children. If these biomarkers can be validated and shown to be both specific and sensitive, they would have immediate and significant clinical utility.

---

171   **125.171** Advances in the Genetics of Dup15q Syndrome: Insights Gained from Induced Pluripotent Stem Cells

S. Chamberlain*, Genetics and Developmental Biology, University of Connecticut, Farmington, CT*

Background: Duplications of maternal chromosome 15q11.2-q13 are one of the most common cytogenetic anomalies associated with autism spectrum disorders (ASD). There are two major structural versions of this copy number variant: isodicentric chromosome 15 [idic(15)] and interstitial duplication of chromosome 15 [int.dup(15)]. Both structural versions of 15q11.2-q13 duplication syndrome result in a disorder characterized by hypotonia, developmental delay, epilepsy, and ASD.

Objectives: To develop human induced pluripotent stem cell (iPSC) models of 15q11.2-q13

duplication syndrome in order to 1) understand the local gene dysregulation underlying the disorder, 2) understand the impact of 15q11.2-q13 duplications on global gene expression in human iPSC-derived neurons, 3) to identify cellular phenotypes associated with the disorder, and 4) to test potential therapeutic approaches to restore normal 15q gene expression.

Methods: iPSCs with idic (15), maternal and paternal int.dup(15), and maternal interstitial triplication of chromosome 15 were generated from patient fibroblast or cord blood samples using either retrovirus, lentivirus, episomal, or sendai virus reprogramming methods. iPSCs were differentiated into forebrain cortical neurons using an embryoid body-based or monolayer protocol. RT-qPCR and RNA-Seq were used to quantify local and global gene expression. Microscopy and electrophysiology were used to investigate cellular phenotypes.

Results: We have generated iPSCs from five different patients with duplications of chromosome 15q11.2-q13, and have differentiated them into forebrain cortical neurons. We compared 15q gene expression between the different iPSC lines as well as from their neuronal derivatives. We found that gene expression closely followed copy number in iPSCs, but deviated somewhat from copy number in iPSC-derived neurons. We identified global transcriptional changes between idic(15) and neurotypical iPSC-derived neurons that suggest defects in neuronal development pathways and upregulation of genes involved in protein degradation. Early electrophysiology experiments and examination of dendritic spine morphology corroborate a defect in neuronal development.

Conclusions: Human iPSCs derived from chromosome 15q11.2-q13 individuals provide an attractive model to study gene expression and cellular phenotypes of neurodevelopmental disorders, including ASD. They can be used to gain important insight into neuronal development.

172 **125.172** Analysis of Genomic Copy Number Variations and Exome Sequencing in Japanese Autism Spectrum Disorder Subjects

K. Nakamura[1], I. Thanseem[2], N. Mori[2], M. Tsujii[3] and N. Matsumoto[4], (1)Department of Neuropsychiatry, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (2)Department of Psychiatry, Hamamatsu University School of Medicine, Shizuoka, Japan, (3)Chukyo Univesity, Toyota, Japan, (4)Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan

Background: Copy number variation(CNV) studies have revealed the importance of rare *de novo* and inherited CNVs in autism spectrum disorder (ASD). Family-based studies have reported a high rate of *de novo* CNVs in idiopathic ASD cases from simplex families compared to that of multiple families. Recently, exome sequencing studies have revealed the importance of rare single nucleotide variations in ASD risk.

Objectives: To date, almost of the CNV and exome sequencing studies in ASD have focused predominantly on the Caucasian populations, with little reprensentation of the Asians and Africans. In this study, we have examined the global CNV in Japanese sampled and also sequenced the exomes of ASD and their parents samples.

Methods: ASD family samples were recruited in collaboration with the Asperger Society Japan. All the subjects were Japanese; diagnosis was made according to DSM-IV criteria and supported by Autism Diagnostic Interview-Revised scores. Among the 203 familes, 191 were simplex, while the remaining 12 were multiple. The samples were analyzed using Affymetrix Genome-Wide Human SNP Nsp/Sty 6.0 microarray. Three different calling algorithms, PennCNV, Birdseye and Canary, were used to identify the autosomal CNVs.Twenty families which met the highest quality control parameters in array studies, and with at least one rare/interestiog CNV were selected for exome sequencing. Genomic DNA was captured using SureSelect Human All Exon v5 kit, and sequenced on HiSeq2000.

Results: CNV analysis:above 90% of the CNVs in children are found to be inherited; almost equally from both the parents. Among the CNVs which are spanning genes, 71% are deletions in the case of *de novo* events; it's only 53% in inherited cases. 281 highly confident *de novo* CNVs were identified; and hence supposed to have some functional significance. Among these 281 CNVs, 23 are found be rare *de novo* events. These 23 rare *de novo* CNVc were validated with qPCR using SyBr Green. A few potential candidate genes like ABR, PITPNA, YWHAE, TRAPPC9, CSMD3, BRD1, MAPK8IP2, PANX2 etc with a possible role in neurodevelopment were identified.Exome Sequencing: Based on GERP and Grantham scores, 15 *de novo* events that resulted in missense, nonsense, frameshift or splice site mutations were considered to be of major impact. These *de novo* events occurred in the following genes: DPP6, MATN2, AVPRIA, C6orf32, PELI3, ATAD3B, CNKSR3, ARHGAP8, PRPF8, SF3B2, TRIP12, ADAMTS18, DLX1, NEK8, NALCN. Majority of these mutations were predicted to have a damaging effect on the respective protein structure/function. Several of these genes have been implicated in neural functions, while a few of them have been previously reported to be associated with ASD.

Conclusions: We found several novel/ultra-rare *de novo* and inherited CNVs and SNVs, many of them are potentially deleterious, in Japanese ASD subjects.

173 **125.173** Autism Traits in Extended Family Members

M. L. Cuccaro[1,2], N. D. Dueker[2], J. M. Lee[2], J. R. Gilbert[2], E. R. Martin[2] and M. A. Pericak-Vance[2], (1)Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL, (2)John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL

Background: The broad autism phenotype (BAP) is a well-established construct that reflects the presence of sub-threshold ASD traits in non-affected relatives of individuals with ASD. BAP traits are (a) increased in parents of individuals with ASD compared to parents of individuals from non-ASD and (b) more frequent in parents of individuals from multiplex families vs. simplex families. The BAP has been assessed using the Broad Autism Phenotype Questionnaire (BAP-Q; Hurley et al 2007; Sasson et al 2013) and the Social Responsiveness Scale-Adult Research Version (SRS:ARV, Constantino 2005). For this study, we investigated the presence of BAP traits among parents from extended ASD families (i.e., ASD occurs in multiple generations and cousin pairs).

Objectives: This study evaluated BAP traits in parents of individuals with ASD in extended ASD pedigrees. Our hypothesis is that parents (connecting relatives of cousin pairs) from extended ASD families would demonstrate increased scores on measures of ASD traits compared to parents from simplex families.

Methods: 43 parents of individuals with ASD (25 mothers/18 fathers) from extended pedigrees (EXT) were evaluated as part of a larger study of ASD genetics. All parents were from single branches within larger pedigrees and completed the BAP-Q and SRS:ARV as part of a multi-trait evaluation protocol. Parental scores on these measures were compared to those from the Simons Simplex Collection (SSC; N=2616 mothers and fathers) using either a t-test for independent samples or the Wilcoxon signed rank sum test.

Results: Mean [sd] BAP-Q Total scores for the two groups (BAP-Q Total EXT=4.42 [2.13], SSC 1.75 [.43]) differed significantly (unpooled variances t-test p<0.0001). BAP-Q subscores (Aloof p<0.0002, Pragmatic p<0.0001, Rigid p<0.0001) also were significantly higher in the EXT parents. Comparison of maternal and paternal EXT and SSC mean BAP-Q showed a similar pattern of results as EXT maternal and paternal BAP-Q means were significantly higher than SSC means with the exception of the maternal Aloof subscore (p=0.17). Mean SRS Total scores and subscores for the EXT and SSC groups did not differ significantly; this same pattern was observed when comparing maternal SRS scores for the EXT and SSC groups. However, paternal Total SRS scores were higher among EXT fathers (p=.019). In addition, paternal means for the Motivation (p=.014), Communication (.036), and Cognition subscales were significantly higher in the EXT fathers.

Conclusions: Sub-threshold autism traits as measured by the BAP-Q are significantly greater in parents of individuals with ASD from extended pedigrees. However there is limited evidence that these same parents are more impaired on the SRS:ARV. This may reflect different degrees of "sensitivity" to ASD impairments and is in line with findings showing that the BAP-Q detected greater numbers of parents with sub-threshold impairments vs. the SRS:ARV (Davidson et al 2014). The presence of elevated BAP-Q scores in parents from extended ASD adds to the evidence that such families are enriched for ASD and related traits and should continue to be a focus of genetic studies.

174 **125.174** Autism-Risk, Schizophrenia-Risk, and Central Nervous System-Related Genes Display Genomic Features Common to Genes of Developmental Regulation

E. L. Casanova[1], A. E. Switala[2] and M. F. Casanova[3], (1)University of Louisville, Louisville, KY, (2)Psychiatry & Behavioral Sciences, University of Louisville, Louisville, KY, (3)Psychiatry and Behavioral Science, University of Louisville, Louisville, KY

Background: A large subset of genes in the human genome are involved in regulation of developmental processes. These include functional subsets like chromatin remodelers, transcription factors, translational regulators, and intracellular signaling transducers. They typically contain large introns, produce longer more complex proteins, and preference retention of transposable element (TE) insertion into intronic sequences over time for reasons not entirely understood. Each of these features is related to general functions of these developmental genes. A previous study of ours reported higher absolute TE content in autism-risk genes (Williams et al., 2013). In addition, King et al. (2013) reported preliminary findings of longer gene size in risk genes. Therefore, in this study we investigate whether autism (ASD)-risk, schizophrenia (SZ)-risk, and central nervous system (CNS)-related genes share features with genes of developmental regulation, so that we may better understand the functions and mutational trends of our genes of interest.

Objectives: Using whole genome control (WGC) for comparison, we determine whether ASD-risk, SZ-risk, and CNS-related genes are enriched in TEs, are longer, and code for larger proteins. Housekeeping (HK) genes are used as a comparison group due to their compactness.

Methods: All known protein-coding genes were acquired from *RefSeq* to compile the WGC. Autism genes with 10+ rating were downloaded from *AutismKB* database (N = 451). Core SZ-risk genes were acquired from *SzGene* database (N = 38). CNS genes were taken from the human *Neurogenesis and Neural Stem Cell (PAMM-404)* PCR array from *Qiagen* to be used as a representative sample (N = 85). Human HK genes were taken from Eisenberg and Levanon (2003) (N = 565). TE content was acquired on human genome 18 from the *TranspoGene* database and data on gene and protein lengths from *NCBI RefSeq*. TE analysis was performed using a negative binomial regression, meanwhile a gamma regression was used for assessing gene and protein lengths.

Results: All groups significantly varied from WGC in terms of intronic TE content; meanwhile, there were no significant differences in non-intronic (promoter, exonic, exonized) content in experimental groups versus control, with the exception of the HK genes, which displayed significantly greater numbers of exonized TEs and fewer exonic elements (p-values < 0.001). Gene length varied significantly across all groups: ASD, SZ, and CNS gene groups were significantly longer in length than WGC, while HK genes exhibited the opposite trend (p-values < 0.001). Protein lengths followed similar

trends as gene length across groups, with the exception of the SZ gene group, whose protein lengths did not vary compared to WGC in spite of having the largest gene length average.
Conclusions:
ASD-risk, SZ-risk, and CNS-related genes house considerable TE content, are larger, and produce larger protein products as compared to WGC. Meanwhile, HK genes, known for their overall compactness and small intronic sizes, exhibit opposite trends as seen in the other experimental gene groups. These results suggest that ASD-risk, SZ-risk, and CNS-related genes may be classed with developmental regulatory genes and, as such, likely follow functional and mutational trends in this large subset of mammalian genes.

175 **125.175** Characterization of Gene Variants Involved in Synaptic Pathways in Extended Utah ASD Pedigrees

ABSTRACT WITHDRAWN

Background: Genes in synaptic pathways have been identified as risk factors for ASD in several large recent studies of Autism Spectrum Disorders (ASD) using exome sequencing in parent-child trios and/or cases and controls. Study of these gene variants and phenotypic characterization of carriers will be critical to inform future in vitro analyses of synaptic structure and function resulting from specific mutations.
Objectives: We have focused on variants in synaptic genes with significant evidence in previous studies where potentially functional variants also occur in ASD families ascertained in Utah. We describe occurrence in cases and unaffected relatives and give detail on phenotypic characteristics of Utah variant carriers including ASD severity (or evidence of any clinical symptoms if the individual is unaffected), IQ, and reported presence/absence of seizures and other health conditions.
Methods: Our data resource includes 518 individuals from Utah families. The Illumina HumanExome chip was genotyped on 186 with ASD and 332 unaffected relatives, and whole exome sequencing (Agilent SureSelect and Illumina GAIIx) was done on 61 relatives with ASD and 27 unaffected relatives in eight extended high-risk pedigrees. The genes studied in these families include *CACNA2D3, SCN2A, TRIO. SHANK3, NRXN1, NRXN2, NRXN3. NLGN1, NLGN2, NLGN3,* and *NLGN4.* Each gene is involved in synaptic transmission, formation, or function, and each has been implicated in ASD and other psychiatric conditions. For each gene, we describe the occurrence of variants that are likely functional in at least one Utah ASD case. We give further variant information using available sequence annotation tools (e.g., PolyPhen, Annovar). We then describe occurrence of the variant in other affected and unaffected family members, and associated phenotypic characteristics.
Results: Multiple variants in synaptic genes were found. We focus particularly on those where functional variants occurred in both affected and unaffected relatives. For example, a rare variant in *SCN2A* (rs2228980) occurred in three families, including three affected cases, three unaffected parents, an unaffected grandparent, and two unaffected siblings. However, in these families, 8 additional siblings (4 affected and 4 unaffected) did not carry the variant. Another example is a rare variant in *CACNA2D3* (rs142687394), which occurred in three different families, including three cases, three unaffected parents, and two unaffected siblings. The variant was not found in five other unaffected siblings.
Conclusions: Variants in genes in this important gene pathway occur in both affected and unaffected relatives in Utah families, suggesting reduced penetrance, even when variants appear to be likely damaging. We note associations with possible seizures, clinical severity, and lower IQ, but these associations are not universal, suggesting pleiotropy. Characterization of particular variants in synaptic genes will inspire additional *in vitro* studies of synaptic structure and function resulting from these gene variants. In addition, our sample includes viably frozen peripheral blood mononuclear cells from many subjects, allowing the potential for the creation of derived neuronal cells for further studies of synaptic function specific to both affected and unaffected individuals.

176 **125.176** Characterization of Neuronal Development in Autism Using iPSCs Reveals Disease-Specific Changes in Axon Formation and Expression of Synaptic Function Genes

D. M. Dykxhoorn[1,2], *B. A. DeRosa*[1], *H. N. Cukier*[1,2], *K. C. Belle*[1], *J. M. Lee*[2], *M. L. Cuccaro*[1,2], *J. M. Vance*[1,2] *and M. A. Pericak-Vance*[1,2], *(1)Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL, (2)John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL*

Background: Autism spectrum disorders (ASD) comprise a genetically and phenotypically heterogeneous group of complex neurodevelopmental conditions. Although tremendous progress had been made in identifying ASD risk loci, the impact that these genetic variants have on ASD pathophysiology remains largely unknown. This is largely a result of the lack of genetically-relevant human disease models. The advent of human induced pluripotent stem cell (iPSC) technology and advances in neural differentiation methodologies, have made it possible to study the cellular and molecular mechanisms that underlie ASD. It is now possible to functionally analyze specific populations of developing neurons derived from ASD-affected individuals. These stem cell-based differentiation approaches mimic in vivo neurogenesis and, as such, provide valuable information about activity-dependent maturation of synapses during neural network formation.
Objectives: The objective of the current study is to functionally characterized ASD-specific

phenotypes in iPSC-derived neuronal cultures.

Methods: We have generated a collection of iPSC lines from peripheral blood mononuclear cells attained from clinically and genetically well-characterized patients affected with idiopathic ASD. These iPSC lines have been differentiated into forebrain neurons by mimicking the steps in neurodevelopment from stem cells through to embryoid bodies, neural progenitor cells, immature neurons, and onto differentiated neuronal cultures. Given the developmental nature of ASD, we focused on analyzing ASD-associated cellular phenotypes by employing microscopy based analysis of neurite outgrowth coupled to transcriptome analysis.

Results: Comparative analysis of ASD-specific and control iPSC-derived forebrain neurons has revealed disease-specific alterations in neurite outgrowth. In addition, high content transcriptome analyses has revealed abnormalities in the expression of key genes involved in neuronal development and axonal growth, including pathways associated with the extracellular matrix and the development of supporting cells such as oligodendrocytes.

Conclusions: ASD-specific iPSC-derived neurons have altered phenotypes compared to those from control individuals. Consistent with its developmental nature, these alterations are observable even at early time points during neural development.

177   **125.177** Chromosomal Microarray Results and Medical Management for Children with Autism Spectrum Disorder and Other Developmental Conditions

K. S. Ho, R. J. Vanzo, A. Peiffer and C. H. Hensel, Lineagen, Inc., Salt Lake City, UT

Background: As part of first-tier clinical testing for patients with autism spectrum disorder (ASD) and/or developmental delay (DD), we have performed whole genome, high density chromosomal microarray analysis (CMA) on 2200 individuals with either or both of these diagnoses over the last four years. A significant number of individuals with an ASD diagnosis (21.7%) or other developmental delays (30%) were shown to have clinically reportable genomic copy number variants (CNVs).

Objectives:

1. To determine the magnitude of the impact of genetic testing results on diagnoses and medical management strategies. This was measured by the frequency at which a general diagnosis of ASD and/or DD could be further refined to a known syndrome or rare disease with genetic testing. Another metric we present is the frequency at which the known syndrome or rare disease has associated medical guidelines for more specific care.

2. To analyze the functional roles of the genes involved in our clinically reported CNVs and determine the specific molecular pathways most commonly represented by genes in these CNVs.

Methods: **We performed a retrospective analysis of de-identified data collected by Lineagen on 2200 individuals. We used physician-provided diagnoses and ICD-9 codes to determine clinical diagnoses of ASD and/or DD. Clinically reported CNVs were analyzed using public databases (OMIM, DECIPHER, PUBMED) for association with known syndromes, rare diseases, and accompanying medical management guidelines. DAVID software was used to perform bioinformatics analyses on genes within CNVs.**

Results: **A significant number of the CNVs were associated with known microdeletion/microduplication syndromes or other genetic disorders, with some of these having distinct medical guidelines for treatment and care. We occasionally found and reported incidental findings that would also affect medical management. Furthermore, bioinformatic analysis indicates that many of the genes contained in the CNVs are thought to be involved in the etiology of ASD, have known neural functions, and/or have functions in energy-related pathways. We summarize and present all these findings from our patient cohort.**

Conclusions: **Our study indicates that CMA testing has significant benefit to physicians managing patients with these conditions. Large scale, clinical CMA testing results can also give insight into potential pharmaceutical targets and the molecular pathways involved, in order that effective and targeted treatments for these conditions may be developed.**

---

178   **125.178** Circadian Network and Autism: Unusual Alternative Splicing Pattern of the JARID1 Genes

Z. Talebizadeh[1], A. Shah[1] and L. DiTacchio[2], (1)Children's Mercy Hospital, Kansas City, MO, (2)University of Kansas Medical Center, Kansas City, KS

Background: The circadian clock coordinates diverse cellular processes and functional outcomes, including behavior and cognition. Abnormalities in the clock genes may have a role in autism, but the underlying mechanism remains unknown. Members of the JARID1 gene family (JARID1a-d), histone demethylases, have been shown to be involved in the circadian molecular machinery in a recent work of our collaborator. JARID1a activates CLOCK-BMAL1, whereas JARID1b and JARID1c act as repressors. These opposing roles suggest that the optimal ratio among JARID1 isoforms is vital in maintaining the proper function of the circadian system. Imbalance in these isoform ratios may contribute to the etiology of diseases. Furthermore, miR132 orchestrates translational control of the circadian clock by targeting chromatin remodeling genes, including MECP2 and JARID1a. The splicing profiles of JARID1, and factors that regulate the expression of such isoforms, are not fully known. Our hypothesis is that

JARID1 mis-splicing may present in at least a subset of subjects with autism. Recent findings have shown cross links between DNA methylation and gene regulatory processes, including alternative splicing and miRNA. Therefore, we used data from a DNA methylation marker for subject stratifications.

Objectives: To investigate the role of circadian genes and their potential mis-splicing in autism.

Methods: We evaluated the expression level of multiple JARID1 alternative splicing transcripts in autistic subjects stratified based on the absence or presence of a given DNA methylation-related marker (DM) in lymphoblastoid cell line-derived RNAs, using Exon array profiling, TaqMan assays, followed by DNA sequencing. Expression levels of the identified isoforms were also investigated in the brain samples from control and a Jarid1 mice model at different circadian timing.

Results: A distinct pattern was detected in the expression level of alternatively spliced JARID1 isoforms for autistic subjects with DM compared to those without DM and controls. Additional experiments, including miRNA mimics, are underway to further characterize the role of miR132 in regulating JARID1a by finding which isoforms(s) show miR132-dependent expression.

Conclusions: This is the first study to evaluate a clock gene in autism, at the alternative splicing level in conjunction with DM markers. Our data indicates an unusual splicing process for the X-linked member of this circadian gene family (JARID1c), resulting in unusually high level of intron retained isoforms, as well as the potential role of the long noncoding RNAs and circular RNAs in the regulation of this circadian gene expression.

179 **125.179** Common Autism Genetic Polymorphisms Hidden in HLA and KIR Genes

A. Torres[1], M. Benson[2], P. L. Bray-Ward[1], D. C. Ward[1] and R. Johnson[3], (1)Center for Persons with Disabilities, Utah State University, Logan, UT, (2)Research and Evaluation, Utah State University; CPD, Logan, UT, (3)BSP CCR Genetics Core at Frederick National Laboratory, Leidos Biomedical Research, Inc., Frederick, MD

Background: Although there has been extensive research into the genetics of autism, only a small percentage of the genetic risk has been identified after studying thousands of subjects. Genome wide association studies (GWAS) examining up to a million SNPs have detected rare variants in a small number of autism spectrum disorder (ASD) cases (under 10%). It has been suggested that rare variants are major contributor to genetic diseases and that autism involves the interaction of many rare variants. The extreme genetic heterogeneity of genes involved in both innate and adaptive immunity indicates that GWAS technology inadequately interrogates these complex gene families (Gourraud & et al., 2014, PLOS One, 9(7):e97282). We have, therefore, taken a more targeted approach to ASD genetic risk by examining human leukocyte antigens (HLA) and killer immunoglobulin-like receptor (KIR) genes (chromosomes 6 and 19 respectively), and have found several genetic associations that appear to fulfill the criteria of "common variants" for ASD.

Objectives: To demonstrate unequivocally that specific HLA alleles and KIR gene content/haplotypes constitute important "common ASD variants" (greater than 5% differences between ASD and control populations).

Methods: PCR-site specific primers (SSP) methodology is used to type HLA alleles and KIR genes from subjects and parents to determine inheritance and haplotypes. Standard statistical procedures are used for determining chi square, odds ratios, and meta-analysis.

Results: We, and others have documented that genes in the HLA and KIR gene complexes are strongly associated with ASD. The data, summarized in Table 1, documents that specific HLA alleles/haplotypes and KIR genes/haplotypes fulfill the "common variant criteria". For example, in three different population studies (P1-P3), the HLA-A2 allele is increased in the ASD subjects between 10.8 and 15.8% with odds ratios between 1.74 and 3.02. Furthermore, the killer-cell activating gene alleles, KIR3DS1 and KIR2DS1, also are found in ASD subjects 15-22% more frequently than in normal controls. Other HLA class I alleles (B7 and B15) and Class II alleles (DR15 and DR1104) are significantly more frequently found in ASD subjects, as are HLA extended haplotypes and KIR gene-content haplotypes (unpublished). Several alleles (A11 and DR7) and KIR haplotype CA01 are found less frequently in ASD subjects, suggesting that they may have a protective effect against ASD.

Conclusions: Our results suggest that HLA and KIR gene variants fulfill the criteria as common variant associations in ASD. These two immune gene complexes work together to modulate NK-cell killing with HLA as ligands for KIR receptors. The role that genes in the immune system play in the etiology of ASD is presently unclear but warrants further investigation.

180 **125.180** Contribution of Small Copy Number Variations (CNVs) to Autism Spectrum Disorder (ASD)

I. M. W. Silva[1], E. S. Moreira[1], N. C. V. Lourenço[2], A. L. Bossolani-Martins[3], M. Lazar[4], K. M. Rocha[4], M. Aguena[4], D. S. Marco Antonio[1], A. C. Fett-Conte[5], C. Rosenberg[6], E. Vadasz[7] and M. R. Passos-Bueno[8], (1)Department of Genetics and Evolutionary Biology, University of Sao Paulo, Sao Paulo, Brazil, (2)University of Sao Paulo - USP, Sao Paulo, Brazil, (3)Federal University of Mato Grosso do Sul, Mato Grosso do Sul, Brazil, (4)University of Sao Paulo, Sao Paulo, Brazil, (5)School of Medicine in São Jose do Rio Preto- FAMERP, Sao Jose do Rio Preto, Brazil, (6)Department of Genetics and Evolutionary Biology, University Sao Paulo, Biosciences Institute, Sao Paulo, Brazil, (7)university of sao paulo-institute of psychiatry, Sao Paulo, Brazil, (8)Department of Genetics and Evolutionary Biology, University of Sao Paulo - USP, Sao Paulo, Brazil

Background: Autism Spectrum Disorder (ASD) is characterized by significant and persistent deficits in communication/social interaction and by restricted and repetitive patterns of behavior, interests or activities. ASD has a complex genetic architecture, with involvement of rare, relatively large Copy Number Variations (CNVs) in nearly 10% of the cases. Despite the advancement of high-throughput genomic approaches, the detection of small CNVs (1 to 100 Kb) and large indels is still challenging and therefore little is known about their contribution to ASD. We used a customized Comparative Genomic Hybridization array (aCGH) in order to screen small potentially pathogenic CNVs in a sample of Brazilian subjects with idiopathic ASD.
Objectives: To assess the importance of small CNVs in the etiology of ASD.
Methods: All patients were diagnosed by psychiatrists using DSM-IV, ICD-10 and ASQ. Children's behavior was characterized by score questions of CARS. Patients with known autism-related syndromes, or exposed to teratogenic drugs /infectious agents during pregnancy were excluded from the study. All patients were negative for *FMR1* expansion and for CNVs at 15q11.13, 16p11.2 (proximal region) and 22q13 through multiplex ligation probe amplification (MLPA) analysis (SALSA KIT P343-B1 AUTISM-1; MRC-Holland, Amsterdam). The customized aCGH included 269 ASD candidate genes, with a high density of probes targeting exons and exon-intron junctions. CNVs ($\geq$ 1 kb) were only considered potentially pathogenic if they were located at coding regions and had a frequency $\leq$ 1% in our sample of 200 non-affected Brazilian subjects and in the Database of Genomic Variants (DGV). All CNVs were validated through Affymetrix 500K SNP-array, MLPA, and/or qPCR.
Results: The customized aCGH was validated by analyzing 15 patients with CNVs from around 60 to 375 Kb at 3p26.3, 15q11-13, 16p11.2, and 22q13 previously detected by the Affymetrix 500K SNP array or by the commercial P343-B1 MLPA kit. All these CNVs were detected by the customized aCGH. Eighty patients with non-syndromic ASD and 20 with syndromic ASD were included in the study. We identified nine CNVs that fulfilled our abovementioned criteria of potential pathogenicity, ranging from 9.5 Kb to 25 Mb, in nine patients with idiopathic ASD. Four CNVs were considered small (< 100 kb). Two of them, detected in non-syndromic patients, affected single genes, namely a duplication at *SLC17A6* and a deletion at *GRM5*. Other two distal 16p11.2 deletions, detected in one syndromic and in one non-syndromic patient, have between 38.9 and 61.8 kb, and involved three genes.
Conclusions: The use of an array designed to detect small CNVs, along with large ones, is a good strategy to improve the elucidation of ASD etiology, as we found a prevalence of 9% of CNVs in our cohort of idiopathic ASD patients, 44% of them smaller than 100 kb. To our knowledge, the two CNVs detected at 16p11.2 are the smallest distal 16p11.2 deletions described so far, and these findings may help to identify the causative ASD gene(s) in this region.

181   **125.181** Differences in Small Non-Coding RNA Expression in Primary Auditory and Temporal Lobe Association Cortex May Have Effects on Cell Cycle, Immune and Other Pathways in Autism Spectrum Disorders

B. P. Ander[1], N. Barger[2], B. Stamova[3], F. R. Sharp[3] and C. M. Schumann[2], (1)Neurology, UC Davis MIND Institute, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)MIND Institute and Department of Neurology, University of California Davis Medical Center, Sacramento, CA

Background: Dysregulation of multiple expressed genes related to brain function and development is a key component of autism spectrum disorders (ASD). Atypical expression of individual regulatory small non-coding RNA (sncRNA), including microRNA (miRNA), could have profound effects upon many important functional pathways. The superior temporal sulcus (STS) is a brain region with a critical role in social perception and associated with core social impairments of ASD. In contrast, the adjacent primary auditory cortex (PAC) has function less central to the core features of ASD. We set to examine expression differences of sncRNA in these two regions of the brain.
Objectives: The goal of this study is to identify sncRNA that are differentially expressed in ASD in the STS, where we expect to see differences compared to typically developing subjects, and PAC where we do not. Furthermore, we investigate the functional implications of these expression differences through evaluating the biological and cellular pathways represented by the gene transcripts targeted by the altered miRNA.
Methods: We measured sncRNA expression levels in total RNA extracted from STS and PAC dissected from fresh-frozen brain of ASD and typically developing individuals. Affymetrix miRNA 3.0 microarrays were used to screen a total of 36 samples for 5,607 sncRNA including 1,733 mature human miRNA, 1,658 human pre-miRNA, and 2,216 human snoRNA, CDBox RNA, H/ACA Box RNA and scaRNA. Predicted mRNA targets of significantly altered miRNA were found using DIANA microT-CDS and their biological function was assessed by overrepresentation analysis against the KEGG database. As a validation study of these results, brain regions were pooled and reanalyzed to determine changes in ASD brain and these functional results were compared to studies publishing mRNA expression data.
Results: Among miRNA, miR-4753-5p and miR-1 were dysregulated in the superior temporal sulcus (STS) of ASD compared to typically developing brain. miR-664-3p, miR-4709-3p, miR-4742-3p and miR-297 were dysregulated in primary auditory cortex (PAC) of ASD compared to controls. Four small nucleolar RNA (snoRNA) and 8 pre-miRNA were dysregulated in STS and 5 snoRNA and 7 pre-miRNA were dysregulated in PAC of ASD. In both regions, miRNA were functionally related to various nervous system, cell cycle and canonical signaling pathways including PI3K-Akt signaling which has been implicated in previous ASD studies. Disruption of immune related pathways was unique to STS. Our

predicted functional pathways had significant overlap with studies looking at genes associated with ASD and others looking at expression in other regions of brain.

Conclusions: Altered sncRNA expression appears not only in STS, but also in primary auditory cortex, suggesting that transcriptional abnormalities in ASD may also impact brain regions not directly associated with core behavioral impairments. Disruption of immune related pathways, commonly implicated in genetic analyses of ASD, was unique to STS. Alterations in sncRNA may underlie dysregulation of molecular pathways implicated in autism.

182   **125.182** Distribution and Mutational Specificity of Autistic Trait Severity in Neurofibromatosis Type 1 (NF1)

J. N. Constantino[1], *Y. Zhang*[2], *S. Sant*[2], *K. Long*[3], *L. Malik*[4] *and D. H. Gutmann*[5], *(1)Washington University School of Medicine, Saint Louis, MO, (2)Psychiatry, Washington University School of Medicine, Saint Louis, MO, (3)Psychiatry, Washington University in St Louis, St. Louis, MO, (4)Psychiatry, Washington University School of Medicine, st louis, MO, (5)Neurology, Washington University in St Louis, St Louis, MO*

Background: Very recent studies of quantitative autistic trait (QAT) burden in individuals with Neurofibromatosis Type 1 (NF1) have estimated the prevalence of the broader autism phenotype (BAP) to be on the order of 40-60%. NF1 presents a unique opportunity for the examination of genotype-phenotype correlation because it is: a) caused by a highly penetrant mutation of a single gene; b) reasonably prevalent (1 in 2500); c) exhibits autosomal dominant transmission in families; and d) every family's mutation is unique.

Objectives: In this study, we examined the distribution of quantitative autistic traits in NF1, their relationships with sex and ADHD symptomatology, and explored evidence for mutational specificity by examining within-family trait correlations for QAT.

Methods: 160 of 320 invited individuals from 253 families (50.0%) agreed to participate. Participants completed and mailed in age-appropriate versions of the Social Responsiveness Scale-2 (SRS-2) and a Conners ADHD Rating Scale. Of the enrolled individuals, the SRS-2 was completed for 103 individuals with a range of age from 30 months to 74 years from 78 families. ADHD rating scales were completed on 97 subjects. A within-family intra class correlation coefficient for SRS-2 scores was computed for pairings of co-affected first degree relatives in 18 families.

Results: These data replicated a pronounced pathological shift in the distribution of SRS2 scores (see Figure 1 below) in comparison to the general population distribution. In contrast to what is observed in familial autistic syndromes, no statistically-significant sex effects on scores were observed, and SRS2 scores for male and female NF1 subjects appeared continuously distributed. An SRS2 intra class correlation of 0.767 was observed for pairings of first degree relatives with NF1, substantially higher than correlations on the order of 0.30 typically observed for first degree relatives in clinical samples (Lyall et al., 2014; Constantino et al., 2006) and in the general population (Constantino and Todd, 2003)--a scatter plot is provided in Figure 2. The correlation between SRS2 and ADHD index scores was moderate, as previously reported in population-based samples.

Conclusions: Exploration of the relationship between specific NF1 genotypes and autistic social impairment appears strongly warranted and may offer insights into mechanisms by which mutational variation in this unique autism candidate gene influences autistic trait severity. The magnitude of the within-family correlation strongly suggests that it is specific to NF1 genotype and not attributable to family genetic background, since the latter typically manifests in substantially lower trait correlations between first degree relatives.

183   **125.183** Do Parental Medical and Psychiatric Conditions Have Sex-Differential Risk Effects for Autism?

M. C. Lai[1,2], *A. L. Pohl*[3], *M. Whitehall*[1] *and S. Baron-Cohen*[1,4], *(1)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (2)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (3)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (4)CLASS Clinic, Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom*

Background: The male predominance in autism suggests that generally, the liability to developing autism may be sex/gender-differential. However, exact mechanisms contributing to this sex/gender-differential liability remain unclear. When investigating etiological-developmental mechanisms and risk/protective factors for autism, it is important to consider sex/gender-differential effects, rather than simply "controlling for" sex/gender. Both sex/gender-independent and -dependent effects should be tested in epidemiological and causal investigations.

Objectives: To test whether parental medical and psychiatric conditions contribute to any sex-dependent and/or -independent risks for autism in offspring.

Methods: Parent-report data from studies utilizing the medical history questionnaire of the Childhood Autism Risk from Genetics and Environment (CHARGE) study, publicly available on the National Database for Autism Research (NDAR) were analyzed, with a specific focus on testing for sex-differential risk effects. Parental conditions were grouped into 8 composite predictors: (1) maternal lifetime immune-dysregulation, (2) maternal immune-dysregulation during pregnancy, (3) maternal lifetime neuro/developmental conditions, (4) maternal lifetime psychiatric conditions, (5) maternal

lifetime obesity, (6) paternal lifetime immune-dysregulation, (7) paternal lifetime neuro/developmental conditions, and (8) paternal lifetime psychiatric conditions. We used loglinear analysis to test for sex-differential risks of parental conditions to child ASD diagnosis, followed by logistic regression to evaluate odds ratio (OR). Finally, we calculated a fully adjusted logistic regression model, including all risk conditions and their interaction with child sex.

Results: An initial 1,511 reports were collected. Only participants without missing data on the variables of interest were entered into the analysis, resulting in 867 reports (children with autism: 203 males, 41 females; control children: 468 males, 155 females). Loglinear analysis showed trends towards significant 3-way interactions among child ASD diagnosis, child sex, and (i) paternal lifetime immune-dysregulation (p=0.067), (ii) maternal lifetime obesity (p=0.066). Follow-up logistic regressions showed trends towards a significant "sex-paternal immune-dysregulation" multiplicative effect (p=0.070, male child plus the condition increased risk, OR=2.064), and a "sex-maternal obesity" multiplicative effect (p=0.074, female child plus the condition increased risk, OR=2.988). In the final model, maternal immune-dysregulation during pregnancy (p=0.013, OR=1.544, 95% CI=1.097-2.171) and paternal lifetime psychiatric condition (p=0.015, OR=1.639, 95% CI=1.099-2.445) increased autism risk independent of sex, while maternal lifetime obesity increased autism risk in a marginally sex-dependent manner, that female child plus the condition increased risk (p=0.052, OR=3.495, 95% CI=0.990-12.346).

Conclusions: Maternal immune-dysregulation during pregnancy and paternal lifetime psychiatric conditions may increase risk for child ASD diagnosis independent of sex/gender, while maternal lifetime obesity confers a possible heightened risk for ASD in females. Sex/gender-differential effects should be regularly investigated in understanding the risk/protective factors and etiological-developmental mechanisms of autism.

184 **125.184** Documentation of HLA-DRB1*1302 As a Maternal Prenatal Risk Factor for Autism Using Imputation in a Maternal-Fetal Incompatibility Model

W. G. Johnson[1], E. S. Stenroos[2] and S. Buyske[3], (1)661 Hoes Lane, Rutgers University, Piscataway, NJ, (2)Neurology, Rutgers University - Robert Wood Johnson Medial School, Piscataway, NJ, (3)Statistics and Biostatistics, Rutgers University, Piscataway, NJ

Background: The Major Histocompatibility Class (MHC) *HLA-DR*, and in particular its highly polymorphic beta chain gene, *HLA-DRB1,* have been studied in autism. The association of autism with HLA genes and haplotypes suggests that an underlying dysregulation of the immune system in autism may be mediated at least in part by HLA genes (Torres AR et al, 2012). Early studies by Reed Warren and others raised the question of whether an *HLA-DRB1* gene acting in the mother during pregnancy might contribute to autism in her fetus. Later, Lee et al, 2006, analyzed two datasets and reported that in one of them, individuals with autism and their mothers but not their fathers had a significantly higher frequency of *HLA-DR4* alleles compared with controls. We followed up these studies using TDT in maternal trios (maternal grandparents & mothers) as well as TDT in case trios, and found an odds ratio of 4.7 (95% CI: 1.3 to 16.2) for transmissions of *HLA-DR4* to mothers of individuals with autism from maternal grandparents, but we did not see increased transmission to the individuals with autism. In the present study, we used the very large Simons Simplex dataset to extend these findings *in silico* by HLA imputation of GWAS data.

Objectives: To attempt a more in-depth study of the HLA region in autism by a newer method.

Methods: We used HLA*IMP2, Dilthey et al. 2013, and HIBAG, Zheng et al. 2013, to impute *HLA* alleles for *HLA-A, -B, -C, -DPB1, -DQA1, -DQB1, -DRB1, -DRB3, -DRB4,* and *-DRB5* in individuals with autism and their parents from GWAS data available in the Simons Simplex Collection Version 14 on the Illumina Human 1M Duo dataset. Families were limited to those of European descent. All individuals' data were imputed without familial information. We tested for association with autism by the Maternal-Fetal Genotype Incompatibility Test as implemented in the Mendel software. We received IRB permission for this study.

Results: *HLA-DRB1*1302* showed a significant effect (p<3.6 x 10-4) under the non-inherited maternal antigens model, in which offspring without the allele whose mothers who were heterozygous for the allele had increased risk. No alleles showed significant RHD-type incompatibility effects (i.e., heightened risk for heterozygous offspring of mother without the allele). This result remained significant after correction for multiple comparisons.

Conclusions: The present study supported action of an *HLA-DRB1* allele in autism as a maternally acting gene allele in a very large dataset. Maternally acting gene alleles are key determinants of the intrauterine environment during pregnancy. They may be of particular importance very early during pregnancy when the ratio of maternal to fetal mass is largest. This is important for the pathogenesis of autism as well as for potential treatment, since the prenatal period is the earliest opportunity for treatment of autism.

185 **125.185** Dysregulation of Regulatory Small Non-Coding RNAs in the Superior Temporal Gyrus Brain Region of Autism Spectrum Disorders

B. Stamova[1], B. P. Ander[1], N. Barger[2], F. R. Sharp[3] and C. M. Schumann[2], (1)Neurology, UC Davis MIND Institute, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)MIND Institute and Department of Neurology, University of California Davis Medical Center, Sacramento, CA

Background:
mRNA transcriptomes vary enormously between brain regions. Neocortex transcriptomes are relatively homogeneous with physical proximity correlating with transcriptome similarity. However, transcriptomes of primary sensorimotor cortices are quite distinct from adjacent cortex. Molecular mechanisms responsible for normal regional patterning could involve regulatory RNA, such as small non-coding RNAs (sncRNA) (miRNA, snoRNA), which play fundamental roles in brain development throughout lifespan. Superior temporal gyrus (STG) is a region with importance to neuropsychiatric disorders, including ASD. It consists of two regions, superior temporal sulcus (STS) and primary auditory cortex (PAC), which although adjacent, have different functions. STS is association cortex, involved in social perception, joint attention, interpreting facial gaze and speech inputs, and implicated in ASD. PAC is a primary sensory cortex modulating auditory processing, not associated with ASD.
Objectives:
1) To assess differential regional and age-related expression in STS and PAC in postmortem human brains of TD and ASD. 2) To compare to previous miRNA ASD studies.
Methods:
Affymetrix miRNA 3.0 arrays were run on 28 samples (8 ASD / 6 TD subjects; 2 brain regions; ages 4-50 years of age). Mixed Regression Models were used to identify regionally differentially expressed genes (p<0.005, |fold-change|>1.2). Spearman Rank correlation was used for age-related expression and co-expression relationships (p<0.005).
Results:
We found distinct regional and age-related changes of differentially expressed sncRNAs in TD in STS and PAC, which were significantly attenuated in ASD. This is in line with observations of regional attenuated mRNA expression in ASD brain (Voineagu et al, 2012, Ziats and Rennert, 2012). In addition, because genes function in coordinated networks, to characterize network alterations in ASD, we investigated the co-expression relationships of the age-related miRNAs in TD brains, based on similarity of expression profiles, and compared them to the ones in ASD. In TD, defined positive and negative co-expression clusters were identified, suggesting coordinate expression and/or regulation (Fig. 1). In contrast, ASD brains displayed significant deviations from this coordinated expression, thus potentially dysregulating a large number of downstream mRNA targets (Fig. 1). We then compared our findings to other miRNA studies in ASD to find gene families with broad dysregulation in ASD (Table 1). Seven miRNA gene families were dysregulated in subsets of ASD cerebellar cortex samples versus non-ASD controls (P of overlap=0.0002) (Table 1, (Abu-Elneel et al., 2008)). Five miRNAs were differentially expressed in lymphoblastoid cell clines (LCL) of affected versus unaffected monozygotic twins discordant for ASD diagnosis/severity (P=0.046) (Table 1, (Sarachana et al., 2010)). Two miRNAs were differentially expressed in LCL between ASD and controls (P=0.047) (Table 1, (Talebizadeh et al., 2008)). One miRNA was differentially expressed in LCL between ASD affected sibs vs unaffected sibs (P=0.413, n.s.) (Table 1, (Ghahramani Seno et al., 2011)). Several of these overlapping miRNAs have fundamental roles in brain development and function.
Conclusions: The combined effects of the differentially expressed sncRNA in ASD brains, likely contribute to aberrant development and function of STS and PAC and may contribute to core ASD symptoms including social dysfunction and communication.

186   **125.186** Exploring Non-Coding Regulatory SNPs As Genetic Markers for Autism Spectrum Disorders

L. Peixoto[1], S. Poplawski[1], C. Kao[2], H. Hakonarson[2], R. T. Schultz[3] and T. Abel[1], (1)University of Pennsylvania, Philadelphia, PA, (2)Children's Hospital of Philadelphia, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder of high prevalence that clearly involves genetic risk factors. However, the connection between ASD genetic risk factors and the development of ASD is poorly understood. Most current approaches to understand genetic risk factors in ASD focus on genes, although most human disease-associated single-nucleotide polymorphisms (SNPs) are located in regulatory regions which control gene expression. It remains challenging to pinpoint regulatory regions that are likely to be important for a specific disease. It is known, however, that functionally relevant regulatory regions are determined through epigenetic modifications which define where chromatin is accessible in the genome.
Objectives: The goal of this study was to evaluate whether regulatory regions obtained from epigenetic studies of mouse behavior could highlight non-coding regions with genetic links to ASD in human populations.
Methods: We used high-throughput sequencing (HTS) to uncover regulatory regions that show an increase in chromatin accessibility following contextual conditioning in the mouse hippocampus, which were disproportionally enriched around genes known to be linked to ASD according to the SFARI gene database (https://gene.sfari.org/autdb/Welcome.do). We then used genotyping to investigate whether SNPs in one of the candidate regions, located within and intron of Shank3, were significantly associated with ASD in in a cohort of 472 ASD (diagnosed by research reliable clinicians using the ADOS and ADI) and 209 typically developing children.
Results: Using HTS we show that learning produces increases in chromatin accessibility at 3064 regulatory regions in the mouse hippocampus. 59 of the 420 autosomal ASD associated genes

according to SFARI show an increase in chromatin accessibility following conditioning within their regulatory regions (promoters or introns), including an internal promoter within the Shank3 gene. Genotyping of common SNPs within this region reveals that there is a significant increase in frequency (Fisher exact test p=0.03) of the heterozygous allele in ASD cases versus controls for SNP rs6010065.

Conclusions: Overall our results demonstrate that using epigenetic data obtained from mouse is a viable strategy to highlight functionally relevant regulatory regions for genetic association studies of ASD. Future work will include genotyping of the remaining 58 candidate regions as well as further investigation of the mechanism underlying the effect of mutations within the Shank3 internal promoter.

---

187   **125.187** Genetic Variation in Melatonin Pathway Enzymes in Children with Autism Spectrum Disorder and Comorbid Sleep Onset Delay

O. J. Veatch[1], *J. S. Pendergast*[1], *R. M. Leu*[2], *C. H. Johnson*[1], *S. H. Elsea*[3] *and B. A. Malow*[4], *(1)Vanderbilt University, Nashville, TN, (2)Pediatrics, Emory University, Atlanta, GA, (3)Baylor College of Medicine, Houston, TX, (4)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN*

Background:
A large proportion of individuals with autism spectrum disorder (ASD) present with comorbid sleep disorders. Disrupted sleep not only affects cognitive functioning, but exacerbates ASD-related behavioral impairments. Previous studies established a strong influence of common genetic variation in the etiology of ASD. Genetic factors likely contribute also to comorbid expression of sleep disorders in ASD. Variations in genes whose products regulate endogenous melatonin modify sleep patterns in humans, and have also been implicated in ASD. However, there are major challenges identifying even modest, replicable effects related to this variation. It is possible that variable phenotypic expressivity in ASD, specifically expression of comorbidities, can be explained by underlying genetic differences. Stratifying ASD cases based on presentation of sleep disruption may help address issues related to phenotypic heterogeneity in genetic analyses and help reveal underlying relationships between genotype and phenotype.

Objectives:
Our hypothesis was that individuals with ASD and comorbid insomnia would harbor a greater load of variation in genes related to maintenance

Methods:
We studied a clinically unique ASD subgroup, consisting solely of children with comorbid expression of sleep onset delay. We evaluated variation in two melatonin pathway genes, a*cetylserotonin O-methyltransferase* (*ASMT*) and *cytochrome P450 1A2* (*CYP1A2*). We sequenced the protein coding region of *ASMT*, and genotyped seven predicted 'dysfunctional' single nucleotide polymorphisms (SNPs) in *CYP1A2*.

Results:
All patients were either homozygous, or heterozygous, for variants evidenced to alter *ASMT* transcript production. Compared to current estimates in ASD without reported evidence of sleep disturbances we observed higher frequencies (p≤0.04) for variants evidenced to decrease *ASMT* expression. We also observed substantially higher frequencies than currently reported in populations of European ancestry (p≤0.0007) for variant alleles in three SNPs that have been associated with decreased CYP1A2 enzymatic activity. Finally, we detected a relationship between genotypes in *ASMT* that are associated with lower gene expression, and genotypes in *CYP1A2* that are associated with decreased enzymatic activity (r^2=0.63).

Conclusions:
Our results indicate that expression of sleep onset delay in individuals with ASD relates to melatonin pathway genes. Our findings suggest a mechanism connecting lower levels of *ASMT* transcript production with reduced CYP1A2 metabolic activity in children with ASD and comorbid sleep onset delay. We are currently in the process of attempting to replicate these genetic findings in a larger, clinically similar dataset.

---

188   **125.188** Homozygous Deletions of Non-Coding Transcriptional Control Sites Leads to Autism Spectrum Disorder

K. Schmitz-Abe, *Boston Children's Hospital, Boston, MA*

Background: Noncoding DNA comprises 99% of the genome but methods for understanding its normal function have greatly lagged our understanding of the protein coding sequence. Autism Spectrum Disorder (ASD), associated with defects in social and/or cognitive function, has previously been linked to disruptions of gene coding regions by *de novo* Copy Number Variants (CNVs), Single Nucleotide Variants (SNVs), or inherited recessive biallelic SNVs, but most cases remain unexplained

Objectives: Identify and understand new mechanism in Autism.

