Nineteen children with ASD (3 females; *M* age = 13.68) and 20 neurotypical (NT) children (8 females; *M* age = 13.80), matched for language and nonverbal intelligence, were given a short narrative prompt which included two male characters and were asked to think about how they would end the story. Since both male characters could be referred to with the pronoun *he*, 3rd-person singular pronouns produced in the narratives could be ambiguous. Children were given three minutes to tell the ending of the story. Narratives produced by the children were analyzed for clarity of third-person pronominal reference and production of mental state terms, as well as standard measures of syntax (mean length of utterance, MLU) and semantic complexity (number of different words, NDW).

Results:

We found no difference in the length of narratives produced by the groups in terms of number of words ($t(37)=1.78$, $p=0.08$), MLU ($t(37)=-.44$, $p=.66$), or NDW ($t(37)=.1.60$, $p=.12$). However, NT children produced more 3rd-person pronouns with clear referents ($M=18.4$, SD=11.34) than children with ASD ($M=12.45$, SD=8.94), $p<.05$. Conversely, children with ASD produced more 3rd-person pronouns with ambiguous referents ($M=11.2$, SD=10.68) than NT children ($M=6.1$, SD=6.82), $p<.05$. NT children also produced more mental state terms ($M=21.65$, SD=7.78) than children with ASD ($M=15.53$, SD=7.43), $p<.05$. In both groups, greater production of mental state terms was significantly correlated with the production of clear 3rd-person pronouns ($r=0.55$, $p<.001$) as well as with age ($r=0.46$, $p<.01$); age was also significantly related to overall word count ($r=0.34$, $p<.05$) and NDW ($r=0.34$, $p<.05$).

Conclusions:

We find a moderate-to-strong relationship between children's abilities to use 3rd-person pronouns with clear referents and the production of mental state terms, suggesting that children with stronger notions of internal states are more active in monitoring their interlocutors' interpretation of pronouns. We also find that older children produce more mental state terms and longer narratives than younger children, suggesting a developmental trajectory.

48 **235.048** Benefits and Challenges of Multilingualism for Autistic Children

O. Ozturk[1,2], *J. L. Gibson*[2] *and N. Katsos*[2], *(1)Speech and Language Therapy, University of Sheffield, Sheffield, United Kingdom, (2)University of Cambridge, Cambridge, United Kingdom*

Background: Despite the growing prevalence of multilingualism in the world (Grosjean, 2010), there is little research into multilingualism in children with neurodevelopmental disorders (Hampton et al., 2017). Bilingual parents of children with autism spectrum disorder (ASD) are sometimes advised to keep to a single language, often the majority language of the society (Lim et al., 2018). A handful of studies investigating whether bilingual exposure is associated with additional difficulties for the language development of children with ASD focused on receptive and expressive language (Ohashi et al, 2012), vocabulary (Petersen et al, 2012), structural and pragmatic language competence (Reetzke et al., 2015), and gestures (Valicenti-McDermott et al., 2013). A systematic review by Uljarevic et al. (2016) examined 50 studies and concluded that bilingualism has no negative effects on various aspects of functioning across a range of neurodevelopmental disorders and in the case of ASD, positive effects of bilingualism on communication and social functioning have been observed.
However, previous studies examining bilingualism in autistic children often exclusively relied on parental reports, they often excluded non-verbal children from the sample, and they sometimes did not include a general cognitive assessment of the participants to evaluate their level of general functioning. Crucially, previous studies often measured bilingual children's skills only in the language that is dominant in their society and do not report the child's development in the language used at home. This is a substantial gap in our current understanding.

Objectives: In this paper we aimed to address the gaps in previous research by avoiding the shortcomings identified above and critically, by studying children's linguistic development in all the languages spoken by a child.

Methods: Our study includes parental reports for all languages spoken by a child as well as direct data for English comprehension and production through face-to-face interactions with autistic children in England. Our data collection is still on going. To date, we collected parent-reported data from 39 children (6 females, 18 bilinguals, 5 trilinguals) and direct data from 30 children (3 females, 15 bilinguals, 3 trilinguals) aged 4;4-12;0. Our target is to present direct and parent-reported data from 60 autistic children, approximately half of whom would be bilingual.