Methods: Here we present CNV and homozygosity analyses in 183 families ascertained through the Homozygosity Mapping Collaborative for Autism (HMCA). This is a specialized ASD cohort highly enriched for families that are consanguineous and/or have multiple affected children. For this study we genotyped parents, children, and additional family members where available, for a total of 747

individuals (255 affected children) from 183 families. To compare findings in our cohort to other autism data sets with distinct ascertainment practices, we also analyzed 706 families from the Autism Genetic Resource Exchange (AGRE) cohort (3013 individuals, 1591 affected) and 1024 families from the Simons Simplex Collection (SSC) (3875 individuals, 1027 affected). The AGRE cohort is enriched for multiplex families, but is largely non-consanguineous, while the SSC is a non-consanguineous cohort enriched for simplex families.

Results: In the entire HMCA about ~25% of affected individuals (39/237) carry a rare homozygous deletion versus ~15% of unaffected. Thus approximately 10% of affected children may be explained by double deletions. We sought to enrich for causative variants through (a) experimental validation with an independent technology (b) strict segregation within the family (c) rejection of double deletions present among unaffected individuals, children or parents, in all three data sets. Overall we identified 16 events that satisfy all three-selection criteria. Most of the selected events (12/16) disrupt regions identified as transcriptional control sites by the ENCODE project (H3K4Me1, H3K4Me3, and H3K27Ac marks). MonteCarlo simulation confirmed the statistical significance of the finding. In addition, derived from multiple pure cell culture experiments, the importance of control regions is supported by methylation marks defined in primary neuron cultures.

Conclusions: CNV analysis of 183 ASD families enriched for consanguinity demonstrates that children affected with ASD in these families are significantly enriched for autosomal homozygous deletions compared to unaffected siblings, especially in highly consanguineous families (25% versus 15%), suggesting that homozygous deletions account for up to 10% of affected children in consanguineous families. Most homozygous deletions are small (<100 kb) and few interrupt coding regions, presumably inactivating genes, but most do not. Instead we find that affected children are significantly enriched for deletions of DNA regulatory regions, with 12/16 regions disrupting ENCODE regulatory elements, a rate much higher than expected by chance (p<0.05). Our data suggest an important new mechanism of ASD, define a powerful approach to identify essential noncoding DNA regions, and highlight the importance of patterned gene activation in cognitive and social function.

189 **125.189** Identification of Gene-Environment Interactions Associated with Autism Spectrum Disorders

C. Ladd-Acosta[1], B. Lee[2], B. Sheppard[3], N. B. Gidaya[4], L. A. Weiss[5], G. C. Windham[6], A. M. Reynolds[7], L. A. Croen[8], D. E. Schendel[9], C. J. Newschaffer[10] and M. D. Fallin[11], (1)Johns Hopkins University, Baltimore, MD, (2)Drexel University School of Public Health, Philadelphia, PA, (3)Johns Hopkins School of Public Health, Baltimore, MD, (4)Drexel University, Kennett Square, PA, (5)Psychiatry, University of California San Francisco, San Francisco, CA, (6)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (7)University of Colorado Denver, Aurora, CO, (8)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (9)University of Aarhus, Aarhus, Denmark, (10)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (11)Mental Health & Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Background: There is increasing interest in understanding genetic and environmental risk factors and their interplay in autism spectrum disorders. However genome-wide gene-environment interaction studies have been hindered mainly due to the lack of specific exposure and genome-wide genotyping data from the same individuals. We have previously presented preliminary gene-environment results from The Study to Explore Early Development (SEED), a multi-site case-control study of ASD with comprehensive phenotyping and genome-wide genetic and prenatal environmental exposure data. Since that presentation, we have genotyped additional cases and controls and examined additional exposures.

Objectives: The main purpose of this study is to identify genetic and environmental factors that influence risk for ASD. Specifically, we sought to identify single nucleotide polymorphisms (SNPs) whose effects on ASD risk vary across levels of selected prenatal environmental exposures including SSRI use, B2AR use, smoking, alcohol use, and infection.

Methods: For our GxE analysis, we examined prenatal exposures across four domains including maternal use of tobacco, alcohol, and medication (B2ARs and SSRIs) as well as maternal infection. Prenatal environmental exposure information was obtained from maternal self-reported data using a structured interview. Genotypes for 1,321 SEED children (590 cases and 731 controls) were measured using Illumina Omni1 and Affymetrix Axiom arrays. After applying data quality control measures, and performing imputation to obtain about 4 million genotypes per person, initial analysis was performed using a new joint likelihood ratio test for marginal genetic main effects and gene-environment interaction. To maximize our power and appropriately account for gene and environment independence assumptions we also plan to implement a case-only GxE likelihood ratio test of association that uses an Empirical Bayes-type shrinkage estimator to address gene-environment independence.

Results: Our GxE analysis using data from 873 SEED children revealed a genome-wide significant ($P < 5 \times 10^{-7}$) interaction between genotype and smoking for several neighboring SNPs on chromosome 2. We are in the process of completing final GxE analyses for the complete set of 1,321 SEED samples and will present our latest findings, in the largest set of samples, at the conference.

Conclusions: We have identified interactions between genomic regions and specific *in utero* environmental exposures that are associated with ASD. Our results suggest that coupling genetic

and environmental exposure information to determine ASD risk may be more fruitful than looking for genetic marginal effects alone. SEED has proven to be a particularly useful resource for these types of integrative of studies.

190 **125.190** Imaging Autism in Mouse and Man

J. P. Lerch *and J. Ellegood, Hospital for Sick Children, Toronto, ON, Canada*

Background: Autism Spectrum Disorders (ASDs) are complex and still poorly understood. They are highly heritable, yet no single gene discovered to date accounts for more than 1-2% of known cases. Currently 250+ genes have been associated with Autism in the human population, and while ASD is associated with communication and social deficits, as well as repetitive behaviours, individual clinical presentations are highly heterogeneous.
Objectives: To identify clusters within the autistic spectrum using brain imaging as a shared endophenotype in both clinical studies and mouse models of the disease.
Methods: A cohort of over 100 children and adolescents diagnosed with autism were imaged on a 3T MRI. A separate control cohort of over 300 was also acquired on the same scanner using the same imaging protocols. Information about neuroanatomy and brain connectivity was extracted using state of the art image processing algorithms.
At the same time, over 30 mouse lines carrying mutations linked to autism were imaged on a 7T MRI, totaling over 500 scans. Data were assessed for alterations in anatomy and then further clustered into distinct groupings of mouse models sharing common anatomical phenotypes. We additionally investigated which areas of the brain were most consistently affected across all mouse models. Lastly, the mouse imaging data was integrated with the gene expression maps from the Allen Brain Institute to explore potential processes driving the imaging findings.
Results: Human imaging results comparing children and adolescents with autism to typically developing controls showed patterns that were diffuse throughout the brain and furthermore significantly more variable in the autistic cohort. The mouse data revealed that the brain areas affected were specific to each individual mouse model studied, resulting in a similarly diffuse and heterogeneous pattern of brain alterations once all the models were taken in aggregate. The most consistently affected brain regions were the corpus callosum, cortex, and cerebellum. The mouse models further clustered into three sets with shared imaging phenotypes.
Conclusions: Autism presents with marked hetereogeneity in phenotype. Using imaging of neuroanatomy and brain connectivity we identified the same variability in these endophenotypes. Combining mouse and human imaging data suggests potential stratifications of autism into clusters sharing similar phenotypes.

191 **125.191** Integrating Analytical Methods to Identify Rare Variants Associated with ASD in High-Risk Utah Pedigrees

T. M. Darlington[1]*, V. Rajamanickam*[2]*, R. Sargent*[2]*, A. V. Bakian*[1]*, D. A. Bilder*[1]*, G. Schellenberg*[3]*, N. J. Camp*[2] *and H. Coon*[1]*, (1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Genetic Epidemiology, University of Utah, Salt Lake City, UT, (3)Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA*

Background: Despite recent advances in research on autism spectrum disorder (ASD), most genetic risk factors remain elusive. Previous large-scale genetic studies estimate >1000 genes are involved in ASD; however, this heterogeneity may be reduced when looking within individual pedigrees.
Objectives: Integrate genome-wide Shared Genomic Segments (SGS) analysis with the pedigree extension of the Variant Annotation, Analysis, and Search Tool (pVAAST) to increase power to detect rare genetic variation contributing to ASD risk in high-risk ASD pedigrees.
Methods: High-risk pedigrees were identified through the Utah Population Database. The Familial Standardized Incidence Ratio (FSIR) was used to find pedigrees with significantly more cases than expected compared to similar background pedigrees matched for age, sex, and size. DNA was collected through blood draws on affected and unaffected family members. A total of 196 samples were genotyped (Illumina OmniExpress12v1.1) on four of the largest high-risk pedigrees, including 44 affected relatives, 4 relatives with broad autism phenotype, and 146 unaffected relatives (siblings, parents, grandparents). Genotyping data was used to identify genomic sharing using SGS analysis. A subset of 88 samples from these pedigrees underwent exome sequencing (Agilent SureSelect and Illumina GAIIx). Variants in significant SGS regions were functionally annotated and analyzed with pVAAST to identify the likelihood of the variants contributing to disease risk. Pedigree variants were compared to background exomes sequenced through the 1000 genomes project, and were selected to match ethnicities with the pedigrees.
Results: In pedigree 25002 (ASD FSIR=5.56, p<0.0001), we identified a 12Mb region on chromosome 15 that was significantly shared between family members diagnosed with autistic disorder, compared to unaffected family members (wpSGS p<0.001). Subsequent pVAAST analysis of exomic variants in this region identified 4 genes most likely to contribute to risk for autistic disorder. The variants in these genes were shared between multiple affected family members, and include rs35697691 in mitogen-activated protein kinase 6 (*MAPK6*, p=0.048), two variants, rs1867380 and rs142159680 in aquaporin 9 (*AQP9*, p=0.0087), rs55686434 in myosin 5C (*MYO5C*, p=0.037), and rs16976466 in protogenin (*PRTG*, p=0.041).

Conclusions: The complexity and heterogeneity of autism spectrum disorder require innovative strategies for identifying genetic risk factors. Here, we combined two pedigree based analyses, SGS and pVAAST. First, SGS identified a significantly shared region of interest at 15q21-15q22. Then, pVAAST interrogated rare variants from sequenced exomes to identify 4 genes with evidence for ASD risk. The 4 genes, *MAPK6*, *AQP9*, *MYO5C*, and *PRTG* are expressed in brain. Of particular interest are *PRTG* and *MAPK6*. *PRTG* has been previously linked to attention-deficit hyperactivity disorder and reading disabilities. Variants in *MAPK6* has been previously associated with autism, as well as other neurological disorders like bipolar disorder and epilepsy. This analysis strategy has been effective at identifying regions and genes involved in genetic risk for ASD, and increase understanding of the genetic etiology of ASD.

192 **125.192** Intergenerational Patterns of Quantitative Autistic Traits in Hispanic Families

A. Abbacchi[1], Y. Zhang[2], K. A. Zambrana[3], D. S. Messinger[4] and **J. N. Constantino**[5], (1)Washington University School of Medicine, St. Louis, MO, (2)Psychiatry, Washington University School of Medicine, Saint Louis, MO, (3)Department of Psychology, University of Miami, Coral Gables, FL, (4)University of Miami, Coral Gables, FL, (5)Washington University School of Medicine, Saint Louis, MO

Background: Previous research in predominantly Caucasian samples has revealed distinct patterns of aggregation of quantitative autistic traits (QAT) in close family members of individuals affected by Autism Spectrum Disorders (ASD), including siblings (Virkud et. al., 2009) and parents (Lyall et al., 2014).
Objectives: To characterize quantitative autistic trait patterns in Hispanic families affected by ASD using English and Spanish versions of the Social Responsiveness Scale-2 (SRS-2).
Methods: The sample was comprised of 168 families of self-reported Hispanic ethnicity recruited from the University of Miami, who fell into one of three groups: i) families with a child affected by ASD, ii) families in whom a child had a non-ASD psychiatric diagnosis, psychiatric controls (PC), or iii) families of typical controls (TC). Each family included one index child that defined family category and at least one sibling. All index children and siblings had at least one biological parent of self-report Hispanic ethnicity (s-rHE): for each group a minimum of 75% of fathers and 75% of mothers were of s-rHE. Quantitative autistic trait scores of index children (n=164) and siblings (n=153), were assessed by parent-reports using the Social Responsiveness Scale-2 (SRS-2, Constantino & Gruber, 2012). Fifty-nine index children and 53 siblings were additionally rated by teacher-reports, and 142 mothers and 157 fathers (138 pairs) were rated by spousal-report using the SRS-2. In this study, we implemented either *English* or *Spanish versions* of the SRS-2, depending on the primary language spoken by the rater. Index cases of ASD were confirmed using the Autism Diagnostic Observation Schedule and either the Autism Diagnostic Interview – Revised (ADI-R) or the Social Communication Questionnaire (to ascertain developmental history).
Results: In keeping with prior studies in non-Hispanic samples, QAT scores of children with ASD diagnosis were three standard deviations higher than those of typical controls; unaffected sibs and children in families affected by other psychiatric conditions exhibited intermediate levels of QAT (Table 1). SRS-2 intra class correlation coefficients between biological mothers and fathers by spousal-reports were uniformly elevated: ASD group ICC=.52, df=61, p<.0001; PC group ICC=.66, df=15, p<.002; TC group ICC=.59, df=59, p<.0001. A significantly higher proportion of concordantly elevated SRS scores for spousal pairs (i.e. *both* parents in *upper* quartile of the distribution, defined in Table 2) were observed in the ASD group than in the typical control group (16.1% vs. 3.3%, Fisher's exact, p=.03).
Conclusions: This study provides cross-cultural confirmation of the aggregation of QAT in the family members (parents and siblings) of Hispanic children affected by ASD. There was evidence of pronounced preferential mating for QAT, and spousal concordance for sub clinical elevation in QAT was significantly associated with clinical affectation in offspring. Findings support the role of additive genetic influences in the intergenerational transmission of ASD susceptibility in Hispanic families, suggest the possible role of mate selection in offspring ASD risk, and support the ability of the SRS-2 to trace sub clinical affectation as a proxy for transmission of inherited liability in this population.

193 **125.193** Investigation of Parent-of-Origin Effects in Autism Spectrum Disorders

S. Connolly[1], R. J. Anney[2], L. Gallagher[2] and E. A. Heron[1], (1)Psychiatry, Trinity College Dublin, Dublin, Ireland, (2)Trinity College Dublin, Dublin, Ireland

Background:
The detection of Parent-of-Origin (PofO) effects aims to identify whether or not the functionality of alleles, and in turn associated phenotypic traits, depends on the parental origin of the alleles. Autism Spectrum Disorders (ASD) are considered to be heritable neurodevelopmental disorders but in the majority of ASD cases, the genetic cause cannot be identified. Exploring and identifying possible PofO effects is an important step in trying to understand the genetic mechanisms underlying ASDs.
Objectives:
To investigate parent-of-origin effects, such as imprinting and maternal genetic effects, in ASD using Genome Wide Association Study (GWAS) datasets.
Methods:
We use a multinomial model run in the software EMIM to investigate parent-of-origin effects in the

Autism Genomic Project (AGP) dataset. Since this model is complex, it has less power than a typical GWAS analysis, and given that the GWA threshold of 5×10^{-8} has been considered strict, we employ a Bayesian adapted threshold that takes into account the power at each SNP.
Results:
Based on the use of the Bayesian threshold approach, we found 103 different regions that were found to have an imprinting and/or maternal genetic effect(s). We found two results $< 5 \times10^{-7}$, one for paternal imprinting on chromosome 7 and the other for a maternal genetic effect on chromosome 15 in the MGA gene. We found 4 regions that have been previously identified as showing evidence of PofO effects in ASD. These include a maternal genetic effect in a region that was also identified as having a maternal genetic effect by Tsang et al. 2013 on chromosome 11 in the MAML2 gene and a maternal imprinting effect on chromosome 18 where Yuan and Dougherty 2014 found a maternal genetic effect (it is worth noting that maternal imprinting and maternal genetic effects have been known to mimic each other).
Conclusions:
To our knowledge, this is the first genome-wide study to test for both imprinting and maternal genetic effects simultaneously in ASD and the first to implement the Bayesian adapted thresholds that take into consideration the power of the test. We found some promising results that we are currently hoping to replicate in the Simons Simplex Collection autism data set.

194   **125.194** Linkage Analysis of Whole Exome Sequence Data in Multiplex Autism Families Including Cholesterol Covariates

C. L. Simpson[1], Y. Kim[1], C. A. Wassif[2], J. Mullikin[3], E. Tierney[4], F. D. Porter[2] and J. E. Bailey-Wilson[1], (1)Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD, (2)Section on Molecular Dysmorphology, National Institute of Child Health, National Institutes of Health, Bethesda, MD, (3)NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, (4)Kennedy Krieger Institute, Baltimore, MD

Background:
The analysis of multiplex autism families may provide valuable insights into the risk of developing autism spectrum disorder (ASD). It is not known whether "sporadic" ASD is truly sporadic or a consequence of reduced penetrance, but our previous analyses of *de novo* variation suggest that multiplex families have a different underlying etiology. Linkage analysis is a method that is once again increasing in popularity for analyzing next-generation sequence data as it can leverage family structure to increase power compared to population-based methods and multiplex families may be enriched for high-penetrance, functional rare variants. It has also been observed that individuals with Smith-Lemli-Opitz syndrome show many autistic features and abnormal cholesterol measures have been demonstrated in individuals with ASD who do not have SLOS.
Objectives:
We aimed to analyze whole exome sequence (WES) data in multiplex ASD families from the Autism Genetic Resource Exchange collection using linkage analysis methods designed to incorporate covariate measures to see if some families show stronger evidence of linkage to particular loci in the presence of these covariate measures.
Methods:
WES was performed in 69 families with 2-3 affected children from the AGRE collection. Quality filtering was performed in GoldenHelix SVS and Mendelian inconsistencies removed using Sibpair. Seven covariate measures were tested; total cholesterol, HDL cholesterol, ApoA1, ApoB, triglycerides and two categorical variables, hypercholesterolaemia and hypocholesterolaemia. Incorporating covariates into categorical trait linkage analysis is more challenging than quantitative traits, however some nonparametric methods exist. Here we use IBDReg, an approach that uses quasi-likelihood measures to test for which covariates might be influencing evidence for linkage at particular loci.
Results:
Significant evidence of linkage to ASD when including covariates was found on chromosome 1 (p=2.2×10^{-7}), chromosome 2 (p=7.2×10^{-6}) and chromosome 21 (p=6.1×10^{-6}) for hypercholesterolaemia as the covariate and chromosomes 1 (p=1.1×10^{-7}), 2 (p=1.6×10^{-6}), and 21 (p=5.1×10^{-6}) when hypocholesterolaemia were used as covariates. Several other regions with suggestive evidence of linkage of ASD were also observed for all covariates except ApoB, which had no signals even in the suggestive range.
Conclusions:
Including covariates which may be relevant to ASD may help with interpretating WES results, particularly in families with multiple affected children. Different covariates produced different evidence of linkage to ASD, depending on which covariate was included, which may assist in classifying families with different underlying ASD etiologies. Interpreting the results of these kinds of linkage analyses is challenging and simulations are currently underway to calculate empirical p values. However, all of our signals have previously been reported in AGRE families or other ASD cohorts. The signals on chromosome 1 and 2 are close to reported linkage peaks in the literature, in particular the signal on chromosome 2 is in the 2q21.2 region which is part of the 2q21-q33 region which has been repeatedly reported in linkage analyses of ASD families. The locus on chromosome 21 is close to a region previously reported in a subset of ASD families with language regression. These regions are

being examined in detail to attempt to identify the linked causal variants.

195 **125.195** Modulating RBFOX1 Expression in Human Stem Cell-Derived Glutamatergic Neurons

H. N. Cukier[1], B. A. DeRosa[1,2], K. C. Belle[1,2], Y. Park[1,2], A. J. Griswold[1], J. M. Lee[1], J. L. Haines[3], M. L. Cuccaro[1,2], J. R. Gilbert[1,2], D. M. Dykxhoorn[1,2] and M. A. Pericak-Vance[1,2], (1)John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, (2)Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL, (3)Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH

Background:
Autism spectrum disorders (ASDs) are a group of neurodevelopmental conditions that currently afflict about 1 in every 68 children. The hunt is ongoing for the highly heterogeneous genetic causes of ASD. Both our group and others have identified potentially pathogenic copy number variants (CNVs) and point mutations in ASD individuals in the *RNA binding protein, fox-1 homolog 1* (*RBFOX1*) gene (Griswold, et al, 2012). *RBFOX1* is a neural splicing cofactor that regulates alternative splicing. Due to the high level of ASD genetic heterogeneity, investigations of ASD loci using genome wide association studies (GWAS) have identified relatively few consistent signals of interest. However, when we conducted a combined analysis of over 20,000 individuals from four independent family-based GWAS datasets, one of our strongest signals was in *RBFOX1* (top SNP, rs74733079, discovery p=1.558 x 10^{-6}, meta p=2.635 x 10^{-5}). In addition to ASD, *RBFOX1*has been connected to bipolar disorder, epilepsy, and schizophrenia.
Objectives:
To better understand the impact of *RBFOX1* on ASD, we are evaluating how *RBFOX1* expression modulates neuronal function in iPSC-derived glutamatergic neuronal cells.
Methods:
Given the neurodevelopmental nature of ASD, iPSC provide a unique opportunity to understand potential pathogenic mechanisms that may be at work during early phases of development. To that end, we have examined the impact that changes in RBFOX1 expression have on neuronal functionality in the developing neuronal cultures. The viability and functionality of the glutamatergic neurons in which *RBFOX1* has either been overexpressed or silenced by RNA interference are assessed at multiple time points during *in vitro* neurogenesis. Overexpression experiments are performed with lentiviral transduction and genomic integration the wild type form of *RBFOX1* variant 4 driven under a CMV promoter, as well as an ASD-specific nonsense mutation at R173X that we identified in a sporadic ASD family. Each condition is compared at a gross morphological level to determine if modulating *RBFOX1* produces recognizable qualitative or quantitative phenotypes. Since *RBFOX1* plays a key role in splicing and transcription, RNA-seq analysis of the iPSC-derived neurons under three conditions (*RBFOX1* knockdown, overexpression and no treatment) will be used to complement the functional analysis to identify key networks regulated by *RBFOX1*.
Results:
Neuronal precursors cells (NPCs) from the control stem cell line were transduced with lentivirus on day 27 of the glutamatergic differentiation scheme. Cells overexpressing a RBFOX1-eGFP construct successfully glowed. RNA was extracted from all cells, purified, and reverse transcribed for quantification by qPCR. Following measurement of both *RBFOX1* and the internal control *GAPDH*, the shRNA was determined to be successful at ~40-45% knockdown of endogenous *RBFOX1* expression and the RBFOX1-eGFP vector was strongly (~35x) overexpressing the gene. The alteration of *RBFOX1* levels through the RNAi-mediated silencing of *RBFOX1* or the transgene overexpression showed alterations in transcriptional profiles, including differences in splice variant composition of the transcriptome. These changes are consistent with the known function of *RBFOX1*as a regulator of splicing.
Conclusions:
Initial results suggest that *RBFOX1* plays a central role in establishing key transcriptional networks in neural development.

196 **125.196** Mutation Characteristics in Families with Two or More Siblings with Autism Spectrum Disorder

S. W. Scherer, Hospital for Sick Children, University of Toronto, Toronto, ON, Canada

Background:
Autism spectrum disorder (ASD) is genetically heterogeneous, with >100 susceptibility genes known.
Objectives:
To examine the characteristics of all classes of genetic mutation (small sequence-level changes, structural variation, and copy number variation) in well-characterized ASD-multiplex families by analyzing both de novo and rare inherited mutations.
Methods:
We used whole-genome sequencing (WGS) of 85 quartet families (two parents and two ASD-affected siblings) to comprehensively examine the roles of all classes of mutation in familial ASD.
Results:
In 36/85 (42%) of families, at least one child with ASD had DNA alterations potentially relevant to the disorder. We detected de novo damaging missense and loss-of-function (LoF) single nucleotide and

structural mutations in ASD-risk genes in 13/85 (15%) of families. Fifteen additional families carried rare inherited LoF mutations in known ASD-susceptibility genes, and eight more families had de novo or inherited LoF variants in genes associated with autosomal dominant neurodevelopmental disorders. In only one of these families was the same damaging de novo mutation (1.8kb deletion in SCN2A) found in both ASD siblings, but in another 10 families, affected siblings shared inherited ASD-risk variants.

Conclusions:
Taken together, in 11/36 (31%) of families a de novo or rare inherited and presumed penetrant ASD-risk variant(s), identified in the index case, was also found in the sibling with ASD. These siblings tended to be more alike in their phenotypic features than those who did not share a risk variant. In the remaining   families with familial ASD, the siblings carried different mutations, emphasizing the need for WGS in confirmatory and predictive diagnosis.

197   **125.197** PTEN Mutation in Children with Autism and Macrocephaly: A Case Report of Two Previously Unrecognized Promoter Region Mutations

D. U. Menon, *Kennedy Krieger Institute, Baltimore, MD*

Background:
Autism is characterized by impairment in communication, social interaction, insistence on sameness and restricted repetitive actions & stereotyped movements. 20% of children with Autism Spectrum Disorders (ASD) have macrocephaly and 10% are associated with known genetic syndromes. Phosphatase and tensin analogue on chromosome 10q23.3 gene (PTEN), is a tumor suppressor gene which encodes a dual specificity Phosphatase ,that negatively regulates the PI3K/AKT pathway. PTEN germline mutations have been associated with macrocephaly, seizures, tumors and mental retardation with four hamartomous syndromes Recent work by Butler et al (2005) and Goffin et al (2001) have shown the association of PTEN germline mutation in patients with macrocephaly and ASD.
Objectives: Prevalence of PTEN mutation in a clinical population of ADOS proven cases of autism spectrum disorder (ASD) and relative and absolute macrocephaly (>2SD above mean HC for age and sex).
Mutation identification for these patients by DNA sequencing of the promoter and coding regions of the PTEN gene.
Phenotype-genotype correlation of subjects with ASD and PTEN mutation
Methods:
Study eligible participants in the Autism Clinic and the JHH Genetics clinics were enrolled after obtaining signed informed . Parents of eligible subjects completed intake questionnaires (SRS) ,the children were administered the Mullen Scales of Early Learning or the subtests of the Stanford Binet . Children over age 12 months of age were administered the Autism Diagnostic Observation Schedule (ADOS) .6 ml-10 ml of blood was drawn for this assessment in children with ASD who are above the age of 18 months and were sent to the DNA Diagnostic Center at JHH. Genomic DNA (gDNA) was isolated from the blood sample within 24 hours of. A portion of the gDNA was diluted and used for PCR amplification of the promoter region and coding exons of the PTEN gene and were then sequenced bi-directionally and compared to normal control reference sequence *in silico* to identify mutations
Medical records for subjects with positive PTEN mutation were reviewed for an initial correlation of potentially pathological mutations, and cognitive and behavioral phenotype that may be associated with the underlying mutation.
Results:
Five out of 25 subjects were found to have mutations in the promoter region of the PTEN gene , of which three were previously reported rare PTEN variants, and 2 had not been previously reported in the scientific literature.
Conclusions:
This is a case report of two new variants in the PTEN mutations in a subset of children with ASD and macrocephaly and indicates that PTEN mutation screening should be done in the initial diagnostic workup of children with macrocephaly and autism.

198   **125.198** Penetrance and Specificity of Significant Chromatin Pathway Sequence Risk Variants in Utah Extended ASD Pedigrees

ABSTRACT WITHDRAWN

Background: Progress has been made in identifying rare genetic risk variants for autism spectrum disorders (ASD) in collaborative case-control and/or parent-child trio studies. A recent Autism Sequence Consortium (ASC) study identified chromatin remodeling as one significant gene pathway for ASD risk. Functional variants in chromatin remodeling-related genes may lead to changes in brain cell development or migration.
Objectives: We studied Utah high-risk ASD families where specific variants reported by the ASC in chromatin remodeling genes occurred. We are characterizing additional likely damaging variants in this pathway not reported by the ASC but occurring in our family sample. Because our families have large sibships with multiple affected and unaffected individuals, we have the opportunity to observe

penetrance, specific associations with clinical phenotypes, and differences in environmental exposures.

Methods: Our analysis used 518 individuals from Utah families distinct from the ASC sample. These included 186 with ASD and 332 unaffected relatives genotyped with Illumina HumanExome chip, and 61 with ASD and 27 unaffected relatives with whole exome sequence data (Agilent SureSelect and Illumina GAIIx). We first searched for occurrence of specific likely-damaging chromatin pathway gene variants reported in the ASC study in our existing molecular data. We characterized additional variants in our families in all genes in this pathway implicated by the ASC using available sequence annotation (e.g., PolyPhen, Annovar), and validated variants found in exome sequencing using Sanger sequencing. For each variant, we report demographics and phenotype data (ASD severity, IQ, behavioral questionnaires, evidence of medical and/or psychiatric co-morbidities). Finally, we report differences in the occurrence of previously validated environmental risks (pregnancy risk factors) in affected individuals with variants vs. unaffected individuals with variants.

Results: Eight Utah families were found to segregate six rare, non-synonymous, likely damaging variants appearing in the ASC in five chromatin pathway genes. Twelve other chromatin pathway genes were not found to harbor variants seen in the ASC study; however, we are determining the presence of other novel, potentially damaging variants in these genes. Table 1 shows gene variants studied to date which include only those that appeared in the recent ASC study. Each of these variants occurs in unaffected relatives, indicating reduced penetrance. The variant in *ASH1L* only occurred in unaffected relatives, suggesting that it may have been a false positive in the ASC study. Across all variants studied to date, the ADI (affected relatives) and Social Responsiveness Scale (unaffected relatives) scores with and without each variant do not demonstrate a clear pattern of elevation in any subgroup.

Conclusions: Variants in highly significant risk genes from the ASC study studied to date show reduced penetrance in our family data through occurrence in unaffected relatives. Associations with clinical and subclinical variables are complex and differ by gene and gene variant. We are in the process of studying additional available environmental .exposure data (additional birth risk factors, infections in early life, air quality data) to determine if exposure differences could partially account for presence/absence of ASD in siblings with the same variant.

199 **125.199** Province of Ontario Neurodevelopmental Disorders Network: Integrated Discovery from Genes to Treatment

E. Anagnostou[1], J. P. Lerch[2], S. W. Scherer[3], P. Szatmari[4], R. Nicolson[5], R. Schachar[6], P. D. Arnold[7] and R. Weksberg[8], (1)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Medical Biophysics, University of Toronto, Toronto, ON, Canada, (3)Hospital for Sick Children, University of Toronto, Toronto, ON, Canada, (4)University of Toronto, Toronto, ON, Canada, (5)Psychiatry, Western University, London, ON, Canada, (6)Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (7)Psychiatry, Hospital for Sick Children, Toronto, ON, Canada, (8)Dept. of Paediatrics and the Institute of Medical Science, University of Toronto, Toronto, ON, Canada

Background:
Emerging data from human and animal studies have been producing several potential molecular targets, yet there still exists a large gap between the time at which a potential target is identified and the first phase III trial, due to either (1) a target that is not relevant to the disease or not amenable to pharmacological intervention or (2) difficulty in stratifying patients into those most likely to respond to the intervention and/or identifying appropriate clinical end-points or biomarkers. While autism is highly heritable, over 450 genes have been implicated, and no single gene accounts for more than 1% of cases. In areas of other biomarkers, such as imaging, there is also great variability in findings. The observed heterogeneity in ASD suggests that a single treatment is unlikely be effective for most individuals and that in addition to novel targets, we need biologically informed ways of predicting treatment response.

Objectives: To develop an integrated discovery system that will facilitate the translation of genomic and epigenomic findings into treatments by accelerating the discovery of new molecular targets and stratification strategies.

Methods:
With funding from the Ontario Brain Institute and several industry partners, we developed an ICH—GCP compliant clinical trials network dedicated to neurodevelopmental disorders, which we embedded in a multiplatform , multisite biomarker core. Children recruited contribute a genomic sample, extensive phenotypic behavioral and cognitive data, some specific to their diagnosis and some quantifying cognition and behavioral deficits irrespectively of diagnosis (e.g. empathic accuracy, inhibition, attention, social function) as well structural and functional imaging and electrophysiological data. Classification algorithms are used within heterogeneous data to allow for new clustering techniques, in an effort to identify biologically homogeneous subgroups. Children recruited in the clinical trials already have contributed all of the above to allow for prediction of treatment response. In addition, we develop biological models of neurodevelopmental disorders, including mouse models as well as induced pluripotent stem cell (iPS) lines derived from skin or blood of research participants, based on knowledge of mutations in patients. We use cutting-edge technologies, including induced pluripotent stem-cells, and high-throughput imaging and behavioural phenotyping in genetically altered mice to identify mechanisms of disease and the effectiveness of therapeutics.

Results:
At the time of submission, more than 1000 children ages 18 months to 18 years have been recruited and characterized across four sites. More than 45 mouse models of ASD related mutations have been characterized and imaged. This presentation will use empathic accuracy to demonstrate the translational paradigm from genomics and epigenomics to imaging and ultimately to treatment. The rest of the pNEL will highlight novel findings in genomics, epigenomics and imaging in children across the platforms, as well as, cross species data within the POND platforms.
Conclusions:
We present the rational, methods and feasibility of an integrated discovery system aimed at exploring the biological heterogeneity of ASD and related disorders, using cross species genomic, phenotypic and imaging data, with the ultimate goal of predicting treatment response. Early data demonstrates the effectiveness of this approach

200 **125.200** Quantification of FMRP in Human and Mouse Tissues By Capture Immunoassays

W. T. Brown[1], T. Adayev[2], C. Dobkin[3], R. J. Kascsak[4], R. Kascsak[4], S. Nolin[1] and G. LaFauci[2], (1)Institute for Basic Research in Developmental Disabilities, Staten Island, NY, (2)Developmental Biochemistry, Institute for Basic Research in Developmental Disabilities, Staten Island, NY, (3)Institute for Basic Research in Developmental DIsabilities, Staten Island, NY, (4)Monoclonal Antibody Facility, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY

Background: The Fragile X syndrome is due to mutations of the FMR1 gene that result in the absence of fragile X mental retardation protein (FMRP). About half of males with the fragile X syndrome have ASD. Fragile X is recognized as being one of the most common syndromic causes of ASD. Fragile X screening is recommended for autism evaluations.
Objectives: Current methods for quantitating the levels of FMRP are not very sensitive. Our objective was to improve the methods.
Methods: We have developed a rapid, highly sensitive method for quantifying FMRP from dried blood spots and lymphocytes. This assay uses two new antibodies mAb 6B8 (BioLegend) and R477, a bacterially expressed abbreviated FMRP standard, and a Luminex platform to quantify FMRP. The assay readily distinguishes between samples from males with fragile X full mutations and samples from normal males. It also differentiates mosaic from non-mosaic full-mutation male samples. Using mAb 5C2 (BioLegend) and R477 (an inhouse rabbit polyclonal to FMRP), we have also developed a similar immunoassay for the quantification of Fmrp in mouse tissues.
Results: We have employed the assay to screen 2000 newborn dried blood spots (DBS) and present their distribution. We found a high variable expression of FMRP that had an average level 7 folder higher than that of normal adults. We also applied the assay in a retrospective study of 76 newborn DBS that had been stored for an extended period and included full mutation males as well as normal individuals. We were able to correctly identify all 4 known male fragile X positive cases among samples stored up to 47 months. We have used the mouse tissue assay to quantify Fmrp in brainstem, cerebellum, hippocampus, and cortex strains of mouse (C57 BL and FVB) in seven weeks-old animals. The latter assay will allow studying the developmental variation of Fmrp expression in different organs.
Conclusions: Our new assay allows for sensitive and accurate quantitation of FMRP, in human and mouse blood and tissues. It is particularly sensitive for detecting and quantitating newborn blood spots on filter paper, as the drying of blood appears to inactivate proteases that reduce FMRP in stored whole blood samples.

201 **125.201** Recurrence Rates for Autism in Multiplex Families and Twins Demonstrate Sex Differences in Familial Genetic Liability

D. M. Werling[1] and D. H. Geschwind[2], (1)Psychiatry, UCSF, San Francisco, CA, (2)Department of Neurology, David Geffen School of Medicine, UCLA, Los Angeles, CA

Background: Autism spectrum disorders (ASDs) are more prevalent in males, suggesting a multiple threshold model for ASD liability. This model states that females in the population are protected by sex-differential mechanisms, and that a greater genetic burden is required for females to manifest an ASD phenotype than for males. Under this model, autistic females' siblings are also predicted to share this greater genetic liability, whereas the siblings of autistic males are predicted to share comparatively lesser genetic liability. However, ASD recurrence rates reported in the literature have not demonstrated a significantly increased risk to siblings of affected girls as compared with siblings of boys.
Objectives: Previous studies of recurrence risk utilized population cohorts or infant siblings of children with ASD, samples that include a combination of families with simplex and multiplex genetic architecture. Since sporadic cases from simplex families are enriched for *de novo* risk variants that are unlikely to be shared with siblings, including these families is likely to obscure recurrence patterns. The purpose of this study is therefore to utilize a strictly multiplex family sample from the Autism Genetic Resource Exchange (AGRE) to determine if recurrence risk in these families follows predictions from a female protective model.
Methods: We assess recurrence rates and associated quantitative traits in full siblings from 1,120 multiplex nuclear families and concordance rates in 305 twin pairs from AGRE. We compare recurrence rates and phenotypes between males and females overall, and between twin pairs or

families with at least one affected female (female-containing, FC), versus those with only affected males (male-only, MO).

Results: We observe a significantly higher recurrence rate in males than females, siblings of female than male probands, and higher concordance in FC than MO twin pairs. Recurrence rates approach 50%, consistent with a dominant inheritance pattern in high-risk families as has been proposed. We also find a significant negative relationship between interbirth interval and ASD recurrence that is driven by male children in MO families.

Conclusions: By classifying families as MO or FC *post hoc*, using full pedigree information, we observe significant recurrence rate differences between families harboring sex-differential familial liability. However, recurrence rates near 50% for females from FC families and for males overall suggest that simply conceptualizing females' genetic risk as quantitatively greater than males' may be insufficient. Consideration of the robustness of female protective factors and/or the sex-differential penetrance of specific risk variants is necessary. Furthermore, the male-specific relationship between shorter interbirth intervals and increased ASD risk speaks to the higher genetic risk load in females and potentially more frequent contributions from environmental, including maternal, risk factors in males. Understanding the mechanisms driving these sex-differential risk profiles will be useful for treatment development and prevention.

202   **125.202** Scalable Sequencing Pipeline on Cloud

J. Y. Jung[1,2], *A. Lancaster*[1,2], *Y. Souilmi*[1], *P. J. Tonellato*[1] and *D. Wall*[2], (1)Center for Biomedical Informatics, Harvard Medical School, Boston, MA, (2)Stanford University, Palo Alto, CA

Background: While sequencing methods have been approved as clinical diagonosis tools, computation time and cost are still substantial barriers preventing the use of next generation sequencing (NGS) in a clinical setting. For this technology to be adopted by clinicians, the turnaround time of genomic data analysis must be within hours and the cost of rendering to clinically actionable information should be reduced to the level of typical lab test costs.

Objectives: Here we introduce our cloud-based NGS analysis pipeline and benchmark results of all public whole exome and genome data from autism studies.

Methods: We built a generic workflow management system running on clouds, then implemented Genome analysis toolkit (GATK) workflow as our NGS pipeline. We tested this system on Amazon Web Service (AWS) platform with all autism whole exome and whole genome data sets available to us, in order to examine scalaiblity and cost-effectiveness of our pipeline.

Results: Test results showed that the pipeline works in a scalable manner up to hundred exomes or genomes which is a typical batch size in sequencing. We will also discuss our findings on autism specific data in joint variant calling and characteristics of rare / de novo / knockout variants.

Conclusions: N/A

203   **125.203** Sleep Problem Profiles of Individuals with ASD-Associated Mutations

R. K. Earl[1], *C. M. Hudac*[1], *T. Ward*[2], *J. Gerdts*[1], *E. E. Eichler*[3] and *R. Bernier*[1], (1)University of Washington, Seattle, WA, (2)Clinical Psychology, Seattle Pacific University, Seattle, WA, (3)Howard Hughes Medical Institute, Seattle, WA

Background:

Classifying ASD phenotypes by recurrent gene disrupting mutations has promise as an effective means of identifying potential subtypes of the disorder (Bernier et al, 2014). Sleep difficulties, such as difficulty falling asleep, frequent waking, and restless sleep, are frequently reported comorbidities in ASD (Liu et al, 2006; Matsuoka et al, 2014; Williams, Sears, & Allard, 2004). Recent studies report profound sleep problems in children with ASD-associated gene disruptions, *CHD8* and *ADNP* (Bernier et al, 2014; Helsmoortel et al, 2014; Vandeweyer et al, 2014). Further exploration of sleep problems in individuals with disruptive, ASD-associated gene mutations can inform common etiological contributions to ASD and sleep by expanding symptom profiles associated with gene disruptions. Clarifying specific kinds of sleep issues accompanying ASD can better inform support of daytime behavior and functioning for children and their families.

Objectives:

To provide an assay of sleep problems in individuals with *ADNP*, *CHD8*, *DYRK1A*, and *TBR1* loss-of-function mutations.

Methods:

Participants were 14 children from the Simons Simplex Collection (SSC) sample who met strict criteria for ASD and had an ASD-associated loss-of-function gene event. Due to recurrence in the literature, the following gene events were chosen for analysis out of a larger sample of 265 children (54 female) with identified loss-of-function mutations in the SSC: *CHD8* (n=8 (2 female)), *ADNP* (n=2 (1 female)), *DYRK1A* (n=2 (1 female)), and *TBR1* (n=2 (1 female)). Incidences of various sleep problems were measured by parent report on a clinician-administered medical history questionnaire. Sleep-specific items were clustered into summary variables: bedtime problems, daytime sleepiness, night-time awakenings, and sleep-disordered breathing (see Table 1 for category items). For preliminary analysis, sleep summary variables were analyzed with a multivariate general linear model in relation to gene disruption type, controlling for IQ and comorbid behavior problems.

Results:

See Table 1 for incidence of sleep problems for each gene mutation group in the present sample. Preliminary analysis indicated that *ADNP*, *CHD8*, *DYRK1A*, and *TBR1* groups differ significantly from each other in parent-reported night-time awakenings ($F_{(1,2)} = 21.05$, $p = 0.046$). Half of each gene group endorsed frequent or prolonged awakenings at night, while the *CHD8* group shows additional awakening problems in the form of sleepwalking and frequent nightmares (See Table 1, Figure 1). The incidence of night-time awakenings appears to be a significant sleep issue for individuals with one of these selected mutations (>50% endorsed) compared to the whole loss-of-function sample (<40% endorsed, see Figure 1). As additional subjects are being evaluated, continued analyses will tease apart group differences.
Conclusions:
Deeper inspection of sleep problems in individuals with noted ASD-associated mutations to *ADNP*, *CHD8*, *DYRK1A*, and *TBR1*, while preliminary, suggests that endorsement of night-time awakenings is exacerbated in individuals with particular ASD-associated mutations. This suggests a potentially disruptive impact of these loss-of-function mutations on biological mechanisms responsible for sleep maintenance. Findings highlight night-time awakenings in this population as an area needing further study.

204 **125.204** Social Communication Skills and Impairments in Children with Dup15q Syndrome: Is There a Distinctive Phenotype That May Inform Intervention Targets?

S. S. Jeste[1], A. Gulsrud[1] and C. Kasari[2], (1)UCLA, Los Angeles, CA, (2)UCLA Center for Autism Research & Treatment, Westwood, CA

Background: Duplications on chromosome 15q11.2-13 are highly associated with autism spectrum disorder (ASD), intellectual disability (ID), and epilepsy. Most studies to date have focused on diagnostic categorization of this cohort rather than performing a deeper characterization of the social communication, cognitive, and language profiles of this high-risk cohort.
Objectives: To determine whether there are distinctive features of the social- communication deficits found in children with Dup15q mutations and, if so, whether these characteristics could guide more targeted interventions for this genetically-based subgroup within the autism spectrum. Our study is driven by the hypothesis that there will be a distinctive developmental phenotype in children with Dup15q syndrome that will vary in severity across mutation size and location, and that this phenotype will be defined by expressive language and motor impairment with relatively preserved non-verbal social abilities. Interventions that capitalize on these strengths may ultimately facilitate gains in social communication function in these children.
Methods: In this ongoing study, children ages 18 months to 10 years with Dup15q syndrome are recruited from the Dup15q Alliance registry as well as the national Dup15q clinics, and they undergo a comprehensive, developmentally informed clinical phenotyping battery. We compare cognition, expressive and receptive language, social communication, play, and motor ability in this cohort (both intersitial and isodicentric cases) to that of an age matched cohort of children with non-syndromic ASD drawn from several existing studies in our UCLA Center for Autism Research and Treatment (CART). Measures include: Autism Diagnostic Observation Schedule (ADOS), Mullen Scales of Early Learning and/or Stanford- Binet Intelligence Scales, Early Social Communication Scale (ESCS), the Vineland Adaptive Behavior Scales, and the Structured Play Assessment (SPA).
Results: 14 children with Dup15q syndrome have been recruited for the study. Age range is 22 to 94 months, 6 males . All have isodicentric 15q [idic(15)], all have global developmental delay and/or intellectual disability. 8 children had developmental levels appropriate for ADOS testing and all of these children (8/8) met criteria for ASD on the ADOS, 1/8 with mild-moderate severity and 7/8 with moderate-high severity. Common, consistent characteristics that distinguished this group from those with non-syndrome ASD included: Expressive language delays greater than receptive language delays, verbal IQ lower than nonverbal IQ, significant gross motor delays (>2 standard deviations from normal), consistent lack of eye contact and *inability to initiate* joint attention on the ADOS and ESCS, and consistent *evidence of response* to joint attention on the ADOS and ESCS.
Conclusions: A distinctive social communication profile is emerging in children with Dup15q syndrome, with impairments in motor function, visual attention, and initiation of engagement that may prevent the development of appropriate language and social communication behaviors. Targets for intervention include expressive language, initiation of joint attention, and overall attention to social cues in the environment.

205 **125.205** Social-Communication and Restricted and Repetitive Behavior (RRB) Profiles in Children with Phelan-Mcdermid Syndrome Compared to Non-Syndromic Autism Spectrum Disorder (ASD)

L. V. Soorya[1], C. Farmer[2], L. Bush[3], S. Youngkin[1], A. Kolevzon[4] and A. Thurm[5], (1)Psychiatry, Rush University Medical Center, Chicago, IL, (2)NIH, Bethesda, MD, (3)Roxelyn and Richard Pepper Department of Communication Sciences and Disorders, Northwestern University, Evanston, IL, (4)Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY, (5)Pediatrics & Developmental Neuroscience, National Institute of Mental Health, Bethesda, MD

Background: Phelan-McDermid syndrome (PMS) is a genetic syndrome caused by mostly de novo chromosomal abnormalities in the terminal end of 22q that includes the *SHANK3* gene. Loss of *SHANK3*, either through deletion or mutation, results in a phenotype characterized by significant

intellectual disability, severe speech delay, hypotonia, minor dysmorphic features, and autistic-like behaviors. PMS is described as a common genetic form of ASD, accounting for up to 1% of ASD cases, with features including poor eye contact, self-stimulation, and repetitive mannerisms. However, the specificity, type, and degree of ASD symptoms in PMS remain unclear.

Objectives: The purpose of this investigation is to examine overlap and differences in ASD phenotype between PMS and non-syndromic ASD and to inform measurement targets for intervention research in PMS and ASD.

Methods: We analyzed ASD symptom profiles in a prospectively recruited sample of (n=24) of children with PMS (age 1.7 to 8.4 years) and a convenience sample of non-syndromic children with ASD, intellectual disability (ID), and language delay (n=38, age 2.1-8.2 years). The comparison group was a subsample of a larger community-based study of autism, selected on chronological age and developmental quotient scores <45. Measures included the ADOSG/ADOS2, ADI-R, and developmental/behavioral assessments. Non-parametric tests (Mann-Whitney U) were conducted on demographic and domain scores on the ADOS and ADI-R.

Results: Mean ADOS2 and ADI-R domain scores were in the ASD range for the PMS sample. Children with PMS did not differ on mean social-communication (or social affect) domain scores on the ADOS2 or ADI-R. However, subdomain analyses showed more severe communication impairments in PMS relative to non-syndromic ASD (ADOSG, communication domain). Peer relationships were less impaired in PMS relative to non-syndromic ASD (ADI-R, A2). The RRB domain also differed significantly between groups with lower scores in PMS relative to non-syndromic ASD on the ADOS2. Domain analysis of ADI-R scores indicate the PMS group had significantly fewer lower-order repetitive behaviors (ADI-R, C3 & C4) and higher scores on encompassing preoccupations/circumscribed interests (ADI-R, C1).

Conclusions: Results from our study are the first to characterize ASD features in PMS relative to non-syndromic ASD. Findings are consistent with a growing body of literature indicating the overlap between ASD and the clinical features of PMS. Our findings suggest potential for a distinct RRB profile in PMS relative to non-syndromic ASD with ID. Investigations of neurobehavioral profiles in PMS are needed to understand the unique behavioral phenotype associated with *SHANK3* deficiency.

206   **125.206** Strategies for Detecting Increased ASD Risk in Male and Female Probands

S. J. Sanders, *UCSF, San Francisco, CA*

Background: An excess of male cases has consistently been observed in autism spectrum disorder (ASD), however no clear mechanism for this sex bias has been demonstrated. The possibility of a female protective effect (FPE) has received considerable attention, especially given the excess of *de novo* CNVs in females with ASD in several cohorts. Under this FPE model we would expect an excess of ASD risk in females (as is observed for *de novo* mutations) and an increased ASD recurrence rate in the siblings of females with ASD, compared to the siblings of males with ASD (often called the Carter Effect). However, despite several studies with large sample sizes the Carter Effect has not been observed for ASD diagnosis. The evidence for the FPE mediating ASD sex bias is therefore contradictory.

Objectives: To assess the likelihood of observing increased ASD risk in females under an FPE model directly (*de novo* mutation) and indirectly (Carter Effect).

Methods: A family-based simulation was used to estimate the power to detect the FPE directly (proband *de novo* mutation rate) and indirectly (sibling ASD recurrence rate). To perform this calculation estimates of the ASD risk architecture were required. Two models were used: 1) ASD is caused entirely by inherited genetic risk (the ideal scenario for observing the Carter Effect); and 2) 50% of ASD risk is from common variation, 3% from de novo and 47% from unique environmental effects (estimates based on Gaugler et al, *Nature Genetics*, 2014).

Results: Under the first model (100% inherited risk), approximately 3,000 probands were required to detect the Carter Effect with 80% power. To date, only one analysis of ASD recurrence rate has exceeded this threshold (Grønberg, JAMA Pediatrics, 2013). However, under the second model (50% inherited risk, 3% de novo) this power was reduced considerably. Even with a samples size of 10,000 the probability of detecting the Carter Effect was less than 20%. Under this second model the probability of detecting a significant difference in the burden of *de novo* mutation between affected females and males was 80% with only 500 probands.

Conclusions: The sample size required to reliably detect the Carter Effect is at least an order of magnitude greater than the largest study of ASD recurrence rate performed to date. In contrast, the direct observation of a higher burden of known ASD risk factors (such as *de novo* mutation) can be observed with the sample sizes currently available for analysis. Therefore, a model of ASD sex bias being predominantly a consequence of a female protective effect fits the available data well.

207   **125.207** Systems Biology Approaches to Determine Genetic Risk Factors for Autism Spectrum Disorders

A. Yousaf[1], R. Waltes[1], D. Haslinger[1], S. M. Klauck[2], M. Sachse[1], A. Voran[3], M. Schaefer[4], M. Schulte-Rüther[5], S. Chichon[6], M. Noethen[6], J. Ackermann[7], I. Koch[7], C. M. Freitag[1] and A. G. Chiocchetti[1], (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe University, Frankfurt a. M., Germany, (2)Cancer Genome Research Group, German Cancer Research Center (DKFZ), Heidelberg, Germany, (3)Department of Child and Adolescent Psychiatry, Saarland

University, Homburg, Germany, (4)Department of Child and Adolescent Psychiatry, Psychotherapy, and Psychosomatics, University Medical Center Freiburg, University Medical Centre Freiburg, Freiburg, Germany, (5)University Hospital Aachen (UKA), Aachen, Germany, (6)Institute of Human Genetics, University of Bonn, Germany., Bonn, Germany, (7)Molecular Bioinformatics, Institute of Computer Science, Goethe-University Frankfurt am Main, Frankfurt, Germany

Background: Autism spectrum disorder (ASD), a complex neurodevelopmental syndrome, presents with an extreme degree of clinical and genetic heterogeneity. Common variants have been shown to explain up to 50% of ASD liability whereas rare genetic causes can be identified in 10% of ASD cases. The analysis of the genetic architecture of the variable ASD phenotype is mandatory in understanding the complex basis of this disease. Several single gene studies have been reported shaping the ASD phenotype. However, no study so far has considered the network context of underlying genes to understand phenotypic variability.

Objectives: Using systems biology approaches, we aimed at identifying genetic patterns and networks that shape the autism phenotype as defined through the Autism Diagnostic Instrument Revised (ADI-R). Our approach includes identification of underlying genes influenced by associated common and rare variants integrating available knowledge on eQTL, gene-expression during brain development, regulatory sequence patterns as well as protein-protein network information. Finally, we model the phenotypic presentation using the network state of an individual patient.

Methods: Regression modeling predicting ADI-R derived factors was performed using the Autism Genome Project (AGP) data set with whole genome single nucleotide polymorphism (SNP) data. Modeling was further supported by machine learning approaches. Underlying network model construction was based on brain expression data (Kang et al 2011), eQTL and mQTL data (GeneVar, Gibbs et al 2010) and protein-protein interaction database (STRING, GeneMania). Models were validated and further refined by integrating information on functional rare variants in an independent German ASD data set with whole genome SNP data, CNV and exome sequencing data (Autism Sequencing Consortium). Both dataset are matched for gender and ethnicity, and all models were controlled for ethnicity.

Results: Here we show preliminary results: We reproduced previously published ADI-R factor analysis (Liu et al 2011) in both the AGP and the German dataset supporting a six factor (Eigenphenotypes) solution corresponding to Joint attention, Social interaction and communication, Non-verbal communication, Repetitive sensory-motor behavior, Peer interaction as well as Compulsion/Restricted interests. A total of 730525 SNPs were included in regression modeling predicting the extracted six factors. In addition, 6 components controlling for ethnicity based on the genetic background were included. Results of Eigenphenotype modeling and subsequent network analysis are presented.

Conclusions: As ASD is a complex neuropsychiatric disorder with a varying genetic heterogeneity, our research will aid in discovering the association of SNPs with disease phenotype. This project will contribute to a deeper insight into ASD pathomechanisms and potentially provide predictive models for clinical setups.

208 **125.208** Systems Biology of Late-Onset Severe Regressive Autism
A. R. Gupta, *Yale University School of Medicine, New Haven, CT*

Background: Regression is commonly described in ASD. However, the causes of regressive ASD in the vast majority of cases are unclear. Furthermore, there is debate regarding the precise definition of regression and whether it is a distinct phenomenon within ASD.

Objectives: To pursue an intense, multimodal investigation of a rare, severe example of this phenomenon, ASD with late-onset severe Regression (ASDR). Examining an extreme cohort will maximize our ability to identify neurobiological features relevant to regression.

Methods: In addition to meeting criteria for ASD, ASDR subjects met the following criteria: (1) loss of language skills, (2) loss in at least one other domain: social skills or adaptive behavior, bowel or bladder control, play, and motor skills, (3) loss must have occurred after 24 months of age, (4) must not have regained level of skill prior to loss, and (5) full-scale IQ<70. To investigate the genetic contribution to regression, we performed whole-exome sequencing and CNV analyses on 15 ASDR probands and their unaffected siblings and parents to search for novel or rare *de novo*, recessive, and hemizygous mutations. To study neural systems, we performed fMRI analyses involving a block design of alternating fearful face versus house images in 4 cohorts: 7 ASDR, 7 low-functioning ASD (LFASD), 14 high-functioning ASD (HFASD), and 19 typically-developing (TD) subjects. To quantify the social phenotype, we collected eye-tracking data as our 4 cohorts viewed emotional faces: 5 ASDR, 7 LFASD, 40 HFASD, and 11 TD.

Results: Genetic analysis identified one or more novel or rare mutations in almost all of the probands and a diverse list of candidate genes. Coexpression network analysis showed that a significant number of these genes converge in the cerebellum and thalamus during mid-late fetal development (P=0.009, permutation testing). fMRI revealed abnormal hyperactivity in these brain regions compared to LFASD, HFASD, and TD subjects. Eye-tracking results replicated prior findings of decreased fixation on the eyes and increased fixation on the mouth in HFASD relative to TD. However, the amount of time subjects with LFASD and ASDR spend looking at the eyes is not significantly different from TD. Among individuals on the autism spectrum, those with ASDR fixated on eyes the most.

Conclusions: The combination of genetic findings and coexpression network analysis predicted a

distinct neuroimaging signature in ASDR subjects: enhanced, face-evoked activity in the cerebellum and thalamus. The cerebellum is involved in the use of visual social cues for making mental inferences. Given the role of the thalamus in modulating cortical neural rhythms, abnormal hyperactivity may explain why individuals with ASDR generally have high levels of encephalographic abnormalities, anxiety, and stereotyped patterns of behavior. The initial normal development of children with ASDR suggests that the early development of the social brain may follow a typical trajectory, raising the possibility that some aspects of social function will be preserved, as reflected by our eye-tracking results. Although ASDR and other forms of ASD are, eventually, clinically similar, the natural history of ASDR marks a unique set of genetic, neural, and behavioral mechanisms.

209 **125.209** Targeted Behavioral Intervention for Children with Dup15q Syndrome Focuses on Language and Joint Attention

C. DiStefano[1] and C. Kasari[2], (1)Center for Autism Research and Treatment, University of California, Los Angeles, Los Angeles, CA, (2)UCLA Center for Autism Research & Treatment, Westwood, CA

Background: Duplication of 15q11.2-q13.1, or Dup15q Syndrome, is one of the most common copy number variations (CNV's) associated with autism spectrum disorders (ASD). The Dup15q phenotype is characterized by social communication deficits, intellectual disability, impaired speech, hypotonia, motor delays, and epilepsy (Battaglia, Parrini & Tancredi, 2010). Many children with Dup15q syndrome are minimally verbal. To date, there has been no research on targeted behavioral interventions for this population. An ideal intervention for the specific deficits found in Dup15q syndrome is JASPER (Joint Attention, Symbolic Play, Engagement and Regulation). JASPER is a play-based intervention focused on joint engagement in play routines with the therapists as a platform for developing play and communication skills (Kasari et al., 2006). JASPER has been used successfully to increase communication in minimally verbal children with ASD (Kasari et al., 2008; 2014).
Objectives: To evaluate the feasibility and effectiveness of JASPER in a pilot sample of children with Dup15q syndrome.
Methods: Three children participated in this pilot study (2 female). Two participants were non-verbal (ages 3:2 and 5) and the third used phrases (age 7:11 years). Assessments included the Autism Diagnostic Observation Schedule 2 (ADOS-2), the Early Social Communication Scales (ESCS) to measure joint attention and requesting, the Mullen Scales of Early Learning/Stanford-Binet Intelligence Scales, and the Vineland Adaptive Behavior Scales. Participants received between 10 and 16 JASPER intervention sessions. Sessions were 30 minutes in length and occurred twice per week. The first and last sessions were coded for the time the child spent engaged in joint activities.
Results: All three participants met diagnostic criteria for ASD, based on ADOS-2 scores, and all scored in the very impaired range on cognitive assessments. The ESCS was administered to the two non-verbal participants. Both participants demonstrated low rates of joint attention skills. Notably, both participants showed more responses to joint attention during the book task, compared to pictures on the wall, likely secondary to the fact that shifting gaze to the book required less motor control and visual attention. All participants showed large increases in the amount of time spent engaged from first to last session (Participant 1: 22% engagement in reciprocal activities to 45% engagement in reciprocal activities; Participant 2: 21% to 50%; Participant 3: 33% to 100%).
Conclusions: This is the first intervention study in Dup15q syndrome. JASPER is not only feasible but beneficial for children with 15q11.2-13.1 duplications, as it targets the core deficits that characterize the syndrome. Specifically, children demonstrated inflated ADOS scores, indicative of autism characteristics, intellectual disability, low rates of joint attention skills and impaired language. Given these characteristics, an intervention that focuses on supporting joint attention and language through an engaging, developmentally appropriate play interaction is warranted. Initial results indicate that the JASPER sessions were successful in terms of increasing the amount of time that participants were able to engage in reciprocal activities. These data support the need for larger scale research to evaluate the effects of a targeted behavioral intervention in children with Dup15q syndrome.

210 **125.210** The Language Phenotype of the 16p11.2 Deletion and Duplication in Children with and without Autism Spectrum Disorders (ASD): The Svip Study

S. H. Kim[1], C. Lord[2], L. Green-Snyder[3], R. Bernier[4], W. Chung[5], E. Hanson[6] and R. P. Goin-Kochel[7], (1)40 Temple St., Suite 7D, Yale University School of Medicine, New Haven, CT, (2)Weill Cornell Medical College, White Plains, NY, (3)Boston Children's Hospital, Boston, MA, (4)University of Washington, Seattle, WA, (5)Pediatrics and Medicine, Columbia University Medical Center, New York, NY, (6)Developmental Medicine, Boston Children's Hospital, Boston, MA, (7)Autism Center, Texas Children's Hospital, Houston, TX

Background: Studies have shown that a significant number of individuals with the BP4-BP5 16p11.2 copy number variant (CNV), deletion or duplication, are more likely to show cognitive and language impairments (e.g., Hanson et al., 2014) and higher prevalence of Autism Spectrum Disorders (ASD). However, our understanding on the language phenotype of 16p11.2 CNV in children with/without ASD is still limited.
Objectives: To examine the patterns of language phenotype of 16p11.2 CNV with and without ASD based on clinician observations of spontaneous expressive language (Observation of Spontaneous

Expressive Language [OSEL]; Kim, Junker, & Lord, 2014) and parent reports (Children's Communication Checklist-2 [CCC-2], Bishop, 2003).

Methods: General Linear Model (GLM) was performed to examine the effects of 16p11.2 CNV and diagnosis (ASD/non-ASD) while controlling for gender, verbal IQ (VIQ), and chronological age in predicting OSEL syntax and OSEL pragmatic-semantic-profile (PSP) totals as well as CCC-2 scaled scores. The OSEL syntax totals are computed by combining grammatical usages of 24 items including different types of *pronouns* [e.g., *subjective/objective/possessive*], *verb tenses* [e.g., *regular/irregular past, progressive*], *sentence forms* [e.g., *coordination/subordination*]. The OSEL PSP totals include three domains. The first domain represents skills associated with *Initiation of Reciprocal Communication*, which includes items such as *Verbal request* and *Asks for information about others' experiences.* The second domain, *Narrative Skills*, includes items such as *Reporting main ideas* and *Reporting sequence of events*. The third domain, *Unusual Features*, includes items such as *Dominates conversations* and *Stereotyped/idiosyncratic language*. The CCC-2 results in scaled scores for 10 domains targeting grammar (*Syntax*), phonology (*Speech*), and semantic (*Semantics*) and pragmatic skills (*Initiation, Nonverbal Communication*) as well as a *Social interaction Difference Index* (SIDI) created to measure communication impairments in ASD.

Results: The GLM revealed a significant effect of 16p11.2 CNV for OSEL syntax totals and several domains on the CCC-2. Children with 16p11.2 deletion demonstrated significantly lower OSEL syntax and CCC-2 *Syntax* scale scores compared to children with 16p11.2 duplication (p's<0.05). Children with the deletion also scored significantly lower on CCC-2 *Speech* (phonology) scale. On the contrary, children with the duplication showed more impairments on CCC-2 *Semantics* and *Initiation* scales (p's<0.05) and on the SIDI. Similar trends emerged for the OSEL PSP totals with children with the duplication scoring lower, but the effect did not reach statistical significance. A significant effect of ASD diagnosis emerged for the OSEL syntax and PSP domain totals as well as CCC-2 SIDI while controlling for the CNV. Children with ASD showed significantly lower OSEL syntax totals and higher scores (meaning more impairments) on the PSP *Narrative Skills* as well as more impairments in SIDI compared to the non-ASD group (p's<0.05).

Conclusions: Both clinician observations and parent reports show children with 16p11.2 deletion demonstrate more limited syntactic and phonological skills compared to those with the duplication even while controlling for the presence of ASD; whereas children with the duplication show more impairments in pragmatic-semantic skills compared to the deletion group. Not surprisingly, children with ASD showed more impairments in syntactic and narrative skills while controlling for the CNV.

211   **125.211** Tissue-Specific Expression Quantitative Trait Loci (eQTL) in GI Symptomatic ASD Children

S. J. Walker[1,2,3], *A. Krigsman*[4] *and C. D. Langefeld*[1,2], *(1)Wake Forest Health Sciences, Winston Salem, NC, (2)Center for Public Health Genomics and Department of Biostatistical Sciences, Winston Salem, NC, (3)Wake Forest Institute for Regenerative Medicine, Winston Salem, NC, (4)Pediatric Gastroenterology Resources of New York and Texas, Far Rockaway, NY*

Background: Previously, we characterized, via whole transcriptome analysis of ileocolonic biopsy tissue, an IBD-like condition that occurs with high frequency in autism spectrum disorder (ASD) children. Using gene expression data from that study, together with a second dataset derived from SNP analysis of DNA from the same individuals, we are exploring expression quantitative trait loci (eQTL).

Objectives: The immediate goal of this study is to search for statistical associations between gene expression data and genetic polymorphisms in a population (ASD) and tissues (colon and terminal ileum) previously uncharacterized by eQTL studies. The longer-term goal is to determine if there are specific eQTLs that track with individual IBD subtypes.

Methods: Gene expression data (generated from Agilent whole genome microarrays) and SNP data (generated at 23&me on custom Illumina SNP chips) from 64 individuals were used for the eQTL analyses. Standard quality control was completed for association studies (e.g., SNP call rate, Hardy-Weinberg Equilibrium). Analyses were computed separately for colon and terminal illium samples and by ASD[IC] (ASD with ileocolitis). For each transcript and tissue type, we computed a genome-wide association analysis using linear regression on single nucleotide polymorphism (SNP) *cis* (within 500kb) to the probe's gene. In this eQTL analysis, we regressed the SNP's genotype and the first principal components onto $\log_2$expression for the transcript. Given the modest sample size, only the dominant genetic model was computed. A fixed effect meta-analysis and the corresponding test for heterogeneity of effects were computed across disease groups. Significance of an eQTL effect was measured as the magnitude of the p-value conditional on an expression fold change of at least 1.5.

Results: The number of children analyzed varies by tissue. There were 18 ASD[IC] with colon samples and 22 ASD[IC] terminal ileum samples. Within the colon, 27 SNP-transcript combinations met the p<1x10E-6 and fold change >1.5. These 27 SNP-transcript combinations reside in 13 regions. Within the terminal ileum, 24 SNP-transcript combinations, residing in 13 regions, met the same threshold criteria. At this level of significance, one gene was observed in both tissues: Williams Beuren syndrome chromosome region 27 on chr 7q11.23. Deletion of genes in this region is known to cause the neurodevelopmental disorder Williams Beuren Syndrome and was recently implicated with ASD in a linkage study (Nijmeijer 2014). Additional genes at the given eQTL significance threshold, such as RYR2 (colon: rs10802598 $p=2.25 \times 10^{-8}$) and EPHB1 (colon: rs10512944 $p=1.88 \times 10^{-12}$) have been previously related to ASD and/or ASD-phenotypes through other studies and approaches.

Conclusions: This is the first eQTL analysis of colonic and terminal ileum tissues within an ASD population, providing a novel dataset. The benefits of such an eQTL analysis are two-fold: 1) potential elucidation of ASD SNP associations, by relating SNPs to gene expression and, 2) identification of polymorphisms that tag colonic and/or terminal ileum gene expression. Additional analyses are underway to identify eQTLs in IBD (non-ASD) samples. A subsequent comparison across all groups will potentially identify eQTLs associated with specific tissue and that may have contrasting expression levels between disease and non-disease groups.

212　**125.212** Use of Blood Transcriptomes to Characterize ASD Phenotypes

B. Stamova[1], Y. Tian[1], C. W. Nordahl[2], M. D. Shen[2], S. J. Rogers[2], D. G. Amaral[2] and F. R. Sharp[1], (1)MIND Institute and Department of Neurology, University of California Davis Medical Center, Sacramento, CA, (2)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis Medical Center, Sacramento, CA

Background: RNA expression differences have been reported in autism spectrum disorders (ASD) for blood and brain. Significantly for the present study, a recent investigation of ASD brain found that some genes displayed differential alternative splicing (DAS) of targets of the splicing factor A2BP1. This data and the fact that DAS is implicated in a number of neuropsychiatric disorders led us to consider to following aims.
Objectives:

- To determine if there is DAS in blood mRNA in: a) ASD subjects compared to typically developing (TD) controls; and b) ASD subgroups related to total cerebral volume (TCV), since abnormal brain enlargement is one of the most consistent findings in the neuropathology of a subset of ASD.
- To develop a method, which addresses ASD heterogeneity at transcriptome level and can identify subgroups of ASD with common affected pathways. This can be instrumental in identifying candidates for specific pharmacological treatments, and in associating these pathways with specific clinical or molecular phenotypes.

Methods: RNA from blood was processed on whole genome exon arrays for 2-4 year old ASD and TD boys. Mixed Effects Regression Models were used to predict DAS for all ASD (n=30), ASD with normal TCV, and ASD with large TCV compared to TD controls (n=20) (FDR p<0.05).
Results: A specific DAS signature was observed for All ASD, and distinct DAS was observed for the TCV-based ASD subgroups. A number of genes predicted to have DAS in ASD are known to regulate DAS (SFPQ, SRPK1, SRSF11, SRSF2IP, FUS, LSM14A). In addition, a number of genes with predicted DAS were involved in pathways implicated in previous ASD studies, such as Natural Killer Cell, mTOR, and NGF signaling. However, this was the first study to suggest DAS occurred in these pathways. To address ASD heterogeneity and identify convergent pathways in ASD subgroups, we performed sub-analysis at the level of each individual ASD subject. A variety of different combinations of pathways appeared to be associated with idiopathic ASD. This would be consistent with many genetic and/or environmental causes of ASD which are also associated with many different pathways. However, it also showed convergence on similar biological processes at least for subgroups of ASD subjects. Notably, 60% of ASD subjects in this study had DAS abnormalities of mTOR signaling, of significance since single-gene disorders often associated with ASD clinical features also had aberrant mTOR signaling including Fragile X, tuberous sclerosis, PTEN, and neurofibromatosis. Thus these data point to possible abnormalities of mTOR pathways in a subgroup of 'idiopathic' ASD which may have clinical relevance since mTOR inhibitors, like rapamycin can modulate these pathways.
Conclusions: This study suggests DAS occurs in blood of 2-4-year old boys with ASD compared to TD controls. ASD subgroups based on TCV exhibited distinct DAS, suggesting they may have different biological underpinnings. It is likely that many of these changes reflect differences in the ASD peripheral immune system and may be associated with the immune and autoimmune dysregulation observed in some ASD subjects.

213　**125.213** Use of a Quantitative Autism Score (QAS) Reveals Genetic Associations

E. R. Martin[1,2], N. D. Dueker[1], A. J. Griswold[1], H. N. Cukier[1], D. Van Booven[1], J. M. Lee[1], P. L. Whitehead[1], J. R. Gilbert[1,2], J. L. Haines[3], J. P. Hussman[4], M. L. Cuccaro[1,2] and M. A. Pericak-Vance[1,2], (1)John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, (2)Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL, (3)Case Western, Cleveland, OH, (4)Hussman Institute for Autism, Baltimore, MD

Background:
The clinical diagnosis of ASD has changed considerably since its introduction into the formal nomenclature, reflecting conceptualization of ASD as a multi-dimensional phenotype. We hypothesize that genetic variants modify the expression of ASD symptomatology within subjects diagnosed with ASD, and specifically that variants within ASD candidate genes will lead to an increased number of core autism features. To evaluate this hypothesis, we developed a quantitative autism score (QAS) using variables on the ADI-R which reflect ASD features that have remained consistent throughout the

changing diagnostic criteria (core ASD features).

Objectives:

To identify genes that explain variation in the number of core ASD features.

Methods:

The QAS was developed using the ADI-R, the semi-structured informant interview used to classify individuals for research studies in ASD. The QAS was defined using ADI-R algorithm items which consistently distinguish ASD from non-ASD or are present in early development and persist. The 15 QAS items are scored as present/absent and summed to yield a total score (0-15). Individuals with higher scores are those with more core features of ASD. The score was then calculated in 1051 ASD subjects from the Hussman Institute for Human Genomics (HIHG) and the Simons Simplex Collections. These individuals also had DNA sequence data available from a 17Mb custom capture covering 681 genes within regions identified by GWAS of ASD (Hussman et al 2013). SKAT-O (Li et al 2012) was used to conduct gene-based and single-variant tests for association with QAS as a quantitative trait. We examined combinations of synonymous, non-synonymous, missense, stop, loss-of-function and splice variants in different hypothesis tests. A Bonferroni correction for the number of genes tested was used as a significance threshold for each hypothesis with an experiment-wise significance level of 0.05.

Results:

Values for the QAS in the 1051 subjects ranged from 2 to 15 with a mean value of 9.44 (sd=2.49). We found significant association for the gene *CDH4* (p= 1.0×10^{-5}) when all exonic variants were included in the gene-based test. This gene is a neuronal cell adhesion molecule known to play a role in brain segmentation and neuronal outgrowth and is a member of the cadherin family of genes, many of which have previously identified as ASD candidate genes and have been implicated by genetic association and sequencing for rare variants. Including only synonymous variants increased significance for *CDH4* (p=1.6×10^{-6}) and also resulted in significant association at *AP4M1* (p=8.1×10^{-5}). *AP4M1* was identified in our extended ASD family study (Cukier et al 2014), plays a role in intracellular trafficking of glutamate receptors, and has been implicated in intellectual development. Single-variant tests within these two genes identified seven variants (5 rare, 1 low frequency, 1 common) in *CDH4* and two variants (1 low frequency and 1 common) in *AP4M1* associated (p<0.05) with QAS.

Conclusions:

Our study identified two genes, *CDH4* and *AP4M1*, associated with the number of core ASD features. These ASD genes add support to the importance of genes involved in neuronal cell adhesion and excitatory/inhibitory balance in ASD etiology.

214   **126.214**   Locomotor, Anxiety, and Risk Assessment Related Phenotyping and Striatal Transcriptome Analysis in Four Autism Mouse Models

E. Elliott and O. Oron, *Faculty of Medicine, Bar Ilan University, Safed, Israel*

Background: In recent years, multiple mouse models have been produced to study autism. In order to gain high-impact information from these mice models, we propose that the parallel behavioral and molecular phenotyping of several mouse will help to identify behaviors and molecular mechanisms that are in common in multiple models, and are therefore more likely to be directly involved in autistic behavior.

Objectives: In our current study, we looked at locomotor function, anxiety, and risk assessment behaviors in four autism mouse models. In order to discover common molecular pathways that are dysregulated in all mouse models, we did whole transcriptome sequencing in the striatum of these mice models. By comparing the behavior of these multiple models and the transcriptome dysregulation in the striatum, a brain area highly involved in these behaviors, we can determine specific molecular mechanisms that are directly responsible for the relevant behavioral dysfunctions.

Methods: We performed motor-related and risk- assessment related behavioral and molecular experimentation on four mouse models of ASD: Shank3 KO, CNTNAP2 KO, Chr16p11.2del, and BTBR mice. We performed Open Field (OF), Dark Light (DL), and Elevated Plus Maze (EPM) on all mouse models at basal conditions, and also at one hour, and 24 hours, after restraint stress. Rotorod test was also performed on all animals to test motor function. We extracted RNA from the striatum of all four mouse models, and their controls, and performed whole throughput RNA sequencing (RNA-seq) on all samples. This has produced data about the whole genome transcriptome in the striatum of all four mouse models.

Results: In the OF test, the CNTNAP2 and BTBR mice displayed hyperactivity at all conditions, the Chr16p11.2del displayed hyperactivity after stress, and Shank3 KO displayed hypoactivity. However, Shank3 KO also displayed motor deficits in the rotorod test. In DL, both the Shank3 KO and CNTNAP2 KO mice spent more time in the light area, suggesting less anxiety-like behavior, as well as less risk-assessment. In addition, in the EPM test, the Shank3KO, CNTNAPKO, and Chr16p11.2del models all spent significantly more time in the open arms, suggesting less anxiety-like behavior as well. Close

analysis of the behavior of the CNTNAP2KO model in both the EPM and DL tests shows that their behavior can be explained by less time doing risk assessment. RNA-seq data collection has already been performed and the data is currently being analyzed to be presented in the conference. Conclusions: All four mouse models displayed a dysregulation in locomotor activity, highlighting the importance of locomotion and motor function in autistic behavior. In addition, all genetic mouse models displayed a similar behavioral profile in the EPM and DL mazes, demonstrating that there is a shared behavioral outcome to several genetic mutations involved in autism. The profile suggests less anxiety-like behavior, which may be explained by less assessment of potential risks. By comparing these behaviors to whole transcriptome analysis in the striatum, we will be able to identify shared molecular dysregulation that is directly involved in these behavioral phenotypes.

215   **126.215** Extracellular Signal Related Kinase Activation in Autistic Disorder

C. Erickson[1], *L. K. Wink*[1], *E. V. Pedapati*[1], *T. L. Schaefer*[1], *R. Shaffer*[1], *B. Bayon*[2], *B. Ray*[2] and *D. K. Lahiri*[3], *(1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Indiana University School of Medicine, Indianapolis, IN, (3)Psychiatry and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN*

Background: Limited pathophysiological understanding of autistic disorder has plagued treatment development efforts in the field. Extracellular signal related kinase (ERK1/2) is a subfamily of mitogen-activated protein (MAP) kinases that mediate transmission of signals from cell surface receptors to cytoplasmic and nuclear effectors. Direct and indirect evidence from mouse and human models points to potential ERK1/2 dysregulation as a potential molecular marker of autistic disorder pathophysiology. ERK1/2 activation (phosphorylation) is an index of overall cellular activity.
 Lymphocytic ERK1/2 activation has been shown to be dysregulated and correlate with brain ERK1/2 dysregulation in humans with and animal models of fragile X syndrome (FXS), a common single gene cause of autism. Taking steps to assess ERK1/2 activation in the pathophysiology of idiopathic autistic disorder will open up new targeted treatment opportunities focused on this potential marker of molecular dysregulation.
Objectives: We sought to evaluate peripheral lymphocytic ERK1/2 activation in an initial group of youth with idiopathic autistic disorder compared to age- and gender-matched neurotypical peers. We hypothesize that lymphocytic ERK1/2 activation will be increased in youth with ASD compared to control subjects consistent with preclinical findings of enhanced ERK1/2 activation in murine models of ASD.
Methods: We enrolled as many subjects as possible into this study (enrollment period January-June 2012) of lymphocytic ERK1/2 activation in youth with autistic disorder compared to matched neurotypical peers. Diagnostic criteria from the Diagnostic and Statistical Manual for Mental Disorders, 4[th]Edition, Text Revision (DSM-IV-TR) were utilized. All subjects with autistic disorder met strict criteria for autistic disorder based on a score of greater than 13 on the Social Communication Questionnaire (SCQ) combined with a clinical interview using DSM-IV-TR autistic disorder criteria conducted by a physician with extensive experience in ASD diagnostics and research. All subjects, those with autistic disorder and controls, completed the SCQ and full medical and developmental histories. Additionally, subjects with autistic disorder completed the Aberrant Behavior Checklist (ABC), cognitive testing, and the Social Responsiveness Scale (SRS). To study peripheral lymphocytic ERK1/2 activation, lymphocytes from patients' blood were collected, washed, counted, fixed in formaldehyde, and stained with phospho-ERK1/2 anti-body. ERK1/2 activation was reported as the percentage of ERK1/2 positive staining cells, minimum of 200 cells counted.
Results: 36 youth with autistic disorder and 19 youth with neurotypical development were enrolled (see Table 1; Subject Characteristics). Mean ERK1/2 activation was significantly increased in the samples from the youth with autistic disorder compared to controls (6.2 ± 4.0% versus 2.8 ± 2.1%; p=0.001). A receiver operating curve (ROC) analysis looking at ERK1/2 activation and diagnosis had an area under the curve of 0.792 (p<0.0001) showing a significant association between ERK1/2 activation and diagnosis of autistic disorder in our sample. Future analysis will include correlation assessments of ERK1/2 activation and results from the ABC, SRS, and cognitive testing.
Conclusions: Peripheral ERK1/2 holds promise as a potential marker of molecular dysregulation in youth with autistic disorder. Future larger-scale study is warranted to study ERK1/2 activation in autism.

Keynote Address
131 - Reflections on 50 years of ASD Early Intervention Science
9:00 AM - 10:00 AM - Grand Ballroom

Speaker: S. J. Rogers, University of California at Davis, Sacramento, CA

In May of 1965, Life Magazine published a cover story on Ivar Lovaas's UCLA autism intervention study, bringing autism and the challenges it creates for children and families into the public eye for the first time. Fifty years later, early autism intervention is the topic of lawsuits, protests, and hope. The powerful effects of high quality intensive early intervention delivered in the first few years of life provide new insights into the multiple mechanisms underlying developmental and behavioral impairments associated with early ASD. This

keynote will (1) describe and illustrate the kinds of gains that high quality intervention can facilitate, (2) identify treatment elements common to the most successful approaches, highlighting research from the Early Start Denver Model (Dawson and Rogers 2010), and (3) consider varying ways of conceptualizing treatment response.

9:00 **128.001** Reflections on 50 years of ASD Early Intervention Science
S. J. Rogers, *University of California at Davis, Sacramento, CA*

In May of 1965, Life Magazine published a cover story on Ivar Lovaas's UCLA autism intervention study, bringing autism and the challenges it creates for children and families into the public eye for the first time. Fifty years later, early autism intervention is the topic of lawsuits, protests, and hope. The powerful effects of high quality intensive early intervention delivered in the first few years of life provide new insights into the multiple mechanisms underlying developmental and behavioral impairments associated with early ASD. This keynote will (1) describe and illustrate the kinds of gains that high quality intervention can facilitate, (2) identify treatment elements common to the most successful approaches, highlighting research from the Early Start Denver Model (Dawson and Rogers 2010), and (3) consider varying ways of conceptualizing treatment response.

Panel Session
132 - Responses to Early Intervention and Mechanisms of Change
10:30 AM - 12:30 PM - Grand Ballroom B

Panel Chair: Sally Rogers, *MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis Medical Center, Sacramento, CA*

Discussant: Charles Nelson, *Harvard University Boston Children's Hospital, Boston, MA*

New studies of early intervention effects in ASD are being published monthly, with varying designs, methods, measures, and outcomes. There is growing acceptance of the ideas that (1) individual outcomes in autism reflect transactional processes among environmental and biological variables throughout life and (2) that developmental processes and rates may be particularly malleable in early childhood. There is increasing impetus among families and care professionals for early intervention research findings to be incorporated into an increased range, sophistication, and availability of services to young children and their families. However, this impetus is tempered by concerns about overemphasis on early childhood services, unreliability of early symptoms, difficulties with assessment processes, and lack of community services for early identification, diagnosis, and treatment. In order to guide public services and clinical practice, early intervention science must move more deeply into two areas (among many): (1) mechanisms by which specific intervention practices may be changing children's developmental trajectories or rates, (2) individual or subgroup patterns of response to specific interventions, and (3) variables that mediate and moderate intervention response. This international panel brings together a distinguished group of scientists involved in studying the processes and mechanisms involved in response to early interventions.

10:30 **132.001** The Social Brain and Language Learning
P. K. Kuhl, *University of Washington, Seattle, WA*

Background: Research on typically developing infants during the initial stages of language learning suggest that social interaction is a necessary component for learning. Work has shown, for example, that infants exposed to a new language during an early sensitive period for phonetic learning, can learn phonemes from the new language if exposed socially during interaction with a live human being. Infants exposed to the same language material, in the identical setting and on the same schedule but via television, learned nothing. This stark contrast between learning under social and nonsocial conditions led to the "social gating hypothesis (SGH)," the notion that infants require social interaction to enact other computational processes ("statistical learning") when exposed to natural language.
Objectives: I will describe the research stemming from the SGH, which includes research on children with autism spectrum disorder (ASD) using phonemes, words, and the motherese style of speaking to infants to probe possible early markers of risk in children with autism.
Methods: The studies described utilize both behavioral measures on typically developing infants and children with ASD as well as brain measures (EEG and MEG).
Results: The results suggest, in typically developing children, that early language learning depend on a social context and social interaction. In children with ASD, our results hold promise that our brain measures of language processing may some day contribute to the development of reliable "biomarkers" for children at risk for ASD.
Conclusions: I discuss the meaning and implications of the claim that language learning is "gated" by the social brain.

10:55 **132.002** Studying Why and for Whom Intervention Works
P. J. Yoder, *Special Education, Vanderbilt University, Nashville, TN*

Background: This presentation will provide a methodological overview of how research methods and statistical procedures can be used to identify (a) the defining characteristic of a subgroup for whom treatment works best (i.e., moderators) and (b) a mechanism by which treatment works (i.e., a mediator).

Objectives: Audience members will be able to identify the common misconceptions about how to identify mechanisms and characteristics of treatment responders. Audience members will be able to say why using the experimental design element in mediational and moderation analysis provides a better way to identify mechanisms and characteristics of treatment responders. Audience members will be able identify the key statistical test required to identify a treatment mechanism. Audience members will be able to identify the two key findings required to identify the characteristic of children who benefited most from a treatment.

Methods: Lecture format will be used to talk about the general issues. Two studies, each using a randomized between-group experimental design and samples of children with Down syndrome (N > 50), will be used to illustrate the issues.

Results: The first study confirmed the hypothesis that daily therapy sessions was more facilitative of spoken vocabulary than weekly therapy sessions because the former affect speech-like nonverbal vocal communication early in the treatment phase. The second study confirmed the hypothesis that initial verbal imitation ability defined the subgroup of children in which speech recasts worked better than a common therapy method. The region of significance for "high verbal imitators" was .5 SD above the sample mean and included 26% of the sample.

Conclusions: Identifying correlates of change within a treated group is insufficient to identify characteristics of treatment responders. Fortunately, we have the methods to identify for whom treatment works and why: mediational and moderation analyses in the context of randomized between-group experiments.

11:20 **132.003** Social Learning Processes Underlying Treatment-Related Changes in Children with ASD Receiving the Early Start Denver Model

G. Vivanti, Olga Tennison Autism Research Centre, Melbourne, Australia

Background: Social learning, i.e. the transmission of behavior from one person to another, requires the successful deployment of multiple attentional, cognitive and motivational processes. Understanding the specific components and mechanisms of social learning that are involved in response to early intervention in children with ASD is critical to select, refine and individualize educational procedures in this population.

Objectives: To identify the specific social learning processes that moderate and mediate response to the Early Start Denver Model in preschoolers with ASD.

Methods: A number of novel experimental eye-tracking and behavioural tasks aimed at 'dissecting' the different attentional, cognitive and motivational processes underlying social learning were administered to a group of preschoolers with ASD receiving the Early Start Denver Model (ESDM) program (anticipated final sample size = 50). Participants were tested at baseline and after one year of treatment. The link between performance in the tasks and 1-year treatment outcomes will be analyzed to determine the specific social learning processes that underlie response to the ESDM.

Results: Data collection and analysis is still ongoing. Preliminary findings based on a subset of participants suggest that social motivational processes underlying social learning, including spontaneous propensity to imitate others, spontaneous purposeful (versus purposeless) use of play materials, and social response to a playful- versus an emotionally-neutral partner, are more relevant in predicting ESDM treatment outcomes than attentional and cognitive learning mechanisms, initial IQ and language.

Conclusions: This is the first research program to examine the link between social learning profiles in children with ASD and treatment outcomes in response to the Early Start Denver Model through a fine-grained, theory-driven analysis of the multiple components underlying social learning. Preliminary results of this ongoing study suggest that spontaneous propensity to engage with and imitate others might be a critical active ingredient in the response of children with ASD to the ESDM.

11:45 **132.004** Early Interventions for Autism: Mechanism and Developmental Science

J. Green[1], A. Pickles[2], H. McConachie[3], E. Jones[4], T. Gliga[5], T. Charman[6] and M. H. Johnson[5], (1)Institute of Brain, Behaviour and Mental Health, University of Manchester, Manchester, United Kingdom, (2)Department of Biostatistics, King's College London, London, United Kingdom, (3)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom, (4)Birkbeck College, University of London, London, United Kingdom, (5)Centre for Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (6)Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background: Suitably designed trials of early interventions for autism, combining the benefits of randomisation with repeated measures follow-up in a developmental context, can illuminate both the processes behind treatment effectiveness, and causal mechanisms within developmental science (Green and Dunn 2008).

Objectives: To identify the active ingredients of autism intervention and to use intervention trials to illuminate developmental science.

Methods: The presentation will draw from findings within two randomised controlled trials of parent-mediated, video-aided and developmentally-focused social communication intervention for autism. 1) The Preschool Autism Communication trial (PACT; Green et al 2010), a three site RCT (N=152) of the PACT social communication intervention against usual care in 2-5 year old children diagnosed with core autism; pre-designed to enable the study of treatment mechanism. The PACT mediation analysis (Pickles et al 2014) extended traditional techniques by including exploration of instrumental variables to address post-randomisation confounding, and exploited repeated measures to address measurement error in the mediator.
2) Intervention within the British Autism Study of Infant Siblings (iBASIS), a two site RCT (N=54), testing parent mediated intervention for infants at familial risk for autism, not selected for atypicality. Baseline at 9 months, treatment endpoint 14 months, follow up 24 months. The design tested intervention impact on pre-specified infancy risk markers for later autism using intention to treat analysis.
Results: PACT mediation analysis showed that a treatment effect on parental communicative synchrony with the child (effect size (ES) 1.22 (0.85,1.59) at 13 month endpoint, 1.44 at 6 months), strongly mediated (70%) an improvement in child communication initiation with parent (ES 0.41 (0.08, 0.74) at 13 months, 0.5 at 6 months). Other parental interactive behaviours did not significantly contribute to this mediation. In turn, the improvement in the child's communication initiation strongly mediated (73%) a more modest treatment effect on autism symptoms (ADOS; ES -0.24 (-0.59, 0.11) at endpoint).
New complimentary data will be presented from iBASIS on the intervention effect on parent-infant interaction (parent nondirectiveness, child attention), atypical infant behavior (AOSI), infant cognition (GAP attention disengagement) and brain function (ERP to speech sounds).
Conclusions: PACT mediation suggests a causal chain of effect from parent behavior with child to child behaviour with parent, to child behavior with researcher; identifying the active process of intervention and supporting the intervention theory. It also suggests the ADOS symptom change may be meaningful in direction and amenable to further improvement if the causal chain of effect can be enhanced; thus implying logical ways of strengthening treatment effectiveness. For developmental science, the causal direction of effect from parent behaviour to improved child social communication amplifies previous findings on the assocation between early parental synchrony and later child functioning (eg Siller et al 2008).
The comparative data from iBASIS will show how intervention can similarly effect parental communication behaviour in infancy; along with impact on infant's attention to caregiver, atypical behaviour, ERP response, attention disengagement, language and adaptive outcomes. Implication of these findings for the developmental science of the autism prodrome will be presented.

Panel Session
133 - EU-AIMS: Translating Cellular and Animal Models of Synaptic Gene Deficits to Large-Scale Clinical Studies
10:30 AM - 12:30 PM - Grand Ballroom A

Panel Chair: Eva Loth, *Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Discussant: Jan Buitelaar, *Department of General Psychiatry and Child and Adolescent Psychiatry, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands*

Autism spectrum disorders are one of the most common and severe neurodevelopmental disorders yet effective treatments for the core symptoms are still lacking. This is mainly due to a) the high clinical, etiological and genetic heterogeneity between affected individuals, b) restricted knowledge of the underpinning pathophysiological mechanism(s), and c) the absence of reliable biomarkers to identify more biologically homogeneous subgroups. This panel will present examples of the integrated translational approach adopted in EU-AIMS, a large-scale public-private partnership, to identify biomarkers and new treatment targets for ASD. First, we combine patient-derived pluripotent stem cells (Price) and animal models (Steckler) of monogenic forms of ASD to understand pathophysiological mechanisms. Here, we focus on genes affecting synapse development and function (SHANKs, neurexins, neuroligins) and their downstream effects on excitatory-inhibitory balance and brain connectivity. Next, we translate this to patients using methods such as MRS. Preliminary findings from a pharmacological study validate the Glutamate/ GABA system as a tractable treatment target. Finally, we carry out linked large-scale clinical studies spanning children and adults with ASD and patients with specific synaptic gene deficits to identify biomarkers (including markers of E/I imbalances) for patient stratification that can be used in future clinical trials.

10:30 **133.001** Utility of Rodent Mutants with Altered Synaptic Signaling Pathways to Test Possible Pharmacological Interventions for ASD

*T. Steckler[1], S. Baudouin[2], T. M. Boeckers[3], F. Esclassan[4], G. Gilmour[5], G. Kumar[6], **M. E. Modi**[7], M. M. Petrinovic[8], J. Talpos[9] and P. Scheiffele[10], (1)Neuroscience Therapeutic Area, Janssen Research and Development, Johnson & Johnson, Beerse, Belgium, (2)Cardiff School of Biosciences, Cardiff, United Kingdom, (3)Institute for Anatomy and Cell Biology, Ulm University, Ulm, Germany, (4)Eli Lilly,*

Sunningdale, United Kingdom, (5)In Vivo Pharmacology, Eli Lilly, Sunningdale, United Kingdom, (6)Neurosciences, Janssen Pharmaceuticals, Beerse, Belgium, (7)Neuroscience, Pfizer, Cambridge, MA, (8)F. Hoffmann-La Roche, Basel, Switzerland, (9)Janssen Pharmaceuticals, Beerse, Belgium, (10)Biozentrum University of Basel, Basel, BS, Switzerland

Background: The lack of robust and replicable animal models of ASD has hindered progress in the development of effective therapeutic interventions for ASD. Recent advances in understanding the neurobiology underlying ASD led to the generation of novel animal models with high construct validity, based on gene mutations and altered CNVs reported in patients suffering from ASD, including those with mutations of genes involved in the formation of neuronal networks and synaptic plasticity. Common to these genetic models are abnormalities in glutamatergic and/or GABAergic systems.
Objectives: One goal of EU-AIMS (European Autism Interventions - A Multicentre Study for Developing New Medications), a public-private partnership within the context of the EU's Innovative Medicines Initiative, is to develop and validate novel mouse and rat models to facilitate the advancement of novel therapies to treat ASD. We hypothesized that compounds acting at glutamatergic or GABAergic mechanisms might be efficacious to (partially) reverse abnormalities seen in these rodent models.
Methods: A strong focus within the EU-AIMS consortium has been the phenotypic characterization of behavioral, electrophysiological and morphological alterations in KO mice and rats lacking functional cell adhesion molecules (neurexin/neuroligins) and rodents lacking functional shank proteins. Behavioral testing focused on both key ASD-related symptoms and cognitive function, including novel, touch-screen-based tests of cognitive flexibility. Because glutamatergic abnormalities have been described in some of these models, we have started to evaluate the effects of compounds acting at glutamatergic mechanisms in those models, including compounds acting at group I mGluRs.
Results: The talk will cover the characterization of the rodent models. We will discuss behavioral data from these animals, with special emphasis on cognitive deficits and their potential translational value for the clinic. We will further show EEG and fMRI data and relate them to clinical observations. For example, structural and functional MRI revealed altered brain volume and neural activity in NLGN3 KO rats, and an altered E/I balance was seen in MRS in these animals. In NLGN3 KO mice, an up-regulation of mGluR1 was observed and we will present first data from pharmacological intervention studies, leading to partial rescue of phenotypical abnormalities in these mice.
Conclusions: Behavioral abnormalities, as well as electrophysiological and morphological alterations (e.g., increased repetitive behavior, impaired social interaction, cognitive deficits, changes in neural activity and biochemistry) observed in at least some models are in line with alterations reported in ASD patients, suggesting good face validity on top of high construct validity. These phenotypes are accompanied by altered glutamatergic function. The preliminary pharmacological intervention studies suggest that these models are of utility for drug development. Whether there is also good predictive validity will only be addressed conclusively once efficacy readouts from the animal models have been successfully shown to translate to the clinic. Importantly, this translational aspect is currently addressed in the clinical work-packages of EU-AIMS, making this a powerful consortium to address the unmet medical needs of ASD patients.

10:55 **133.002** Cellular Phenotypes in Induced Pluripotent Stem Cells from Autistic Individuals

J. Price[1], G. Cocks[1], A. Kathuria[2], K. Warre-Cornish[1], R. Taylor[3] and L. Andreae[4], (1)Cells and Behaviour Unit, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)MRC Centre for Developmental Neurobiology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)MRC Centre for Developmental Neurobiology, King's College London, London, United Kingdom

Background: The etiology of autism is poorly understood. Genetic and environmental factors somehow converge during perinatal development to produce the combination of symptoms and co-morbidities that characterize this condition. Induced pluripotent stem cells (iPSCs) permit not only the study of cellular phenotypes associated with autism, but also their developmental trajectory. Thus this cellular system might offer a means to observe aspects of the etiology of autism in a simple in vitro model.
Objectives: To discover cellular phenotypes in iPSC-derived neurons associated with autism, and to observe their ontology
Methods: We generated iPSC lines from hair root biopsies from three categories of individuals: autistic patients carrying deletions in synaptic genes (SHANK3 and NRXN1); non-syndromic patients; and neurotypical control individuals. We differentiated these iPSCs into parvocellular hypothalamic neurons, and devised cellular and molecular analyses to follow their differentiation.
Results: We discovered that cells from all three categories of individuals differentiate into parvocellular neuronal types as identified by RNASeq expression, electrophysiological recordings, and histochemical analyses, with GNrH$^+$cells being the most numerous. In neurons derived from the SHANK3 individuals, we see morphogenetic phenotypes: the cells develop a different size and shape from controls.   We also see differences in responsivity to cytokines that imply that the cells from autistic individuals carry epigenetic differences from controls.
Conclusions: There are detectable cellular phenotypes observable in neurons derived from iPSCs that appear to be associated with autism. This suggests that at least some of the pathophysiology

associated with this condition can be captured in this cellular system. What remains to be determined is how generalizable these phenotypes are across a range of autistic individuals, and the extent to which they correspond with clinical phenotypes, and with clinical heterogeneity.