Results: Preliminary results show that bilingual children's combined comprehension and production scores in English are significantly better than monolingual children's (M_{bil}=118.11, SD=28.19, M_{mono}=98.58, SD=18.89, F(1,28)=4.609, p=0.041). Additionally, bilingual children's production scores were significantly better than monolingual children's production scores (M_{bil}=54.50, SD=12.77, M_{mono}=43.92 SD=19.24, F(1,28)=4.282, p=0.048) in English. Finally, bilingual children also scored significantly higher than the monolinguals in the English comprehension task (M_{bil}=63.61, SD=6.94, M_{mono}=54.67, SD=17.72 F(1,28)=4.227, p=0.049). We also present qualitative data on children's linguistic performance in their second (and third) language(s).

Conclusions: These results provide empirical support for the view that multilingualism does not hamper the linguistic and communicative development in autistic children in the majority language (English). Further analyses will report on home language. This study is likely to offer the most comprehensive profile of language development in bilingual autistic children to date.

49 **235.049** Bilingually Exposed Children with Autism Spectrum Disorder: Language and Socio-Communication Outcomes

Zwaigenbaum[10], C. Waddell[11], T. Bennett[12], E. Duku[13], M. Elsabbagh[14], S. Georgiades[13], W. J. Ungar[15] and A. Zaidman-Zait[16], (1)Autism Research Centre, IWK, Halifax, NS, Canada, (2)Pediatrics / Psychology and Neuroscience, Dalhousie University / IWK Health Centre, Halifax, NS, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (4)Dalhousie University, Halifax, NS, Canada, (5)Psychiatry, Pediatrics & Behavioral Neurosciences, Oregon Health & Science University, Portland, OR, (6)isand, Toronto, ON, Canada, (7)The Hospital for Sick Children, Toronto, ON, Canada, (8)University of British Columbia, Vancouver, BC, Canada, (9)University of Ottawa, Ottawa, ON, Canada, (10)University of Alberta, Edmonton, AB, Canada, (11)Simon Fraser University, Vancouver, BC, Canada, (12)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (13)McMaster University, Hamilton, ON, Canada, (14)McGill University, Montreal, PQ, Canada, (15)University of Toronto / The Hospital for Sick Children, Toronto, ON, Canada, (16)Tel-Aviv University, Tel-Aviv, Israel

Background: Despite concerns of many families and healthcare providers, emerging evidence suggests that bilingually exposed children with autism spectrum disorder (ASD) have similar language, behavioural, and cognitive outcomes to their monolingual counterparts. Furthermore, excluding children from exposure to the minority in favor of the majority language could lead to negative consequences, such as reducing engagement and closeness with family and community. Thus, it is important to understand the characteristics of families that maintain minority-language exposure and the associated positive or negative outcomes.
Objectives: The objectives were to (1) determine if families continue to use the minority language from ASD diagnosis until age six, (2) explore child and family characteristics associated with maintaining a minority language, and (3) compare children whose families continue to use the minority language to families who do not and to monolingually exposed children on majority-language and socio-communication outcomes at six years.

Methods: Data from 39 children with ASD exposed to a minority language by primary caregivers (*M* age =36.0 mo; *SD* =6.5; 74% males) and 17 monolingually exposed children (*M* age =35.1 mo; *SD* =5.5; 88% males) were drawn from the Canadian Pathways in ASD study. Children were assessed within four months of diagnosis (T1), one year later (T2), and at age six (T3). Children's language skills in the majority language were examined using the PLS-4 and CDI. Social and communication skills were assessed using the VABS-II Communication and Socialization subdomain scores.

Results: Only 30% of caregivers who reported primarily using a minority language with their child at T1 (*n* =21) still did so by T2. Mann-Whitney U and Chi-squared tests indicated that child age, IQ, ASD symptom severity, and language-level (minimally verbal vs. verbal) at T1, and caregiver level of education did not predict switching to the majority language. None who used a minority language as secondary at T1 (*n* =18) were using it as primary by T2. Only one of six families using a minority language as primary at T2 stopped by T3. Notably, 38% of caregivers stopped using the minority language entirely by T2: 7/21 who primarily used a minority language and 8/18 who used a minority language as secondary at T1. However, three families from each group re-introduced it by T3. Child and caregiver characteristics at T1 did not distinguish caregivers who stopped using the minority language. Importantly, at age six, ANOVAs with planned contrasts revealed no differences in expressive or receptive language, or socio-communication skills among children whose caregivers continued minority-language exposure (*n* =18), stopped minority-language exposure (*n* =14), and monolingually exposed children (*n* =17), who were matched on child and caregiver characteristics at T1 using propensity score matching.