11:20 **133.003** EU-AIMS Clinical Research Platform to Identify Biomarkers for Patient-Stratification

E. Loth[1], D. G. Murphy[2], T. Banaschewski[3], S. Baron-Cohen[4], S. Bolte[5], T. Bourgeron[6], T. Charman[7], S. Durston[8], J. Horder[9], M. H. Johnson[10], E. Jones[11], L. Mason[11], L. O'Dwyer[12], A. M. M. Persico[13] and J. Buitelaar[12], (1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (3)University of Heidelberg, Heidelberg, Germany, (4)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (5)Division of Child and Adolescent Psychiatry, Stockholm County Council, Stockholm, Sweden, (6)Pasteur Institute, Paris Cedex 15, France, (7)Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (8)Psychiatry, Brain Centre Rudolf Magnus, University Medical Center Utrecht, Utrecht, Netherlands, (9)De Crespigny Park, Institute of Psychiatry, King's College London, London, England, United Kingdom, (10)Centre for Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (11)Birkbeck College, University of London, London, United Kingdom, (12)Department of General Psychiatry and Child and Adolescent Psychiatry, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (13)Child and Adolescent Neuropsychiatry Unit & Lab of Molecular Psychiatry and Neurogenics, Rome, Italy

Background: There are no effective treatments for the core symptoms of ASD because the underlying pathophysiology(ies) remain(s) poorly understood. Clinical trials are further hampered by the profound clinical and etiological heterogeneity among individuals with ASD, as any treatment is likely only effective in some biological sub-groups. Hence, large-scale multi-disciplinary studies and new biomarker stratification approaches are needed to identify more biologically homogeneous ASD subgroups. EU-AIMS capitalizes on rare monogenic forms of ASD affecting synaptic plasticity to identify new tractable treatment targets. This approach generates predictions for potential biomarkers linked to downstream effects on the excitatory-inhibitory balance and cortical-network function underpinning cognitive development. Acceptance of these biomarker approaches by regulatory authorities is crucial to maximize their usefulness for future clinical trials.
Objectives: (1) to develop new approaches and methodologies to identify biomarkers for patient stratification; (2) to obtain qualification advice on these approaches from the European Medicines Agency (EMA); (3) to test candidate biomarkers tapping E/I imbalance in patients who harbor specific synaptic gene deficits (Phelan McDermid Syndrome) and a large cohort of children and adults with ASD.
Methods: (1) The EU-AIMS Longitudinal European Autism Project (LEAP) is carried out in 7 European centres and will include approximately 400 individuals with ASD from 6-30 years and 250 controls with typical development or diverse intellectual disabilities. All participants are comprehensively characterized in terms of clinical symptom profile, comorbidities, quality of life, neurocognitive profile, brain structure and function, biochemical biomarkers, and genomics. We use an accelerated longitudinal design so that predicted biological differences can be compared across developmental stages. This will allow us to assess, e.g., whether differences in E/I imbalance vary according to developmental stages, sex, and/ or between genetically-driven molecular subgroups. (2) The LEAP protocol was submitted to the EMA to obtain qualification advice on the biomarker approaches and methodologies used. (3) The cohort is compared to approximately 50 children and adults with PMS to establish whether biomarkers linked to specific synaptic deficits are shared by other ASD-subgroups.
Results: (1) We developed measures suitable for a broad age and ability range, including direct and indirect proxies of E-I imbalance. For example, a pilot study demonstrates a link between glutamate concentration in the basal ganglia, functional connectivity and severity of ASD symptoms. (2) The EMA endorsed the overall design and methodologies of EU-AIMS LEAP for the identification of biomarkers. We will present a summary of key recommendations. (3) We will report preliminary results comparing children and adults with ASD and those with PMS on candidate biomarkers affecting E-I imbalance and their dimensional relationship with symptom profile.
Conclusions: The design of LEAP provides new approaches to identify biomarkers for patient stratification and to map them both to genetic-molecular and symptom profiles. Obtaining QA from the EMA represents an important first step to inform regulatory guidelines for medication trials in ASD in Europe. The comparison of biomarkers between patients with ASD and PMS will help to ascertain how far treatment targets identified using synaptic gene models may be applicable to broader ASD sub-groups.

11:45 **133.004** Glutamate and GABA in Autism Spectrum: A Clinical in-Vivo Magnetic Resonance Spectroscopy Assay

L. A. Ajram[1], J. Horder[2], M. A. Mendez[3], A. Galanopoulos[4], L. Brennan[5], R. Wichers[6], D. J. Lythgoe[7], S. C. Williams[8], D. G. Murphy[9] and G. M. McAlonan[9], (1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Kings College London, London, United Kingdom, (2)De Crespigny Park, Institute of Psychiatry, King's College London, London, England, United Kingdom, (3)Forensic and

Neurodevelopmental Sciences, Institute of Psychiatry, King's College London, London, United Kingdom, (4)Behavioural and Developmental Clinical Academic Group, King's Health Partners, London, United Kingdom, (5)Institute of Psychiatry, Kings College London, London, United Kingdom, (6)Institute of Psychiatry, King's College London, London, United Kingdom, (7)King's College London, London, United Kingdom, (8)Neuroimaging, Centre for Neuroimaging Sciences, Institute of Psychiatry, King's College London, London, United Kingdom, (9)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

Background: There are currently no pharmacological treatments for the core symptoms of Autism Spectrum Disorder (ASD). However, accumulating evidence indicates an imbalance between excitatory (E) glutamate and inhibitory (I) GABA in ASD. Therefore modulating E/I balance may constitute a tractable treatment approach for this condition and this may explain the early promise of proGABA and anti-glutamate drugs such as riluzole.

Objectives: To investigate the hypothesis that, compared to unaffected controls, individuals with ASD have differences in the E/I response to a riluzole drug challenge.

Methods: We used MEGAPRESS proton magnetic resonance spectroscopy ($[^1H]$-MRS) to measure concentrations of Glx (glutamate + glutamine) and GABA in unmedicated adult men with and without ASD diagnosis. Individuals were scanned twice, one week apart. Fifty mg of riluzole or matched placebo was administered in a randomised, double blind, crossover design, 1 hour before spectra were acquired from the left basal ganglia and bilateral prefrontal cortex. An inhibitory index was calculated as GABA/(GABA+Glx) for both treatment conditions.

Results: Preliminary results show that, in the basal ganglia, riluzole increased the inhibitory index in both groups (drug effect p=0.015). However, in the prefrontal cortex, riluzole increased the inhibitory index in the ASD group only, although the result did not reach statistical significance (ASD prefrontal Inhibitory Index: placebo = 0.69; riluzole = 0.74; drug*group effect p=0.1). Post-hoc testing suggested that increases in inhibitory indices in both groups were mainly driven by an increase in GABA, (and not a reduction in Glx).

Conclusions: Data acquisition is ongoing. If confirmed, these preliminary findings bring us closer to Proof of Concept that individuals with ASD have differences in E/I responsivity. By validating the glutamate-GABA system as a tractable treatment target in ASD, we hope this work will both support trials of existing drugs (such as riluzole), and facilitate the development of new drugs that act on this system. Our MRS approach may also provide a safe, non-invasive tool to help fractionate the sample and predict who will be responsive to glutamate-GABA treatments in a 'personalized' medicine approach to ASD.

Panel Session
134 - Factors Associated with Adult Outcomes for Individuals with ASD
10:30 AM - 12:30 PM - Grand Ballroom C

Panel Chair: Laura Klinger, *TEACCH Autism Program; Department of Psychiatry, University of North Carolina, Chapel Hill, NC*

Discussant: Peter Bell, *Eden Autism Services, Princeton, NJ*

There is a growing literature documenting the social, employment, and mental health difficulties faced by adults with ASD. With the increasing rates of ASD diagnoses, the number of individuals with ASD entering adulthood each year will double over the next 6 years. While we know that employment rates are extremely low, little research has examined what factors are related to positive adult outcome. The talks in this panel describe the results of four separate large-scale studies focused on identifying factors that affect adult outcome. The presentations incorporate a range of methodologies including a long term follow up study from childhood, two prospective studies from adolescence into adulthood, and a high school employment intervention program. Further, the presentations incorporate a variety of adult outcome measures including employment, adaptive behavior, social connectedness, mental health, motor skills, and quality of life. Across these studies, the importance of several childhood and adolescent factors emerges and potential intervention targets are identified. Each presentation will address implications for promoting positive adult outcomes.

10:30 **134.001** Correlates of Middle Adult Outcome: A Follow-up Study of Children Diagnosed with ASD from 1970-1999

L. G. Klinger[1], M. R. Klinger[2], J. L. Mussey[1], S. P. Thomas[2] and P. S. Powell[3], (1)TEACCH Autism Program; Department of Psychiatry, University of North Carolina, Chapel Hill, NC, (2)Allied Health Sciences, University of North Carolina, Chapel Hill, NC, (3)Psychology, University of North Carolina, Chapel Hill, NC

Background: While there is a developing literature on Autism Spectrum Disorder (ASD) in adulthood, few longitudinal studies from childhood to adulthood have been conducted. The majority of these studies have focused on the transition years from adolescence to young adulthood or focused on

describing adult outcomes. Thus, there is little research on autism in middle adulthood or predictors of positive outcome in this age group.

Objectives: This research capitalizes on a unique dataset of individuals diagnosed with ASD as children by the TEACCH Autism Program from 1970-1999. A caregiver survey was conducted to: (1) Document outcomes (employment, social connectedness, mental health, quality of life) in middle adulthood; (2) Examine current predictors of adult outcome; (3) Examine childhood predictors of adult outcome.

Methods: Thus far, surveys have been completed for 81 adults with ASD in middle adulthood (21-64 years of age, Mean = 34 years) diagnosed during childhood (initial diagnoses from 21 months to 17 years, Mean = 6.5 years). Adult outcome was measured by employment status (Taylor & Seltzer Vocational Index), quality of life (Schalock & Keith Quality of Life Questionnaire), social isolation (NLTS-2 items), and mental health (Anxiety Depression and Mood Scale). Current predictors included autism symptom severity (Social Responsiveness Scale, SRS-2), adaptive behavior (Waisman Activities of Daily Living), and language ability (NLTS-2 items). Childhood predictors included symptom severity (Childhood Autism Rating Scale), adaptive behavior (Vineland), and IQ.

Results: Seventy-eight percent of adults with ASD had moderate to severe autism on the SRS-2. Despite significant ASD symptoms, a range of developmental level is represented (e.g., little to no difficulty with conversations were reported for 42% of adults). With regards to adult outcome, caregivers reported that only 43% of adults with ASD were employed and 36% were described as being social isolated (no contact with peers in the past 12 months). Regression analyses were conducted to examine predictors of adult outcome. Current adaptive behavior was the single best correlate of adult outcome. Controlling for both current symptom severity and language skills, adaptive behavior was significantly related to employment (*partial r*=+.55), social isolation (*pr*=-.30), depression (*pr*=-.26), and quality of life (*pr*=+.36). When controlling for adaptive behavior, symptom severity and language ability had little to no impact on adult outcome. Similar analyses were conducted for childhood predictors. Adaptive behavior in childhood controlling for childhood IQ and symptom severity was an equally strong predictor of employment (*pr*=+.38), social isolation (*pr*=-.29), depression (*pr*=-.28), and quality of life (*pr*=+.38). The contributions of current and childhood adaptive behavior were largely independent; each significantly predicted outcome when the other was used as a covariate.

Conclusions: Both childhood and adult adaptive behavior were strong, independent predictors of a wide variety of adult outcomes. The contribution of adaptive behavior went beyond that of either symptom severity or intellectual/language functioning. Interventions targeting adaptive behavior skills are often overlooked; however, these findings emphasize the importance of improving adaptive behavior across the lifespan regardless of symptom severity and communication skills.

10:55 **134.002** Longitudinal Development of Manual Motor Performance in Autism Spectrum Disorder from Childhood to Mid-Adulthood and Predictions of Adaptive Daily Living Skills

B. G. Travers[1], E. D. Bigler[2], M. D. Prigge[3], A. Froehlich[4], N. Lange[5], A. Alexander[6] and J. E. Lainhart[7], (1)Kinesiology, Program of Occupational Therapy, Waisman Center, University of Wisconsin-Madison, Madison, WI, (2)Psychiatry, University of Utah, Salt Lake City, UT, (3)Pediatrics, University of Utah, Salt Lake City, UT, (4)University of Utah, Salt Lake City, UT, (5)McLean Hospital, Belmont, MA, (6)Waisman Center, University of Wisconsin-Madison, Madison, WI, (7)Psychiatry, Waisman Center, University of Wisconsin-Madison, Madison, WI

Background: Cross-sectional studies suggest that individuals with Autism Spectrum Disorder (ASD) exhibit difficulties with motor skills (for a meta-analysis see Fournier et al., 2010). However, the longitudinal development of motor skills in ASD, especially from childhood into adulthood, is unclear. A key question is whether motor skills improve, plateau, or decline in ASD from childhood into adulthood. Because many activities of daily living require manual motor skills (i.e., dressing, preparing food, etc.), another key question is whether difficulty with motor skills is predictive of both current and future adaptive daily living skills.

Objectives: 1) To examine age-related changes in repeated measures of grip strength and finger tapping in ASD compared to typical development from early childhood into mid-adulthood, and 2) to examine manual motor performance as a predictor of current and later (adulthood) daily living skills.

Methods: Ninety males with ASD and 56 age-matched males with typical development between the ages of 5 and 39 years (M = 18.0 years) were included in these analyses. Participants completed bimanual measures of grip strength and finger tapping speed and the Vineland Adaptive Behavior Scales up to three times over the course of 10 years as part of a broader longitudinal study. Mixed-effects penalized regression spline models examined manual motor performance as a function of diagnostic group and age. Partial correlations (controlling for age and IQ) examined whether Time 1 manual motor performance could significantly predict Vineland daily living standard scores concurrently and ten years later.

Results: The ASD and typically developing groups demonstrated significantly different developmental trajectories for grip strength ($p < .001$) and finger tapping speed ($p < .001$). Follow-up analyses demonstrated that in participants younger than 15 years of age, there were trends but no significant group differences in grip strength, $t(88) = 1.76$, $p = .09$, $d = 0.388$, or finger tapping, $t(88) = 0.87$, $p = .39$, $d = 0.191$. However, in individuals 15 years and older, group differences were sizable and significant in both grip strength, $t(139) = 6.56$, $p < .001$, $d = 1.136$, and finger tapping, $t(139) = 5.38$, $p < .001$, $d = 0.933$. Across both groups, grip strength and finger tapping speed significantly

predicted both concurrent daily living skills and daily livings skills 10 years into the future (all p's < .04, controlling for age and IQ). This finding remained even when only including adults in the analyses. **Conclusions**: The group with ASD demonstrated atypical manual motor development, characterized by similar performance on grip strength and finger tapping from 5 to 14 years of age but increasingly poorer performance in grip strength and finger tapping from 15 to 39 years of age. These results suggest that individuals with ASD may experience increasingly more pronounced manual motor performance difficulties as they transition from adolescence into adulthood. Moreover, motor skills were found to relate to both current and future daily living skills (both across our entire sample and only in the adults), which suggests that manual motor performance may predict independent living skills in adulthood.

11:20 **134.003** Disconnection from Postsecondary Education and Employment Among Young Adults on the Autism Spectrum

P. T. Shattuck, A. M. Roux, J. Rast and J. Rava, AJ Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: Young adults who are not employed and not enrolled in school or vocational training after high school are defined as disconnected from pathways that lead to independence. Prior research found that slightly more than half of youth on the autism spectrum do not transition into paid employment, vocational education, or college of any kind in the first two years after high school -- despite the variety of services aimed at preventing disconnection.
Objectives: We aim to answer several questions about this disconnected group. What are the differences in characteristics and experiences between those who had no services after high school and those who had any services? What services have these disconnected young adults used since high school and what unmet services needs do they and their parents report? What are the correlates of not getting any services, ever getting vocational services, and ever having unmet service needs since high school? What experiences during high school reduce the risk of postsecondary disconnection?
Methods: We used secondary data from the National Longitudinal Transition Study 2 (NLTS2) -- a 9-year prospective study of youth who were enrolled in special education and ages 13-17 at the study's outset in 2001. Outcome variables about disconnection came from Wave 5 conducted in 2009 when participants were ages 21-25. Measures of seven types of service use and four types of secondary extracurricular activities come from Waves 1-5. Estimates were weighted to population levels. We used logistic regression to examine correlates of disconnection and service use; propensity score modeling to test the effect of extracurricular participation during high school on the likelihood of postsecondary disconnection. We used multiple imputation to handle missing data.
Results: At Wave 5, 38.8% of youth had never had postsecondary education nor a paid job. Among disconnected youth, 31.3% did not receive any postsecondary services that might help achieve job or postsecondary education attainment. Coming from a household where parents were more educated was associated with lower odds of being completely without services and higher odds of ever getting vocational services. Youth living in a suburban community (versus urban) were significantly more likely to have no services since high school. Participation in extracurricular activities during high school was associated with a reduced risk for poor postsecondary work and school outcomes even after adjusting for the propensity of high school-era participation. About two-thirds of high school students had participated in at least one of the four types of extracurricular activities.
Conclusions: The high rate of total disconnection from postsecondary education, training, and job opportunities is a serious problem. Our work suggests exposure to certain types of experiences during high school, like extracurricular activity participation, can reduce the risk of disconnection. Efforts to promote access to helpful services after high school should be targeted at those with highest risk of not getting any services.

11:45 **134.004** Evaluating the Effectiveness of Project Search to Support Employment for Young Adults with Autism Spectrum Disorder

M. R. Klinger[1], A. W. Duncan[2], L. G. Klinger[3], M. M. Daston[4] and E. Riehle[5], (1)Allied Health Sciences, University of North Carolina, Chapel Hill, NC, (2)Div of Developmental and Behavioral Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)TEACCH Autism Program; Department of Psychiatry, University of North Carolina, Chapel Hill, NC, (4)Project SEARCH, Cincinnati Children's Hospital, Cincinnati, OH, (5)Cincinnati Children's Hospital, Cincinnati, OH

Background: Young adults with Autism Spectrum Disorder (ASD) experience chronically low rates of post-school employment significantly below those for youth with other developmental disabilities. Roux et al. (2013) reported that 46% of youth with ASD between 21-25 years of age had never been employed and only one-third were currently employed. Thus, it is imperative to identify programs that support transition-aged youth with ASD to obtain competitive employment.
Project SEARCH is a widely used model of high school transition designed to improve employment outcomes for youth with developmental disabilities (DDs) in their last year of school (Rutkowski et al. 2006). Over the course of the year, youth rotate through three internships that allow them to experience workplace immersion and learn marketable job skills. In an onsite classroom, they learn employability skills such as appropriate workplace conduct. The goal is competitive employment with

high rates of success reported. Little research has examined Project SEARCH's effectiveness for individuals with ASD.

Objectives: The purpose of this study was to compare employment outcomes of young adults with ASD to young adults with other DDs who completed Project SEARCH. This study represented a large, community-based intervention across multiple intervention teams and sites.

Methods: Data were collected across 175 school system intervention sites located across the US and the UK during 2009-2013. All sites received training and support delivering the intervention from Project SEARCH. A database was created to measure Project SEARCH effectiveness including whether each student was employed, where they were employed, hourly wage, and hours/week worked. Data were collected from 4275 individuals (3467 did not have ASD but had other DDs; 808 had ASD).

Results: Gender and presence of multiple disabilities were included as covariates in logistic regression analyses of diagnosis (ASD vs. Non-ASD) because the diagnostic groups significantly differed from one another on these factors and these factors were related to employment outcomes. The effect of ASD on whether individuals were employed at the end of Project SEARCH was examined. ASD diagnosis significantly affected employment (p=.001) with those with ASD being less likely to be employed than those without ASD (53% versus 61%). Additionally, hours worked per week and hourly wages were examined for those employed using ANOVA. ASD diagnosis significantly affected hours worked [p=.02; marginal means: ASD=22.6 hours/week, non-ASD=24.5 hours/week]. However, ASD diagnosis did not affect hourly wages [ASD=$9.20/hour, non-ASD=$9.15].

Conclusions: Roux et al. (2013) reported that 33% of individuals with ASD 1-4 years post high school were currently employed and those employed earned an average $8.10/hour. The rates observed here were considerably higher (53% individuals with ASD currently employed at an average of $9.20/hour). However, those with ASD were less successful at obtaining employment and worked fewer hours than individuals with other DDs. This study represents one of the largest examinations of adult ASD employment interventions and shows that while Project SEARCH is effective for individuals with ASD, it is less successful than for other DD populations. Possible ASD specific modifications to Project SEARCH to increase its efficacy will be discussed.

Panel Session
135 - From Genomic Discovery to Genetically Defined Autism Subtypes
10:30 AM - 12:30 PM - Grand Ballroom D

Panel Chair: Brian O'Roak, *Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR*

Discovering the genetic basis of idiopathic autism spectrum disorder has been challenging. Recently, new genomic approaches leveraging exome sequencing have identified large numbers of new candidate genes based on new or "de novo" mutations in families with a single affected child, so called simplex families. Even with the likelihood of hundreds of genes involved, many genes are now moving beyond candidates to bona fide risk factors for autism. Detailed analysis of genetically defined autism subtypes may revolutionize our understanding of the disorder and provide significant targets for interventions. In this session, the results of the complete sequencing of the Simons Simplex Collection, ~2,500 families will be presented. The roles of different mutation types and classes of genes will be addressed, as well as how roles may differ in boys and girls with autism. We will also explore how novel biomolecular modules relevant to autism are being discovered using emerging data from the developing brain and new computational approaches. These potentially link many risk genes together into common pathways. Finally, the session will end with detailed discussions of two new genetically defined autism subtypes, unexpected clinical associations, and rationale for moving forward with this genotype first approach.

10:30 **135.001** Defining the Contribution of Different Classes of De Novo Mutation to Autism

I. Iossifov[1], B. J. O'Roak[2], S. J. Sanders[3], M. Ronemus[4], N. Krumm[5], D. Levy[4], J. Shendure[6], E. E. Eichler[7], M. W. State[3] and M. Wigler[4], (1)Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, (2)Oregon Health & Science University, Portland, OR, (3)Psychiatry, UCSF, San Francisco, CA, (4)CSHL, Cold Spring Harbor, NY, (5)University of Washington, Seattle, WA, (6)Department of Genome Sciences, University of Washington, Seattle, WA, (7)Howard Hughes Medical Institute, Seattle, WA

Background: Genetics is a major contributor to autism spectrum disorders (ASD) and the role for de novo (DN) mutations in these disorders has been established

Objectives: We sought to make precise estimates of the contributions of different types of de novo mutations in different classes of idiopathic autism.

Methods: We used comparative genomic hybridization (CGH) over ~1,000 families, whole exome sequencing (WES) over ~2,500 families and whole genome sequencing (WGS) over 40 families from the Simons Simplex Collection (SSC), each with a single affected child.

Results: We found that children with ASD have an increased incidence of DN missense, 'likely gene-disrupting' (LGD), and copy number variant (CNV) mutations compared to unaffected siblings. We estimated that 70% of DN CNV, 42% of DN LGD and 13% of DN missense mutations contributed to 6%, 9% and 12% of diagnoses in simplex families, respectively. DN mutation in coding sequence contributes to nearly 30% of all simplex and 45% of female diagnoses. We found a list of ~40 genes

with DN LGD mutations in more than one affected child. Males with DN LGDs or DN CNVs have lower IQ. The gene targets of DN LGDs in ASD males with lower IQ overlap with targets in ASD females and with individuals having intellectual disability or schizophrenia, but not significantly with targets in ASD males having higher IQ. We estimate the number of vulnerable genes in which LGD mutation can cause ASD in females or lower IQ ASD in males to be ~400, with a similar number of genes vulnerable to missense mutation. LGD targets are enriched for chromatin modifiers and FMRP-associated genes in both affected males of lower IQ and females. Embryonically expressed genes are significantly enriched in DN targets, LGD and missense, only in affected females.

Conclusions: WES and CGH have proven to be powerful tools for understanding the genetic architecture of ASD and for identifying ASD genes. But larger family collections will be necessary to identify the majority of the ASD genes and to characterize DN mutation in non-coding regions through WGS.

11:00 **135.002** The Discovery of Gene Modules for Autism Utilizing Co-Expression and PPI Networks

F. Hormozdiari[1], O. Penn[1], E. Borenstein[1] and E. E. Eichler[2], (1)University of Washington, Seattle, WA, (2)Howard Hughes Medical Institute, Seattle, WA

Background:
Despite extensive genetic heterogeneity underlying disorders such as autism spectrum disorders (ASD) and intellectual disability (ID), there is compelling evidence that risk genes will map to a much smaller number of biologically functional modules. However, discovering and distinguishing between these modules is still a major challenge.
Objectives:
We introduce a novel computational method (MAGI) for the discovery of disease modules enriched for mutations in probands and apply it to the recently published *de novo* mutations from ASD/ID samples to discover ASD biomolecular modules with specific phenotypic properties.
Methods:
MAGI simultaneously considers protein-protein interaction and RNAseq expression profiles during brain development. It is based on a combinatorial optimization algorithm that aims to find modules of genes that maximize the number of mutations seen in cases and limit the number of mutations observed in controls, while ensuring a high number of protein interactions and high coexpression among these genes. The method first finds a set of small seed pathways, enriched in *de novo* mutations, and then merge them into larger modules using a local search approach.
Results:
Applying the method to published exome sequencing data from 1,116 ASD and ID patients, we discovered two distinct modules ($p < 0.005$) that differ in their properties and associated phenotypes. The first module consists of 80 genes associated with the Wnt and Notch signaling pathways. In addition the module is significantly enriched in genes associated with chromatin remodeling and transcription regulations. Probands with truncating mutations in this module are enriched for micro and macrocephaly (KS test $p = 0.013$). The second module associated with synaptic function, including long-term potentiation and shows higher levels of postnatal expression. Probands with *de novo* mutations in these modules are found to have lower IQ. In addition, missense mutations in both modules are predicted to be more deleterious. Applying the method independently to epilepsy and schizophrenia exome sequencing cohorts, we found marked overlap among modules suggesting shared common neurodevelopmental pathways. Furthermore, analyzing the full Simon Simplex Collection (SSC) and Autism Sequencing Consortium (ASC) studies revealed an 8.1-fold enrichment of newly discovered *de novo* mutations in these two predicted modules ($p < 10^{-8}$). Preliminary results of adding mutations found in the full Simons Simplex Collection (SSC) to the analysis (2,661 probands in total) identification more refined and biologically coherent modules (e.g. SWI/SNF complex, Wnt signaling, long-term potentiation, proteasome, and ubiquitin-mediated proteolysis pathways).
Conclusions:
Our approach provides a molecular framework for reducing the genetic heterogeneity of these diseases and a method for identifying *de novo* missense mutations important in ASD etiology. We believe that using MAGI to find more refined gene modules for ASD will not only improve our understanding of relevant biological pathways important for neuronal development in general and autism specifically, but also has the potential to further refine distinguished subtypes of ASD that may lead to the development of future specific disease therapy.

11:30 **135.003** Disruptive CHD8 Mutations Define a Subtype of Autism Early in Development

R. Bernier[1], H. A. Stessman[2], B. Coe[1], J. Gerdts[1], B. J. O'Roak[3] and E. E. Eichler[4], (1)University of Washington, Seattle, WA, (2)Genome Sciences, University of Washington, Seattle, WA, (3)Oregon Health & Science University, Portland, OR, (4)Howard Hughes Medical Institute, Seattle, WA

Background: Autism spectrum disorder (ASD) is a heterogeneous disorder with significant genotypic and phenotypic complexity (Geschwind, 2009). While various behaviorally defined subtypes have been proposed, these have not been tied to genetic etiology, linked to treatment indicators, nor been diagnosed consistently by expert clinicians (King et al, 2014). Indeed, with the transition to the DSM-5, all behaviorally defined subtypes have been subsumed by the umbrella term Autism Spectrum

Disorder, allowing for identification of subtypes more closely aligned to biological mechanisms (APA, 2013). The genetic etiology of ASD is no less varied. Over 100 genes and genomic regions have been suggested as candidates or associated with ASD (Betancur, 2011), and over 800 genes have been predicted to play a role in ASD (Iossifov et al, 2012; Neale et al, 2012; O'Roak et al, 2012a; Sanders et al, 2012). Given that parsing the behavioral heterogeneity has yielded limited utility, genetically defined subtypes may prove more beneficial in illuminating molecular mechanisms underlying ASD, the course and prognosis of a subgroup of individuals with ASD, and individualized treatment targets. Severe disruptive mutations in chromodomain helicase DNA binding protein 8 (*CHD8*) have been strongly associated with ASD and provide a likely candidate for a specific subtype of ASD (O'Roak et al, 2012b; Talkowski et al, 2012; Neale et al, 2012).

Objectives: To determine if *CHD8* mutations define a specific subtype of ASD through the identification of patients, comprehensive follow up evaluation, and extensive phenotype-genotype correlations.

Methods: Expanding upon our description of individuals with truncating mutations to CHD8 reported in Bernier et al, 2014, we identified a total of 25 independent mutations through targeted sequencing (N=22) of 7,097 individuals with autism or developmental delay from multiple research cohorts as well as through clinical referral (N=3); no truncating events were identified in 8,916 controls, including 2,413 unaffected siblings. We re-contacted all patients and their families who were willing to participate in follow up assessment (N=18) and collected medical records for those unavailable for assessment (N=7). In-depth, structured clinical assessment, review of medical records, and medical/dysmorphological evaluation was conducted. Clinical assessment included diagnostic assessment and evaluation of cognitive, adaptive, language, motor, and executive functioning abilities.

Results: ASD was the most common diagnosis observed in our cohort. Of the 25 identified individuals evaluated, 23 meet strict diagnostic criteria for ASD. Although patients varied in age from 4-41 years of age, we observed striking similarities in their facial characteristics. Predominant features included increased occipitofrontal circumference (OFC), pronounced supraorbital brow ridges, hypertelorism with down-slanted palpebral fissures, broad nose with full nasal tip, and pointed chin. Other recurrent physical features included slender, tall build and large, flat feet, which were reported in several individuals. 80% of individuals reported significant GI problems, characterized as recurrent and consistent problems with constipation. Cognitive ability ranged from intellectual disability to average functioning. Sleep problems were common as was precocious puberty in the female patients.

Conclusions: Our findings indicate that *CHD8* disruptions define a distinct ASD subtype and reveal comorbidities between brain development and enteric innervation.

12:00 **135.004** The Transcriptional Regulator Adnp Links the Nbaf(mSWI/SNF) Complexes with Autism

***F. Kooy**[1], G. Vandeweyer[1], C. Helsmoortel[1], A. Van Dijck[1], C. Romano[2], B. de Vries[3], E. E. Eichler[4] and N. Van der Aa[1], (1)University of Antwerp, Antwerp, Belgium, (2)Oasi Institute, Troina, Italy, (3)Radboud Universtiy Medical Center, Nijmegen, Netherlands, (4)Howard Hughes Medical Institute, Seattle, WA*

Background:
Mutations in ADNP were recently identified as a frequent cause of syndromic autism, characterized by deficits in social communication and interaction and restricted, repetitive behavioral patterns. remodeling complex. Compared to controls, the frequency of truncating mutations in ADNP is significantly higher in patients (p:0.001852, odds ratio 13.24668, one-sided Fisher's exact test). We estimated this gene to be mutated in approximately 0.2% of ASD cases, making it one of the most frequent ASD genes known to date. Based on its functional domains, ADNP is a presumed transcription factor.

Objectives:
To understand more of the functional and clinical consequences of mutations in ADNP.

Methods:
A detailed and systematic clinical assessment of the symptoms observed in our patients allows a detailed comparison with the symptoms observed in other SWI/SNF disorders. Functional studies include the expression profiling of the mutated cell lines.

Results:
The gene interacts closely with the SWI/SNF complex by direct and experimentally verified binding of its C- terminus to three of its core components. While the mutational mechanism of the first 10 patients identified suggested a gain of function mechanism, an additional patient reported here is predicted haploinsufficient. The latter observation may raise hope for therapy, as addition of NAP, a neuroprotective octapeptide named after the first three amino acids of the sequence NAPVSPIQ, has been reported by others to ameliorate some of the cognitive abnormalities observed in a knockout mouse model.

Conclusions:
While we are beginning to understand the genotype-phenotype correlation, it is concluded that detailed clinical and molecular studies on larger cohorts of patients are necessary to establish a better insight in the genotype phenotype correlation and in the mutational mechanism.

**Panel Session
136 - Co-Occurring Psychiatric Disorders and the Lifecourse in ASD: Clinical**

and Epidemiological Perspectives
10:30 AM - 12:30 PM - Grand Salon

Panel Chair: Connor Kerns, *AJ Drexel Autism Institute, Drexel University, Philadelphia, PA*

Discussant: Brian Lee, *Drexel University School of Public Health, Philadelphia, PA*

There is a growing body of evidence that individuals with autism spectrum disorder (ASD) frequently experience co-occurring psychiatric symptoms. This scientific panel integrates clinical and epidemiological perspectives to examine the conceptualization, measurement, and negative outcomes of this co-occurrence. Our first talk highlights key insights regarding the conceptualization of psychiatric syndromes in ASD derived from clinical evaluations of several thousand children and adolescents with ASD, other psychiatric syndromes and typical development. Talk 2 synthesizes the literature on comorbid psychopathology in ASD, examining how different measurement approaches may influence prevalence estimates. Using national data, talks 2 and 3 then examine the relationship of co-occurring psychiatric symptoms in ASD to life course outcomes, in particular adverse childhood experiences and criminality. The overarching goal of this panel will be to consider the implications of co-occurring psychiatric syndromes in ASD to epidemiologic research, clinical practice and public health – that is, to consider how our conceptualization of psychiatric co-occurrence may inform etiological models, measurement and treatment development as well as our ability to address the real-word service needs of individuals with ASD.

10:30 **136.001** Programmatic Research into Co-Occurring Psychiatric Syndromes in Autism Spectrum Disorder

K. D. Gadow, *Psychiatry, Stony Brook University, Stony Brook, NY*

Background: People with autism spectrum disorder (ASD) commonly experience the symptoms of a wide range of non-ASD psychiatric syndromes, which raises a number of questions about diagnosis and treatment and has important implications for models of pathogenesis. Do seeming psychiatric syndromes meet conventional criteria for diagnostic validity? To what extent are psychiatric syndromes in ASD similar to or different from disorders diagnosed in typically developing (TD) individuals? Do the core deficits associated with ASD alter the clinical presentation of traditionally-defined syndromes? Are psychiatric syndromes in ASD associated with the same clinical correlates (risk factors) as similar syndromes in TD populations. Is the assessment of co-occurring symptoms clinically informative?
Objectives: For the past 20 years our research team has addressed these and related questions in children and adolescents referred for clinical evaluation of ASD and non-ASD psychiatric syndromes as well as community-based TD samples. This presentation summarizes the results of these studies and suggests directions for future research.
Methods: Parents and teachers completed a DSM-IV-referenced rating scale with established psychometric properties in several thousand children and adolescents (ages 3-18 years) with ASD, psychiatric referrals, and public school children. The parents of the referred children also completed an extensive background questionnaire that included a range of psychosocial variables commonly used in epidemiologic and case-control studies, and subsamples of these youth are currently participating in genetic and imaging studies
Results: Co-occurring psychiatric symptoms in ASD appear to meet conventional criteria for diagnostic validity, share many similarities with conventional DSM-defined syndromes, result in relatively high levels of symptom-induced impairment, are associated the important real-world outcomes, and evidence similar biopsychosocial clinical features (risk factors) as comparable syndromes in TD populations. Nevertheless, findings from studies comparing ASD and TD samples also evidence group differences therefore challenging conventional ideas about nosology
Conclusions:
Evidence for the existence of behavioral syndromes within the ASD clinical phenotype is compelling. Moving forward, future studies will need to address not only diagnostic heterogeneity within ASD (e.g., HFA, males) and heterogeneity in co-morbidities (e.g., anxiety) but also heterogeneity within co-morbid symptoms (e.g., social anxiety) and heterogeneity in etiological pathways (e.g., stress, cytokines). The incorporation of neuroscience into traditional, behaviorally-oriented research strategies for addressing the real-world service needs of people with ASD holds considerable promise for answering some of the more vexing questions about diagnosis and nosology and is essential in examining pathogenic processes, developmental trajectory, and response to intervention.

10:55 **136.002** Modifying Symptom and Diagnostic Criteria for Additional Psychiatric Disorders in ASD: What Is the Evidence?

E. Simonoff, *Department of Child and Adolescent Psychiatry, King's College London, London, United Kingdom*

Background: Research has consistently demonstrated that a high proportion of people with ASD experience additional mental health problems and fulfil the diagnostic criteria for other psychiatric disorders, such as ADHD, oppositional defiant disorder, anxiety disorders and depression. The reported rates are extremely high, with more than 70% of individuals fulfilling criteria for at least one psychiatric disorder, and this has raised questions about the conceptual diagnostic framework, the

breadth of autism spectrum and the appropriate methods to evaluate symptomatology amongst people with ASD. Psychopathology studies have used two assessment methods: (1) standardized instruments, including questionnaires and interviews, applied in the usual way and (2) modified measures, in which the questions and/or symptom criteria have been modified. At present there is a lack of systematic comparison of the two methods and hence no consensus regarding the best strategy for evaluation psychiatric symptoms and disorders in people with ASD.

Objectives: To improve understanding of the different methods of psychopathology assessment in ASD and their implications for the prevalence, comorbidity and risk factors.

Methods: A systematic review of articles reporting on the prevalence and co-occurrence of psychopathology amongst people with ASD is undertaken. Databases used to ascertain articles were Medline, PsycInfo and PubMed, which were searched for the last 20 years. This includes both clinical and population-based samples but is limited to main areas of psychopathology, including behavioural (oppositional defiant and conduct) disorder, affective (anxiety and mood) disorder and ADHD. As well as classifying studies according to the use of standardized vs ASD-modified assessment criteria, articles are also stratified according to participant age, level of intellectual functioning, and informant used to assess psychopathology.

Results: Data review and analysis is underway. The focus will be on whether there are systematic differences in the prevalence and patterns of co-occurrence of psychiatric symptoms and disorders according to the method of assessment and accounting for other factors.

Conclusions: The implications of standardized vs ASD-specific assessment methods will be discussed in light of the findings. Comparison will be made with other instances in which this issue has been explored, e.g., affective disorders in children, psychiatric diagnosis in significant intellectual impairment.

11:20 **136.003** Adverse Childhood Experiences and ASD: The Role of Co-Occurring Psychiatric Symptoms

C. M. Kerns[1] and B. Lee[2], (1)Drexel University, Philadelphia, PA, (2)Drexel University School of Public Health, Philadelphia, PA

Background: Children with autism spectrum disorders (ASD) are at risk for adverse childhood experiences (ACEs) such as domestic violence or family socioeconomic hardship, which predict numerous negative outcomes later in life. However, the extent to which children with ASD experiences ACEs, relative to children without ASD, is not known.

Objectives: We describe differences in the prevalence of ACEs for children with and without ASD in a nationally representative sample of children in the U.S. Furthermore, we investigate whether such differences may be attributable to co-occurring psychiatric symptoms.

Methods: We examined data on 84,352 children (ages 2-17 years; 1,608 with ASD) from the 2011-2012 National Survey of Children's Health conducted by the CDC. Cross-sectional data were obtained from parental self-report. Specific ACEs of interest included socioeconomic hardship, parental separation, household substance abuse, neighborhood violence, household mental illness, domestic violence, parental incarceration, and parental death. The presence of parent-reported co-occurring psychiatric symptoms (anxiety problems, depression, behavioral or conduct problems, and AttentionDeficit-Hyperactivity Disorder (ADHD)) was also assessed. All analyses accounted for the complex survey sampling design using sample weights.

Results: While 24.4% of children without ASD were reported as having multiple (2+) ACEs, 34.4% of children with ASD had multiple ACEs. Similarly, 42.4% of children with ASD were reported as having at least one co-occurring psychiatric symptom, as compared with only 6.0% of children without ASD. For many of the specific ACEs examined, children with ASD experienced more ACEs than children without ASD. For example, children with ASD were twice as likely to have lived with someone who was mentally ill or suicidal, compared to children without ASD (18.1% vs. 9.1%). In survey-weighted logistic regression models adjusting for age, sex, race, family structure, and poverty level, children with ASD were more likely to have multiple ACEs than children without ASD (OR: 1.66, 95% CI: 1.18-2.34). However, after further adjustment for the presence of a co-occurring psychiatric symptom, children with ASD were no more likely to have multiple ACEs than children without ASD (OR: 0.92, 95% CI: 0.66, 1.30).

Conclusions: Children with ASD experience ACEs at a higher rate than children without ASD. However, this appears to be largely explained by the co-occurrence of psychiatric symptoms, such as anxiety, depression, behavioral or conduct problems, and ADHD.

11:45 **136.004** Autism Spectrum Disorders and Criminal Convictions: The Role of Psychiatric Comorbidity

*R. Heeramun[1], C. Magnusson[2], C. H. Gumpert[3], S. Granath[4], C. Dalman[5], M. Lundberg[5] and **D. Rai**[6,7], (1)Avon and Wiltshire Mental Health Trust, Bristol, England, United Kingdom, (2)Karolinska Institutet, Stockholm, Sweden, (3)Centre for Psychiatry Research & Education, Karolinska Institutet, Stockholm, Sweden, (4)Research and Development Unit, The Swedish National Council for Crime Prevention, Stockholm, Sweden, (5)Department of Public Health Sciences, Karolinska Institutet, Stockholm, Sweden, (6)Avon and Wiltshire Partnership NHS Mental Health Trust, Bristol, United Kingdom, (7)Centre for Academic Mental Health, University of Bristol, Bristol, United Kingdom*

Background: The literature related to criminal offending in individuals with autism spectrum disorders (autism) is inconsistent. It is still unclear whether individuals diagnosed with autism are more likely to

engage in, or be convicted for criminal activity. Importantly, there is little information on potentially modifiable factors, such as psychiatric co-morbidity, that may help identify individuals at high risk of criminal activity and inform preventative strategies.

Objectives: To test the following hypotheses: 1) that individuals with autism are more likely to receive a criminal conviction than the general population in Sweden, and 2) that potentially treatable psychiatric co-morbidities may be important factors that modify this risk.

Methods: Longitudinal population-based study based on a record-linkage cohort of all non-adopted singletons in Sweden born between 1984 and 1995 with data on both biological parents and at least 15 years (the age of criminal responsibility in Sweden) follow up until 31 December 2011 (n=1,339,255 including n=15,368 with autism). Unique personal identification numbers were used to link data with the National Crime Register and other Swedish health and administrative registers leading to an information rich cohort with extensive data. After testing the proportional hazards assumption, the risks of criminal convictions in individuals with autism compared with those without were estimated using Cox proportional hazards regression models. The models were adjusted for various individual and family level socioeconomic and demographic characteristics.

Results: Individuals with autism appeared to be at a higher risk of having criminal convictions than those without [Hazard Ratio (HR) 1.31, 95% Confidence Interval (CI) 1.26-1.37]. However, stratifying the risk estimates by a recorded history of co-morbid psychiatric diagnosis revealed that: as compared to individuals without a diagnosis of autism or psychiatric conditions, individuals with autism with a psychiatric co-morbidity were more likely [adjusted HR 1.45 95% CI (1.39-1.52)], but those with autism without a co-morbid psychiatric diagnosis were less likely [adjusted HR 0.59 95% CI (0.51-0.67)] to be convicted for a criminal offence in Sweden. Further analyses on the types of criminal activity (e.g. convictions for violent vs. non violent crimes) and the role of individual co-morbidities (e.g. ADHD, conduct disorder, psychotic disorders) is underway and will be presented at the meeting.

Conclusions: These preliminary results suggest that co-morbid psychiatric conditions may be a major factor in relation to the risk of criminal offending in individuals with autism.

Poster Session
137 - Innovative Technology Demonstrations
10:00 AM - 1:30 PM - Imperial Ballroom

1   **137.001** Shared Genomic Segments (SGS) Analysis Method: Application to Extended Utah Pedigrees at High Risk for ASD

V. Rajamanickam[1], T. M. Darlington[2], R. Sargent[1], N. J. Camp[1] and H. Coon[2], (1)Genetic Epidemiology, University of Utah, Salt Lake City, UT, (2)Psychiatry, University of Utah, Salt Lake City, UT

Background: Shared Genome Segments (SGS) analysis is a method used to identify shared regions of DNA among cases using high-density SNP genotypes. These regions can then be used to prioritize subsequent experiments to search for causal sequence variants. This approach will be particularly advantageous when functionally relevant variants are regulatory, allowing an investigator to focus on full targeted sequencing with an SGS region, a compliment to the whole exome approach.

Objectives: The method will be described in detail, including a flow chart of the steps required to apply the method successfully, input file formats, examples of run commands, example output, and a visualization tool for output. We have analyzed extended pedigrees at high risk for Autism Spectrum Disorder (ASD). Different options to apply the method using this data resource will be demonstrated.

Methods: The SGS test identifies if the length of consecutively shared SNPs, identified as identical-by-state, or IBS, is longer than expected by chance. IBS is established by determining if allelic types at sequential SNPs are consistent across cases. IBS does not infer identity-by-descent (IBD; the same inherited segment from a common ancestor) which is our true interest. However, if the length of SGS shared IBS is significantly longer than by chance, given the known relationships, then IBD is implied. Theoretically, chance IBD sharing in distant relatives is extremely improbable. Genomewide statistical significance can be found for pedigrees with at least 15 meioses. SGS is efficient, and can have more power than traditional association tests.

Results: Pedigree members were genotyped using the Illumina HumanOmniExpress12v1.1 array. While SGS can be used to test for sharing across all pedigree cases, due to heterogeneity we did not expect all affected cases to share the same segments in these large pedigrees. We therefore started with a program option, weighted pairwise SGS (wpSGS), which combines sharing across all possible pairs, weighted by number of meioses between the pairs. We show results of wpSGS; with the increased length illustrated by the ratio against both internal pedigree controls, and also to unrelated controls (pairs selected from 168 North-West European individuals—CEU/GBR—from the 1000 Genome Project). Statistical significance for observed SGS regions (p-values) are estimated by generating null genome simulations (a user-specified number), based on a genetic model estimated from the 1000 Genome Project controls.

Conclusions: We present a flow chart and example commands to use the software with different analysis options and control sets. We show input file structures and format of the output. We show how the null genomes are simulated; including incorporation of linkage disequilibrium (LD) and a

recombination model. We show how SGS can also be set up for validation testing of sharing across subsets of pedigree cases identified by wpSGS. We demonstrate additional software to visualize and prioritize results. Through this demonstration, we show that SGS is an easily applied, efficient, useful pedigree analysis tool in the search for susceptibility variants for complex diseases, such as ASD.

2   **137.002**   Creating a Spatial Data Architecture for the National Database for Autism Research

M. L. Miranda[1,2], P. Maxson[1], N. Sandberg[1] and D. Hall[3], (1)National Center for Geospatial Medicine, University of Michigan, Ann Arbor, MI, (2)School of Natural Resources and Environment, University of Michigan, Ann Arbor, MI, (3)Omnitec Solutions Inc., Bethesda, MD

Background: The etiology of autism spectrum disorder (ASD) remains largely unknown. While genetic vulnerabilities have been linked to development of ASD, much remains unexplained. Researchers have begun to identify social and environmental stressors that might influence early brain development which may manifest as changes commonly associated with ASD. Linking social and environmental data to the clinical, genomic, and imaging data in the National Database for Autism Research (NDAR) holds great potential for building a more robust research platform for basic science and clinical research on ASD.
Objectives: The National Institute for Mental Health, Omnitec, and the National Center for Geospatial Medicine (NCGM) at the University of Michigan are partnering to capture geospatial information on families affected by ASD. The collaborative team is especially interested in residential information on parents and children over both space and time. The resulting spatially-enabled data architecture will link environmental and social data to existing NDAR data. By combining clinical, social, and environmental data on a national scale, scientists can investigate the relationships among chemical and non-chemical stressors and ASD.
Methods: NCGM will employ strategies to consent families living with ASD, many of whom may already be enrolled in the NDAR. NCGM will launch a website through which affected families can enter self-reported information. Families will complete a short, secure, online questionnaire designed to gather geographic data to facilitate linkage of NDAR clinical, genomic, and imaging data with social and environmental exposure data.
Results: The resulting website and subsequent datasets will facilitate collaboration across families, clinicians, and researchers to better understand autism spectrum disorder. This national effort will grow as families become more aware of the resource. Once clinical information is linked with social and environmental data, the research community will be able to look at spatial relationships. Spatial patterns in the data can inform new research questions as well as identify areas for targeted recruitment and intervention strategies.
Conclusions: This ground-breaking effort will be the first of its kind to generate self-reported patient information that is geographically linked to relevant social and environmental stressors and to further connect those datasets with research-grade data captured by NIH-funded laboratories. Long-term benefits of this effort include the building of collaborative relationships among affected families, clinicians, and scientists; the creation of nationally-based samples for future research; and increased awareness and understanding of autism spectrum disorders.

3   **137.003**   Delsia: An Innovative Funding Vehicle That Is Turning Science and Technology into Reality for the Autism Community

D. G. Smith[1], E. Clayton[2] and R. H. Ring[3], (1)Autism Speaks, Boston, MA, (2)Autism Speaks, New York, NY, (3)Autism Speaks, Princeton, NJ

Background:
The autism community is faced with a staggering array of unmet medical and behavioral healthcare needs. Research alone will not answer the urgent call for improved healthcare and quality of life coming from individuals, parents and family members living with autism. It is essential that scientific and technological research advances are translated into innovative and accessible products that can transform lives.
A translational "valley of death" is readily apparent along the continuum from autism research to product commercialization. The system for capitalizing new product development, where risk and need are the greatest, is broken. Government funding agencies and academia are not in the business of bridging this gap, and financial return may be too small or speculative for traditional venture investors. Innovative funding models that involve mission-driven nonprofit partners are necessary to expand the impact of basic research.
Objectives:
Our objective is to bridge the "valley of death" with a new, innovative funding mechanism, Delivering Scientific Innovation for Autism LLC (DELSIA). The mission for DELSIA is to transform lives by accelerating the development and commercialization of innovative products that promise to improve healthcare and quality of life for people with autism.
Methods:
DELSIA partners with entrepreneurs, start-ups and small and large companies in biomedical, life sciences, software and electronic technology and services sectors. We aim to efficiently apply our capital and to engage our community and unparalleled network of autism advocacy, research and services experts to deliver the most impactful results.

Results:
DELSIA has given financial awards to businesses and entrepreneurs in biomedical and software technology sectors, and is actively seeking new investment opportunities that span our scope of interest.
Conclusions:
Novel funding models involving nonprofit venture philanthropic enterprises are necessary to repair the broken links between early research and late-stage product development. DELSIA was created to meet this need through partnering with entrepreneurs and companies that are developing products and services for the improvement of healthcare and quality of life for the autism community.