Conclusions: Child and caregiver characteristics at ASD diagnosis did not distinguish between families who continued and families who stopped minority-language exposure during the preschool years. Further, bilingually and monolingually exposed children had similar majority-language and socio-communication outcomes. Our results add to growing evidence that bilingualism does not hinder majority-language development in ASD.

50 **235.050** Narrative Abilities in Bilingual and Monolingual Children with ASD

ABSTRACT WITHDRAWN

Background: Narrative skills are the product of the interaction of our cognitive, linguistic, and social-cultural knowledge (Losh & Capps, 2003). They allow us to examine how the mind makes sense of the self and the world, and therefore, research has been dedicated to studying narrative abilities in children with atypical cognitive development, especially children with autism (e.g., Diehl et al., 2006). Children with autism have been shown to have difficulty in organizing a coherent story and in explaining the mental states of characters (e.g., Losh & Capps, 2003). Moreover, given that narrative practices are culturally grounded, researchers are also interested in probing the effect of linguistic input and cultural context on narrative development (Heath, 1983; Wang & Leichtman, 2000). As narrative skills have been identified as strong predictors of later language and literary achievement for monolingual children (Paul & Smith, 1993), researchers have also been studying narrative development in a bilingual context (e.g., Uchikoshi, 2000). However, there has been virtually no research done on narrative abilities in bilingual children with autism.
Objectives: This study compared the narrative abilities between three groups of children-- typically developing Mandarin-English bilingual children, Mandarin-English bilingual children with autism, and English monolingual children with autism. The main objectives are: (1) to fill in the gap in current knowledge on narrative competence in bilingual children with autism, and (2) to study potential benefits or problems bilingualism can exert on the communicative competence of children with autism.

Methods: Nine typically developing bilingual children, 10 high-functioning bilingual children with autism, and 13 high-functioning English monolingual children with autism who are verbal participated in the study. The participants with autism were matched on mental age, and vocabulary size. Narratives were elicited using the wordless picture book, *Frog, Where Are You?* (Mayer, 1969), and the bilingual children were asked to generate a story in both languages. The narratives were analyzed according to their global structure, local linguistic structure, and the child's ability to provide evaluative comments.

Results: Comparisons between the monolingual children with autism and bilingual children with autism revealed no group differences. Comparisons between the two bilingual groups on the global structure revealed that bilingual children with autism included fewer story episodes and fewer types of orientations. However, both groups were able to grasp the theme of the story. With regards to the local structure, bilingual children with autism told stories of similar length, but employed less complex syntax and fewer types of conjunction, and also made more reference errors than their typically developing peers. Finally, the two groups did not differ significantly on the evaluative aspects of narratives.

Conclusions: This study was one of the first ones to investigate narrative abilities in bilingual children with autism. Results of this study demonstrated that bilingual children with autism did find certain aspects of narrative challenging, but their performance was comparable to that of monolingual children with autism, suggesting that bilingualism does not further impede language development in this population and that

verbal children with autism have the capacity to be bilingual.

51 **235.051** Language and Narrative Skills of School-Age Bilingual Children with Autism Spectrum Disorders

ABSTRACT WITHDRAWN

Background: Parents of bilingual children with Autism Spectrum Disorders (ASD) are often advised to communicate with their children using only one language (Hudry et al., 2017). Yet, the available evidence, largely from pre-school and kindergarten-age children, suggests that bilingualism does not hinder early language development in ASD (Hambly and Fombonne 2012; Kay-Raining Bird et al., 2016). Less is known about bilingual development in ASD at later ages, when language abilities become more complex and are used in academic settings. This knowledge is essential to inform childrearing and educational decisions for the growing number of families with a child with ASD living in bilingual contexts.
Objectives: The aim of the current set of studies was to compare the language skills of bilingual and monolingual school-age children with ASD without intellectual disability, using both standardized tests and a picture sequencing narrative task.