4 **137.004** A Novel Approach for Efficient Submission of Research Data to the National Database for Autism Research (NDAR)

P. Langthorne, *F. Farach, D. Voccola, C. Tirrell and L. Rozenblit, Prometheus Research, LLC, New Haven, CT*

Background: Researchers seeking to share their data with coordinating centers such as NDAR, face numerous barriers to establishing new connections and maintaining existing ones, including the high cost of restructuring or recoding datasets and disconnects between dataset attributes.
Objectives: We sought to dramatically reduce the time and money required to establish and maintain the interoperability of data between research centers, with particular attention to interfacing with NDAR. The ideal solution would maintain high data quality on both sides of the interaction, so that all beneficiaries of the data sharing agreement would have high confidence in the accuracy of the data. The solution needed to scale to large volumes of research data collected without a substantial increase in the effort required to establish or maintain the sharing connection.
Methods: We created a process where manual recoding of data is replaced by data sharing instructions in the form of extraction and transformation scripts. These scripts are stored in revision-controlled file repositories accessible to all members of the data sharing team. The source data from transmitting researchers are stored in relational databases built on the RexDB® platform, while the data sharing team works exclusively on the data extraction and transformation scripts. This division ensures that the researchers' data are not impacted or altered in any way. NDAR receives flat data files that conform fully to the organization's published expectations for data structure and assessment values, while researchers continue to enter and analyze data in structures with which they are familiar.
Results: Over the course of seven typical (20-60 subjects, 400-1000 fields each) data submissions to NDAR, the need for duplication, retranscription, or restructuring of the source data is fully eliminated. Separating the extraction and transformation scripts from data files has also eradicated the impact of additional data collection on the time required to repeat successful transmissions. Revision controlled management of these scripts provides a new benefit: traceability of the transformation process itself. Now, point-in-time retrieval of extraction scripts and explanations for modifications to the data sharing interface are possible. None of the datasets provided to NDAR within this framework drew any audits or revision requests following any of the submissions, an indication of the high data quality levels achieved.
Conclusions: This method has proven to be successful and efficient for interfacing research data with NDAR. It presents little-to-no impact to transmitting investigators' data, ensures high data integrity, trivializes the complexities of repeatedly modifying a growing dataset over time, and introduces traceability to the collaborative process of integrating two collections of data with one another. Anecdotal evidence indicates that NDAR submissions have transformed from a time consuming process into an opportunity to improve the quality of research data for future analyses. As this framework becomes more widely utilized, we expect even broader adoption of ad-hoc data sharing agreements within the research community, permitting researchers to investigate questions of increasing complexity.

5 **137.005** Olfactory Detection Thresholds in Children with Autism Spectrum Disorders Using Pulse Ejection Systems

H. Kumazaki[1,2], A. Tomoda[1], K. Okada[3], T. Muramatsu[2] and M. Mimura[2], (1)Research Center for Child Mental Development, University of Fukui, Yoshida-gun, Fukui Prefecture, Japan, (2)Department of Neuropsychiatry, School of Medicine, Keio University, Tokyo, Japan, (3)Department of Information & Computer Science , Graduate School of Science and Technology, Keio University, Yokohama, Japan

Background: Sensory abnormalities occur in patients with autism spectrum disorder (ASD) worldwide. Unusual reactions to odor stimuli are well known sensory symptoms in ASD. However, olfactory laboratory tests have provided limited information about such abnormalities in ASD. Conventional techniques for measurement of olfactory function have problems of dispersion of scents in the air, and tedious examination.
Objectives: In this study, we used an olfactory measurement that uses pulse ejection. Pulse ejection systems are capable of presenting scents for a short duration even at the picoliter level. Unlike existing techniques for measurement of olfactory function, our olfactory display employs pulse ejection and measures olfaction by varying the quantity of ejected odorant. The odor detection

threshold can be quantified by the ejection quantity. This allows the pulse ejection system to quantify the human ability to smell with great precision. This study examined odor detection thresholds with this new system for measurement of olfactory function in a sample of adolescents with ASD.
Methods: Of the 30 participants, 15 were patients with ASD (3 women, 12 men) and 15, controls (3 females, 12 males). They were referred to our laboratory in August 2014 for examination of sensory symptoms. All the patients satisfied the diagnostic criteria for ASD in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (American Psychiatric Association, 2013). To exclude other psychiatric diagnoses, the Mini-International Neuropsychiatric Interview for Children and Adolescents was conducted by a licensed pediatric-psychiatric clinician. To obtain data from normal age-matched healthy controls (HC), healthy schoolchildren and adolescents aged 8–18 years were recruited from the community. None had a below-average IQ, physical problems, or psychiatric psychopathology. Odor detection thresholds were assessed using the olfactory measurement system with olfactory display by pulse ejection. The equipment comprised an ejection head that could hold three small and one large tank, for a maximum of four scents. We used isoamyl acetate and ethyl butyrate flavor for the odorants. The subjects' scores ranged between 10 and 160. Statistical analysis was performed with the Statistical Package for the Social Sciences, version 15.0. Descriptive statistics were used for the samples. Age differences between the groups were analyzed using the independent samples t-test. Differences in odor detection thresholds were analyzed using the Mann–Whitney U-Test.
Results: There were no significant differences between groups with regard to mean age and gender proportion. The odor detection threshold for both flavors was significantly impaired in the ASD group compared to the HCs (for the isoamyl acetate flavor; ASD, 75.6 ± 57.3 vs. HC, 17.8 ± 13.6; $p < 0.01$ and for the ethyl butyrate flavor; ASD, 78.9 ± 52.1 vs. HC, 12.2 ± 4.6; $p < 0.01$).
Conclusions: Odor detection for the isoamyl acetate and ethyl butyrate flavors was impaired in adolescents with ASD. Implications for further research are discussed.

6   **137.006** Feasibility of Ecological Momentary Assessment of Emotion in Adolescents with Autism Spectrum Disorders

M. L. Kovac[1], E. Hanna[2], S. Miller[3] and G. S. Dichter[4], (1)University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Duke University, Durham, NC, (3)Carolina Institute for Developmental Disabilities, University of North Carolina at Chapel Hill, Carrboro, NC, (4)University of North Carolina, Chapel Hill, NC

Background: Ecological Momentary Assessment (EMA) is a method of obtaining subjective information from respondents in a natural setting (Shiffman & Stone, 1998). EMA has been implemented successfully with different populations, including adolescents and severely mentally ill individuals (aan, Hogenelst, & Schoevers, 2012; Forbes et al., 2012); however, the feasibility of using EMA with adolescents who have Autism Spectrum Disorders (ASD) has only recently been investigated (Khor et al., 2014).
Objectives: EMA was used in the present study to gather subjective reports of affect and behavior in order to: (1) determine the feasibility of using a low-cost EMA protocol with this population (2) examine the frequency of social and nonsocial behavior and (3) examine positive affect (PA) among adolescents with and without ASD in real-world contexts.
Methods: Thirty-nine adolescents participated in the present study. Sample characteristics are displayed in Table 1.

Table 1: Sample Characteristics for Participants with EMA Data

	N	Mean Age	%Male	Mean IQ
ASD	19	14.11 (SD=3.33)	74%	102.2 (SD=16.9)
TD	20	14.5 (SD=1.96)	80%	113.1 (SD=10.6)

Participants with autism met criteria for ASD on the ADOS. Technology used in the EMA protocol was free to researchers in order to optimize accessibility and minimize cost. Prompts were delivered using automated Outlook messaging and surveys were accessed on Qualtrics by participants' home computers or smartphones. Six EMA prompts were delivered over the course of four days. Each prompt contained a link to an online survey which asked participants where they were when they were contacted, whom they were with, and what they were doing. Participants then completed the Positive and Negative Affect Scale for Children (PANAS-C) (Laurent et al., 1999) online.
Results: Participants completed 210 (out of 234) surveys, yielding a 90% response rate (94% among typically developing participants, 85% among participants with ASD). There was no correlation between age and the number of surveys completed (r=-.23, p>.16) or IQ and the number of surveys completed (r=.27, p>.05). With regard to behavior, there were no group differences in frequency of social or nonsocial behavior. However, when the nonsocial category was further divided into circumscribed interests for the ASD group and "Primary Interests" for the TD group, a group difference emerged, such that the ASD group participated in more circumscribed interests (relative to time spent engaging in primary interests in the control group), t=2.59, p=.01 (see Figure 1). There were no group differences in self-reported positive affect (*p*>.05).
Conclusions: The results of the present study confirm that EMA is a promising tool for research with individuals with ASD. Participants were highly adherent with the protocol, and there were no correlations between age and survey completion rates or IQ and survey completion rates. Notably, the EMA protocol was low-cost and accessible and thus has great potential for use in under-

resourced settings. Participants with ASD did not engage in nonsocial behaviors significantly more than their typically developing peers; however, they did engage in activities related to their circumscribed interests more than their peers engaged in hobbies or interests they identified as "primary."

7   **137.007** Can Virtual Reality be Used for Behavioral Analysis in Autism Spectrum Disorder? a Simulation for Interpersonal Distance Preference Assessment

M. Simoes[1,2], S. Mouga[1,3], A. C. Pereira[1], P. Carvalho[2], G. G. Oliveira[1,3,4,5] and M. Castelo-Branco[1,6,7], (1)Institute for Biomedical Imaging and Life Sciences, Faculty of Medicine, University of Coimbra, Coimbra, Portugal, (2)Center for Informatics and Systems, University of Coimbra, Coimbra, Portugal, (3)Unidade de Neurodesenvolvimento e Autismo do Serviço do Centro de Desenvolvimento da Criança, Pediatric Hospital, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal, (4)University Clinic of Pediatrics, Faculty of Medicine, University of Coimbra, Coimbra, Portugal, (5)Centro de Investigação e Formação Clínica, Pediatric Hospital, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal, (6)ICNAS Produção, Coimbra, Portugal, (7)ICNAS, University of Coimbra, Coimbra, Portugal

Background: Virtual reality technology (VRT) is frequently addressed as a possible approach for rehabilitation in individuals with autism spectrum disorder (ASD) by promoting improvement in social interaction abilities and executive function. However, few studies use fully immersive virtual reality setups and evidence on the ability of ASD subjects to interact in such environments in the same manner as they do in the real world is scarce.
Objectives: In this study we aim to evaluate the potential of VRT to assess behavioral measures in the study of interpersonal distance preference in ASD, interacting with an adult for conversation.
Methods: Five male teenagers with high-functioning ASD (9-12years, 10.8±1.64) and four neurotypical male teenagers (8-15years, 11.25±2.99) performed a stop-distance paradigm in two environmental settings: a real environment (open room) and its virtual replication. Participants were instructed to stop (or request it from the other person or avatar) when the interpersonal distance was comfortable for having a conversation. Two experimenters conducted the study: one male and one female of ages 25 and 30, respectively, without any previous contact with the participants. Once the participant established the distance, a waist-to-waist measure was taken with a digital laser measure. In the virtual replication, two virtual humans (VH) with the experimenters' apparent age were used. The experiment varied randomly in walking mode (approaching: starting away and walking towards; receding: starting close and walking away), the walking person (experimenter or participant), experimenter's gaze orientation (direct or averted) and gender of the experimenter. The same conditions were imposed in the virtual setup, where the user wore a head-mounted stereoscopic display (Oculus® Rift) and its position in the room was tracked via an infrared emitter (WorldViz® PPT), placing the participant in the virtual room matching his real position. When the participant established the distance to the VH, it was registered based on the virtual positions of him and the VH. Values were transformed into the eye contact distance. Statistical analysis were conducted with $\alpha=0.05$.
Results: Distances in the control group, for both real and virtual setups, matched a normal distribution ($p=0.2$ for real and $p=0.10$ for virtual setups), whereas ASD group did not ($p<0.01$ for both settings). Positive significant *Spearman's* correlations were found between real and virtual measured distances, for both ASD ($\rho(79) = 0.58$, $p<0.01$) and controls ($\rho(63) = 0.39$, $p<0.01$). In the ASD group, the real and virtual setups resulted in statistically equal distance evaluations (Wilcoxon signed ranks test: ṡ+=38.58; ṡ-=43.38; Z=-1.113; $p=0.27$; N=80). When comparing with the control group (Wilcoxon-Mann-Whitney test), the mean interpersonal distance of ASD group differed statistically in both real (U=2007; W=5247; $p=0.026$) and virtual setups (U=1812; W=5052; $p<0.01$).
Conclusions: Results indicate that the virtual setup achieved comparable results with the real setup. Moreover, differences from the control group found in both setups show that the computerized simulation was able to identify the deficits observed in the real environment. Such results enforce the idea that fully immersive technology might aid in the study and intervention in ASD, expanding the possibilities of rehabilitation techniques when incorporating this type of systems.

8   **137.008** Eye Tracking Analysis of Attention to Text for Children with Autism Spectrum Disorders

J. B. Plavnick[1], L. Skibbe[2], J. L. Thompson[1] and S. Bak[1], (1)Michigan State University, East Lansing, MI, (2)Human Development and Family Studies, Michigan State University, East Lansing, MI

Background: Despite the pivotal nature of learning to read, a sub-group of individuals diagnosed with autism spectrum disorder (ASD), typically those with co-occurring intellectual disabilities or speech and language impairments, lack the reading skills needed to achieve independence (Howlin, Goode, Hutton, & Rutter, 2004). Reading instruction for these children should therefore begin at an early age, with procedures known to enhance early literacy outcomes. However, it is currently unknown whether strategies that promote early literacy for typical children, such as print-salient, repetitive books coupled with simple words and print referencing, have the same impact on children with ASD.
Objectives: The primary objective of this study was to use eye tracking technology to examine how children with moderate to severe ASD differentially attended to pictures and text when presented with each on a computer screen. A second objective was to evaluate whether print referencing tactics (i.e., text highlighting) could increase the extent to which children attended to relevant textual and

pictorial cues.

Methods: Eleven children with moderate to severe ASD viewed two brief video displays, each lasting approximately 100 seconds, of textual and pictorial stimuli presented on a laptop computer. One display consisted of 14 unrelated slides of textual and pictorial stimuli and a second display consisted of a 13-page electronic book with related text and pictures across all pages. Presentation order was counterbalanced across participants. Eye gaze was assessed using the Tobii X2-60 portable eye tracking unit and Tobii Studio Professional Software. Using a within subject design, we compared total fixation duration (total seconds each child looks at the presented stimuli), total gaze directed toward text vs. picture, mean latency to fixation, and stimulus of initial fixation (text or picture) for each child during each video display.

Results: Some participants demonstrated higher levels of attention to stimuli in the unrelated slides and others to stimuli in the electronic book. Almost all participants demonstrated greater attention to pictures than to text, though print referencing tactics (highlighting) led to an increase in attending to text for some participants. In addition to statistical and visual analyses, we will demonstrate videos that depict the temporal path including fixations and saccades, as well as a video and audio recording of the child during the eye tracking session.

Conclusions: Overall, the participants in the present investigation were more likely to attend to pictorial and textual stimuli that was unrelated from one page to the next than to a repetitive electronic book. This is somewhat surprising given the consistent finding that children with ASD often perform better under predictable routines. The outcomes suggest print referencing, in the form of text highlighting, may be an effective early literacy intervention to increase attention to text among individuals with ASD. Eye tracking analyses of children with moderate to severe ASD when presented with pictures and text might provide important information that can be used to hypothesize potential early reading interventions for this group.

9   **137.009** The Effect of Gaze-Contingent Feedback on the Performance of Adolescents with ASD in a Virtual Reality Driving Environment

J. W. Wade[1], D. Bian[1], J. Fan[1], L. Zhang[1], A. Swanson[2], M. S. Sarkar[3], Z. Warren[2] and N. Sarkar[4], (1)Electrical Engineering and Computer Science, Vanderbilt University, Nashville, TN, (2)Vanderbilt University, Nashville, TN, (3)Computer Science, Middle Tennessee State University, Murfreesboro, TN, (4)Mechanical Engineering, Vanderbilt University, Nashville, TN

Background: Increasingly researchers are attempting to utilize virtual reality (VR) environments as paradigms for potential intervention with individuals with ASD. Recent studies examining VR driving environments have suggested that individuals with ASD may demonstrate atypical gaze patterns during driving tasks (Reimer et al., 2013; Wade et al., 2014). Given potential differences of gaze pattern and information processing during driving tasks (Sheppard et al., 2009), VR platforms that integrate feedback regarding gaze patterns may represent powerful tools for teaching driving skills.

Objectives: With this work, we introduce the design of, and preliminary experimental results from, a gaze-contingent VR driving environment. This system extends our previous work by (1) generating targeted feedback aimed at correcting inappropriate gaze patterns, (2) integrating electroencephalography (EEG) data acquisition as an additional metric of driver state and (3) investigating the effectiveness of such a system on a sample population.

Methods: A novel VR driving module was linked to various data acquisition modules in a local area network in order to measure a range of signals from participants. Eye gaze information was collected using a remote eye tracking device from Tobii at a sampling rate of 120 Hz. This information included gaze position as well as fixation duration times for key regions of the virtual environment. Eight channels of physiological signals were wirelessly logged at 1000 Hz and included ECG, PPG and GSR. In addition, EEG data were recorded wirelessly at 128 Hz. Two groups of adolescents with ASD aged 13 to 18 years were recruited for this study. One group received targeted feedback based on both driving performance and gaze pattern while the other group received feedback related only to performance. Participants in both groups participated in 6 lab visits, each lasting approximately one hour. Seven individuals in the gaze-contingent group and 9 in the strictly performance-based group completed the protocol.

Results: Analysis of the data indicates that there are significant differences between the two groups with respect to gaze pattern. Interestingly, the group receiving gaze-related feedback seems to show a shift in gaze pattern towards a pattern more characteristic of TD individuals. The gaze position of this group was on average 1.13 cm lower and 1.11 cm further to the left than the gaze position of the group receiving only performance-related feedback. Further analysis remains for other measures of performance and gaze as well as for EEG and physiology.

Conclusions: Individuals with ASD demonstrate gaze patterns while driving that may not be safe for optimal driving. Dynamic feedback related to gaze pattern during driving may shift gaze patterns of individuals with ASD towards a more appropriate pattern.

10   **137.010** Littlehelper: Using Google Glass to Assist Individuals with Autism in Job Interviews

Q. Xu[1], S. C. S. Cheung[2] and N. Soares[3], (1)University of Kentucky, Lexington, KY, (2)Center for Visualization and Virtual Environments, University of Kentucky, Lexington, KY, (3)Geisinger Autism & Developmental Medicine Institute, Geisinger Health System, Lewisburg, PA

Background: With the rapid increase in the prevalence of autism spectrum disorders (ASD) in 1990s (Gurney et al. 2003), there are approximately 50,000 individuals with ASD turning 18 years old every year (Shattuck et al. 2012). The community-based employment rate is quite low, ranging from 25% to 50% (Shattuck et al. 2012). The hallmark social impairments of ASD, most notably poor eye-contact and inappropriately modulated speech, may provide an inaccurate impression of one's ability. There has been little work in developing assistive technology to help individuals with ASD to overcome these social obstacles.

Objectives: To develop an application called LittleHelper on the Google Glass platform to assist individuals with ASD in maintaining appropriate eye contact and speech volume in an environment simulating a job interview with a single interviewer.

Methods: We rely on a face detector to detect the location of the interviewer's face. When the face is off-center, a red square will appear at the center of the display, and a flashing semi-transparent arrow will guide the user to turn so as to align the interviewer's face within the square. With the cooperation from a local server, LittleHelper progressively builds an image mosaic of the entire environment so as to locate the face if it falls out of the visual field. For the sound level detection, we use a temporally-smoothed root mean square (RMS) in measuring the sound level from the audio signal. We first train a noise floor level to adapt to the ambient sound level. This noise floor allows us to determine when the user speaks and the corresponding sound level. In an offline process, we determine the socially-acceptable voice volume as a function of the ambient noise level and the distance with the interviewer. The latter is estimated based on the size of the face as detected by the face detector. At real-time, we measure the voice level of the user and use a graphical slider to visually indicate if the level is within the acceptable range.

Results: We have measured the socially-accepted volume range based on the opinion of five subjects, in response to the same speaker speaking at different volume levels and at different distance from the subjects. The distance ranges from 0.5m to 3m at an interval of 0.5m. The voice detection and visual feedback are all computed in real-time locally at the Google Glass. To build the image mosaic, LittleHelper sends an image and the face location to a local server through Wi-Fi every one second to create the image mosaic (Brown and Lowe 2007). Figure 1 shows the two screen shots captured from the display when the Google Glass user followed the arrow towards the face and started speaking loudly.

Conclusions: We have designed a Google Glass app, LittleHelper, to help individuals with ASD to maintain proper eye contact and voice level during a job-interview-like setting. The current limitations include the requirement of a server to offload complex computation and the inability to handle multiple persons in a social setting.

11   **137.011**   Using Wearables to Augment Social Interactions for Adults with ASD

L. E. Boyd[1], *A. Rangel*[2], *S. Hirano*[1], *L. Escobedo*[3], *M. Tentori*[2] *and G. R. Hayes*[1], *(1)Informatics, UCI, Irvine, CA, (2)Computer Science, Center for Scientific Research and Higher Education of Ensenada, Ensenada, Mexico, (3)Computacion y sistemas, Instituto Tecnologico de Tijuana, Tijuana, Mexico*

Background: Leveraging the success of our android-based assistive application to support social skills (MOSOCO), we are building a tool on a Glass platform to further cut down on on the stigma associated with bulky assistive technologies by making a seamless tool that can be accessed without having to interrupt the social interaction it is supporting.

Objectives: The overarching goal of this work is to establish the effectiveness of using the Glass platform to support social skills for adults with ASD in real-time and identify the underlying mechanisms that support improvements in social interactions. To prepare our tool for a deployment study, we aim to ensure our users find the tool helpful and easy to use in social interactions.

Methods: We conducted design sessions with adults with ASD to advance of initial prototype supported by the Glass Accessibility Program.

Results: Using the Technology Acceptance Model, feedback from adults with ASD yielded user's values related to assistive technology that impacted our design.

Conclusions: Acceptability of a tool by the user is a critical component to ensure technologies are truly useful and support the values of the user.

12   **137.012**   Teaching Executive Function and Social Cognition Using a Kinect-Based Intervention Tool

C. Whalen, *M. Casale, M. Small, A. Mittal and J. Quiocho, Research and Development, West Health Insitute, La Jolla, CA*

Background: Although many studies have demonstrated success in teaching social skills through various behavioral, developmental, and psychological approaches, these interventions are typically costly and/or are not available in many communities. In addition, social skills groups or teaching social skills in busy, social settings such as school may be overwhelming to some children and may impact the child's ability to learn the skills being taught. The majority of the social skills interventions that have shown success do not necessarily include access to neuro-typical peers or even measure the generalizability to their peers. To successfully learn social skills, certain cognitive skills such as planning, memory, and flexible thinking (i.e. executive function skills) may be necessary. Few social skills interventions consider this prerequisite and this may affect outcomes for some students.

Objectives: While decreasing cost and increasing accessibility, the objectives of this project are to: 1) develop a KINECT-based game that effectively teaches executive function and social skills while

keeping motivation for learning high and sustainable; 2) measure the effectiveness of the game in teaching the target skills with school-age ASD children who do not have intellectual impairment; 3) assess the usability of the system in the home environment with parent implementation; and 3) measure the generalization of the skills being taught in typical peer interactions.

Methods: A single subject, multiple baseline design was implemented with 8 children in 1-4 week baselines. Each child received the intervention in the home via the KINECT system for 20 minutes/session for 5 sessions each week for 6 weeks for a total of 10 hours of intervention. During baseline and following the intervention, participants were observed in a naturalistic gaming sessions with neurotypical peers, with parents, and alone to test the generalization of the skills learned through the gaming system.

Results: Data are being analyzed to assess the effectiveness of the intervention including standardized measures of executive function and social skills, and behavioral observations coded by blind raters. Data will also look for strong indicators of characteristics of children and parents who may be best suited for this type of intervention.

Conclusions: If executive function and social understanding can be taught in an efficient, effective, motivating, generalizable and feasible way using technology, this could have huge implications for how treatment is delivered. This kind of technology could allow individuals with ASDs, and potentially other populations, to practice and learn social rules in a safe and predictable environment, and then practice the skills with peers in the natural environment. Results from our research, video clips of children using the game, and an interactive display of the KINECT game will be demonstrated.

13 **137.013** Socially Animated Machine (SAM): A Novel Design for Robotic Research in Children with Autism Spectrum Disorders

S. A. Koch[1], C. D. Clesi[1], J. B. Lebersfeld[1], C. E. Stevens[1], A. G. Parker[1], M. E. McNew[1], M. I. Hopkins[2], F. R. Amthor[2] and F. J. Biasini[2], (1)University of Alabama at Birmingham, Birmingham, AL, (2)Psychology, University of Alabama at Birmingham, Birmingham, AL

Background:
Children with Autism Spectrum Disorder (ASD) display significant impairments in social communication that can have serious implications for long-term social and emotional functioning. Recent research suggests the value of using robots to improve social communication. Researchers investigating robots as tools for therapy in ASD have reported increased engagement and novel social behaviors (i.e., turn-taking, imitation, joint attention) when robots are part of the social interaction. Although a wide variety of robotic designs have been employed in previous studies, research shows that children with ASD respond more positively to robots that are cartoonish than robots that take on a humanoid form. However, as these animal-like robots typically offer only a limited range of facial expressions, they may not translate well to the human face and therefore skills learned within the session may fail to generalize to real-world social situations.

Objectives:
The overall objective of this study is to design a novel social robot, or Socially Animated Machine (SAM), with a unique mix of anthropomorphic and non-humanoid features. The aims of this study are to 1) conduct a pilot study to explore whether SAM is capable of forming complex facial expressions similar to those observed in the human face, and 2) conduct a usability study to examine the acceptability of SAM.

Methods:
Approximately 100 typically developing children ranging from 7-12 years will participate in the pilot study. These children will be asked to label and match photos of SAM expressing various emotions to schematic drawings and photos of human faces displaying these emotions. Approximately 20 children with ASD ranging from 7-12 years will participate in the usability study. These children will participate in a fifteen-minute social interaction with SAM. During the interaction, level of engagement will be measured based on eye-gaze patterns using faceLAB[TM] eye-tracking technology. Self-reported levels of enjoyment will also be measured using ten-point Likert-type scale items.

Results:
Preliminary results of the pilot study (N=9) suggest that typically developing children are able to label SAM's emotions with 67% accuracy and match SAM's emotions to schematic drawings and human expressions with 69% and 54% accuracy, respectively. Preliminary results of the usability study (N=8) suggest that children with ASD are able to maintain gaze on SAM's face during the social interaction. Children who completed the robot-based interaction reported feeling very happy (M=9.57, SD=1.13) and comfortable (M=10, SD=0) while talking with SAM. They were also very eager to have an additional interaction with SAM (M=9.86, SD=.38).

Conclusions:
Preliminary findings suggest that SAM is capable of forming facial expressions that can be labeled and matched with adequate accuracy. The degree of accuracy is expected to increase with a larger sample size. Additionally, results indicate that children with ASD are engaged and enjoy interacting with SAM. Overall, these findings suggest that SAM's robotic design helps to fill the void in current research by offering an animal-like, approachable appearance while still maintaining some subtle details of the human face. Additional data collection is expected to clarify and strengthen results.

14 **137.014** Social Personalized Human-Machine Interaction for People with Autism: A Close Look at

Proprioceptive and Visual Orientation Integration

P. Chevalier[1], A. Tapus[2], J. C. Martin[3], C. Bazile[4] and B. Isableu[5], (1)ENSTA ParisTech, Palaiseau, France, (2)Computer Science and System Engineering, ENSTA-ParisTech, Palaiseau, France, (3)LIMSI, CNRS/ Université paris-Sud, Orsay, France, (4)FAM-La Lendemaine, Les Molières, France, (5)Université Paris Sud, Orsay, France

Background: Research in socially assistive robotics (SAR) is in expansion, and enable to propose more personalized social learning environments for individuals with Autistic Spectrum Disorder (ASD)(Feil-Seifer2005;Tapus2012), to cope with their impaired skills in communication and social interaction while using their affinity towards robots(Hart2005). Individuals with ASD also suffer from visual and sensorimotor impairments (Haswell2009;Greffou et al.2012).
Objectives: We work in collaboration with 2 care facilities (MAIA Autisme;FAM-La Lendemaine) with the final objective to propose a personalized human-robot environment for social learning. We hypothesize that the individual's reliance to proprioceptive and kinematic visual cues will affect the way s/he interacts with a robot. Hyporeactivity to visual motion of the scene and overreliance on proprioceptive information is linked in ASD subjects to difficulties to integrate social cues and to engage in successful interactions. Our present research defines each participants' perceptivo-cognitive and sensorimotor profile with respect to the integration of visual inputs.
Methods: Our subject pool is composed of 7 autistic adults (26.1±7.9years), 6 autistic children (10.9±1.8), and 7 typically developed adults (21.8±10.3). We evaluated the participants' profiles with two methodologies. First, the Sensory Profile and the Adolescents/Adults Sensory Profiles (AASP) developed by Dunn (1999,2002) were filled in accordance with participants' age. In addition, in order to have homogeneous scores between age groups to assess Movement, Visual, Touch, and Auditory processing, we matched and adapted the items with a special care on their belonging of neurological threshold and behavior response/self-regulation. Second, we designed an experimental setup to assess the effect of a moving virtual visual scene (VVS) on postural control, and the individual's capability to use proprioceptive inputs provided in dynamics of balance to reduce visual dependency(Isableu et al.2011). Participants were asked to stand quietly in postural conditions of increasing balance difficulty (normal vs tandem Romberg) in front of a virtual scene rolling at 0.25Hz with an inclination of ±10°.
Results: We observed a correspondence between AASP patterns and postural behaviors. A higher movement sensitivity in AASP leads to greater postural stability, and postural sway is less driven by VVS. A visual sensation seeking behavior also leads to smaller postural responses to VVS and a higher visual sensitivity leads to a greater postural coupling response with VVS. A relation between age and postural instability has been found, but not between age and postural response to VVS. Clustering analyses allowed us to identify 3 groups with significant different behavioral responses: (G1)strong visual independence to VVS suggesting an overreliance on proprioceptive input, (G2)moderate reactivity to VVS suggesting a reliance on both visual and proprioceptive input, and (G3)hyperreactivity to VVS suggesting a weak proprioceptive integration and strong visual dependency.
Conclusions: Our work permits us to characterize 3 groups within our participants. These results will help us to model customized Human-Robot Interaction sessions and adapt the robot's behaviors as a function of the participants profile (dependence on visual and proprioceptive input).

15   **137.015**   Using Robots As Therapeutic Agents to Teach Children with Autism Recognize Facial Expression

S. Mavadati[1], H. Feng[2], P. B. Sanger[1], S. Silver[1], A. Gutierrez[3] and M. H. Mahoor[2], (1)University of Denver, Denver, CO, (2)Electrical and Computer Engineering, University of Denver, Denver, CO, (3)Psychology, Florida International University, Miami, FL

Background: Recognizing and mimicking facial expressions are important cues for building great rapport and relationship in human-human communication. Individuals with Autism Spectrum Disorder (ASD) have often difficulties in recognizing and mimicking social cues, such as facial expressions. In the last decade several studies have shown the individuals with ASD have superior engagement toward objects and particularly robots. However, majority of the studies have focused on investigating robot's appearances and the engineering design concepts and very few research have investigated the effectiveness of robots in therapeutic and treatment applications. In fact, the critical question that "*how robots can help individuals with autism to practice and learn some social communicational skills and applied them in their daily interactions*" have not been addressed yet.
Objectives: In a multidisciplinary research study we have explored how robot-based therapeutic sessions can be effective and to what extent they can improve the social-experiences of children with ASD. We developed and executed a robot-based multi-session therapeutic protocol which consists of three phases (i.e. baseline, Intervention and human-validation sessions) that can serve as a treatment mechanism for individuals with ASD.
Methods: We recruited seven (2F/5M) children 6-13 years old (Mean=10.14 years), diagnosed with High Functioning Autism. We employed NAO, a programmable humanoid robot, to interact with children in a series of social games for several sessions. We captured all the visual and audio communications between NAO and the child using multiple cameras. All the capturing devices were connected to a monitoring system outside of the study room, where a coder observed and annotated

the responses of the child online. In every session, NAO asked the child to recognize the type of prototypic facial expression (i.e. happy, sad, angry, and neutral) shown on five different photos. In the 'baseline' sessions we calculated the prior knowledge of every child about the emotion and facial expression concepts. In the 'intervention' sessions, NAO provides some verbal feedback (if needed), to help the child recognizing the facial expression. After finishing the intervention sessions, we included two 'human-validation' sessions (with no feedback) to evaluate how well the child can apply the learned concepts when a human is replaced with NAO.

Results: The following Table demonstrates the Mean and Standard Deviation (STD) of face recognition rates for all subjects in three phases of our study.

Facial Expression Recognition Rate(%)	Baseline	Intervention	Human-Validation
Mean(STD)	**69.52(**36.28)	**85.83(**20.54)	**94.28(**15.11)

Conclusions: The results demonstrate the effectiveness of NAO for teaching and improving facial expression recognition (FER) skills by children with ASD. More specifically, in the baseline, the low FER rate (69.52%) with high variability (STD=36.28) demonstrate that overall, participants had difficulty recognizing expressions. The intervention results, confirms that NAO can teach children recognizing facial expressions reliably (higher accuracy with lower STD). Interestingly, in the human-validation phase children could even recognize the basic facial expressions with a higher accuracy (94%) and very limited variability (STD = 15.11). These results conclude that robot-based feedback and intervention with a customized protocol can improve the learning capabilities and social skills of children with ASD.

16 **137.016** Affect and Social Behaviors of School-Aged, High Functioning Children with ASD during Robot Interaction

C. Daniell[1], E. S. Kim[1], C. Makar[1], J. Elia[1], B. Scassellati[2] and F. Shic[3], (1)Yale University, New Haven, CT, (2)Computer Science and Mechanical Engineering, Yale University, New Haven, CT, (3)Child Study Center, Yale University School of Medicine, New Haven, CT

Background: Recent group studies confirm earlier case study observations that social robots both elicit and mediate adaptive social behaviors in children with autism spectrum disorders (ASD). Robots have the potential to serve as powerful reinforcers in communication and social skills interventions. Previously, we found that a social robot mediates greater speech production than an adult in a cross-sectional group of school-aged children with high-functioning autism spectrum disorders (HFA) (Kim et al., 2013).

Objectives: To explore and enrich our understanding of increased speech production mediated by interaction with the social robot, in terms of participants' affect and engagement behaviors.

Methods: Participants were school-aged children with high-functioning autism (N = 26; ages: M = 9.4 SD = 2.4; FSIQ: M = 94.2 SD = 11.7; diagnoses confirmed by clinical best estimate using ADOS). Each completed brief, semi-structured, triadic interactions with a confederate and either a social robot or another adult, in randomized crossover. Using qualitative, Likert-scale measures, two independent raters judged video recordings of these interactions on the adaptive quality of social, regulatory, and affective behaviors. Measured behaviors included 1) affective valence; 2) quality of eye contact; 3) willingness to engage in social physical contact (e.g., shaking hands with the adult or petting the robot); 4) acknowledgement of confederate's or interaction partner's spoken or nonverbal bids; and 5) number of increasingly restrictive cues required to elicit response to a question or an instruction to act. Interactions with the confederate and interaction partner were judged for each behavior. Where ratings disagreed by differences greater than one, raters discussed their ratings and achieved consensus.

Results: Children with HFA exhibited more positive affect during interaction with the robot than during interaction with the adult (p < .001; d = 0.97). When interacting with the robot, children also exhibited better eye contact (p < .001, d = 0.97), greater willingness to engage in physical touch aspects of the structured interaction (p < .001, d = 0.71), and better acknowledgment of the interaction partner's social overtures (p < .001, d = 0.98), than when interacting with a human adult. Previous findings of increased utterance production during robot interaction, as opposed to interaction with the adult partner, were positively correlated with eye contact ratings (r = .467, p < .05) and positivity of affect (r = .402, p = .052) during interaction with the robot, but not during interaction with an adult (r = -.02, r = .08, respectively).

Conclusions: Our explorations suggest that children with HFA who enjoyed interacting with the robot, or who demonstrated better eye contact, showed greater robot-mediated behavioral improvement (as measured by speech production). We also found that children with HFA enjoyed interacting with the robot more than with the adult interaction partner. These results shed light on the mechanisms by which robots may facilitate communication in children with ASD. Further work will need to examine the sustainability of these increases over extended usage, en route towards the development of more automated tools to provide additional learning opportunities to individuals affected with ASD.

17 **137.017** Understanding Interaction Dynamics in Socially Assistive Robotics with Children with ASD

E. Short[1] and M. J. Mataric[2], (1)University of Southern California, Los Angeles, CA, (2)Computer

Science, University of Southern California, Los Angeles, CA

We present a novel analysis of an existing dataset examining one-on-one interactions between children with an ASD diagnosis and a robot. We conclude that children's reaction to the robot can vary on a continuum of object-to-agent, at least partially independent of the designers' intent. We also find that some behaviors meant to promote social responses may inadvertently inhibit them by promoting other, conflicting behaviors.

Background:
An increasing body of work in human-robot interaction for socially assistive robotics (SAR) for children with ASDs points towards the value of SAR as an intervention tool (Scassellati, Admoni, and Matarić, 2012). Our work contributes to this area by extending our understanding of children's behavior using dynamics of the interaction to understand children's perceptions of robot agency.

Objectives:
Based on a qualitative evaluation of the video data from the study, we defined the following broad hypotheses:

1. For the children who spoke most, the robot's bubble-blowing distracted from the interaction;
2. For the children who spoke least, the robot's bubble-blowing engaged them in the interaction;
3. Differences in behavior were more a function of individual reactions than the implemented differences between the robots and can be classified into agent-like vs. object-like treatment of the robot.

Methods:
The data discussed in this abstract come from a prior experiment described in Feil-Seifer and Matarić (2012); the analysis and results described are new. The data were hand-coded for 20 robot, child, and parent behaviors. In order to model the dynamics of behavior, we examine ordered pairs of events (first A happened, then B). In addition, we use a clustering algorithm to group sessions based on participants' behavior.

Results:
We find limited differences in the behavior of children across the original experimental conditions. However, we find correlations between their overall speech and their reactions to the robot's bubble-blowing behavior, suggesting that the behavior is not beneficial with more verbal children, while it can be a way to engage less verbal children. Our clustering uncovers a more meaningful classification based on the child-robot interaction pattern: while some children are highly engaged with the robot verbally (as if with an agent), other children are more engaged with the button pushing or movement behaviors (as if with an object).

Conclusions: One of the most exciting aspects of SAR for children with ASDs is the potential for robots that can support therapeutic goals. We suggest the division of robot behaviors into agent-like and object-like, and the customization of the robot's role to an individual child's needs.

18 **137.018** A 3-D Learning Environment for Infants and Toddlers at-Risk for ASD: Can Technology Improve Early Social Communication Vulnerabilities

Z. Zheng[1], Q. Fu[1], H. Zhao[1], A. Swanson[1], A. S. Weitlauf[2], N. Sarkar[3] and Z. Warren[4], (1)Vanderbilt University, Nashville, TN, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)Mechanical Engineering, Vanderbilt University, Nashville, TN, (4)Pediatrics, Vanderbilt University, Nashville, TN

Background: Early detection and intervention is critical to optimal treatment for children with ASD. [1, 2]. Technology-assisted intervention approaches are being considered due to their potential flexibility, controllability, duplicability, and overall lower costs when compared to traditional human dominant intervention [3-5]. However, very few systems have been designed for infants and toddlers. In the current work we present a proof-of-concept system designed to enhance early social orienting, specifically enhancing early response to name within a three dimensional technological learning environment.

Objectives: We designed a closed-loop, computer-assisted intervention system for potential future use with infants and toddlers at risk for ASD. The system incorporated a series of target monitors, a non-contact eye-tracking system, and a series of audio and visual cues within a reinforcement hierarchy designed to improve children's social orienting within this technological environment. The system was designed to operate in closed-loop fashion (i.e., automatically responded to estimated child gaze to activate components of the hierarchy) in real time. The ultimate goal of the current system was to create a technological learning environment that systematically enhances a child's ability to respond to caregiver's attempts to garner attention by calling his/her name from a variety of

locations.

Methods: The name prompting system encompassed a series of coordinated target monitors within a room. These monitors would initially display a name press (i.e., recording of individual calling child's name) and activate an internal prompt hierarchy based on estimated child gaze in real time. If the child did not look at the target monitor when name was called, then coordinated visual/audio attention attractors appeared based estimated gaze in order to cue for orientation to correct target. When the participant looked at the target monitor, then social and non-social reward videos and animations were displayed to reinforce this orientation. The attention tracking system computed orientation in real-time via vision driven head pose estimation algorithms. This data was fed back into system to further advance the experimental protocol. In order to test system feasibility 7 typically developing infants and toddlers (all under 2) participated in a coordinated series of 10 trials within the system. Trials were interspersed with introductory, transition, and conclusion activities to familiarize children with the system.

Results: All the participants tolerated the system well with all infants and toddlers completing the entire experiment. The participants' performance was well distributed across the prompting levels with in excess of 98.57% of all trials ultimately resulting in correct orientation. Preliminary data also suggest that the attention attractor was capable of shaping participants' attention to the target position.

Conclusions: This work provides preliminary support for the feasibility for employing technologies with very young children potentially at risk for ASD. The development of robust technological systems capable of addressing meaningful core early social communication vulnerabilities prior to the full manifestation of ASD impairments may represent new paradigms for intervention science.

19 **137.019** The Benefits of Online Play: An Investigation of Virtual Worlds for Children with Autism Spectrum Disorder

K. E. Ringland[1], C. T. Wolf[1] and G. R. Hayes[2], (1)Informatics, University of California, Irvine, Irvine, CA, (2)Informatics, UCI, Irvine, CA

Background: Children with autism and their families participate in virtual worlds, a persistent digital environment which participants can access via the internet and interact with one another. Previous work has shown how parents create safe online environments within virtual worlds for their children with autism to play and socialize without fear (Ringland et al., 2015). Play is an important part of childhood development and these virtual worlds provide a space to play that is free from bullying and harassment, dangers often encountered in other environments children with autism play in. Minecraft is an open-ended, free-play type of game, where players can interact in a virtual world with no particular goals or play requirements. The open-endedness of Minecraft allows for an expression of individuality and creativity during play, which may make the game particularly compelling for players. Minecraft allows players to interact with others and be as socially engaged as the individual player desires in a procedurally generated virtual world. This allows for a freedom of expression and open play for children participating in a Minecraft virtual world. Parents have created and maintain a Minecraft virtual world specifically for their children with autism.

Objectives: To explore the role that virtual worlds play in the daily lives of children with autism, including potential therapeutic benefits.

Methods: This work reports on results from an ongoing digital ethnography. The digital ethnography includes immersive participant observations in the virtual world, analysis of digital artifacts associated with the virtual world's community, and in-depth, semi-structured interviews with players of the virtual world. This study is structurally similar to others conducted with disability communities in virtual worlds, such as Irani et al.'s work in Second Life (2008). In-world observations include participating in activities on the server, recording dialogue as it appears in the chat, and writing extensive field notes on everyday practices and events as they occur in the virtual world. Researcher participation in the world also included building an in-world home office that acts as a home-base for in-world activities and enabled other players to visit and ask the researcher questions, as the researcher's presence and purpose were made clear to the community through announcements on Autcraft web forums and through in-world chat. We used an inductive approach to derive the emergent themes from our data, following techniques similar to those employed in grounded theory.

Results: We will present the results of our observations and interviews to illustrate how families of children with autism integrate technology such as virtual worlds into their daily living and how these types of play may be beneficial.

Conclusions: Virtual worlds have the potential to be an important part of a child with autism's daily living experience. Members of the Minecraft virtual world form relationships with each other and participate in group-play, which is an important part of development for children with autism.

20 **137.020** ASC-Inclusion – a Virtual World Teaching Children with ASC about Emotions

S. Newman[1], O. Golan[2], S. Baron-Cohen[3], S. Bolte[4], A. Rynkiewicz[5], A. Baranger[6], B. Schuller[7], P. Robinson[8], A. Camurri[9], M. Sezgin[10], N. Meir-Goren[1], S. Tal[2], S. Fridenson-Hayo[2], A. Lassalle[3], S. Berggren[4], N. Sullings[6], D. Pigat[3], K. Ptaszek[5], E. Marchi[7], S. Piana[9] and T. Baltrusaitis[8], (1)Compedia, Ramat-Gan, Israel, (2)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (3)Autism Research Centre, University of Cambridge, Cambridge, United Kingdom, (4)Center of neurodevelopmental disorders, Karolinska Institutet, Stockholm, Sweden, (5)Spectrum ASC-Med,

Gdansk, Poland, (6)Autism Europe, Brussels, Belgium, (7)Institute for Human-Machine Communication, Technische Universität München, Munich, Germany, (8)Computer Laboratory, University of Cambridge, Cambridge, United Kingdom, (9)University of Genova, Genova, Italy, (10)Department of Computer Engineering, Koç University, Istanbul,, Turkey

Background: Children with Autism Spectrum Conditions (ASC) experience difficulties communicating their own emotions and recognizing the emotions of others. These difficulties appear in different modalities, including facial expressions, vocal intonation, and body language. Such deficits may hamper the social functioning of children with ASC and increase their exclusion. Alongside these difficulties, individuals with ASC tend to have intact and sometimes superior abilities to comprehend and manipulate closed, rule-based, predictable systems, such as computerized environments, and may better learn from them than from non-structured settings. Computerized environments can produce simplified versions of the socio-emotional world, reduce sensory stimulation, and support a featured-based learning style of socio-emotional cues, gradually integrating them into a holistic picture. Harnessing these qualities for the sake of emotion recognition and expression training, children with ASC may be more motivated to learn about the emotion world through virtual computerized environments.

Objectives: To demonstrate the up to date status of the ASC-Inclusion project, as well as a summary of open trials of the system, conducted so far.

Methods: The program is embedded in a virtual world and includes highly engaging elements, aimed at enhancing the child's motivation, including games, animation, video and audio clips, rewards, a child's avatar, and communication with smart agents and peers. The system combines several state-of-the art technologies in one comprehensive environment, including computerized analysis of users' gestures, facial and vocal expressions. Two additional features were added this year, addressing parent-child collaborative use of the system, and computer's formative assessment of feedback to users. When complete, the system is planned to be available for home or school use, and as an aid to therapists. An iterative process of testing, feedback and evaluation supports the system's development. So far, the system has versions in four different languages: English, Hebrew, Swedish, and Polish.

Results: The current presentation will demonstrate:
1. The system at its open trial evaluation status: its virtual world and emotion recognition training in the different modalities, as well as the expression training components, using the above technologies for analysis and feedback on the children's' performance. The environment, tutorials and games presented have been evaluated and approved by our panels of families and professionals.
2. Preliminary results of the open trials conducted with 30 children per site in the UK, Israel, Sweden, and Poland.

Conclusions: The ASC-Inclusion project offers children with ASC and their families the benefit of state of the art educational technology for enhancement of their socio-emotional communication repertoire. A multi-site evaluation of the project is in process and preliminary results will be presented.

---

21   **137.021** Design of a Collaborative Virtual Environment to Foster Collaborative Skills for Children with ASD

L. Zhang[1], A. Swanson[1], A. S. Weitlauf[2], Z. Warren[3] and N. Sarkar[4], (1)Vanderbilt University, Nashville, TN, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)Pediatrics, Vanderbilt University, Nashville, TN, (4)Mechanical Engineering, Vanderbilt University, Nashville, TN

Background:
Researchers are increasingly exploring virtual reality environments as potential intervention platforms for children with autism spectrum disorder (ASD). To date much of this work has focused on interaction with preprogrammed and/or confederate avatars in hopes that such interactions may foster higher level social communication skills. Such systems are often limited by the programming burden of realizing fluid social communication paradigms and/or restraints in the flexibility of employing confederate partners. Another paradigm with potential use in ASD intervention may be distributed Collaborative Virtual Environments (CVEs). CVEs may represent safe, flexible environments for children with autism to communicate and interact with one another and/or peers. Further, controlled tasks may be designed within the environments that may ultimately enhance interaction skills, with potential for generalization, without relying on preprogrammed or facilitated interaction.

Objectives:
In the current work we present a novel CVE environment with the potential capability of promoting communication between children with autism and their peers. This CVE utilizes a flexible conversation environment, instead of a limited and predefined conversation environment, across a series of collaborative task where the interaction is governed by contingent cooperative behavior of the participants.

Methods:
Our CVE was developed with Unity3D game engine (http://unity3d.com/). A series of seven block pattern games were designed in a shared virtual environment, which can be accessed by two users from different locations through internet. The connection between two agents was realized using network socket. The distributed users communicate by voice in real time in the CVE. The interaction was governed by implicit rules that required cooperation and communication in order to achieve

success (e.g., turn taking of varied intervals, tasks where participant had to simultaneously move the mouse to achieve success, and tasks where participants required their partners to identify colors of blocks not visible to them to achieve success). Quite simply tasks were designed such that participants would have to communicate with their partners in order to achieve success.
Results:
The Unity-based CVE system has been developed with seven different collaborative tasks. We were able to achieve real-time voice interaction and registration of cooperative movement within task. We conducted initial pilot and interview/feedback sessions with 3 adult participants. All participants indicated that the contingent activities both (1) required them to think about collaborative strategies for communicating with their partner and (2) that they enjoyed completing the puzzles. Participants also indicated a degree of frustration with the system noting that the tasks seemed to require very precise coordination of activities that was hard to achieve.
Conclusions:
Initial pilot feasibility results supported the potential value of CVE in fostering collaboration and communication skills for participants. Our CVE may offer a way to explore and train the collaboration skills of children with autism beyond the limits of traditional VR paradigms. Opportunity of feedback from verbal and nonverbal (eye gaze) information may represent a future enhancement of this paradigm.

22   **137.022**   Generative Language Learning in Severe Autism: Experimental Evaluation of a Mobile Application

O. Wendt[1], N. Hsu[2], A. Torelli[3], K. Warner[3] and A. Goss[3], (1)Heav 202D, Purdue University, West Lafayette, IN, (2)Educational Studies, Purdue University, West Lafayette, IN, (3)Speech, Language, and Hearing Sciences, Purdue University, West Lafayette, IN

Background: Severe autism includes a "delay in, or total lack of, the development of spoken language". Many learn to communicate through alternative means such as tablets and mobile technology. However, utterances on these devices are often very limited; minimally-verbal individuals with autism do not surpass single-word responses limited to requesting and labeling purposes, and vocabulary repertoires are small. Matrix training is a language intervention to systematically build up vocabulary and teach longer word combinations to produce more complex utterances. In this generative approach to instruction, words are arranged in a matrix format so that some multiword phrases are taught and others develop without direct instruction. Specifically, linguistic elements (e.g., nouns, verbs, etc.) are presented in systematic combination matrices, which are arranged to induce generalized rule-like behavior, a particular difficulty in autism.
Objectives: A mobile application, SPEAKmore!, was developed to carry out matrix training on a tablet device (see Figure 1). This study aimed to answer

1. Does language training with SPEAKmore! facilitate production of action-object combinations on a tablet device? This was accomplished by measuring the percentage of correct target forms in intervention probes.
2. Do newly learned skills generalize to untrained action-object combinations. This was achieved by taking generalization probes during the intervention phase assessing performance on combinations that were never taught before.

Methods: An experimental single subject design, that is a multiple probe design (Horner & Baer, 1978), was used across sets of action-object combinations with generalization probes of untrained combinations. This design is currently implemented with five participants, who are between 8-12 years old, have an official diagnosis of severe autism according to CARS-2 and ADOS-2 scores, qualify as minimally verbal by having no more than 10 spoken words, and communicate primarily on a tablet. These students were taught action-object combinations on a 6x6 matrix with SPEAKmore!. From the total pool of 36 possible symbol combinations, the researcher created four different sets of three symbol combinations each that were actively taught. The remaining 24 combinations were tested for generalization effects.
Results: Preliminary results are available for two of the five participants. Figure 2 shows participants' performance measured as the percentage of correct symbol combinations. Both participants demonstrate a similar pattern of successful acquisition of word combinations during the intervention condition and subsequent generalization to untrained stimuli. Within three intervention sessions, both participants reached over 80% correct and their performance remained at this level. Performance on generalization increased steadily for both over the course of intervention. Effect sizes as measured by the Non-overlap of all Pairs Index indicate a medium-strong effect for participant 1 and a strong effect for participant 2.
Conclusions: Results suggest that matrix training through a mobile application may be a promising approach to teach new vocabulary and enhance the complexity of utterances for tablet communicators with severe autism. To further investigate the robustness of this technology intervention, findings need to be replicated using (a) different language targets (e.g., agent-action, adjective-object combinations), and (b) expansions from two-term to three-term semantic relations (e.g., agent-action-object).

23   **137.023**   Creating Exploratory Touch-Screen Games That Include Novel and Surprising Aspects As

Motivators of Communication for Children with Autism

A. M. Alcorn[1], *J. Good*[2], *H. Pain*[3] *and S. Fletcher-Watson*[4], *(1)School of Informatics, University of Edinburgh, Edinburgh, United Kingdom, (2)Department of Informatics, University of Sussex, Falmer, Brighton, England, (3)School of Informatics, University of Edinburgh, Edinburgh, Scotland, (4)University of Edinburgh, Edinburgh, Scotland, United Kingdom*

Background: Unpredictability and "lack of sameness" are frequently stressful for children with ASC. However, work with the ECHOES virtual environment suggests that novel and surprising aspects (i.e. *discrepancies*) can be experienced as interesting, positive motivators of communication when present in a technology alongside substantial sameness. ECHOES deliberately included novelty (e.g. new digital objects), however, intermittent software errors also caused *unintentional* surprises, such as the character making "mistakes" in an activity he had previously demonstrated correctly. Children were observed to frequently and spontaneously initiate to social partners about these discrepancies (Alcorn, Pain, & Good, 2013). Subsequent qualitative and quantitative analyses of child-ECHOES interactions, combined with "lessons learned" from school studies, have identified characteristics that may have allowed discrepancies to be perceived as motivating but still emotionally manageable. These have been formulated as six high-level principles intended to support transfer of "motivating but manageable" discrepancies to new designs: establishing and maintaining *integrity* of the environment and activities, ensuring *flexibility* and *resolvability* of child-system interactions, and offering wide *variety* of discrepancies at an appropriate *frequency*. These should pose *ambiguous* opportunities for communication, rather than demanding specific behaviours or communicative forms.
Objectives: To reproduce the phenomenon of discrepancies as positive communicative motivators for young children with ASC, in a new interactive technology.
Methods: Transfer lessons learned from ECHOES to the design of three new touch-screen games, guided by the high-level principles for incorporating discrepancies.
Results: Games draw upon the original ECHOES "Magic Garden" setting, cause-and-effect play, and exploratory, non-competitive format (originally developed with extensive stakeholder input). One involves sorting apples by colour; two centre on growing flowers or vegetables by shaking a magic cloud. Each has a "baseline" and a "discrepant" version. The main source of novelty is the child initially encountering digital objects and forming expectations about their behaviours. After baseline versions are familiar, additional objects and properties are introduced in discrepant versions. Surprises include altered object appearances, sound effects, and timings between events. The character also makes occasional "mistakes" with his actions and utterances. These things are expected to interest children and pose opportunities for them to spontaneously initiate communication for a range of goals (e.g. share information or affect, ask question, request), and using any behaviours (e.g. speech, gestures, gaze).
Conclusions: Three games were successfully developed, embodying principles thought to effectively motivate spontaneous communication using discrepant aspects. This process has highlighted that designing "motivating but manageable" games requires concurrently designing how they will be used. For example, the *integrity* principle determined the need for baseline versions which children should play multiple times in order to develop clear expectations—a pre-requisite for violating expectations later (i.e. surprises). Establishing sufficient "sameness" to counterbalance discrepancies will always partly rely on variables *outside* the game itself, including the physical environment, social partner actions, and the frequency and duration of game play. The principles must be realised collectively in the technology *and* its context.
Preliminary results will soon be available from games testing with children, as the first step in gauging their success at motivating communications.

24 **137.024** Design and Assessment of a Web-Based Training Tutorial Developed to Empower Parents with the Knowledge and Skills Necessary to Effectively Improve Their Child's Communication and Behavior during Daily Activities

K. A. Kobak[1], **A. Swanson**[2], *L. Wallace*[3], *Z. Warren*[2] *and W. L. Stone*[4], *(1)Center for Psychological Consultation, Madison, WI, (2)Vanderbilt University, Nashville, TN, (3)Vanderbilt Kennedy Center, Nashville, TN, (4)Psychology, University of Washington, Seattle, WA*

Background: There is a growing consensus that early intervention strategies can significantly improve long-term outcomes for children with autism and their families. Due to a critical shortage of trained professionals in this area many children who are eligible for early intervention services do not receive them. One way to bridge the gap between the need for services and their availability is to provide access to the information parents need to foster their child's development within daily interactions at home. More effective interactions would improve long-term outcomes by helping to remediate the core deficits associated with the disorder and reduce caregiver stress. While successful parent training programs have been developed, access to such programs is limited due to the lack of trained clinicians providing such services. One powerful way to increase the accessibility of this program is through web-based technologies.
Objectives: To develop and evaluate the feasibility and efficacy of technology-based, multi-media, interactive tutorial ("Enhancing Interactions"), which utilizes the principles of instructional design to help caregivers identify individual steps in everyday routines that can help to move a child from intolerance of an activity towards independent participation and engagement.

Methods: 96 parents with a child between 18 months to 6 years of age with autism enrolled in the study. Mean age of parents was 34 (range 21-52).   The sample was 4% African American, 88% Caucasian, 2% Asian, and 6% other. 30 percent received their child's diagnosis within the past 6 months. Participating parents were randomly assigned to either "immediate" participation or "delayed" participation (i.e., completing the program after an eight week waiting period, following post-test measures). Pre- and post-test scores of parents' knowledge of the concepts presented in the tutorial were used to evaluate teaching effectiveness. For parents assigned to the immediate participation group, user satisfaction was gauged with The System Usability Scale (SUS) (for technical aspects) and the User Satisfaction Questionnaire (for tutorial content). Group comparisons in behavioral change in parenting skills and child behavior over the 8 week period was assessed with the Parent Interview of Autism-Clinical Version (PIA-CV), Parent Efficacy Scale (PES), and parent questionnaires. Changes in parenting stress were assessed by the Parenting Stress Index/Short Form (PSI/SF).

Results: Previous analyses of the Enhancing Interactions content show an increase in the number of correct items on a test of concepts, from 12.6 to 20.4 (t=10.72, p<.001.) and an increase percentage of participants receive passing scores from pre- to post-test (8% compared to 80%). Survey data collection is ongoing and scheduled to be complete in 8 weeks. Full analysis of changes in parental stress levels and in child and parenting behaviors will be presented.

Conclusions: We have developed a customize approach to teaching parents how to use daily activities as a context for enhancing their child's interactions and communication skills. By targeting a child's daily routines and interactions, the tutorial shows potential to provide a means for caregivers to feel empowered with the knowledge and skills necessary to effectively help soothe the pressures created by autism.

25   **137.025** Investigating the Usability of a Tablet-Based Interface for Management of Anxiety-Related Arousal in Children with Autism Spectrum Disorder

T. A. Chiu[1] and A. Kushki[1,2], (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada

Background: Comorbid anxiety is a significant concern in autism spectrum disorder (ASD) due to its high prevalence, negative impact on physical and psychological well-being, and interaction with the core deficits of ASD. Current methods for assessment and treatment of anxiety rely on the observation of behaviour or self-reports, which are often ineffective in children with ASD due to known deficits in communication and diminished introspective ability. To reduce these barriers, we have developed a device, called the Anxiety Meter, that translates a user's heart rate into a visual display of arousal level. The Anxiety Meter interface consists of a tri-colour gradient (red, yellow, and green) with a moving bar to mark the user's level of arousal in real time.

Objectives: Evaluate the usability of the Anxiety Meter interface in a sample of children with ASD.

Methods: A sample of children with ASD (n=9; age: 10.7 +/- 1.8 years; full-scale IQ: 101.4 +/- 11.2; 6 male) completed device training and one anxiety-inducing task (public speaking), preceded and followed by a baseline task (movie-watching). For the anxiety-inducing task, participants were given 2 minutes to prepare for a 3-minute speech on a topic of their choice. Participants sat in front of a tablet computer with the Anxiety Meter placed at eye level and were asked to indicate when they recognized they were anxious through pressing a button. Usability was evaluated according the to the ISO 9241 Standard using measures of interface effectiveness, efficiency, and user satisfaction. Interface effectiveness was defined as the user's ability to recognize arousal states. Efficiency was measured as the time between indication of arousal on the device and the user's recognition of the arousal level. Satisfaction was evaluated based on a user-rated likeability score from 1 to 5.

Results: Users were detected anxiety states indicated by the device with sensitivity and specificity of 0.7±0.3 and 0.9±0.2, respectively (effectiveness). Average time needed for recognition of anxiety states across participant was 70.6±48.5 seconds (efficiency). The likeability of the application was rated as 4.1±0.9 (satisfaction). Based on these results, the main usability issue identified was the need for an auditory or tactile indicator to user attention during arousal states. Participants also suggested personalization of gradient colors.

Conclusions: Our results suggest that the Anxiety Meter interface is usable for children with ASD, though there is a need for an auditory or tactile signal to gain user's attention during arousal states. Future studies should investigate the clinical effectiveness of the device in improving awareness of arousal signs in this population.

26   **137.026** Seeing the Doctor without Fear: Systematic Desensitization for Medical Visits in ASD

*V. Pensosi[1] and **B. Villamia**[2], (1)28223 Pozuelo de Alarcon, Fundación Orange, Madrid, MAD, Spain, (2)Fundación Orange, Madrid, Spain*

Background: People with asd not only have greater medical needs than the rest of the population (Gurney, McPheethers and Davis, 2006), but they also have particular characteristics that make it very difficult for them to get the medical services (need for anticipation, lack of flexibility, problems identifying and describing symptoms, hypersensitivity to certain stimuli, stress over waiting times, etc.). Going to a medical visit can be a traumatic experience for people with ASD and their families.

Objectives: To respond to this difficulty an important Spanish Hospital together with a private foundation are developing a free software and a Web called "Doctor TEA" for desensitization before medical visits. The project explain with cartoons, pictograms and movies several medical services so people with ASD can anticipate the event and feel less stress.
Methods:
The project will focused on the following:
-To design, implement, and evaluate a program based on
new technologies that make the medical environment more
familiar and less stressful to patients with ASD before, during,
and after a hospital visit.
- To evaluate the effectiveness of this program for reducing
patient stress and anxiety, improving the family's quality care
perception, and reducing medical visit time.
Results: The project design software is built on a Web platform with a set of structured contents (in film format of a real hospital, in 2D and 3D) showing the physical spaces, medical professionals, techniques, and instruments used during a medical examination, including many interactive games. The project is freely available at www.doctortea.org
Conclusions: Daily clinical practice demonstrates that with preparation and specific training in reducing sensitivity to medical procedures, patient anxiety is considerably reduced. The reasoning behind this program, which will be freely available to the public in the future, is to try to demonstrate that information, communications and technologies (ICTs) can help people with autism to anticipate and understand medical visits and tests that any hospital or health centre may perform.

27   **137.027** A Smartphone Application Designed for Teaching Emergency Safety Skills to Children with Autism Spectrum Disorders

J. Huber[1,2,3,4], *S. So*[5], *T. Jegathesan*[1], *S. Davis*[1], *M. Goodman*[1], *E. Young*[1,3], *N. Mistry*[1], *D. M. Campbell*[1,6,7], *H. J. Bonifacio*[1,7,8] *and A. Mihailidis*[4,5], (1)Pediatrics, St.Michael's Hospital, Toronto, ON, Canada, (2)Division of Neurology, Hospital for Sick Children, Toronto, ON, Canada, (3)Division of Developmental Pediatrics, Department of Pediatrics, University of Toronto, Toronto, ON, Canada, (4)Department of Rehabilitation Sciences, University of Toronto, Toronto, ON, Canada, (5)Artificial Intelligence & Robotics in Rehab Team, Toronto Rehabilitation Institute/University Health Network, Toronto, ON, Canada, (6)Allan Waters Family Simulation Centre, St.Michael's Hospital, Toronto, ON, Canada, (7)Pediatrics, University of Toronto, Toronto, ON, Canada, (8)Divisions of Adolescent Medicine and Emergency Medicine, Hospital for Sick Children, Toronto, ON, Canada*

Background: Safety in emergency situations is a major concern for parents of children with Autism Spectrum Disorders (ASD). Many children with ASD demonstrate a lack of safety awareness and may be more at risk of injury than typically developing children. Training children to recognize emergencies, dial 911 and communicate to a dispatcher can save lives.
Personal mobile smartphones are rapidly replacing landline phone use and children are reported to be the largest new user group of mobile technology. However, due to the complexity of mobile smartphone devices, compared to landline phones, children may not know how to access the emergency call function, bypass a passcode, access the phone keypad, and/or dial 911 on a mobile device. Further, 911 dispatchers are often unable to verify a location from a mobile phone call and therefore require a caller's report of their address and/or location, name, and emergency.
Applied Behavior Analysis (ABA) has been shown to be an effective way to teach children with ASD new target skills. The Behavior Skills Training (BST) model (i.e., instruction, modeling, rehearsal and feedback) is an effective way to teach emergency skills. Given the unique needs of children with ASD, and the progression toward widespread use of mobile technology, an emergency skills training program for mobile phones using ABA principles would be a novel and effective way to prepare children with ASD for emergencies. Traditional emergency education programs do not incorporate ABA techniques or address the specific needs of children with ASD.
Objectives: The objective of this study was to design a smartphone mobile training application (app) using ABA principles and simulated practice to teach children with ASD to recognize an emergency and to respond to the emergency by calling 911 on a mobile phone to seek help.
Methods: Using a sociotechnical approach an inter-disciplinary team of experts from developmental pediatric medicine, behaviour therapy, simulation, biomedical engineering, and mobile app design developed a smartphone app that utilizes the principles of ABA and simulation training techniques, including video modelling, simulated practice (rehearsal), prompting strategies and fading of promtps (for errorless learning opportunities) and feedback (via positive reinforcement).
Results: The app includes a video model, simulated training to recognize emergency situations, and teaching how to dial 911. The app includes both verbal and visual prompts which gradually fade when mastery is achieved. Feedback is given through gamification, with points for success. The advanced levels also provide practice responding to a simulated 911 dispatcher with voice recognition capabilities, including identifying type of emergency, name, location and description of emeregency event. Accuracy (percentage of steps correct) , frequency of use and level of achievement are collected.
Conclusions: Using ABA principles, we developed a fully operational prototype of a smartphone app designed to teach children with ASD to recognize emergencies, to respond to the emergency by

dialing 911 and to communicate with a 911 dispatcher on a mobile phone. Studies are planned to evaluate effectiveness and utility of the app for emergency skills training in children with ASD.

28   **137.028** An Interactive App for Social Skills Training in Autism Spectrum Disorder

B. Kinsella[1] and A. Kushki[1,2], (1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada

Background: Deficits in social communication are defining features of autism spectrum disorder (ASD). These deficits negatively affect long-term outcomes for those with ASD and have been associated with unemployment and under-employment, low rates of independent living, and increased risk of psychiatric disorders. While prognosis can be significantly improved with intervention, few evidence-based clinical interventions exist for social skill deficits in ASD. Existing interventions are resource-intensive, their outcomes vary widely for different individuals, and they often do not generalize to new contexts. Technology-aided intervention is a motivating, low-cost, and versatile approach for social skills training in ASD. It can provide a safe and controlled venue for rehearsal of skills in a self-paced and personalized manner, allow for treatments to be implemented with high precision and fidelity, and reduce the cost, resource, and other accessibility barriers to existing treatments. Although early studies support the feasibility and potential effectiveness of technology-aided intervention for social skills training in ASD, existing approaches have been criticized for their shortcomings in teaching skills that can be generalized to new contexts.
Objectives: The objective of this study is to build and evaluate a novel technology for supporting social skills training in children with ASD in order to facilitate skill generalization.
Methods: An interactive "app" was developed on the Android platform to allow rehearsal of skills in social situations. Building on key strategies for teaching generalizable skills in ASD, the app features rehearsal with variation (repetition of skills across different situations), systematic fading of prompts (decreasing user supports with progress), reinforcement (rewards for positive behaviours), and feedback (reports of user performance). Each social scenario is designed as a multi-level game that personalizes training based on each child's needs and strengths. At each level, the scenario details (e.g., background, interaction partner) are varied. With increasing difficulty level, the amount of visual and auditory noise increases and user prompts decrease. To allow seamless user interactions, the app employs speech recognition and generation. An eye-tracking algorithm is used to ensure appropriate eye contact throughout the interaction. Various features for personalization of scenarios and rewards are provided for both the child and the caregiver.
Results: A fully functional prototype has been implemented (Figure 1). A usability study with 10 children with ASD is in progress.
Conclusions: To the best of our knowledge, Holli is the first interactive technology-supported prompting system for social skills training in ASD. This app can ultimately improve outcomes for individuals with ASD by providing a portable, accessible, and cost-effective system for social skills intervention.

29   **137.029** Mebook – a First-Person Social Narrative Game

N. M. Uzuegbunam[1], W. H. Wong[2], S. C. S. Cheung[3] and L. A. Ruble[2], (1)Electrical Engineering, University of Kentucky, Center for Visualization and Virtual Environments, Lexington, KY, (2)University of Kentucky, Lexington, KY, (3)Center for Visualization and Virtual Environments, University of Kentucky, Lexington, KY

Background: The gateway to social interaction is greeting. It is the first and last thing in many social situations. Unfortunately, individuals diagnosed with Autism Spectrum Disorder (ASD) face significant challenges when engaging in social interactions (APA, 2000). Social narrative intervention has proved useful in helping children with ASD learn social skills (Collett-Klingenberg and Franzone, 2008). However, social narratives are delivered in text and still images, often based on scenarios and characters that are foreign to the reader. As young ASD readers often have short attention span, such a presentation may be enhanced by taking advantage of modern gaming platforms. Digital learning games have been shown to stimulate the learners' interest in the material, even engaging students with low self-efficacy (Amon and Campbell, 2008, Saridaki and Mourlass, 2011). Many platforms also include cameras that allow customization of games through the use of self-images. Self-images, as a tool for interventions, have been shown to be effective for establishing desirable responses in young children with ASD (Ihrig and Wolchik, 1988). The combination of games and self-images may improve the efficacy of social narratives by engaging and holding the attention of the reader, allowing the child to connect with the characters in a story, and subsequently, learning the material faster.
Objectives: This technical demonstration showcases **MEBook** , effective social narrative intervention for increasing social greeting behavior with peers and adults.
Methods: **MEBook** is an animated social narrative game consisting of: 1) an animated social narrative story with the self-image of the child as the main character (Figure 1 left) and 2) a gaming session to practice the target behavior with other characters (Figure 1 right). **MEBook** shows the child, with adults and peers, in various greeting scenarios with animations of the child and/or other characters waving, speaking or engaging in appropriate greeting behavior. The story is read by, or narrated to,

the child. Gaming sessions follow a story. These sessions use a Microsoft Kinect™camera to detect when the desired greeting gesture (a wave) is performed either in response to an animated character's greeting wave or in initiation when an animated character appears on the screen. Visual, sound, and verbal feedback are given continuously. A child can have as many chances as desired.
Results: A multiple baseline single subject study, with three boys with ASD (7-12 years), was conducted**.** Details of the study are described in a separate IMFAR submission. Participants showed significant increase in their total responses rates. This occurred as the participants began **MEBook** intervention. In addition, after the introduction of the **MEBook** intervention, and all through their intervention phase, two participants showed much eagerness to play **MEBook** even before their therapy session.
Conclusions: **MEBook**, a software system that creates individualized social greeting stories using games and self-images of the participants, was designed. The application, via the Microsoft Kinect™ camera, provides participants with practice chances to rehearse different greeting scenarios. A multiple baseline single-subject study saw showed promising results.

30   **137.030** Using Mobile Phones Screen Mirroring to Improve Social Skills for Children with Autism
M. Habash, *Leeds Becket University, Ottawa, ON, Canada*

Background: The Android OS for mobile devices has the build-in capability of allowing a user to mirror his or her screen into another person's Android device. This simple but great feature may be used to communicate own thoughts or reflect on others' thoughts or behaviors. A simple mobile application called "Mirror-T" was designed to enable the use of the mirroring feature to improve social skills through engagement and enjoyment in children with autism
Objectives: to assess benefits of the Mirror-T program as an intervention in improving social skills in highly functional children with autism
Methods: Eight high-functioning children with autism and 10 typically developing children who were matched on chronological age are being tested using the Mirror-T application and screen mirroring feature to determine the engagement and enjoyment factors during the use of the program.
Results: Results will be available upon completion of the testing in Feb 2015
Conclusions: No conclusions available yet.

31   **137.031** Technology-Based Framework to Improve Quality of Life of Parents of Children with Autism in Gaza Strip
M. Habash, *Leeds Becket University, Ottawa, ON, Canada*

Background: Gaza Strip suffers from severe political and socio-economic challenges. The region lacks any institutional or governmental facilities to offer help to people with autism and their families. The lack of abilities to screen, assess, or provide intervention to children with autism increases families stress and leads to further suffering for the children. A technology-based framework was designed and reviewed, and currently under implementation with four families of children with autism to offer them world-class services for their children with autism using computers and mobile technology.
Objectives: To evaluate the effectiveness of a culturally-appropriate technology based framework for families of children with autism in the Gaza Strip and assess the possible areas of improvements to the lives of the families and their children using technology.
Methods: A 2-way computer application and a video channel were developed to enable the delivery of information and facilitate the communication with the participating families. Currently at the first phase, families were given the opportunity to share and request information from volunteer expert facilitators regarding their children's cases. Families participated in the implementation of different interventions and received feedback on regular basis based on data they collected and submitted on regular basis. Quantitative and qualitative data is being collected during the first phase of the study and will be reported on for the meeting
Results: Results will be available for the meeting
Conclusions: Conclusions will be published upon completion of the phase

32   **137.032** Enhancing the Perceptive and Cognitive Visual Processes in Low-Functioning Autism: Sigueme (FOLLOW-ME)
V. Pensosi, *28223 Pozuelo de Alarcon, Fundación Orange, Madrid, MAD, Spain*

Background:

 Individuals with low-functioning autism often are not prepared to manage the abstraction level that the language requires cannot use programs oriented to it. Besides, in the most severe cases they cannot manage graphical representations and do not understand that what is represented in image corresponds to a specific meaning.

Objectives:

Sigueme´s goal is to design and develop an educative software tool to allow the teaching and learning of skills to enhance the development of two processes in people with low-functioning autism:
the visual-perception and the cognitive-visual processes. The software developed is made up of six incremental phases, which range from basal stimulation to the classification of pictograms,
photographs and text, making use also of videos, gestures and words.

Methods:

The phases are:

Attention. This phase presents a series of animation sequences divided in four groups. Its objective is to improve the user's attention to various visual and auditory stimuli.
Video. To train visual attention through moving images in realistic 3D video sequences. This phase is divided into scenes, environments and areas containing different everyday concepts.
Image. To increase the abstraction of the previous phase presenting the same concepts using animated 2D photographs with simple movements.
Drawing. To work an equivalence between concepts presented as a photo, as a picture and as a grey scale silhouette.
Pictograms. To help in the recognition of pictograms and the generalization of concepts from previous phases. Its goal is to enhance mental and linguistic representation.
Games. Different exercises are suggested to classify simple objects taking into account colour, functionality, similarity, etc.

Depending on the skills of the user, some phases can be performed in three interactive modes: just see, touch or hit. The second one requires that the user touches the screen to continue the

exercise, and the third that the user touches the correct image that they are asked to.
Results:
Daily observation SIGUEME tool use and PECS system implementation show that:
a)   Thirteen students have used "Image Phase" of SIGUEME to train the "cause-effect" relationships. They have achieved visual attention to basal stimuli and videos, increasing visual and auditory attention and facilitating access to levels 1 and 2 of PECS.
b)   Ten students who have done activities of "Image, drawing, pictograms Phases" of SIGUEME with the objective to train equivalence between a concept shown as a photograph, picture or grey-scale silhouette have achieved level 3 of PECS.
c)   "Games Phase" of SIGUEME focuses on the recognition of concepts and training of cognitive processes by categorizing and sorting. Nineteen students who have worked this phase have accessed to levels 4 and 5 of PECS.
d)   All students have shown great motivation because content personalization of SIGUEME tool.
Conclusions:
SIGUEME is a useful tool as reinforcement in the implementation of communication systems such as PECS. In addition, the personalization obtained with the editor tool allows creating a version of SIGUEME per user, with adapted content to his/her interests and immediately environment. There are so many versions of SIGUEME as customization made of the same.

33   **137.033** AMP: An Autism Management Platform
E. J. Linstead, R. Burns, D. Nguyen and D. Tyler, *Schmid College of Science and Technology, Chapman University, Orange, CA*

Background:
To ease the burden of collecting and managing data in support of the treatment and education of those diagnosed with autism spectrum disorder, we have built AMP (Autism Management Platform), a health care and educational information system consisting of a mobile application, web client, secure data repository, and analytics engine. Together these components simplify the means by which multimedia data can be captured, disseminated, navigated, and analyzed by caregivers, educators, and clinicians. The result is a fully-integrated, intuitive system that aims to improve data sharing and facilitate data mining, with the ultimate goal of streamlining the treatment process for families and

professionals alike. Because AMP has been designed as a modular platform, features can be easily augmented in response to new users, or new perspectives on treatment plans.

Objectives:

In designing AMP priority was given to producing a cohesive and integrated suite of tools capable of supporting multiple users with multiple roles within ASD treatment. In particular, a multi-modal interface that can easily deployed on tablets, smart phones, and desktop computers was a driving requirement in order to easily support in-the-field usage. This includes tracking IEP goals, collecting clinical data during therapy sessions, and analyzing data in real-time to identify pertinent trends. While several commercial solutions exist that provide some of these functions individually, AMP is notable in the level of integration provided, as well as the fact that the system is based completely on free and open source software. The result is an affordable, evolvable system.

Methods:

The AMP system can be decomposed into several major subcomponents. A mobile app allows users involved in the day-to-day care of an individual, such as a parent or teacher, to capture data ``in the moment'' using a smart phone or tablet. A healthcare professional, such as a neurologist, can use the web client to monitor their patients' data using a dashboard view, drilling down into items of interest, responding to feed items, or making private notes as they see fit. Finally, an analytics engine works in conjunction with a database to aggregate and mine patient data for patterns, the results of which can be visualized in the web client.

Results:

The subcomponents of AMP are fully implemented and capable of scaling to real-world clinical and educational environments. The mobile application has been tested for compatibility with a wide variety of Android tablets and smart phones. The system is currently in the user-testing phase, and recently completed a one-month pilot study in a high-school special day class supporting 10 students and 23 staff members. Initial feedback is positive with 80% of staff reporting an increase in the ease with which data is collected and tracked. We are currently transitioning to testing in a clinical setting.

Conclusions:

Though still in its infancy, AMP fills a gap in existing autism technologies, and shows promise for improving the ease with which data can be collected, shared, and analyzed to improve the treatment and education of those living with an ASD diagnosis.

34   **137.034** Use of Behavior Imaging to Assess Inter-Rater Reliability in a Multi-Site Pharmaceutical Trial

R. M. Oberleitner[1], U. Reischl[2] and K. G. Gazieva[1], (1)Behavior Imaging Solutions, Boise, ID, (2)Department of Community and Environmental Health, Boise State University, Boise, ID

Background: Multi-site pharmacological trials offer numerous methodological advantages over single-site trials. Multi-site trials can enhance external validity, provide greater statistical power, are often more representative of the patient population [5,7,8]. However, multi-site trials are sometimes associated with disadvantages such as reduced data quality, greater heterogeneity of results, and poorer interview quality [3,4]. While some of these issues may be controlled statistically, the systematic error due to interviewer errors across multiple sites cannot be addressed statistically [3]. The need to reduce such errors has been highlighted in a number of studies [1,3,5,8]. Approaches used to enhance inter-rater reliability include such measures as rater training and co-rating of video recorded interviews [1]. A behavior imaging (BI) technology was used for such a purpose in a multi-site pharmaceutical trial. This technology facilitated the training of raters and provided automated assessment of inter-rater reliability measures. The system was based on a store-and-forward telehealth method.

Objectives: The objective of the study was to document rater reliability outcomes for two interview protocols that included the Autism Diagnostic Observation Schedule (ADOS) and the Social Communication Interaction Test (SCIT). Both were administered and scored in the multi-site pharmaceutical trial. Attention was placed on identifying items in both of the diagnostic tests that contributed to inconsistencies in ratings between raters and the "Gold Standard" (GS). The feedback allowed targeted training of the raters to improve the inter-rater reliability.

Methods: This experimental study was conducted in collaboration with four national medical research institutions. Reliability checks were done at the beginning of the study. Raters at four sites viewed pre-recorded interviews and scored their observations through the BI on-line platform. After each rater completed the scoring, the results were compared to the GS through an automatically generated report. The report identified discrepancies in the scoring and recommendations for improving the rater's accuracy. Raters were required to repeat their assessments until their scores matched the GS.

Results: All raters completed reliability checks for ADOS and SCIT. Table 1 depicts training examples of rater assessments using SCIT protocol. A rater is considered not reliable if there is a difference of more than 1 for each of the domains and more than 10% for the total score. The summaries show that Rater #1 matched the Gold Standard in the domains A, B, E, and F, while domains C and D were different by one point in relationship to the GS. However, none of the differences were greater than "1" and the total score was the same as that for the GS. Therefore, Rater #1 was considered "Reliable". Rater #4 met the Gold Standard for domains A and F. Domain D was off by 2 points and domain E was off by 1 point. The difference between the GS and Rater #4 was off by 25% and was,

therefore, not considered "Reliable".
Conclusions: The study demonstrated the practicality of using the BI technology to document inter-rater reliability throughout the duration of a pharmacological study, conducting effective interviewer-observer training, and performing ongoing maintenance of assessment reliability.

35 **137.035** Analysis of Parent Responses to Using a Remote Autism Diagnostic Assessment System

*N. L. Matthews[1], C. J. Smith[1], N. Nazneen[2], **R. M. Oberleitner**[3], A. Rozga[4], G. D. Abowd[4] and R. Arriaga[5], (1)Research, Southwest Autism Research & Resource Center, Phoenix, AZ, (2)UserWise Usability Research and Consulting, Mountain View, CA, (3)Behavior Imaging Solutions, Boise, ID, (4)School of Interactive Computing, Georgia Institute of Technology, Atlanta, GA, (5)Georgia Institute of Technology, Atlanta, GA*

Background: A remote autism diagnostic assessment system was designed through a series of research studies conducted with clinicians and parents of children with autism. This system includes a smartphone video capture application for parents to follow clinician instructions to record and share video evidence of their child's behaviors; and a HIPAA-conforming web-based platform for clinicians to complete a diagnostic assessment for autism based on parent-collected naturalistic evidence.
Objectives: A field study was conducted to analyze parents' reaction to using the video capture application in their home.
Methods: Participant families had children between the ages of 21-86 months; 29 were referred for an ASD evaluation, 8 were typically developing, and the remaining 6 had other diagnoses. Using the video capture application parents recorded four 10 minute scenarios that included the child playing alone, the child playing with a sibling or parent, family mealtime, and parent concern(s). These scenarios were chosen because they are likely to encourage social communication and play behavior. A follow up survey was conducted to solicit parents' responses with regards to ease-of-use of the application, validity of the approach, adoption challenges, and their recommendations.
Results: Data shows that 95% (41/43) of parents found the video capture application easy to use. Parents found two aspects of design directly contributing towards the simplified capture experience. First, the design is simple, has clear iconic visuals, and needs "few clicks" to capture and upload. Second, the capture application has embedded clinician's prescription to guide parents in staging the environment (e.g. instructions about probes like books, toys and maintaining appropriate field of view) and use of social presses to engage the child (e.g. name call, pointing, eliciting child request) during the recording. Parents anticipated that the capture application would facilitate effective communication with caregivers about the child's naturalistic behaviors and would enable timely assessment. Although 58% (25/43) of parents reported that their child noticed the recording device, 91% (39/43) indicated that they captured either all (reported by 31 parents) or three (reported by 8 parents) scenarios representing naturalistic behaviors. Furthermore, when asked about privacy, 8 out of 43 parents mentioned some concerns about video sharing but all parents were willing to record and share if it was beneficial to their child. Parents recommended that having control over data capture and deletion, as well explicit data sharing policies could boost their trust and ease their privacy concerns. Parents suggested adding out-of-home recording scenarios since some behaviors of concern are more likely to trigger at school or other out-of-home environments. Majority of the parents (84% = 36/43) considered this method a valid approach for sharing clinical information. Among 7 parents who had some concerns, 5 recommended that this method should compliment in-person diagnosis instead of replacing it and 2 questioned its effectiveness for children with mild conditions.
Conclusions: Through in-home evaluation, parents confirmed that the video capture application facilitated a simplified and effective capture experience. Next, through a systematic study with clinicians the validity of the resulting diagnostic assessments will be analyzed.

36 **137.036** Web-Based Toolkit for Multimodal Data Analysis in ASD Research

O. O. Wilder-Smith *and M. S. Goodwin, Northeastern University, Boston, MA*

Background: Understanding human behavior and development through analysis of internal psychophysiological signals can provide objective insights into subtle behavioral, social, cognitive, and affective characteristics of individuals. Internal measures can afford caregivers, clinicians, and researchers with information that can both enhance and complement their own observations. For example, physiological signals, like electrodermal Activity (EDA), heart rate (HR), and heart rate variability (HRV), provide a window into an individual's internal affective and regulatory state, which may be otherwise unavailable or unobservable through audio-visual cues, especially in individuals with limited communication abilities and/or who have impoverished non-verbal displays (e.g., reduced facial expressivity). Recent advances in wearable sensing technology have made it possible to record ambulatory psychophysiological data from children with Autism Spectrum Disorder (ASD) together with time-synchronized video data in a variety of naturalistic settings. However, qualitative analysis and review of multimodal physiological data synchronized with video remains a cumbersome process, typically requiring multiple specialized software packages and complex configurations of data.
Objectives: To provide a suite of free, open, and easy-to-use tools to support qualitative analysis of physiological and behavioral data together with time-synchronized video to support ASD research.

Methods: We have developed the Computational Behavioral Science Toolkit (CBST), a free, web-based application for viewing and annotation of multimodal psychophysiological and behavioral data together with time-synchronized video. CBST runs in any modern web browser without the need for installing specialized software, and data loading and interaction is accomplished via a simple drag and drop interface.

Results: Members of our lab and collaborators from both technical and non-technical fields have used CBST to review, present, and perform qualitative analyses on data collected in several on-going multi-site studies. Our demonstration will include opportunities for interacting with the application, present examples of physiology and video data from both assessment (ADOS-2) and intervention studies we are engaged in, and provide information on how other researchers can access and use the toolkit in their own research.

Conclusions: CBST provides a simple, free, web-based platform for viewing, analyzing, and presenting multimodal psychophysiological and behavioral data.

37 **137.037** Tablet-Based Method for Handwriting Assessment

B. Dirlikov[1], M. B. Nebel[2], A. J. Bastian[3], L. Younes[4] and S. H. Mostofsky[5], (1)Kennedy Krieger Institute, Baltimore, MD, (2)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (3)Johns Hopkins School of Medicine, Kennedy Krieger Institute, Baltimore, MD, (4)Applied Mathematics and Statistics, Johns Hopkins University, Baltimore, MD, (5)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD

Background: Handwriting is crucial for success in school, daily living, and communication with others. Difficulties with handwriting can interfere with a child's ability to dedicate cognitive resources necessary to learn a wide range of subject matter and consequently mask a child's capabilities in other areas. As high as 37% of children are estimated to have handwriting difficulties; it is one of the most common reasons children are referred for occupational therapy and is associated with a number of developmental diagnoses –including children with autism spectrum disorder (ASD) who struggle to develop a wide range of skilled motor behaviors and are therefore particularly vulnerable to handwriting impairments. Existing handwriting assessments are limited to labor-intensive manual measures of letter formation that produce qualitative, categorical (correct vs. incorrect) ratings and computerized kinematic analyses that lack any measures of letter-form.

Objectives: To developed a fully automated cloud-based handwriting analysis program for Android and Apple tablets that seamlessly enables evaluators and interventionists across a range of disciplines to quantify handwriting performance across multiple dimensions.

Methods: Our approach incorporates both real-time kinematic feedback as well as a detailed, quantitative measure of letter formation. This novel and unique letter-form analysis employs a computational morphometric algorithm that maps the template letter to the subject's letter, and in so doing, generates a continuous measure of letter formation that is highly reliable. To date, a research-suitable version of this program has been developed and piloted in children using two tasks: English characters (42 Typically Developing [TD], 6F; 28 ASD, 2F; 23 Attention-Deficit Hyperactivity Disorder [ADHD], 4F) and Non-English characters (45 TD, 7F; 25 ASD, 3F; 25 ADHD, 5F). For each task, children completed three conditions: copy, trace, and fast trace. All groups were balanced for age, sex, PRI (WISC-IV), Socio-economic status, and handedness. Motor abilities were assessed using the Physical and Neurological Examination for Subtle Signs (PANESS).

Results: Consistent with previous research, our novel computerized assessment of letter-form revealed impairments in children with ASD compared with TD children across all tasks and conditions (English copy p =.031, trace p<.001, fast trace p<.001; Non-English copy p =.062, trace p=.014, fast trace p=.021; figure 1), as well as significant differences between ASD and ADHD in the English fast trace condition (p=.036; figure 1). No group differences (TD, ASD, and ADHD) were observed in terms of handwriting kinematics.

Letter form, in both tasks, was correlated with the WISC-IV's working memory index across all conditions in the ASD group (p<.008) and with PANESS total score for the trace condition (p<.05). These results may suggest decreased automaticity and greater recruitment of higher order cognitive systems (e.g. mPFC and DLPFC) in the ASD group.

Conclusions: Our novel method is sensitive to diagnostic differences, particularly in ASD and can be used for both English and Non-English characters which allows for inclusion of an international community. The tablet based handwriting assessment will empower both professionals and interventionists to readily implement and evaluate the efficacy of targeted interventions for handwriting, serving a large public health need.

41   **138.041** A Comparison of Clinical Versus Self-Report Measures: An Evaluation of the Broad Autism Phenotype in Parents of Individuals with Autism

J. Barstein, K. Nayar, N. M. Heckel, L. Bush and M. C. Losh, *Roxelyn and Richard Pepper Department of Communication Sciences and Disorders, Northwestern University, Evanston, IL*

Background: The Broad Autism Phenotype (BAP) refers to a constellation of subclinical behavioral features related to the core symptoms of autism, expressed among unaffected relatives and indexing genetic liability. Studying the BAP is critical for understanding the complex etiology of autism. While in-person objective assessments of the BAP have been well validated (e.g., Piven et al. 1997), they are often labor- and time-intensive. Questionnaires offer a time-efficient alternative, but may be subject to reporting bias. It is therefore important to identify valid yet efficient assessments that reliably capture the BAP. Recent work (Sasson et al., 2014) reported significant discrepancies on questionnaires of self- and informant-reports of the BAP in fathers of children with autism when they were positive for particular BAP features, suggesting that clinical judgment is required for a deeper characterization of the BAP, particularly in fathers. This study investigates agreement between objective clinical ratings of BAP features using gold standard objective, relative to questionnaire measures.
Objectives: To compare agreement between questionnaire and direct assessment measures of the BAP in a large sample of parents of children with autism.
Methods: Participants included 171 parents of children with autism (107 mothers; 64 fathers). All participants completed a self- and informant-report version of the Broad Autism Phenotype Questionnaire (BAPQ; Hurley et al., 2007), a well-validated questionnaire that quantifies BAP characteristics. Personality features of the BAP were assessed using the Modified Personality Assessment Scale (MPAS; Tyrer, 1988), in which subjects and informants are interviewed separately about personality styles, and ratings are conducted by blind, independent coders relying on concrete behavioral examples. Pragmatic language was assessed using the Pragmatic Rating Scale (PRS, Landa et al., 1992), in which a semi-structured conversational interview is conducted and objective coders rate the presence of clinically significant pragmatic language violations. BAP (+) status was defined by the presence of at least two of the directly assessed BAP characteristics (*Aloof*, *Rigid*, or *Pragmatic Language deficit*). On the BAPQ, parents were classified as BAP (+) based on published criteria.
Results: A series of 2x2 chi-squared analyses were conducted to assess differences between questionnaire (BAPQ) and direct assessment (MPAS/PRS) scores. Overall, the BAPQ was less accurate in classifying fathers as BAP (+) ($p < .05$). This relationship was driven by discrepancies in *Aloof* ratings ($p < .01$). *Rigid* traits and *Pragmatic language* ratings were consistent across questionnaire and direct assessment in both groups.
Conclusions: Results mirror those of Sasson et al. 2014, suggesting that fathers may be less likely to endorse *Aloof* traits and overall BAP features in themselves. Alternatively, clinical evaluation (i.e., MPAS) may be more sensitive in capturing such traits in fathers. Data will be further explored to examine specific agreement between self- and informant-report measures on both the MPAS and BAPQ, assessing whether variables such as social cognition and gender may predict consistency (or lack thereof) between each measure. This study has implications for future phenotyping efforts relevant to molecular genetic, neurobiological studies of autism incorporating data from both affected individuals and unaffected family members.

42   **138.042** A Comparison of Diagnostically Relevant Item Response Characteristics Between Females and Males with Autism

R. A. Embacher[1], A. Y. Hardan[2] and T. W. Frazier[3], *(1)Center for Autism, Cleveland Clinic Children's Hospital, Cleveland, OH, (2)Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, (3)Cleveland Clinic, Center for Autism, Cleveland Clinic Children's, Cleveland, OH*

Background: Males are 4-5 times more likely to be diagnosed with Autism Spectrum Disorder (ASD) than females. This powerful observation implies, not only that males are at greater risk, but that there may be real differences in the expression of ASD between males and females. Previous work from our group and others has primarily focused on broad indicators (IQ, social and repetitive behavior composite scores, etc.). No prior studies have evaluated measurement factors that may lead to sex differences in specific item characteristics relevant to diagnosis.
Objectives: To compare diagnostically-relevant item characteristics (discrimination and thresholds) between females and males with ASD.
Methods: We analyzed data from 2,418 probands with ASD (304 females and 2114 males) included in the Simons Simplex Collection. A series of multi-group confirmatory factor analyses (MG-CFA) were conducted using items measuring four constructs hypothesized to show sex differences in item endorsement - interpersonal relationships, social avoidance, need for sameness, and restriction of interests. Items measuring each of these constructs were selected from the Autism Diagnostic Interview-Revised (ADI-R), Social Responsiveness Scale (SRS), and Repetitive Behavior Scale-Revised (RBS-R). Chi-square difference tests compared item discrimination and threshold differences between males and females with ASD.
Results: Restricted interests items showed highly significant differences in item thresholds between

males and females; item discrimination was consistent across sexes. Restricted interests items were less likely to be endorsed (higher thresholds) for females relative to males across all three instruments. There were also two interpersonal relationships items that showed nominally significant sex differences, reflecting that females with ASD are teased less frequently than males and that females with ASD are more likely to share enjoyment. However, these differences did not meet false discovery rate correction.

Conclusions: No sex differences in the measurement characteristics of social avoidance and need for sameness items were observed. Less frequent teasing and increased endorsement of shared enjoyment, while not meeting false discovery rate correction, may suggest a small influence of early socialization experiences and greater peer support in providing some protection for females with ASD from interpersonal relationship difficulties. Additional research is needed to directly evaluate early learning or peer relationship protective factors as modifiers of the expression of ASD in females. Most striking was the observation that restricted interest items from three separate instruments showed higher thresholds in females but equal discrimination. Equal discrimination implies that restricted interests items are an important and relevant aspect of restricted/repetitive behavior in females and males. Sex differences in item thresholds could be interpreted as implying measurement artifact resulting from the use of male-centric items within existing instruments. However, the present analyses suggest this explanation is unlikely because the restricted interests item from the SRS (#39) had no obvious sex bias in wording/exemplars. Instead, fewer restricted interests in females with ASD appears to be a real phenomenon. Additional research is needed to completely rule out the possibility of measurement or rater bias. If lack of bias is confirmed, future investigations should evaluate biological and environmental protective factors that lead females to express fewer restricted interests.

43   **138.043**   A Longitudinal Evaluation of Restricted Behaviors and Sensory Interests in Angelman's Syndrome Using the Behavior and Sensory Interests Questionnaire

D. Peterson[1], J. Love-Nichols[1], S. Maisel[2] and E. Hanson[2], (1)Division of Development Medicine and Program in Genomics, Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital, Boston, MA

Background: Angelmans Syndrome (AS) is a neuro-genetic disorder characterized by severe intellectual and developmental disability. Clinical reports have described a high level of sensory interests and repetitive behaviors (RRB) in AS, though there has been a paucity of research in this area. Currently only a single study (Walz, 2007) using the Gilliam Autism Rating Scale, has looked at RRBs in this population. However, Richler et. al (2010) examined how restricted and repetitive behaviors and interests (RRBs) developed over time in a sample of children with ASD. For children with ASD, RSM scores remained relatively high over time whereas IS scores started low and increased over time. In addition, having a higher nonverbal intelligence (NVIQ) at age 2 was associated with improvement in RSM behaviors over time. There was no relationship between NVIQ at age 2 and IS behaviors.

Objectives: The current study describes the type, number and intensity of RRB's in large AS population over a four year time period, using a newly standardized scale, the Behavior and Sensory Interest Questionnaire (BSIQ) to describe these behaviors.

Methods: A sample of 152 (50.7% female) children ranging from age 36-209 months (mean 84, SD 42). Participants were drawn from an eight year longitudinal study. Subjects were followed from 1 to 4 years. The BSIQ, a newly standardized interview based measure designed to evaluate the number, type, and intensity of a comprehensive array of RRBs was administered to all parents (Hanson et al, submitted). Children also received additional cognitive and behavioral testing.

Results: This is the first study to take a comprehensive look at RRB behaviors in an AS population. Of the behaviors exhibited, 85% were RSM behaviors and 15% were IS behaviors. Analysis showed that the majority of children (94%) with AS exhibited at least 1 RRB. High percentage of flapping behavior exhibited; heterogeneous among all IQ groups (range of 53-88%). This is consistent with Walz 2007 which also found a commonality between flapping behaviors (56%) in individuals with AS. Analysis is ongoing for the longitudinal trajectory of these behaviors as well as the impact of cognitive ability.

Conclusions: Implications suggest that providers should be aware of the high prevalence of behaviors in individuals with AS and the possibility that these behaviors can impact current and future functioning of children with AS as well as have a negative impact on family members. Future research is needed to explore and confirm these findings. In addition, these behaviors should also be compared to those children with other developmental issues, such as ASD.

44   **138.044**   A Method for Universal Screening of Social Challenges in Elementary School Students

C. J. Smith[1], E. Pollard[2], S. E. Ober-Reynolds[3], N. L. Matthews[4], A. J. Stein[5], R. Melmed[6] and D. Openden[7], (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)Research, SARRC, Phoenix, AZ, (3)Southwest Autism Research & Resource Center (SARRC), Phoenix, AZ, (4)Research, Southwest Autism Research & Resource Center, Phoenix, AZ, (5)Neurology, University of Colorado, Anschutz Medical Campus, Aurora, CO, (6)Southwest Autism Research Center and Melmed Cente, Scottsdale, AZ, (7)Southwest Autism Research and Resource Center, Phoenix, AZ

Background: The current prevalence of ASD is 1 in 68, which is based on eight year old children (CDC,

2014). Yet, the National Children's Health Survey, which included 17,000 households with children between 6 and 16 years, indicated rates of 1 in 50 (Blumberg et al., 2013). Thus, many individuals are diagnosed with ASD after early childhood. Further, a substantial literature indicates that social challenges in elementary school students are associated with limited academic performance (DiPerna & Elliott, 1999; Wentzel, 1991, 1993). However, schools do not perform systematic, general screening for social challenges. Universal screening of elementary school children may help to detect children with milder forms of ASD and lead to improved functioning. This report describes the empirical development of the Social Challenges Screening Questionnaire (SCSQ), a brief questionnaire to identify elementary school students at risk for ASD or other social disorders.

Objectives: To empirically develop and test the SCSQ, which is appropriate for universal screening in elementary schools.

Methods: The development phase included 30 participants (28 males) diagnosed with ASD after age 6 years (ages 6 to 54 years; $M = 19.55$, $SD = 10.93$) and one parent informant.. Diagnosis of ASD was confirmed with ADI-R, ADOS, Vineland 2, and Stanford-Binet 5. Participants for the validation phase were 35 teachers from eight charter schools who completed the SCSQ on 549 general education students (ages 8 to 11 years, $M = 9.51$, $SD = 0.65$). Students with scores in the upper 2.5% of the distribution ($n = 15$) and a comparison sample of students ($n = 35$) from the lower end of the distribution, were selected for follow-up assessment with the Social Responsiveness Scale 2. The subsample ($n = 50$) consisted of 33 males and 17 females (ages 8 to 11 years of age; $M = 9.42$, $SD = 0.67$).

Results: Scores on the SCSQ ranged from 0 to 14 ($M = 1.38$, $SD = 2.42$) and every item was endorsed by this sample. Cronbach's alpha was .85. Inter-item correlations ranged from .008 to .638 and the deletion of any one item did not change reliability substantively in either direction (range =.82 to .85). In the subsample of 50 students, total scores on the SRS-2 ranged from 2 to 167 ($M = 60.22$, $SD = 41.13$) and were significantly correlated ($r = .87$, $p < .01$) with the SCSQ. An ROC curve was applied to compare the SCSQ to an SRS-2 dichotomy (0 = unaffected, 1 = affected) which indicated an optimal threshold score of 6 to yield a sensitivity of .94 and a specificity of .88.

Conclusions: Just as screening for vision and hearing impairments can lead to a referral to a specialist, the SCSQ should lead to a referral for formal evaluation for ASD. Then, students with mild impairments can be identified early within schools and enrolled in appropriate evidence-based intervention programs. The combined effect of universal screening, skilled evaluation, and early intervention may help to improve academic and long term functioning for students with social challenges.

45 **138.045** Ability and Disability in Autism Spectrum Disorder: A Systematic Literature Review Employing the International Classification of Functioning, Disability and Health-Children and Youth Version (ICF-CY)

S. Mahdi, Karolinska Institutet, Kista, Sweden

Background: The International Classification of Functioning, Disability and Health (ICF) was initiated by the World Health Organization (WHO) in 2001 to provide a comprehensive and an universally accepted framework for the description of health-related functioning. The ICF is based on an integrative biopsychosocial model of functioning and comprises over 1,400 categories related to various components of health, specifically; *body functions* (physiological functions of body systems), *body structures* (anatomical parts of the body), *activities* (execution of tasks), *participation* (involvement in a life situation) and *environmental factors* (physical, social and attitudinal environment of people). To facilitate the practical use of this comprehensive framework, so called ICF Core Sets have been developed for several health conditions. These are shortlists of generally-agreed-upon ICF categories that capture the aspects of functioning that are pertinent to individuals with a certain health condition. In order to facilitate the use of the ICF in ASD, the Karolinska Institutet Center of Neurodevelopmental Disorders (KIND) has initiated the process of developing ICF Core Sets for ASD, which are lists of generally-agreed-upon ICF categories that are pertinent to individuals with a certain health condition.

Objectives: The objective was to use a systematic review approach to identify, number, and link functional ability and disability concepts used in the scientific ASD literature to the nomenclature of the ICF-CY (Children and Youth version of the ICF, covering the life span).

Methods: Systematic searches on outcome studies of ASD were carried out in Medline/PubMed, PsycINFO, ERIC and Cinahl, and relevant functional ability and disability concepts extracted from the included studies. These concepts were then linked to the ICF-CY by two independent researchers using a standardized linking procedure. Since the search yielded large number of studies, samples were analyzed until no more new ICF-CY categories were identified.

Results: Seventy-one studies were included in the final analysis and 2475 meaningful concepts contained in these studies were linked to 146 ICF-CY categories. To restrict the results to those categories that are most relevant to ASD, only those that were identified in at least 5 % of the studies were reported. This left 99 categories for the final results, of which 63 were related to *Activities and Participation*, 28 were related to *Body functions*, and 8 were related to *Environmental factors*. The five most frequently identified categories were *basic interpersonal interactions* (51%), *emotional functions* (49%), *complex interpersonal interactions* (48%), *attention functions* (44%), and *mental functions of language* (44%).

Conclusions: The broad variety of ICF-CY categories identified in this study reflects the heterogeneity

of functional alterations found in ASD – both with respect to disability and exceptionality – and underlines the potential value of the ICF-CY as a framework to capture an individual's functioning in all dimensions of life. The current results in combination with three additional preparatory studies (expert survey, focus groups, clinical study) will provide the scientific basis for defining the ICF Core Sets for ASD for multi-purpose use in basic and applied research and every day clinical practice of ASD.

46 **138.046** Accuracy of ASD Diagnoses in a Sample of Black and Hispanic School-Aged Children

J. M. Jamison[1], *M. Oliphant*[1], *P. M. Weinger*[1], *J. Krata*[2], *E. Holl*[2], *J. Shaoul*[2], *B. Hernandez*[2], *J. D. Buxbaum*[1,3,4,5,6] and *A. Kolevzon*[1,7,8], (1)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (2)YAI, New York, NY, (3)The Mindich Child Health and Development Institute,, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Fishberg Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY, (5)Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY, (6)Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, (7)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (8)Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY

Background: Recent prevalence estimates from the Center for Disease Control (CDC) indicate that the rate of autism spectrum disorder (ASD) has risen disproportionately in Black and Hispanic populations, with 110% and 91% increases respectively. While better diagnostic practices and increased awareness may account for part of this increase, it remains unclear whether there is truly an epidemic in these populations or whether misdiagnosis or over-diagnosis may contribute to current prevalence estimates. Results from recent studies are mixed, with some indicating minorities are less likely to be diagnosed with ASD, and others considering minority status an additional risk factor. Further research is needed to better understand the presentation of ASD in minority populations.

Objectives: (1) To establish the diagnosis of ASD using gold-standard practices in an ethnically and racially diverse population of children who were previously diagnosed with ASD through community or educational resources. (2) To determine whether specific risk factors, either alone or in combination, can predict ASD diagnosis in this population.

Methods: Sixty children between the ages of 5 and 12 presented to the Seaver Autism Center at Mount Sinai for autism-focused diagnostic evaluations as part of ongoing studies examining evidence-based practices to improve the health and well-being of Black and Hispanic children with ASD. Sixty percent of the sample (n=36) presented with a previous diagnosis or IEP classification of ASD. All participants received comprehensive gold-standard evaluations, including a psychiatric evaluation, the Autism Diagnostic Observation Schedule (ADOS-2) and the Autism Diagnostic Interview-Revised (ADI-R). ASD diagnoses were based on consensus diagnosis and DSM-5 criteria.

Results: Twenty-eight percent of the sample identified their child as Black, 47% as Hispanic, and 25% as both Black and Hispanic. Of the 36 children presenting with a past diagnosis of ASD, approximately 70% (n=25) of diagnoses were confirmed and 30% (n=11) did not meet criteria for an ASD diagnosis. Of the 25 cases with confirmed ASD, 16% (n=4) also received a diagnosis of Attention Deficit/Hyperactivity Disorder (ADHD). Among the 11 cases previously diagnosed with ASD who did not meet criteria according to our consensus diagnosis, 82% (n=9) received a diagnosis of ADHD. Both groups endorsed multiple risk factors for ASD, including perinatal complications, admission to the neonatal intensive care unit (NICU), and delays in motor and language development. There were no significant differences between groups in the number or type of risk factors reported.

Conclusions: Our results suggest that there is a proportion of Black and Hispanic children who carry a diagnosis or classification of ASD whose symptoms may be better explained by other diagnoses. Within our sample, clinically significant ADHD symptoms were present in all but two participants whose ASD diagnoses were not confirmed through gold-standard evaluation. Future studies must explore ways to enhance diagnostic practices in community-based and educational settings to improve accuracy of diagnoses and to ensure optimal treatment. Given the high prevalence of risk factors found across groups in this study, it is important to continue examining risk factors in larger samples of ethnically and racially diverse children.

47 **138.047** Additional Testing Shows High Performance of Machine Learning Classifiers and Supports Potential for Rapid, Mobile Autism Risk Detection

D. Wall, Stanford University, Palo Alto, CA

Background:
In 2012, we published two pilot studies that used machine learning methods to construct and test the performance a small number of behaviors for autism risk detection. The outcome showed promise, however the studies were limited to archival data, relatively small numbers, an imbalance in the number of cases versus controls, and insufficient testing in less severe forms of autism. We have recently completed two studies aimed at addressing these limitations.
Objectives:
The objective was to test the accuracy of our original machine learning classifiers for detection of autism risk in a larger collection of archived samples and in prospectively generated clinical data.

Methods:
Archival data were gathered from the Simons Simplex Collection, Simons VIP, AGRE, and NDAR. Prospective clinical data were gathered at Boston Children's Hospital during a clinician run IRB-approved study. We ran the "observation" based classifier (OBC), constructed from our original analysis of ADOS, on the archival samples and compared the output to clinical outcome. The caregiver-directed classifier (CDC), constructed from our original analysis of ADI-R data, was mobilized for use on iPads and made available to families in advance of the clinical team evaluation. The outcome from this mobile CDC was later compared to the best estimate clinical diagnosis.
Results: We assembled an independent collection of ADOS data from 2333 spectrum and 283 nonspectrum individuals. We tested OBC outcomes against the outcomes provided by the original and current ADOS algorithms, the best estimate clinical diagnosis, and the Comparison Score severity metric associated with ADOS-2. The OBC was highly statistically correlated with the ADOS ($r = -0.8143$) and ADOS-2 ($r = -0.7793$) and exhibited >97% sensitivity and >77% specificity in comparison to both ADOS algorithm scores. The correspondence to the best estimate clinical diagnosis was also high (accuracy = 97%), with sensitivity of 97% and specificity of 83%. Concomitantly, we recruited 222 participants from Boston Children's Hospital; 69 (31%) were given a clinical diagnosis of ASD. The sensitivity of the MCDC in detecting ASD was 90% and the specificity was 80%.
Conclusions: Using a larger sample size, more controls and higher numbers of lower severity cases of autism, the performance of our classifiers drop expectedly below the initial levels seen in the pilot studies. However, the performance against best estimate clinical outcomes remains high and support the potential for use of machine-learning tools to streamline the process of initial detection and triage of autism risk, opening the bottleneck for more children to receive critical care earlier in development.

48   **138.048** An Item Response Theory Analysis of the Childhood Autism Rating Scale, Second Edition (CARS-2)

M. C. Davis[1], M. D. Toland[1], J. Campbell[1], L. Murphy[2] and L. Gardner[2], (1)Department of Educational, School, and Counseling Psychology, University of Kentucky, Lexington, KY, (2)University of Tennessee Health Science Center, Memphis, TN

Background: Evidence-based autism-specific rating scales yielding valid and reliable scores are often desired in combination with gold standard measures to render the diagnosis of ASD. The Childhood Autism Rating Scale, Second Edition (CARS-2) is an autism-specific rating scale that developers propose is effective in discriminating between children who have autism and those who have severe cognitive deficits. Previous studies examining the CARS have used Rasch scaling; however, there are no studies of CARS-2 psychometric properties and validity using similar techniques.
Objectives: Using a clinic-based secondary dataset, investigators used IRT techniques to examine the distribution of items across the ASD continuum as well as to determine the level of measurement precision across the construct continuum in a sample of participants with ASD, intellectual disability (ID), or ASD with comorbid ID.
Methods: A total of 173 participants (81.5% male; M_{age} = 44.19 months; SD = 12.9 months; 50.9% African-American) with a diagnosis of ASD-only (35.8%; n = 62), ID-only (13.3%; n = 23), or ASD and ID (50.9%; n= 88) were administered the CARS-2, Standard Version (CARS-2-ST).
Results: All 15 items on the CARS-2-ST fit to a Generalized Partial Credit Model (GPC) indicated that items were locally independent based on the standardized LD-χ^2(i.e., |LD| < 2 for all items). Inspection of step parameters and option response functions (ORFs) for each items shows that only item 15 has a unique curve for each response category, while most items show fewer than the suggested number of categories are used as expected. 6 items (4, 6, 9, 10, 13, and 14) had poor discrimination (i.e., a < .5), indicating little contribution to the differentiation between children with varying degrees of ASD. Item 10 (i.e., Fear or Nervousness) performed particularly poorly (see Figure 1). The S-χ2 item-fit statistic for polytomous data was used to determine absolute fit of the model to each item indicating that 4 items (1, 2, 8, and 14) had poor fit. Global fit was deemed acceptable, M_2 = 27.12, p= 0.08 , RMSEA = 0.05 . Marginal reliability for response item scores was deemed acceptable at .93, however, this estimate over and underestimates the level of precision depending on the location along the continuum. Consequently, a revised 15 item scale collapsing items down to 4 response categories reduced the number of unclear ORF's (see Figure 2), improved item discrimination, good fit across items, and acceptable marginal reliability at .90. Additional IRT analyses as well as nominal logistic regression analyses will be conducted to further examine the psychometric properties and validity of the CARS-2.
Conclusions: Preliminary analyses indicate that mid-point ratings (e.g., 3.5) may not be as helpful as expected at discriminating among children on the ASD continuum. In addition, based on content reasons removing item 10 from the sample studied could be considered due to poor differentiation of individuals across the ASD continuum.

49   **138.049** An Online Verbal IQ Test: Development, Validity, and Standardization of an Adaptive Vocabulary Test for Remote Phenotyping of Parents

C. C. Clements[1], G. K. Bartley[2], L. DePolo[3], L. Bateman[3], H. Morton[4], J. Parish-Morris[5], N. Stein[6] and R. T. Schultz[7], (1)Psychology, University of Pennsylvania, Philadelphia, PA, (2)Center for Autism Research,

Children's Hospital of Philadelphia, Malvern, PA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Children's Hospital of Philadelphia, Philadelphia, PA, (5)Children's Hospital of Philadelphia, Philadelphia, PA, (6)Statistics, University of Pennsylvania, Philadelphia, PA, (7)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA

Background: Autism Spectrum Disorders (ASD) are defined by a dyad of behaviors, but comorbid intellectual disability (ID, which affects 30-70% of individuals with ASD) can present equal or even greater challenges to achieving successful adaptation and long term outcomes. In behavioral and neuropsychological studies of autism, researchers use IQ as a matching or co-varying variable. Unfortunately, this practice limits a) statistical power to find case-control group differences on measures that correlate with IQ, and b) our ability to understand the impact of autism on cognitive ability. Because IQ is ~ 50% heritable, offspring typically do not deviate much from average parent IQ. Thus, matching case and control on parent IQ would allow us to assess the impact of autism on IQ and all measures that correlate with it. However, collecting parent IQ can be impractical with standardized clinician administered tests, since both parents often cannot come to the lab. Requiring IQ assessment of both parents would likely bias the sample and prove expensive and time-intensive for both researchers and participants.
Objectives: To develop an online test of verbal IQ (the Verbal Adaptive Test, VAT) that can be administered remotely or on a lab computer in a fraction of the usual time.
Methods: We developed a multiple-choice vocabulary task and piloted 209 items to 1,599 adult participants recruited online. An Item Response Theory (IRT) model was fit to the data, and individual item performance was assessed across several parameters including difficulty, guessing, loadings on the primary factor, and discrimination, which measures how well an item discriminates between two individuals of similar abilities.
Results: A three-parameter model demonstrated the best fit to the item response data. Several indices of performance suggested overall desirable item performance. Briefly, 75.1% of items had discrimination >1 (which is considered 'good'; $M = 1.37$, SD = 0.62), and 90.3% of items loaded saliently on the primary factor. In addition, the VAT Standard Error of Measurement (SEM) is less than or equal to the average SEM of the WAIS VCI (Wechsler Adult Intelligence Scales Verbal Comprehension Index) across a broad range of abilities (see figure). Initial items targeted IQ scores less than 100, and additional items targeting IQ scores greater than 100 and at both ability extremes are being added. Preliminary simulated data results suggest that the VAT will decrease test administration by more than 40%.
Conclusions: The VAT is an efficient and accurate online verbal IQ test that performs above desired metrics at both the individual item and composite test levels. The VAT also offers precise IQ measurement across a broad ability range including the extremes, which are difficult to measure using tests designed with classical test theory. This feature, combined with decreased administration time, makes the VAT appealing for IQ assessment in individuals with ASD and ID, and their family members.

50 **138.050** Assessment of Intelligence in Young Autistic Children: A Comparison of Tests Available Under and over Age 3

***V. Courchesne**[1], C. Jacques[2], A. M. Nader[3], M. Descamps[4], É. Danis[5], L. Mottron[6], M. Dawson[7] and I. Soulières[7], (1)Rivière-des-Prairies Hospital, Centre de recherche de l'Institut universitaire en santé mentale de Montréal, Montréal, QC, Canada, (2)Université du Québec en Outaouais, Gatineau, QC, Canada, (3)Department of Psychology, Université du Québec à Montréal, Montréal, QC, Canada, (4)Université du Québec à Montréal, Montreal, QC, Canada, (5)Psychology, University of Quebec at Montreal, Montréal, QC, Canada, (6)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montreal, QC, Canada, (7)Centre d'excellence en Troubles envahissants du développement de l'Université de Montréal (CETEDUM), Montréal, QC, Canada*

Background: Very early autism diagnosis is often recommended, and DSM-5 autism spectrum diagnosis must specify the presence or absence of accompanying intellectual disability (APA, 2013). However, few tests are available to assess intellectual functioning in children under age 3 years. Further, developmental tests often used in this age range as measures of IQ may not accurately represent the potential of young autistic children, whose developmental paths are highly atypical. School-aged autistic children perform differently depending on the test used to assess their intelligence (Dawson et al., 2007) and present a discrepancy between intelligence and adaptive level (Charman et al., 2011). Thus it is important to document how the intellectual abilities of younger autistic children would be judged using different available tests.
Objectives: To compare the performance of young autistic and typical children on Mullen Scales of Early Learning and Vineland Adaptive Behavior Scales to their performance on intelligence tests which provide norms for the 3-to-5 years age range
Methods: The complete sample will include 25 autistic and 25 typical children aged 18 months to 5 years. To date, 12 autistic and 16 typical children have been tested on Mullen and Vineland. Those aged 3 or more were also tested on WPPSI-IV (autistic N=6, typical N=10) and Leiter-3 (autistic N=8, typical N=10). Those aged 4 or more (autistic N=4, typical N=8) were administered Raven's Colored Progressive Matrices board form (RCPM).
Results: Performance on Mullen was significantly lower than Vineland scores in autistic children

(p<.05), whereas no significant difference was found for the typical group (p=.18). The autistic group's lowest mean scores were on Mullen (IQ=61, SD=19.2; below the 1st percentile), followed by Vineland (IQ=77, SD=12.3; 6th percentile), WPPSI-IV (IQ=79, SD=19.0; 8th percentile), Leiter-3 (IQ=95, SD=9.6; 37th percentile) and RCPM (raw score=15.25/36, SD=6.29; 66th percentile). For the typical children, lowest mean scores were on Vineland (IQ=102, SD=15.2; 55th percentile), followed by Mullen (IQ=107, SD=18.3; 68th percentile), Leiter-3 (IQ=113, SD=9.6; 81st percentile), WPPSI-IV (IQ =117, SD=14.4; 87th percentile), and RCPM (raw score=23.63/36, SD=3.34; 95th percentile). Conclusions: Preliminary results indicate that the intellectual functioning of young autistic children, and therefore the presence or absence of intellectual disability in this population, may be judged very differently depending on the test administered. Autistic children would be judged as most intellectually impaired on Mullen, a commonly used test in autism research and practice. Data from a small number of children suggest dramatic discrepancies between Mullen and both Leiter-3 and RCPM scores in the autistic group, which in turn would suggest caution in judging autistic potential at very young ages.

51   **138.051**   Autism-Spectrum Quotient (AQ): A Preliminary Study of Its Diagnostic Validity in a Clinical Spanish Sample, More Than a Psychometric Test?

C. D. Jimenez de Espinoza[1] and J. L. González-Mora[2], (1)Physiology, University of La Laguna, Santa Cruz de Tenerife, Spain, (2)University of La Laguna, La Laguna, Spain

Background: Autism is defined in terms of abnormalities in social and communication development, in the presence of marked repetitive behavior and limited imagination (American Psychiatric Association [APA], 1994). The cultural background can greatly influence how an individual perceives and presents with psychiatric symptoms, as well as impacts diagnosis and treatment. Establishing who is "affected" and who is not, or the degree to which the accepted standardized diagnostic criteria for ASD condition are applicable to a given patient will lead to better diagnosis.
Objectives: Screening for possibly affected individuals within the typical population, would allow us to refine this diagnostic tool in order to make a diagnosis more consistent with the intrinsic characteristics of ASD.
Methods: This study encompassed two different samples (ASD and TD); they were aged between 17 and 25 years. The first group (TD) consisted of 129 students from the La Laguna University, Tenerife, Spain. During the break of one of their classes, the students were asked to complete the AQ. Students were recruited from the fields of humanities (law and philology; n = 46) and natural sciences (including medicine; n = 83). All participants in the Autistic-high functioning group (n = 21) had a diagnosis and recruited through (APANATE, ALDIS, ASPERTEN). The Autism Spectrum Quotient (AQ) was developed by Baron-Cohen et al. (2001) and translated into Spanish by Betty Trabal, Editorial Amat, S.L., Barcelona, (2005).
Results: The Total AQ score and its subscales were assessed for normality through an examination of absolute skew and kurtosis score for each variable; the data was significant not found to deviate from normality, *P = .04; R^2 = .13 (TD group) and *P = .03; R^2 = .08 (ASD group), respectively (Figure 1) . AQ Total values distribution were analyzed separately for both groups, TD and ASD, which found that was normally distributed, Kolmogorov-Smirnov P > 0.10 respectively (Figure 2). We found that TD individuals had a lower Total AQ score of M = 19 (SD = 7.07), compared to ASD individuals Total AQ score of M = 31.32 (SD = 5.74); this difference was significant, P < .0001 (Figure 3); The discrimination power of the AQ test case and control groups show a significant difference **P = 0.006 and both groups show a Gaussian approximation, R^2 = 0.9955 for TD and R^2= 0.9859 for ASD. The mean comparison for gender and AQ Total score show that TD males scored slightly higher than TD females and that ASD males scored higher than females on Total AQ score (Figure 4). Furthermore our results revealed that was significant difference for gender by diagnosis on the subscales such as social skills, communication, imagination, and attention switching (Figure 5).
Conclusions: The Spanish version of the Autism Spectrum quotient (AQ) has showed satisfactory levels of internal consistency. The results confirmed the AQ Total and Subscale scores. Finally, gender differences were obtained. These findings support the use of the Spanish version of the AQ for the assessment ASD.

52   **138.052**   Child Characteristics As Moderators of Parent-Clinician Agreement on Autism Symptoms

E. E. Neuhaus[1], R. Bernier[2], S. J. Webb[3], S. Faja[4] and K. Pelphrey[5], (1)PO Box 5371, Seattle Children's Research Institute, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)Developmental Medicine, Boston Children's Hospital/Harvard School of Medicine, Boston, MA, (5)Child Study Center, Yale University, New Haven, CT

Background: Gold standard diagnosis of autism spectrum disorder (ASD) is based upon both parent report of child history/behavior and thorough observational assessment by a trained clinician. Marked disagreement between these reporters could result in misdiagnosis, in which parents fail to initiate assessment of a child with unrecognized ASD or clinicians fail to confirm valid parent concerns. Although parent and clinician assessments do often correlate with one another, the degree of correspondence likely varies according to child characteristics. However, these factors have not been

identified, and improved understanding of child or family characteristics influencing symptom agreement could identify families at highest risk for misdiagnosis.

Objectives: Our goal was to explore factors moderating the degree of correspondence between (1) parent report of ASD symptoms on the Autism Diagnostic Interview, Revised (ADI-R), and (2) clinician assessment of ASD symptoms on the Autism Diagnostic Observation Schedule (ADOS). Putative moderators included child age, sex, IQ, adaptive behavior, and comorbid social-emotional difficulties.

Methods: Children and adolescents (ages 4 to 18 years; N = 79) with ASD or a twin with ASD were recruited through two studies encompassing four research sites across the US. Parents completed the ADI-R, CBCL, and Vineland-2, and youth completed the ADOS Module 3 and a standardized cognitive assessment (either DAS-II or WASI). To address parent-clinician correspondence, we created a series of linear regression models predicting ADOS scores. In each model, we entered ADI-R total score, one putative moderator, and their interaction as predictors. Next, significant predictors and their interactions were entered into a new regression model to more directly compare their relative contributions in the prediction of ADOS scores.

Results: The first set of models revealed main effects of ADI-R scores (ß=6.76, $p<.001$), adaptive behavior (ß=-.41, $p=.05$), and CBCL behavior problems (ß=.51, $p<.01$) in the prediction of ADOS scores. Adaptive behavior (ß=.82, $p=.08$) and behavior problems (ß=-2.22, $p<.001$) also interacted with ADI-R scores, indicating that they moderated parent-clinician correspondence on ASD symptoms. Interactions were such that parents and clinicians had better agreement when children had higher levels of adaptive behavior and fewer behavior problems. The subsequent model including ADI-R scores, adaptive behavior, behavior problems, and their interactions was significant ($F(6, 58)=9.28$, $p<.001$) and accounted for 46% of the variance in ADOS scores. Within this model, the interaction of ADI-R scores and behavior problems emerged as the strongest predictor (ß=-1.87, $p=.02$), underscoring the notion that child behavioral symptoms moderate the extent to which parents and clinicians report similar levels of ASD symptoms. See Figure 1.

Conclusions: Comorbid psychological difficulties appear to increase the discrepancy between parent and clinician assessment of ASD symptoms. Such comorbidities are quite common, and this discrepancy likely complicates the diagnostic process and affects families' reception of an ASD diagnosis. More fully characterizing these and additional moderators influencing reporter agreement will be important in improving diagnostic accuracy and family experiences, and future analyses of ongoing data collection will expand to address additional factors such as family socio-economic status, race/ethnicity, and medical comorbidities.

53 **138.053** Classifying Autism Spectrum Disorders By ADI-R: Separate Subtypes or Severity Gradient?

H. Cholemkery[1] and C. M. Freitag[2], (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe University, Frankfurt am Main, Germany, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, JW Goethe University, Frankfurt a. M., Germany

Background: The recently published DSM-5 comprises DSM-IV TR diagnoses Autism, Asperger´s disorder, and Atypical Autism under the umbrella concept of *Autism Spectrum Disorder* suggesting a continuum of symptoms with different grades of severity. The novel diagnosis *social communication disorder*(SCD) encompasses children comprising persistent social communication impairments without restrictive, repetitive behaviors.

Objectives: By using a cluster analytic approach, and building on results of previous studies (Spiker et al. 2002; Verté et al., 2011), this study aimed at describing empirically derived subgroups based on the Autism Diagnostic Interview-revised (ADI-R) algorithm items. We explored if these subgroups are more similar to the DSM-IV TR/ICD-10 or DSM-5 approach.

Methods: Sample size consisted of n=466 individuals with Autism (n=194), Asperger´s syndrome (n=158), Atypical Autism (n=114), aged 3 - 21 (M=10.43, SD=4.15), IQ≥35 (M=94.70, SD=20.60). Clinical diagnoses were based on ICD-10 criteria using a combination of ADI-R, Autism Diagnostic Observation Schedule (ADOS), Social Communication Questionnaire, and clinical judgement. *Statistical analysis:* A single-linkage procedure identified 2 outliers. The ADI-R algorithm subscales were analysed by hierarchical cluster analysis. Fusions were made by Ward´s method, the Euclidean distance was used as proximity measure. The number of clusters was determined by dendrogram. Adjustment was done by the K-means procedure. MANOVAs with cluster affiliation and algorithm scores were calculated for controlling the cluster solution. Quality was ensured by discriminant analyses. The cluster groups were compared for differences in age, gender, IQ, ICD-10 diagnoses, Vineland-II, ADOS-severity scores, and Child Behavior Checklist by (M)ANOVA.

Results: The hierarchical clustering method resulted in a 3-cluster solution. N=153 individuals were included in cluster 1, n=124 in cluster 2, and n=182 in cluster 3. A MANOVA showed significant differences between the three clusters for the ADI-R subscale scores ($F(26)=54.65$, $p>.000$, $\eta^2=.62$). Impairments in reciprocal social interaction, and communication just like abnormality of development were mostly pronounced in cluster 2, followed by 3, and 1. For the domain of stereotyped pattern only significant post-hoc effects between cluster 2 versus 1, and 2 versus 3 were observed. Cluster 1 and 3 did not differ. Discriminant analysis confirmed that 96.3% of the cases were correctly allocated. The clusters did not differ with regard to age ($F(2)=.241$, $p=.786$), IQ ($F(2)=.338$, $p=.713$), gender ($\chi^2(2)=5.028$, $p=.081$), or ICD-10 diagnosis ($\chi^2(6)=5.837$, $p=.442$). No significant differences were found for CBCL ($F(22)=.992$, $p=.473$), Vineland-II ($F(10)=1.260$, $p=.328$), and ADOS severity scores

(F(2)=.472, p=.624).

Conclusions: The ADI-R algorithm scores for reciprocal social interaction, communication, and abnormality of development were distributed across the clusters with differing severity, supporting the DSM-5 concept of ASD. Only the domain of stereotyped behaviour did not differ between cluster 1, and 3. This might be due to the small number of items in this domain. The ASD phenotype as described by the 3 clusters seemed to be independent of demographic variables and cognitive abilities. Interestingly, there was no cluster group characterized by social-communication problems only, making it unlikely that children with ASD may be "misdiagnosed" having a *social communication disorder*. Findings support the current DSM-5 concept of ASD and SCD as different disorders.

---

54   **138.054** Comparing Remote Diagnosis of ASD to Gold Standard, in-Person Assessment

C. J. Smith[1], N. L. Matthews[2], A. Rozga[3], N. Nazneen[4], R. M. Oberleitner[5], R. Melmed[6] and G. D. Abowd[3], (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)Research, Southwest Autism Research & Resource Center, Phoenix, AZ, (3)School of Interactive Computing, Georgia Institute of Technology, Atlanta, GA, (4)UserWise Usability Research and Consulting, Mountain View, CA, (5)Behavior Imaging Solutions, Boise, ID, (6)Southwest Autism Research Center and Melmed Cente, Scottsdale, AZ

Background: A telemedicine approach to diagnosis of ASD, the Naturalistic Observation Diagnostic Assessment (NODA) may accelerate the diagnostic process by connecting families with diagnosticians via the internet. Parents download a mobile application and complete a developmental history questionnaire. The NODA app then guides parents to record four 10-minute videos of their child in their home (i.e., mealtime, playtime with others, playtime alone, and parent concerns) and uploads them to a HIPAA-compliant, web-based platform. A diagnostician logs in to the web portal, reviews each video to identify specific behavioral examples of atypical or typical development. Examples are "tagged" from predefined behavior descriptors informed by clinical expertise. Each tag is linked to a specific DSM-5 criterion for ASD. The diagnostician reviews the DSM-5 checklist and determines whether each criterion is satisfied based on the tags, the developmental history, and their own clinical judgment.

Objectives: The goal of this study was to determine the percentage agreement for DSM-5 diagnosis of ASD between the remote method (NODA) and an in-person assessment utilizing gold-standard diagnostic procedures across three participant groups: 30 children referred for an ASD evaluation (ASD), 10 typically developing children (TD), and 10 children with other diagnoses (OTH).

Methods: To date, 44 children have completed both the in-person assessment and the NODA procedure. Of these 44, 30 were in the ASD group (23 males), 9 in the TYP group (6 males) and 5 in the OTH group (4 males). Participants were between 21 and 86 months (M = 50.27, SD = 16.33); there were no significant between group differences in age (p = .21). The in-person diagnostic assessment included the ADI-R, ADOS-2, Vineland, and Mullen. Families returned home and completed the NODA procedure. A blinded clinician completed the NODA diagnostic assessment. For borderline cases (e.g., only one DSM-5 criterion unsatisfied), a second review was conducted.

Results: For each child, the diagnostic decision (ASD, not ASD) between the in-person assessment and the NODA assessment was compared. The same diagnostic decision was reached in 86.42% of the cases. There was perfect agreement in the TD and OTH groups and 80% agreement in the ASD group (24/30). In 20% of ASD cases, NODA did not endorse ASD when the in-person assessment did. However, there were sufficient criteria established within NODA to identify developmental delays.

Conclusions: The results from this study demonstrate that NODA results in a valid diagnosis of ASD in 80% of cases. Approximately 20% of cases may still require an in-person evaluation. NODA represents a key opportunity to increase timely diagnosis for most children with ASD, a critical first step to accessing appropriate early intervention programs. Further, NODA may help alleviate the demand placed on professionals who perform diagnostic assessments as part of their practice and reduce wait lists, thereby allowing families who need an in-person assessment to be seen faster. Additional analyses will explore whether child characteristics (e.g., intellectual disability, language impairment) impact diagnostic agreement, and whether there are differences in expression of autism symptoms in a home vs. a clinical setting.

---

55   **138.055** Construct Validity and Measurement Invariance of the Children's Scale for Hostility and Aggression: Reactive/Proactive (C-SHARP)

C. Farmer[1], A. J. Kaat[2] and M. G. Aman[2], (1)NIMH, NIH, Bethesda, MD, (2)Nisonger Center, Ohio State University, Columbus, OH

Background: Aggression is a serious concern for some children with intellectual and developmental disabilities (IDD), including those with autism spectrum disorder (ASD). Aggression confers greater risk of classroom removal, psychotropic treatment, is a leading cause of residential placement (Tsakanikos et al., 2007), and is also a significant source of parental and caregiver stress (Hodgets et al., 2013). For these reasons, the study of aggression is important to improve the lives of children with ASD/IDD and their families. A major impediment to this research is a dearth of detailed instruments; the most popular instruments measure general oppositionality (e.g., NCBRF) or devote only a short subscale to aggression (e.g., CBCL). The Children's Scale for Hostility and Aggression: Reactive/Proactive (C-SHARP; Farmer & Aman, 2009) is a detailed measure of aggression. The original

factor structure was derived in a heterogeneous sample of children receiving special education services (Farmer & Aman, 2009), but has since been used to compare aggression in children with and without ASD (Farmer & Aman, 2011; Farmer et al., 2014).

Objectives: The objective of this study was to assess the psychometric characteristics of the C-SHARP by replicating the factor structure, assessing factorial invariance, and exploring its convergent validity in a sample of developmental clinic-referred children with and without ASD.

Methods: The C-SHARP is a parent-report instrument comprising 48 items on five subscales: Verbal Aggression, Bullying, Covert Aggression, Hostility, and Physical Aggression. Data were collected from six sites across the United States. The sample consisted of clinic-referred children who were diagnosed with ASD (n=414) and those who were not (n=243). We conducted confirmatory factor analysis on the mean structure of the C-SHARP across groups (ASD versus non-ASD), and then sequentially evaluated configural, strong, and strict factorial invariance using the lavaan package for R (Rosseel, 2012). Convergent/divergent validity was assessed by correlation of the C-SHARP raw subscale scores with selected CBCL Syndrome Scale T-scores. We hypothesized that the externalizing subscales, especially Aggression, would be more strongly correlated with the C-SHARP than the internalizing subscales.

Results: All models [configural, weak, strong, strict 1 (equal residuals), and strict 2 (equal residuals and latent variance/covariance)] had a significant Satorra-Bentler Chi Square (p<.001). However, a combination of fit measures (AIC, BIC, RMSEA, and TLI) except SRMR favored the more restricted model, where the factor loadings, item intercepts, residuals, and latent variance/covariance were fixed to be equal but group means were freely estimated (see Table 1 for factor loadings, intercepts, and residuals). The C-SHARP and the CBCL were significantly (p<.01) correlated across most subscales. The strongest correlations were with CBCL Aggressive Behavior. Consistent with expectations, the Internalizing subscales were generally weakly correlated (r<.30) with the C-SHARP subscales, with the exception of CBCL Anxious/Depressed and C-SHARP Hostility (r=.42).

Conclusions: The original five-factor structure of the C-SHARP was confirmed, and construct validity was supported. Aggression, as conceptualized by the C-SHARP, is invariant across the clinic-referred population, making the C-SHARP an ideal measure for children suspected of having an IDD.

56 **138.056** DSM-IV-TR Criteria That Best Differentiate Intellectual Disability from Autism Spectrum Disorders

A. L. Pedersen[1,2], S. Pettygrove[3], Z. Lu[2], J. Andrews[2], F. J. Meaney[4], M. Kurzius-Spencer[2], L. C. Lee[5], M. S. Durkin[6] and C. Cunniff[2,7], (1)Psychology & Child Development, California State University, Stanislaus, Turlock, CA, (2)Department of Pediatrics, College of Medicine, University of Arizona, Tucson, AZ, (3)Epidemiology and Biostatistics, University of Arizona, Tucson, AZ, (4)University of Arizona, Tucson, AZ, (5)Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (6)Waisman Center, University of Wisconsin-Madison, Madison, WI, (7)Division of Medical Genetics, Weill Cornell Medical College, New York, NY

Background: A high proportion of children with Autism Spectrum Disorder (ASD) also have intellectual disability (ID), complicating their symptom presentation. While ID is characterized by global delays in cognition and adaptive skills, children with both ID and ASD additionally show deficits in social interaction, communication, and restricted interests and repetitive behaviors. The somewhat similar characteristics of the two disorders pose a challenge for accurate differential diagnosis.

Objectives: In order to minimize diagnostic confusion, the current study sought to identify the DSM-IV-TR criteria that best differentiate between ID and ASD among children with features of both disorders.

Methods: Population-based surveillance of ASD was conducted in 14 U.S. sites on children who turned 8 years old in 2006 and 2008. Evaluation of clinical and educational records identified 2,816 children who met case definition for ID, with or without ASD. Sensitivity and specificity, logistic regression, and an Area Under the Curve (AUC) Receiver Operating Characteristic analysis were conducted to determine which DSM-IV-TR criteria for ASD best differentiated children with ID and some ASD features (who did not meet criteria for ASD; N = 937) from those with co-occurring ID+ASD (N = 1,879).

Results: DSM-IV-TR Criteria related to social skills deficits, restricted interests and repetitive behaviors showed high sensitivity and specificity in differentiating the two diagnostic groups. AUC analyses indicated that, when considered singly, adherence to routines (AUC = 0.821) and stereotyped and repetitive behaviors (AUC = 0.823) showed the greatest power to discriminate between the two diagnostic groups. Criteria related to communication deficits, such as delay in spoken language (AUC = 0.660) and impairment in conversation ability (AUC = 0.659) showed the least discriminatory power. Results of the logistic regression indicated that a subset of 6 criteria in the areas of social skills deficits, restricted interests and repetitive behaviors was the most effective at differentiating the two diagnostic groups (AUC = 0.923). The specific subset included impaired use of nonverbal behaviors, lack of social reciprocity, stereotyped patterns of interest, adherence to routines, stereotyped and repetitive behaviors, and preoccupation with parts of objects.

Conclusions: Restricted interests and repetitive behaviors appear to be critical in differentiating individuals with ID and some ASD features from co-occurring ID+ASD. This is in contrast to prior assertions that, due to high rates of repetitive behaviors in the ID population, this is not a meaningful method of differentiating global cognitive delays from the specific constellation of behaviors found in ASD. Social skills deficits appear to have less discriminatory power than previously reported. Whereas

deficits in social and communication skills may initially trigger concern regarding the presence of ASD, the *absence* of such skills does appear to as clearly differentiate ID from co-occurring ID+ASD as the *presence* of more unusual behaviors (restricted interests and repetitive behaviors). An understanding of the discriminatory power of different DSM-IV-TR criteria may help clinicians reduce diagnostic confusion when patients have features of both ID and ASD, and may lead to improvements in diagnosis.

57 **138.057** Descriptive Assessment of Problem Behavior in a Large-Scale Randomized Trial in Young Children with Autism Spectrum Disorder

T. L. Burrell[1], K. Bearss[2], N. Minshawi-Patterson[3], C. Johnson[4], L. Lecavalier[5], T. Smith[6], N. Swiezy[3] and L. Scahill[7], (1)Research, Marcus Autism Center, Atlanta, GA, (2)Pediatrics, Emory University School of Medicine, Atlanta, GA, (3)Indiana University School of Medicine, Indianapolis, IN, (4)University of Pittsburgh, Pittsburgh, PA, (5)Psychology, The Ohio State University, Columbus, OH, (6)601 Elmwood Ave, Box 671, University of Rochester, Rochester, NY, (7)Pediatrics, Marcus Autism Center, Atlanta, GA

Background: Children with autism spectrum disorder (ASD) exhibit high rates of emotional and behavioral problems. These problem behaviors serve a function for the child: attention, access to a tangible item, escape from demands, or sensory stimulation. Functional analysis (FA), the manipulation of environmental events under experimental conditions, is the gold standard method used to identify the function of problem behaviors. Another less rigorous approach is called descriptive assessment (DA) which involves the direct observation of a target behavior, its antecedents and consequences. FA and DA have been used to assess function of behavior in a wide range of clinical populations and age ranges. However, they typically are administered by experts and in the context of single-subject design studies. The relative ease in implementation of DA makes it a valid option for use by parents and to characterize the function of problem behaviors in large samples. To our knowledge, this is the first study of its kind to use descriptive assessments co-created by parent and therapist in order to characterize the behavior, topography, and function of behaviors in a large group of children with ASD.
Objectives: The purposes of this poster are: 1) to describe the process of co-constructing the function of problem behaviors in children with ASD in the context of a structured parent training program; 2) to describe the problem behaviors and topographies that emerged from the parent – therapist collaboration; and 3) to describe the functions of problem behaviors identified in the parent training program.
Methods: Results were derived from a large-scale multi-site, 24-week, randomized clinical trial of 180 children (age 3 to 6 years, 11 months) with ASD and disruptive behaviors. At baseline, eligible children were randomized to receive either parent training (PT) or parent psychoeducation (PE). 89 children were randomized to PT and 91 children were assigned to PE. Descriptions of the child's problem behaviors were documented in a "behavior support plan" that was co-constructed by the parent and the therapist over the course of PT.
Results: To date, 59 of 89 behavior support plans for PT subjects were available for review. Parents reported tantrums in 78.0% (46/59) of the subjects, aggression in 62.7% (37/59) and noncompliance in 39.0% (23/59). Parents reported a total of 175 behavior problems with 53 topographies (e.g. crying, flailing). Of the 175 behavior problems reported, the most common were tantrums (26.3%), aggression (21.1%) and noncompliance (13.1%). Of the four functions of problem behavior, parents reported that 62.4% of the behaviors had multiple functions followed by access to a tangible (59.4%), attention (47.1%), escape (42.0%), and sensory (11.6%).
Conclusions: This is the first study to identify the behaviors, topography, and functions of disruptive behaviors using co-constructed parent-clinician descriptive assessments in a large sample of well-characterized young children with ASD. These results suggest that teaching parents to conduct DAs is an effective method to identify the functions of disruptive behavior in young children with ASD.

58 **138.058** Developing ASD Screening Criteria for the Brief Infant Toddler Social Emotional Assessment (BITSEA)

I. Giserman Kiss and *A. S. Carter, Department of Psychology, University of Massachusetts Boston, Boston, MA*

Background: Retrospective and prospective studies have confirmed that symptoms of ASD emerge during the first two years of life (Ozonoff et al., 2011). Yet, the national average age of diagnosis is above 36 months (CDC, 2012), with a greater delay for children from low socioeconomic statuses, minority groups, and non-native English speaking families (Valicenti-McDermott et al., 2012). With increasing evidence that early intervention significantly improves outcomes for children with ASD, early detection and diagnosis is critically needed (Seida et al., 2009). The AAP and CDC recommend that pediatricians administer developmental screeners at routine visits; universal screening can potentially ameliorate health disparities regarding age of diagnosis. As public awareness of the disorder grows, the number of screening tools available to identify children at risk for developing ASD has also increased. The Brief Infant Toddler Social Emotional Assessment (BITSEA) (Briggs-Gowan & Carter, 2006) is a screening tool designed to identify toddlers with social-emotional/behavioral problems and/or delays/deficits in social-emotional competencies. Of the 42 BITSEA items, 17 items reflect behaviors consistent with ASD symptoms.

Objectives: The goal of this preliminary study was to determine the feasibility of developing cut-points on the new BITSEA ASD-Problem, ASD-Competency, and ASD-Total scales that reliably discriminate children with ASD from those without. The new scales are derived from existing BITSEA items.

Methods: Data are presented on 436 toddlers (71.3% male) between the ages of 12 and 48 months. 51% of toddlers were diagnosed with ASD using gold-standard tools and clinical judgment, while the remaining children were typically developing or diagnosed with intellectual/developmental disabilities or non-ASD psychopathology. Mothers of participants completed the BITSEA. Analyses examined the following subscales: ASD-Problem (including nine items focused on ASD negative symptoms), ASD-Competency (including eight items focused on ASD positive symptoms), and ASD-Total (sum of the ASD-Problem and reverse-scored ASD-Competency subscales).

Results: ROC plots were developed for the ASD subscales (see Figure 1). The following cut-points were determined as most effective for the ASD-Problem, ASD-Competency, and ASD-Total subscales respectively: 4.5, 10.5, and 14.5. The cut-points on all subscales evidenced moderate-to-high discriminative power and moderate-to-high sensitivity, specificity, and PPV. Because the analyses yielded fractionated cut-points, optimal whole number cut-points were determined to increase clinical utility. The following whole number cut-points were calculated as the most effective for the ASD-Problem, ASD-Competency, and ASD-Total subscales respectively: 5, 10, and 14 (see Table 1). Of the three subscales, the ASD-Total was determined as the most effective. The clinical cut-point of 14 yielded 82.43% sensitivity, 84.21% specificity, and 80.26% PPV. False positives had significantly lower cognitive and language abilities than true negatives. False negatives showed higher language abilities, than true positives.

Conclusions: The BITSEA ASD-Total scale was shown to be a highly effective screening measure for ASD in toddlers. These findings contribute to the overarching goal of increased early detection and diagnosis of ASD and give pediatric healthcare providers an efficient and effective ASD screening tool within a broadband behavioral health screener. This preliminary work sets the stage for testing cut-points prospectively in early intervention and pediatric settings.

59   **138.059** Development of a New Measure to Identify Fundamental Emotion Regulation Processes Across the ASD Spectrum: Application to the Autism Inpatient Collection

C. A. Mazefsky[1], M. Siegel[2], R. Gabriels[3], L. Yu[4], D. L. Williams[5], J. Pierri[6], C. Peura[7] and P. A. Pilkonis[1], (1)Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (2)Maine Medical Center Research Institute, Westbrook, ME, (3)Children's Hospital Colorado, Aurora, CO, (4)University of Pittsburgh School of Medicine, Pittsburgh, PA, (5)Duquesne University, Pittsburgh, PA, (6)University of Pittsburgh Medical Center, Pittsburgh, PA, (7)Spring Harbor Hospital, Westbrook, ME

Background: There is increasing recognition that aberrant emotion regulation is a critical process in autism spectrum disorder (ASD) that may underlie problem behaviors and psychiatric comorbidity (Mazefsky et al., 2013). The lack of emotion dysregulation measures that are appropriate for this unique population is a barrier to advances in this area.

Objectives: The overall goal is to develop a measure of emotion dysregulation, the Emotion Dysregulation Inventory (EDI), which captures the full range of presenting concerns in ASD and is free of verbal loading. Specific aims included: 1) Evaluate the EDI's psychometric properties, including potential verbal ability or nonverbal IQ (NVIQ) biases; and 2) Investigate emotion dysregulation patterns in psychiatric inpatients with ASD.

Methods: The Emotion Dysregulation Inventory (EDI) was developed based on guidelines from the Patient Reported Outcomes Measurement Information System (PROMIS), a NIH-initiative focused on creating measures of health status using modern psychometric methods (see Figure 1). Participants included 88 children (M=12 years) with ADOS-2-confirmed ASD who were admitted to an ASD specialized psychiatric inpatient unit as part of the Autism Inpatient Collection (AIC). The EDI and Aberrant Behavior Checklist (ABC) were completed by a consistent parent/guardian at admission and discharge. Participants had NVIQ standard scores ranging from 30-135 (M=71), and 57% (n=48) have limited verbal skills (ADOS-2, Module 1 or 2). Analyses focused on the total EDI intensity score. The EDI also includes past behavior time course ratings to aid in clinical conceptualization which will be explored in future analyses.

Results: The EDI total score covered a wide range (45-229; M=125; SD=38) and was normally distributed. The EDI was correlated (r=.55) with the ABC Irritability Scale ($p < .000$), suggesting adequate convergent validity without excessive overlap. The EDI was not significantly correlated with age (r=-.06) or NVIQ (r=.07). EDI mean scores did not differ between minimally-verbal (M=121, SD=38) and verbal participants (M=128, SD=37), or between participants with NVIQs of ≤70 (M=124, SD=40) and NVIQs >70 (M=127, SD=36), p>.05. Internal consistency was high (Cronbach's alpha =.95). Discharge EDI scores (M=67) were significantly lower than admission scores (M=125), p<.000. Variability in item-total correlations suggested multidimensionality, though the majority of items loaded strongly on the total score. Items with high item-total correlations captured increased negative affect, emotional reactivity, lability, and other indicators of poor emotion regulation, whereas items that typically indicate comorbid depression and anxiety had low item-total correlations. Exploration of item means suggested that emotion dysregulation in psychiatric inpatients with ASD is characterized by problems with sustained and rapidly escalating emotional reactions, with less frequent endorsement of symptoms of decreased vitality, decreased positive affect, and anxiety.

Conclusions: Initial evaluation of the EDI suggests it will be an informative, change-sensitive measure

of important emotional processes (emotional reactivity and poor regulation) in ASD that can be applied across the spectrum of verbal and IQ abilities. The EDI development process (e.g., PROMIS framework, pilot collection with a sample encompassing all verbal and IQ abilities) provides a model that can be applied to address the dearth of sensitive and valid measures for ASD.

60   **138.060** Development of an Autism Risk Index Using Remote Eye Tracking to Social Stimuli: A Preliminary Proof-of-Principle Investigation

T. W. Frazier[1] and E. W. Klingemier[2], (1)Cleveland Clinic Children's, Cleveland, OH, (2)Pediatrics, Cleveland Clinic, Cleveland, OH

Background: Deficits in eye gaze are a hallmark characteristic of autism. Previous research has identified gaze abnormalities to a range of social stimuli, with large differences between autism spectrum disorder (ASD) and healthy control populations. Yet, no studies have examined whether eye gaze to social stimuli can sensitively differentiate individuals with ASD versus those with non-ASD diagnoses - the most clinically-relevant comparison.
Objectives: This preliminary investigation used remote eye tracking to identify expected social attention at key time points and spatial locations across distinct stimuli. Using expected social attention patterns, the primary objective was to develop an autism risk index to aide early identification of ASD.
Methods: Participants were recruited after initial evaluation for ASD. Consensus diagnoses were derived by multi-disciplinary evaluation and based on the Autism Diagnostic Observation Schedule and clinical interview. Eye gaze was collected using the SMI Red-m remote eye tracker (120Hz sampling) during viewing of static and dynamic social stimuli: emotive faces, biological point-of-light motion, and scenes eliciting predictive gaze and theory of mind. Regions-of-interest at pre-specified time intervals (temporal ROIs) were identified within each stimulus based on a priori hypotheses regarding eye gaze to the social context. Proportion dwell time was calculated to each temporal ROI. To develop the risk index, we first examined the significance and magnitude of ASD versus non-ASD differences to the temporal ROIs within each stimulus. Next, we aggregated this information across all stimuli using the results of a bootstrapped logistic regression with dwell times to each temporal ROI as predictors and diagnostic status as the dichotomous outcome. Finally, we computed classification accuracy, areas under the curve, sensitivity, and specificity.
Results: The sample included 20 ASD (Mage=4.96, range=1.8-7.9; 75% male; ADOS total score range=6-23; Receptive language SS range=55-150) and 13 non-ASD participants (Mage=4.02, range=2.5-6.7; 69% male). All ASD vs. non-ASD differences were in the expected direction and a substantial proportion (12/38) of temporal ROIs showed significant and large-to-very large differences (Cohen's d=0.62-1.82). Logistic regression identified 8 temporal ROIs as significant unique predictors of ASD status (X^2=31.96, R^2=.84, p<.00001, 87.9% classification accuracy). Aggregating these predictors into a single risk index yielded high diagnostic discrimination (AUC=.98; 95% CI=.93-1.00) with good sensitivity (.90) and specificity (.93) for the optimal cut score (Figure 1). The autism risk index was highly correlated with ADOS scores (r=.62, p<.001) and, as hypothesized, modestly, but not significantly, correlated with language ability (r=-.32, p=.078).
Conclusions: These findings represent an initial step toward development of an early objective autism risk marker in a challenging clinical sample with broad symptom and cognitive levels. Strong validity within individual stimuli highlights the importance of pinpointing expected spatially- and temporally-dynamic social attention patterns rather than using total dwell times across an entire stimulus. The results, while bootstrapped, will require replication in a large (N≥80 per group) validation sample that includes a broad range of ASD severity and cognitive ability. If validated, the eye gaze risk index may be a useful screening tool and adjunct to clinical judgment in the diagnostic process.

61   **138.061** Developmental Changes in the Cognitive Profile of Individuals with Autism Spectrum Disorders

A. R. Lemelman[1], J. E. Bice[1] and R. K. Kana[2], (1)University of Alabama at Birmingham, Birmingham, AL, (2)Department of Psychology, University of Alabama at Birmingham, Birmingham, AL

Background: Individuals with autism spectrum disorders (ASD) often present with variable cognitive profiles. Despite showing deficits in their verbal abilities, many children with ASD have intact or superior nonverbal skills (Joseph, Tager-Flusberg, & Lord, 2002) and a relative strength in their visuospatial reasoning (Green, Fein, Joy, & Waterhouse, 1995). However, some research has shown that Full Scale IQ (FSIQ), Verbal IQ (VIQ), and Performance IQ (PIQ) scores improve with age in children with ASD, with the gap between VIQ and PIQ eventually closing (Mayes & Calhoun, 2003). While such profiles have been relatively well documented in children with ASD, research examining cognitive profiles of ASD across the lifespan is rather limited.
Objectives: The main objective of this study was to examine the cognitive profile (i.e., VIQ, PIQ, and FSIQ) of high-functioning children and adults with ASD, and compare it to typically developing (TD) control participants.
Methods: Participants were high-functioning individuals (i.e., FSIQ > 70) with and without ASD. The current sample consists of 75 children (ages 8 to 18 years; 47 ASD and 28 TD) and 70 adults (ages 19 to 40 years; 31 ASD and 39 TD). All participants completed the *Wechsler Abbreviated Scales of Intelligence (WASI)* to obtain a measure VIQ, PIQ, and FSIQ. Correlational analyses and two-way

between-groups ANOVAs were conducted to explore the impact of age (i.e., child or adult) and diagnosis (i.e., ASD or TD) on FSIQ, VIQ, and PIQ. An independent samples t-test was conducted to compare the PIQ-VIQ difference between children and adults with ASD.

Results: FSIQ, VIQ and PIQ scores were significantly positively correlated with age in both the ASD and TD groups (r = .49, .47, and .34 respectively; $p < .001$). The FSIQ, VIQ, and PIQ of adults were significantly higher than that in children, for both individuals with ASD and TD ($F(1,142)$ = 47.66, 43.71, and 18.17 respectively; $p < .001$). The main effect of diagnosis was only significant for VIQ ($F(1,142)$ = 5.81, $p < .01$), with a greater increase in VIQ scores from the child to adult group for ASD participants (17.16 points) as compared to TD participants (13.38 points). Although PIQ was higher than VIQ in both child and adult ASD participants, these differences were not statistically significant ($t(76)$ = .76, p= .45).

Conclusions: The results of this study revealed that IQ scores increased with age for both ASD and TD participants. However, individuals with ASD showed greater increases in VIQ from childhood to adulthood, perhaps because the verbal skills of children with ASD may have been more likely to be targeted during school interventions than their nonverbal skills. Notably, there were no significant differences between the VIQ and PIQ scores of children or adults with ASD. This suggests that the PIQ-VIQ difference may not be apparent in high-functioning individuals with ASD, or as Mayes and Calhoun (2003) found, this gap may close prior to age 8 (the youngest age in our sample). Further analyses of the data are in progress.

---

62 **138.062** Developmental Differences Associated with Early Diagnosis: A Comparison of Toddlers Diagnosed with ASD at Age 2 Versus Age 3

S. Hoffenberg[1], J. Cash[1], C. Klaiman[1], J. Lorenzi[1,2] and C. Hall[1], (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Virginia Tech, Blacksburg, VA

Background: Early identification of children with Autism Spectrum Disorders (ASD) and thus early intervention are consensually regarded as critical for improving lifetime outcomes of individuals affected by ASD (Warren et al., 2011; Zwaigenbaum et al., 2013). Though ASD can reliably be diagnosed by 24 months of age, the average age of diagnosis in the US is currently 4.5 years (CDC, 2014), after the window of opportunity afforded by early intervention (Dawson et al., 2012). The question remains as to what the quantitative impact is of earlier diagnosis.

Objectives: The goal of the current study was to examine the effect of early diagnosis on cognitive, language, and adaptive functioning one year following an ASD diagnosis. Specifically, this study compared developmental and adaptive profiles of 3-year-old children at initial diagnosis to 3-year-old children with a previous diagnosis.

Methods: Participants included 25 clinically-referred toddlers, who were initially evaluated around age 2 (M=22.89 months, SD=4.38) and again between 36 and 42 months (M=38.2 months, SD=2.3) and 81 clinically-referred toddlers, who were initially evaluated between 33 and 41 months (M=37 months, SD=2.1). All were diagnosed with ASD. A comparison was made between two groups: Children at age 3 who were previously diagnosed around age 2 and children at age 3 with no prior diagnosis. 87% of children diagnosed at 2 years received some type of intervention prior to 3 years of age. Evaluations included assessment of cognitive/developmental abilities using the Mullen Scales of Early Learning, Bayley Scales of Infant and Toddler Development- 3rd Edition, or Differential Abilities Scales- 2nd Edition; adaptive abilities using the Vineland Adaptive Behavior Scales, 2[nd]Edition, Survey Form; and autism symptomatology using the Autism Diagnostic Observation Schedule. Developmental and adaptive scores were converted to standard scores to compare group means.

Results: Groups did not differ for gender and cognitive/developmental profiles at first diagnosis. Significant differences were found between groups for nonverbal IQ, ($t(30)$=-2.61, p=.014), verbal IQ, ($t(92)$=-3.16, p=.002) and adaptive communication skills ($t(79$(=-4.59, $p<.001$). Specifically, 3-year-olds who were diagnosed a year previously had higher mean nonverbal IQ scores, verbal IQ scores and adaptive communication skills compared to those receiving a first time diagnosis at age 3.

Conclusions: Data from the current study suggests that receiving a diagnosis earlier is associated with greater nonverbal problem solving, verbal reasoning, and adaptive communication skills at age 3. Standard scores on measures of nonverbal problem solving and adaptive communication were more than one standard deviation higher for children who received an earlier diagnosis, while verbal reasoning scores were 14 points higher. These gains suggest that early diagnosis has a meaningful effect on development. However, groups did not show differences in the areas of adaptive daily living, social, and motor skills, suggesting that the earlier interventions are not impacting these areas of early development. A limitation of this study is racial disparity, which needs to be further examined. In addition, future research should examine the developmental trajectory of children diagnosed at various ages controlling for varying levels and types of early intervention, race, ethnicity, and socio-economic status.

---

63 **138.063** Diagnostic Accuracy of ASRS and SRS in Screening ASD in Chinese Community Children

X. Xu[1], B. Zhou[1], H. Zhou[1], L. Wu[2], X. Zou[3], X. Luo[4], W. Yan[1] and Y. Wang[1], (1)Children's Hospital of Fudan University, Shanghai, China, (2)Department of Children's and Adolescent Health, Public Health, Harbin Medical University, Harbin, China, (3)Pediatrics, Child Developmental & Behavioral Center, The 3rd Affiliated Hospital of Sun Yat-sen University (SYSU), Guangzhou, MD, (4)Central South University,

Background: National prevalence of Autism Spectrum Disorder (ASD) is unknown in China; research on ASD has started recently. Up to now, very few screening and diagnostic instruments were available for the Chinese population, instruments that require population norms are still very scarce. An important initiative funded by the Ministry of Health was launched in 2013 in China to boost autism awareness and clinical and research expertise. As part of this recent program, a national epidemiological survey of ASD among the school-aged population of China was designed. In order to conduct the screening phase of this survey involving 120,000 children from 8 provinces, we needed an instrument, properly validated and adapted for the Chinese population. Based on a representative community-based reference sample and aged matched clinical ASD cases from 4 cities of China, we re-examined the factor structure that was proposed in the initial US study. We evaluated the modified Chinese version of Autism Spectrum Rating Scale (ASRS) and the existing Social Responsiveness Scale (SRS) to select a better screening tool for the large scale epidemiological survey.
Objectives: The study aimed at comparing the diagnostic accuracy of ASRS and SRS in screening ASD in community children aged from 6 to 12 years old.
Methods: The study sample consist of 1588 normal children from community (ASRS T-score<70) and 190 children with diagnosed ASD by DSM-IV from clinics from 4 cites of China. Parents of selected children were invited to complete the ASRS and SRS scales with 1-2 weeks interval. Two of the sites were randomly assigned to administer ASRS first; the rest of two sites did the SRS first and followed by ASRS with 1-2 weeks interval. Receiver Operating Characteristic (ROC) analysis was performed by using ASD disease status as gold standard (1 for cases, 0 for community controls) and ASRS as well as SRS scores as test variables, respectively. Area under curve (AUC) and 95%CI, sensitivity, specificity, positive and negative predicts value and positive rate were evaluated and compared between ASRS and SRS performances. The optimal cutoff of ASRS was proposed for screening ASD to obtain best sensitivity and specificity.
Results: The study sample averagely aged 8.8 years old (range 6-12 years), with 51.1% and 87.9% males in normal controls and clinical cases ($P<0.001$). 31.2% and 65.2% questionnaires were administered by father and mother respectively. Both ASRS and SRS showed excellent performance in ROC analysis with AUC of 0.95(95%CI: 0.93-0.96) and 0.97 (95%CI: 0.96-0.98), respectively, with some overlap in the 95%CIs. Using the cutoff of 57 for ASRS and 60 for SRS, ASRS and SRS showed similar sensitivity (96.3% vs 94.2%), specificity (82.8% vs 82.0%) and positive predict value (39.0% vs 38.4%) and negative predict value (99.0% for both). The positive rate of ASRS and SRS scales were 17.23% and 17.9% respectively. Father administering the questionnaire or mother doing did not bias the comparison between the two screening scales.
Conclusions: ASRS shows excellent performance in screening ASD from Chinese population aged 6-12 years old, which is comparable with SRS.

64   **138.064**   Diagnostic Trends in an ASD Population

P. F. Turcotte, K. Miller and M. Mathew, *A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Research on comorbid psychiatric diagnoses in the field of autism has expanded over the last decade. Comorbid psychiatric diagnoses can manifest differently in individuals, with a wide range of behaviors and specific needs depending on the presence or combination of each disorder. Even with current research, trends over time in comorbid psychiatric disorders have been poorly described. Phenomena such as diagnostic substitution need to be more fully explored, in conjunction with describing the clinical manifestations of these co-occurring diagnoses. Individuals with co-occurring ID and autism, as well as other co-occurring psychiatric diagnoses, are distinct groups and identifying their prevalence or rate as a group is an important next step to further describing their needs. Describing these trends over time, and studying their impact, can inform temporal relationships in diagnosis trends, and inform program planning and policy implications.
Objectives: The primary purpose of this study is to investigate prevalences of comorbid psychiatric diagnosis, examine these trends over time, and identify the diagnosis that most contributes to the increase in co-occurring diagnostic prevalence. We will also describe demographic and other factors that contribute to the differences in comorbid psychiatric diagnoses.
Methods: Data used to identify the population with autism were collected from a large northeastern state from individuals eligible for the state Medical Assistance program. Individuals of all ages were included in the analysis, and were selected if they had any one Medicaid claim associated with an ICD-9 299.XX diagnosis in calendar years 2008-2012. Frequencies and proportions of comorbid psychiatric diagnoses were calculated and tested for significance using chi-square analysis. Multivariable logistic regression was used to determine differences in comorbid psychiatric diagnoses over time.
Results: From 2008-2012 the prevalence of individuals with an autism having any comorbid psychiatric diagnosis increased from 47.9% to 59.4%. Across all psychiatric comorbid diagnoses, the largest increase was seen in intellectual disabilities, increasing from 6.8% to 18.3%. The most frequently diagnosed comorbid psychiatric disorder was ADD/ADHD (23%). Multivariable logistic regression analyses are ongoing to determine and control for explanatory demographic variables.
Conclusions: The prevalence of comorbid psychiatric diagnoses in individuals with autism who are receiving services through Medical Assistance has increased from 2008-2012. This increase in multiple psychiatric diagnoses presents a unique challenge in providing services that fit these individuals' complex needs. As Medical Assistance coverage can depend on funding streams, it is

important to determine whether or not these trends in diagnoses are a result of a better characterization of the patients' behaviors, an increase in occurrence of these disorders, or diagnostic substitution. More research on this issue is needed to determine the extent of these diagnoses in the general population, in order to better inform diagnostic trends and service delivery in this unique population.

65   **138.065** Discriminant Validity of the ADI-R in Latino Families: Identifying Differences Between Autism Spectrum Disorder and Developmental Delay

***S. B. Vanegas**, S. Magana and M. Morales, Disability and Human Development, University of Illinois at Chicago, Chicago, IL*

Background: The development of culturally and linguistically appropriate diagnostic tools is crucial in the assessment of Autism Spectrum Disorders (ASD). The Autism Diagnostic Interview-Revised (ADI-R; Lord, Rutter, & LeCouteur, 1994) is considered a gold-standard parent interview that captures children's past and current development. Although the ADI-R has been widely used in clinical and research settings in the diagnostic process, few studies have evaluated the use of the ADI-R in distinguishing between children with ASD and children with other developmental disabilities (e.g., Gray, Tonge, & Sweeney, 2008; Lord, Rutter, & LeCouteur, 1994). Even fewer studies have assessed the validity of the ADI-R in Latino populations (e.g., Blacher, Cohen, & Azad, 2014; Magaña & Smith, 2013). Thus, there is a need to appraise the utility of the ADI-R in the accurate identification of children with ASD in the Latino population. This information is critical in identifying the appropriate supports and resources for parents and their children.
Objectives: The current study aims to assess whether the use of ADI-R in a USA based Spanish speaking Latino population demonstrates adequate discriminant validity in distinguishing between children with ASD and children with DD.
Methods: The current study included Spanish speaking Latino parents (primarily mothers) of children and adolescents who were between 4 and 16 years of age and received a clinical diagnosis of ASD or a Developmental Delay (DD). The official Spanish version of the ADI-R was administered by trained interviewers. Medical records were obtained to establish the clinical diagnosis. Children were grouped by the clinical diagnosis and included diagnoses of ASD (n = 28) and DD (n= 21).
Results: Discriminant validity was assessed by comparing scores for the three domains on the ADI-R. Converted scores were used as recommended by the updated algorithms (e.g., Rutter, LeCouteur, & Lord, 2003). Preliminary analyses found that children with ASD had higher scores than children with DD on the Reciprocal Social Interaction domain, $F(1, 47) = 6.61$, $p = .013$, and the Restricted and Repetitive Behaviors domain, $F(1, 47) = 6.78$, $p = .012$. No significant differences were observed between children with ASD and children with DD on the Communication – Nonverbal, $F(1, 47) = 1.26$, $p = .268$, and Communication – Verbal domains, $F(1, 31) = 1.91$, $p= .176$. Means are displayed in Table 1. Additional analyses will evaluate group differences at the subdomain and individual item level to identify specific areas that might be significant in the diagnostic process.
Conclusions: The preliminary findings indicate that the Spanish ADI-R exhibits adequate discriminant validity for the Reciprocal Social Interaction and the Restricted, Repetitive Behavior domains, but not in the Communication (Verbal and Nonverbal) domain. These results are in line with other studies finding that the validity of the ADI-R may not be as strong for certain populations (e.g., very young children; Tsuchiya et al., 2013). Further analyses are needed to determine which behaviors may distinguish between children with ASD and children with DD.

66   **138.066** Early Diagnosis of Autism Spectrum Disorder Via a Transdisciplinary Clinic

ABSTRACT WITHDRAWN

Background:
Currently, there are multiple barriers during the diagnosis and treatment of Autism Spectrum Disorders (ASD). These barriers include prompt referrals from primary care providers to specialists, long waitlists for diagnostic services, and subsequent intervention (Filipek, et al., 1999). As early diagnosis and intervention for ASD are crucial for positive outcomes (Bryson, Rogers, and Fombonne, 2003), alternative diagnostic methods should be explored. One possible alternative method, the Medical Diagnostic Clinic is a transdisciplinary diagnostic clinic, where children birth to age three are evaluated to assess whether there is a medical reason for their delays. The arena-style evaluation is typically a multidisciplinary team, including a physician, a clinical psychologist, a speech and language pathologist, an occupational therapist, and a developmental therapist all of whom have strong backgrounds in diagnosing and treating children with developmental disabilities (Klin, et al., 2005). Though this approach appears promising, little systematic research has been conducted to determine the reliability and accuracy of ASD diagnoses by a transdisciplinary clinic.
Objectives:
To examine the validity and reliability of an ASD diagnosis before the age of three within a transdisciplinary clinic. The study re-assessed 34 children who were evaluated prior to age three by a transdisciplinary team, 20 with autism spectrum disorder and 14 who did not meet criteria during their initial assessment. The Autism Diagnostic Observation Schedule (ADOS; Lord, et al., 2000) and Autism Diagnostics Interview-Revised (ADI-R; Le Counteur et al., 2003) were completed at follow-up. The stability of the diagnosis was examined by comparing the original diagnosis given by the transdiciplinary team and that of the follow up evaluation.

Methods:
34 participants were evaluated by a transdiciplinary clinic with an age range of 13 – 36 months. The same children were re-evaluated after the age of 3, with an average age of 49.35 months. Either the Screening Tool for Autism in Two Year Olds (STAT; Stone & Ousley, 1997) or the Childhood Autism Rating Scale (CARS; Schopler, Reichl, & Renner, 1998) were administered during the transdisciplinary evaluation. Children were then randomly selected from a database and assigned to the ADI-R and ADOS evaluator, who was blind to diagnosis of the child. The diagnoses from the two time points were compared to determine the accuracy and reliability of the diagnosis assigned by the transdisciplinary clinic prior to the age of three.
Results:
Diagnostic accuracy of the transdisciplinary clinic was high compared to the ADOS/ADI-R. Specifically, inter-rater reliability of diagnosis was found to be 82.35% with a Kappa coefficient of .62 between initial diagnosis and follow up.
Conclusions:
Findings of the current study suggest that the transdisciplinary clinic approach is a reliable and valid method of identifying children at risk for ASD prior to the age of 3. This appears to be highly accurate in the identification of ASD in the birth to three population, which may enhance service delivery and developmental outcomes for these youngsters. Transdisciplinary teams could serve as a way of getting children and families connected with targeted intervention while they wait for a formal diagnostic evaluation.

67 **138.067** Early Predictors of Academic Achievement in School-Aged Children with Autism Spectrum Disorders

L. E. Miller[1], E. Troyb[2], K. Knoch[3], L. E. Herlihy[4] and D. A. Fein[1], (1)Psychology, University of Connecticut, Storrs, CT, (2)Alpert Medical School of Brown University, Providence, RI, (3)MassGeneral for Children at North Shore Medical Center, Salem, MA, (4)Yale School of Medicine Child Study Center, New Haven, CT

Background: Children with autism spectrum disorders (ASDs) commonly experience social and academic challenges within the school setting, often exacerbated by cognitive, language, and motor impairments. Few studies have looked at early predictors of later academic performance in this group, results of which may have important implications for clinical intervention.
Objectives: This study aims to assess early predictors of academic functioning in school-aged children with ASDs.
Methods: Participants were 27 children (23 males) evaluated at three time points as part of a larger study on the early detection of pervasive developmental disorders. ASD diagnosis was established at T1 (mean age 27.2 ± 3.3 months) and confirmed at T2 (mean age 52.8 ± 5.5 months), with diagnoses distributed as follows: 81% Autistic Disorder and 19% Pervasive Developmental Disorder – Not Otherwise Specified (i.e., PDD-NOS). All children continued to meet diagnostic criteria for an ASD at T3 (mean age 119.4 ± 9.7 months), at which time academic achievement was also assessed. As T1 cognitive data was characterized by considerable floor effects, T2 data was used to predict T3 outcomes. Cognitive ability and social functioning at T2 were evaluated by the Mullen Scales of Early Learning (MSEL) and Vineland Adaptive Behavior Scales (VABS), respectively. Academic achievement at T3 was assessed across the domains of reading (i.e., word reading, reading comprehension, and pseudoword decoding) and mathematics (i.e., numerical operations and math reasoning) using the Wechsler Individual Achievement Test. The current study used multiple regression with stepwise entry to determine significant predictors of academic ability at T3 from cognitive and social functioning at T2.
Results: Five T2 variables (MSEL receptive language, expressive language, visual reception, and fine motor; VABS socialization) were entered stepwise to predict T3 achievement. Composite reading skills were best predicted by receptive language ability (R^2 = .68, $F(1,7)$ = 15.089, p = .006). Word reading was best predicted by fine motor skills (R^2 = .45, $F(1,16)$ = 13.109, p = .002), and reading comprehension was best predicted by a combination of receptive language ability and socialization skills (R^2 = .88, $F(2,12)$ = 42.859, p < .001). Pseudoword decoding had no significant predictors ($F(5,4)$ = 1.397, p = .384). In contrast, composite math skills (as well as specific component skills of numerical operations [R^2 = .54, $F(1,14)$ = 16.309, p = .001] and math reasoning [R^2 = .72, $F(1,13)$ = 33.524, p < .001]) were best predicted by expressive language ability (R^2 = .87, $F(1,11)$ = 70.410, p < .001).
Conclusions: This study was designed to determine early predictors of academic achievement in school-aged children with ASDs. The results suggest that, overall, early language skills best predict later academic abilities; specifically, receptive language skills predict reading ability, whereas expressive language skills predict math ability. This study supports the importance of early language interventions for potential improvement of later academic outcomes in children with ASDs.

68 **138.068** Early Temperamental Persistence and Associations with Later Executive Functioning

L. D. Ankeny[1], N. M. Reyes[2] and S. L. Hepburn[3], (1)Psychology, University of Denver, Denver, CO, (2)JFK Partners, Aurora, CO, (3)Psychiatry & Pediatrics, JFK Partners/University of Colorado School of Medicine, Aurora, CO

Background: ASD is a markedly heterogeneous disorder and Bundson and Happe (2014) suggest that specific phenotypic variants that are relevant to later outcomes can be derived at the cognitive level. Executive functioning (EF) is also diverse in ASD, but typically not measured until later ages. In fact, recent research (Rosenthal et al., 2013) suggests that real-world impairments of executive function increases from childhood to adolescence, with particular impairments in the domains of initiation, working memory and shifting. Identifying precursors to EF dysfunction holds important implications for intervening early and may provide opportunities to limit the increasing discrepancies seen in adolescence. A potential precursor of EF that can be measured in early childhood is persistence, or the temperamental tendency to maintain goal-directed behavior in the face of obstacles. Persistence in early childhood has been associated with both attention and school functioning (Guerin et al., 1994) in typically-developing children; however, little is known about its relevance in children with ASD.

Objectives: To examine if parent report of child's persistence in early childhood is associated with executive function skills and gains in adaptive skills in middle childhood.

Methods: Prior to age 7, 90 parents of children with ASD completed the Carey Temperament Scale (CTS; McDevitt & Carey, 1984), which includes a Persistence Dimension Score. Approximately five years later, they returned for a follow-up visit and completed the Behavior Rating Inventory of Executive Function (BRIEF; Giola, Isquith, Guy & Kenworthy, 2000) and the Vineland Adaptive Behavior Scales (Sparrow, Cicchetti & Bella, 2005).

Results: Current results demonstrate a link between parent report of the child's persistence in early childhood and executive function skills in middle childhood. Significant associations were observed for initiation (r=.39), working memory (r=.41) and plan/organize (r=.32), as well as the global executive composite score (r=.34). Examination of associations between persistence, executive function and adaptive skills are underway.

Conclusions: Preliminary analyses suggest that early temperamental persistence is a potential precursor for later executive problems. Identifying early risk factors from a neurocognitive perspective allows for earlier, and more targeted interventions, as well as studies from a neurobiological perspective.

69   **138.069** Examining the Interaction of Social Function and Language Skills in ASD

A. Kushki[1], N. Kong[2], J. A. Brian[3], A. Dupuis[4], S. Chow[2] and E. Anagnostou[5], (1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)150 Kilgour Rd., Holland Bloorview Kids Rehabilitation Hospital/ U of Toronto, Toronto, ON, Canada, (4)The Hospital for Sick Children, Toronto, ON, Canada, (5)Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada

Background: The autism spectrum is associated with significant heterogeneity in terms of etiology, biology, and phenotype and characterizing this heterogeneity is key to development of targeted treatments. In this context, characterization of variability in the language domain has received much attention. Language impairments are a key feature of ASD and predictors of outcome in this population. Moreover, variability in this domain is suggested to be associated with underlying biological mechanisms. Although DSM-5 has deemphasized language ability and removed diagnostic distinctions between Asperger's syndrome and autistic disorder, language impairment remains a "specifier" ASD. One outstanding issue in the area is how this specifier interacts with core ASD symptom domains. Specifically challenging this examination is the confounding effect of communication function on the interaction between language social function in ASD.

Objectives: The objective of this study was to investigate the interaction between structural language ability and social functioning in ASD.

Methods: A sample of children with ASD (n=141, age: 10.2+3.0, 111 male) was recruited. To tease out the confounding effect of communication on the language-social reciprocity interaction, the Reciprocal Social Interaction subtotal from the Autism Diagnostic Observation Schedule (ADOS)-Module 3 was used to characterize reciprocal social function. Language ability was quantified using the Oral and Written Language Scales, respectively. Receptive and expressive language were considered separately and as a composite as recommended by DSM-5. Using a cut-off of 85 in each language domain (one standard deviation below the mean), children were stratified into high and low language groups. This cut-off value also corresponded to the result of clustering the sample based on language ability using the k-means algorithm.

Results: Reciprocal social interaction score decreased significantly as language comprehension, oral expression, and the oral language composite increased (p<0.0001). In all three cases, there was a significant group x language effect on the social interaction scores (p<0.03). In particular, the reciprocal social interaction score decreased significantly with scores on language domains in the "high language" group but not in the "low language" group.

Conclusions: Our results suggest that structural language ability may define two subgroups within the autism spectrum. The interaction between the social and language domains is different between the two subgroups and may be reflective of distinct underlying biology.

70   **138.070** Extension of the PDD Behavior Inventory to Adolescents

I. L. Cohen, 1050 Forest Hill Rd, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY

Background:
The PDD Behavior Inventory (PDDBI) is a reliable and valid informant-based rating scale for ASD designed for assessment, diagnosis, and treatment planning. Studies have indicated that scores from the PDDBI are good indicators of response to intervention, diagnosis, and outcome, and are also associated with certain genetic factors. The PDDBI was designed to cover ages ranging from 18 months to 12 years, five months. However, this age range restricts clinicians and researchers to younger children and prevents use of the PDDBI for longer term clinical follow-up as well as research studies of adolescents with ASD.
Objectives:
In a large cohort of adolescents, examine the cross-sectional effects of age on PDDBI raw cluster scores and total scores; compare internal consistency and inter-rater reliability with established measures for the standardization sample; and examine the construct and criterion-related validity of the PDDBI for this older group.
Methods:
PDDBIs were completed by 138 parents and 100 teachers of adolescents with ASD, ages 12 years, 6 months to 18 years, 5 months. The sample was divided into three age groups (years:months): 12:6 to 14:5; 14:6 to 16:5; and 16:6 to 18:5. Raw cluster and raw total scores were compared across age groups using ANOVAs. Internal consistencies were evaluated with alpha coefficients and factorial validity with principal components analyses (PCA). Criterion-related validity correlations for the PDDBI scores were examined against ADI-R domain scores and against the Aberrant Behavior Checklist (ABC) in a subset (n=18) of parents.
Results:
Across age group, significant attrition (>20%) in completion of the Gestural Approach, Social Play, and Imaginative Play item clusters for the Social Approach (SOCAPP) domain was noted. Regression techniques were then used to estimate missing cluster scores based on the remaining clusters. ANOVAs revealed no significant difference in the revised SOCAPP mean score, as well as all other domain mean scores, across age groups. Internal consistencies were high, ranging from 0.77 to 0.98. Parent-teacher agreement, within a 6 month period, was good for most of the domain scores but poor for the RITUAL, SOCPP, SEMPP, and LMRL domains. Factorial validity replicated previous findings of two behavioral dimensions: Approach/Withdrawal Problems and Receptive/Expressive Social Communication Abilities. Agreement between Approach/Withdrawal Problems domain scores and corresponding ABC factor scores was very good and agreement between the PDDBI and ADI-R was remarkably good given that the ADI-R scores were historical in nature.
Conclusions:
These analyses confirm both the reliability and validity of the PDDBI for adolescents with ASD given minor modification in scoring of the SOCAPP domain.

71 **138.071** Factor Structure and Psychometric Properties of the Revised Home Situations Questionnaire for Autism Spectrum Disorder

M. Chowdhury[1], M. G. Aman[2], L. Lecavalier[3], T. Smith[4], C. Johnson[5], N. Swiezy[6], J. T. McCracken[7], B. H. King[8], C. J. McDougle[9], K. Bearss[10] and L. Scahill[11], (1)Psychology, Allegheny College, Meadville, PA, (2)The Nisonger Center UCEDD, Ohio State University, Columbus, OH, (3)Psychology, The Ohio State University, Columbus, OH, (4)601 Elmwood Ave, Box 671, University of Rochester, Rochester, NY, (5)University of Pittsburgh, Pittsburgh, PA, (6)Indiana University School of Medicine, Indianapolis, IN, (7)Psychiatry and Biobehavioral Sciences, UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (8)Psychiatry, University of Washington & Seattle Children's Hospital, Seattle, WA, (9)Harvard School of Medicine, Massachusettes General Hospital, Lexington, MA, (10)Pediatrics, Emory University School of Medicine, Atlanta, GA, (11)Pediatrics, Marcus Autism Center, Atlanta, GA

Background: The original Home Situations Questionnaire (HSQ; Barkley & Edelbrock, 1987) is a 16-item scale developed to examine the severity of noncompliant behavior in children with disruptive behavior disorders. Previously, we reported on the factor structure of the HSQ in children with pervasive developmental disorders (Chowdhury et al., 2010). Consequently, we further revised the HSQ for use with children with autism spectrum disorder (ASD). To enhance the range of clinical situations covered and to improve reliability, we added seven new items describing home situations where a specific demand is placed on the child.
Objectives: The purpose of the current investigation was to examine the psychometric properties of the revised and expanded 27-item version of the instrument (referred to as the HSQ-ASD). We predicted that the seven new items would factor selectively on the previously reported Demand-Specific subscale. We also predicted clear evidence of convergent and divergent validity with measures of problem behavior, adaptive behavior, and IQ, as well as favorable test-retest reliability.
Methods: Parents completed ratings of 242 disruptive children with ASD (mean age = 5.65 years, SD = 2.21) participating in one of two randomized clinical trials. We used Exploratory Factor Analysis (EFA), with Ordinary Least Squares as the discrepancy function and oblique Crawford-Ferguson quartimax rotations, to assess the factor structure of the HSQ. Pearson correlations were used to assess convergent and divergent validity, and Intra Class Correlations to assess test-retest reliability.
Results: The EFA yielded a two-factor structure similar to that obtained in our previous psychometric examination (2010). These two factors, with 12 items each, were Socially Inflexible (alpha = .84) and Demand-Specific (alpha = .89). The underlying themes of these two factors suggest that Social

Inflexibility is congruent with deficits in social interactions and rigid adherence to routines that are part of ASD, whereas Demand Specific noncompliance appears to reflect oppositional behavior in response to typical daily requests. Three items that did not meet the cut-off factor loading were discarded from the final composition of the HSQ−ASD. Consistent with our prediction, the EFA confirmed that 6 of 7 newly added items loaded on the Demand-Specific factor. One-to-2-week test-retest reliability was statistically significant for almost all items and also statistically significant for the subscale totals (r= .57 for Socially Inflexible and .58 for Demand Specific). The pattern of correspondence between the HSQ–ASD and parent-rated problem behavior scores, clinician assessment of repetitive behavior, adaptive behavior, and IQ provided evidence for concurrent and divergent validity of the HSQ–ASD.

Conclusions: In summary, the modified and expanded 24-item HSQ-ASD provides broad coverage of situations associated with noncompliance, thus supporting its use as an outcome measure for disruptive behaviors in this population. Limitations of this study include limited generalizability of findings since all participants were selected for presence of behavior problems. Future studies will provide a valuable service by evaluating the HSQ-ASD in children with ASD unselected for disruptive behavior and also in *adolescent* populations with ASDs.

72   **138.072** Follow-up ASD Screening Identifies Children Missed at Initial Screening Timepoint

C. Cordeaux[1], K. L. Anderson[1], M. L. Barton[1], D. A. Fein[1] and D. L. Robins[2], (1)Psychology, University of Connecticut, Storrs, CT, (2)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA

Background: The M-CHAT-R/F is a valid screening tool for ASD at 18-30 months. However, no screening instrument can identify all potential ASD cases. Children who screen negative at 18-24 months old but later screen positive at 30-48 months old with the M-CHAT-R/F are "potential miss" cases. A longitudinal evaluation of the M-CHAT-R/F provides an opportunity to identify and study these children.

Objectives: This study present preliminary data from a 2-year follow-up screening with the M-CHAT-R/F and examines items that were failed at both or either time points by "potential miss" cases.

Methods: Participants were drawn from a sample of children who screened negative on the M-CHAT-R/F (n=10,504) and the M-CHAT (n=838) when screened at 18-24 months of age. Approximately 2 years after the initial screening, children were rescreened with the M-CHAT-R/F; it was mailed to families with a stamped return envelope. A subset of rescreened children screened positive on the M-CHAT-R/F and were invited to participate in an ASD evaluation.

Results: At rescreening, 29 children were identified as "potential misses" and invited for diagnostic evaluation. Eleven of 17 evaluated children were given developmental diagnoses. Six children received an ASD diagnosis and were identified as "true misses." Seven children received non-spectrum diagnoses, and four received no diagnosis. The average age of "potential misses" at initial screening was 21.6 months (SD=3.2), the average age at rescreening was 45.6 months (SD=5.6), and the average age at evaluation was 48.3 months (SD=3.2). "True misses" and "potential misses" did not differ on the number of items failed at initial screening (M=0.8, SD=0.9) or at rescreening (M=3.6, SD=1.7). At initial screening, failure on Item 13 (walks) and Item 17 (seeks parent attention) were each moderately associated with receiving an ASD diagnosis at 48 months (χ^2 (1, N=10)=1.7, p=.19, φ_c=.41), though sample size precluded significance. At rescreening, failure of Item 1 (follows point) (χ^2 (1, N=16)=1.6, p=.21, φ_c=.31), Item 3 (pretend play) (χ^2 (1, N=16)=1.7, p=.18, φ_c=.33), Item 5 (unusual finger movements) (χ^2 (1, N=16)=1.3, p=.25, φ_c=.29), and Item 15 (imitates) (χ^2 (1, N=16)=1.7, p=.18, φ_c=.33) were each moderately associated with a diagnosis of ASD at 48 months at a non-significant level.

Conclusions: This study presents preliminary data on a sample of screening cases that screened negative as toddlers but later screened positive on the M-CHAT-R/F, including some verified ASD "true misses." 17 children were evaluated, 76% of whom received developmental diagnoses at 48 months; therefore, rescreening did not misidentify many typically developing children with potential concerns. At initial screening, failed items associated with ASD diagnosis were not core ASD features. This is potentially due to inaccuracies in parent reporting, or because core features manifested after the age of first screening. Interestingly, failed items at rescreening associated with ASD diagnosis represented core ASD features. These results emphasize the importance of ASD screening at multiple timepoints, as a single screening may miss cases. Further analyses will compare clinical characteristics and item-level responses in a larger sample of "potential miss" and "true miss" cases identified through additional screening measures.

73   **138.073** From a Heterogeneous ASD Phenotype to Quantitatively Distinct Putative ASD Subtypes

A. P. Whitten[1] and J. W. Bodfish[2], (1)Hearing & Speech Sciences, Vanderbilt University, Nashville, TN, (2)Vanderbilt Brain Institute, Nashville, TN

Background: Although it is accepted that the autism phenotype is variably expressed across cases and that there are likely underlying subtypes of autism (i.e. the "autisms"), it is not clear how best to identify phenotypic subtypes that are truly distinct. In addition, "gene first" (e.g. comparing genetic conditions associated with ASD), and "brain first" (e.g. brain function -symptom correlations) approaches have yielded mixed results suggesting that efforts to parse ASD at the phenotypic level

may still be useful, and could then in turn inform genetic and neuroimaging studies.
Objectives: To develop a quantitative method for isolating distinct ASD phenotypes.
Methods: In the present study we compared a large and diverse sample of children and adolescents with ASD (n = 224, identified by ADOS, ADIR, & expert clinical diagnosis; age range = 2 to 18 yrs; IQ range = 40 – 140; 13% female) to a sample of typically developing children matched on age, IQ, & gender, using a multi-method (parent ratings, observational measures) and multi-measure (SCQ subscales, SRS, RBS-R subscales, CCC subscales, ADOS subscales) approach for mapping the core features of autism. We used a 3 step process to isolate potential phenotypic subtypes: (1) psychometric analyses identified the subset of measures with superior reliability & validity, (2) multivariate techniques (correlation, regression, & PCA) identified measures of core features with maximum between-measure divergence, (3) radar graphs of standardized scores isolated extreme outlier cases for each measure of divergent core feature (social, communication, RRBs).
Results: There was little evidence that the "core" features of autism were strongly related (e.g. correlations of social-communication function with RRBs across several measures were in the range of 0.2 to 0.4). PCA analyses also yielded consistent evidence for divergence into the 3 core features (social, communication, RRBs), and also divergence within the core features into multiple sub-factors.   Radar graphs identified cases that were extreme outliers (> 1.5 SDs) on only 1 core feature: 9% on social impairment, 18% on communication impairment, and 11% on RRBs suggesting that up to one-third of the sample may be "extreme phenotypic outliers" within the ASD spectrum. To investigate the validity of these putative subtypes, we are examining validation of these subgroups using eye-tracking measures of social and nonsocial attention, and fMRI measures of social and nonsocial reward circuitry activation.
Conclusions: Our analyses indicate that there is significant divergence of the 3 core features of autism (social, communication, RRBs) across methods and measures. Further, multi-method, multivariate approaches using psychometrically acceptable measures may be useful to identify "extreme" phenotypic outlier cases within each of the core features. This approach may be useful in helping to identify specific genetic and neurobiologic factors that are associated with each core feature of autism in a way that previous research using a "one size fits all" phenotypic approach (e.g. ASD versus non-ASD) has not been able to do.

74   **138.074**   Gender Differences in ASD Symptoms: Do Women with HFASD Display Fewer Socio-Communicative Difficulties Than Men?

W. T. Brooks[1], *H. M. Scott*[2] *and B. A. Benson*[2], *(1)TEACCH Autism Program, UNC, Chapel Hill, NC, (2)Nisonger Center, Columbus, OH*

Background: Girls and women with autism spectrum disorders (ASD) have historically been underrepresented in the literature, but there has been an increased interest in gender differences in the characterization and presentation of ASD. Results from some of these studies suggest that females may present with a different pattern of socio-communicative impairments and restricted interests and behavior than males. However, few studies have examined this pattern in adults.
Objectives: The aim of this project is to examine gender differences in ASD symptoms in adults with high functioning autism spectrum disorders (HFASD) using a standardized observational assessment, as well as self-report and parent-report ASD questionnaires.
Methods: This project is part of a larger study examining gender differences in ASD symptoms, social relationships, and emotions in adults with HFASD. Participants included 56 adults (28 women and 28 men) with a mean age of 26.3 years (SD = 6.0 years). Participants were diagnosed with ASD by a clinician in the community and did not have a diagnosis of co-occurring intellectual disability (ID). Researchers assessed participants with the Autism Diagnostic Observation Schedule (ADOS) and the Wechsler Abbreviated Scale of Intelligence-2nd Edition (WASI-2). Parents of participants completed the high-functioning Autism Spectrum Screening Questionnaire (ASSQ), a screening measure for HFASD adapted for use with adults in this study, and the ASSQ-GIRL, an addition to the ASSQ developed to assess ASD features that may be more applicable to females with ASD. Participants completed the Autism Spectrum Quotient (AQ), a self-report ASD screening measure. Men and women with HFASD did not differ significantly on age, living situation, ethnicity, employment, or WASI-2 verbal comprehension index scores.
Results: Women with HFASD scored significantly lower on total ADOS scores (F = 15.43, p < .001), as well as the Social (F =13.07, p = .001) and Communication (F = 9.32, p = .004) domains than men with HFASD, indicating less severe socio-communicative difficulties. Women with HFASD scored lower than men with HFASD on the RRB domain, but this difference was not significant (F =3.48, p = .068). A smaller proportion of women with HFASD (36%) met the cutoff score on the ADOS than men with HFASD (71%), indicating a diagnosis of "autism spectrum" ($\chi2$ = 7.179, p = .007). There were no significant differences between women and men on the AQ or the original ASSQ. However, women with HFASD scored significantly higher than men with HFASD (F = 11.741, p = .001) on mean ASSQ-GIRL scores.
Conclusions: Results from this study suggest that women with HFASD may display less severe observable socio-communicative deficits than men with HFASD, which supports a previous study examining gender differences in adults with HFASD. There were no differences between men and women on self-reported ASD symptoms and on the original ASSQ scale, although women did score higher on the ASSQ-GIRL than men with HFASD. Further research on gender differences is warranted, as it is important to understand how it may impact the diagnosis and course of ASD.

75   **138.075** Heterogeneity at the Minimally Verbal End of the Spectrum

C. DiStefano[1], C. Kasari[2], A. P. Kaiser[3], R. J. Landa[4] and P. Mathy[5], (1)Center for Autism Research and Treatment, University of California, Los Angeles, Los Angeles, CA, (2)UCLA Center for Autism Research & Treatment, Westwood, CA, (3)Special Education, Vanderbilt University, Nashville, TN, (4)Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD, (5)Kennedy Krieger Institute, Baltimore, MD

Background: Approximately 30% of children with autism spectrum disorders (ASD) are minimally verbal past age 5 (Anderson et al., 2007), and these children are rarely reported in research. Preliminary research suggests that despite limited expressive language, there may be considerable variability in their other abilities, such as non-verbal cognition and receptive language. Better characterization of these abilities can lead to increased understanding of the minimally verbal ASD population, more targeted interventions and better longitudinal outcomes.

Objectives: 1) To describe the range of abilities across domains in a sample of minimally verbal children with ASD, 2) determine how those abilities relate to expressive language, and 3) find common skill profiles.

Methods: Participants included 61 minimally verbal children with ASD from a multi-site intervention study (Kasari et al., 2014), ages 4.5 – 9 years. Data was analyzed from the baseline timepoint. Assessments included the Autism Diagnostic Observation Schedule (ADOS), Peabody Picture Vocabulary Test – 4[th]Edition (PPVT), Natural Language Sample (NLS; Kasari et al., 2014), Leiter-R (non-verbal IQ), Early Social Communication Scales (ESCS) and Repetitive Behaviors Scale – Revised (RBSR). Descriptive and correlational statistics were used to describe ability ranges across domains and their relationships to expressive language. Skill profiles were determined using K-means analysis.

Results: All participants were assessed with the ADOS module 1 (no or very little expressive language). On the ADOS, 44 participants used five or fewer words, 12 used more than 5 words and 5 used short, inflexible phrases. Severity scores ranged from 4 – 10, indicating a variety of ASD symptoms. NVIQ ranged from 36 to 123, with a mean of 68. NVIQ was correlated with receptive language ($r=.50$, $p<.001$), but not with expressive language or any other measure. Receptive language age-equivalent ranged from 1.9 to 4.7 years ($M=2.6$) and was related to expressive vocabulary size ($r=.39$, $p=.002$) but no other variables. Joint attention (from the ESCS) was correlated with ADOS severity score ($r=.36$, $p=.005$). K-means cluster analysis was used to identify 4 participant clusters, based on a variety of measures. Cluster 1 ($N=10$) had low abilities across domains, the highest level of repetitive behaviors and highest ADOS scores. Clusters 2 ($N=5$) had a mix of abilities across domains. Cluster 3 ($N=32$) was the largest group and had the lowest rates of repetitive behaviors with scores near the mean on other measures. Cluster 4 ($N=11$) had a moderate rate of communicative utterances, moderate repetitive behaviors and high abilities across other domains.

Conclusions: In this sample of minimally verbal children with ASD, there was substantial heterogeneity across abilities. Of particular interest, children showed great variability in NVIQ, which was not correlated with most other domains. The skill profiles that emerged from the cluster analysis highlight the dissociations among expressive language, NVIQ, joint attention and repetitive behaviors. These characteristics should be explored further, to see if similar skill profiles can be found in additional samples of minimally verbal children with ASD. Particularly, research is needed to determine if these characteristics can be related to intervention response and longitudinal outcomes.

76   **138.076** How Useful Are the Parent-Completed Ages and Stages Questionnaires for Screening of Motor Problems in Preschoolers with High-Functioning Autism?

M. Vanvuchelen[1], M. A. Braeken[2] and L. Van Schuerbeeck[2], (1)Hasselt University Faculty of Medicine and Life Sciences, Diepenbeek, Belgium, (2)Hasselt University, Diepenbeek, Belgium

Background:
Comorbidity is common in autism spectrum disorders (hereafter "autism"). For instance: up to 79% of individuals with autism, including those with intellectual disabilities, have concurrent motor problems (Lai, Lombardo, & Baron-Cohen, 2014). Mild motor problems, which are not attributable to medical conditions such as cerebral palsy, are often seen in children with high-functioning autism (HFA). Unfortunately, motor skills of children with HFA are habitually not a priority for early assessment and intervention teams who may focus primarily on social-communication and behavioural concerns (Lloyd, MacDonald, & Lord, 2013). Developmental screening with a broadband screen that is appropriate for parents may help to identify those children who are in need of further profound motor evaluation.
Objectives:
To determine the usefulness of the Ages and Stages Questionnaires (ASQ-2) for screening gross and fine motor problems in preschoolers with HFA in the clinical setting of an autism diagnostic center.
Methods:
Participants:
39 children with HFA between 22 and 54 months of age (mean chronological age 39.5m, SD 8.5m)

with an IQ above 70 (mean mental age 39.8m, SD 11.3m) were diagnosed in University Autism Clinics (Flanders, Belgium) according to DSM-IV-TR diagnostic criteria for autism confirmed by ADOS-G-classification.