Methods: Participants were 6 to 10 year old speakers of French, English, Spanish or two of these languages. Results reported here are for their dominant language, which was always French or English, both majority languages in Montreal, Quebec. In study 1 we investigated the vocabulary and morphological skills of monolinguals (n = 14) and bilinguals (n = 13) with ASD using standardized tests. In Study 2 we analyzed the short narratives of four groups of French-speaking participants: bilingual children with and without ASD (n = 10), and monolingual children with and without ASD (n = 10). Children were given a set of three pictures depicting a scenario. They were asked to place the pictures in sequence and tell a story about it. The macrostructure (e.g., story's coherence) and microstructure (e.g., use of connectives) of the stories was assessed. In both studies groups were matched on chronological age, nonverbal IQ, symptom severity and maternal education.

Results: Study 1: both groups of children with ASD performed within the average range on the vocabulary test, but the monolinguals outperformed bilinguals. There was not a significant difference between groups on the morphology test, although there was a trend for monolinguals to perform better than bilinguals. Study 2: A main effect of diagnostic group was observed for narrative macrostructure, where typically-developing children performed better with respect to providing coherent narratives. There was no main effect of bilingualism. No significant differences were found in microstructure.

Conclusions: Similar results to those reported for typical development were found for vocabulary and morphological skills, where amount of language exposure plays an important role on language performance, and monolinguals outperform bilinguals when one language is assessed (e.g., Bialystok et al., 2010). Strikingly, however, functional language use during a brief narrative task was similar between groups, suggesting that the differences observed in Study 1 may not have a significant functional impact. For instance, children in all groups used correct grammatical gender, and connectives in their stories. These results provide new insights into the language skills of bilingual children with ASD, and are globally in line with prior work suggesting that bilingualism does not have a negative impact on language development.

52 **235.052** The Effect of Bilingualism and Verbal-Memory on Syntactic Abilities of Children with High Functioning Autism

R. Novogrodsky[1] *and N. Meir*[2]*, (1)University of Haifa, Haifa, Israel, (2)Department of English Literature and Linguistics, Bar-Ilan University, Ramat Gan, Israel*

Background: Little is known about the influence of bilingualism and verbal memory on syntactic abilities of children with High Functioning Autism (HFA). Previous studies exploring syntactic abilities of monolingual children with HFA show large variability (e.g., Roberts, Rice, & Tager–Flusberg 2004). Some monolingual children with HFA have intact morphosyntactic abilities (Kjelgaard & Tager-Flusberg 2001, Novogrodsky 2013), while others show impaired syntax (e.g., Durrleman, Marinis & Franck 2016). Similar picture is shown for verbal memory. Some studies report lower verbal memory in children with ASD as compared to peers with Typical Language Development (TLD), others do not confirm this gap (Durrleman et al. 2017; Schaeffer, 2018). Moreover, it is not clear whether syntactic abilities of children with HFA are linked to deficiencies in verbal memory.
Objectives: The current study assessed separate and combined effects of bilingualism and HFA on verbal memory and syntactic abilities of children. Additionally, it explored to what extent syntactic abilities are associated with the capacity of verbal memory in children with HFA and TLD.

Methods: Eighty-seven monolingual Hebrew-speaking and bilingual Russian-Hebrew-speaking children aged 4;6-9;2 participated in the study: 29 children with HFA (17 monolingual and 14 bilingual) and 58 children with TLD (28 monolingual and 30 bilingual). The groups were matched for age and non-verbal IQ. Syntactic abilities were assessed using LITMUS Sentence Repetition tasks-30 (bilingual children were tested in each of their two languages) based on Armon-Lotem and Meir (2016). In both languages, the test includes 30 sentences that represent simple structures (e.g. SVO sentences with obligatory and optional prepositions) and complex structures (e.g. biclausal sentences with coordination and subordination, object *wh*-questions, relative clause sentences and conditionals). Structures that are specific to one language were included (e.g., subject relatives for Russian; oblique *wh*-questions for Hebrew). Verbal memory was evaluated based on Forward Digit Span for verbal short-term-memory and Backward Digit Span for verbal working memory.

Results: As a group, children with HFA had lower scores compared to their TLD peers on measures of syntactic abilities and verbal memory. However, some monolingual and bilingual children with HFA showed intact syntactic abilities, while others scored at risk for Language Impairment. The syntactic errors of the children at risk for Language Impairment were like those of children with Developmental Language Disorder. Importantly, syntactic abilities in children with HFA were not associated with their verbal memory skills. Furthermore, no differences in verbal memory were found between children with HFA who were at risk of Language Impairment and children with no risk. Our findings showed that bilingualism similarly affected syntactic abilities of children with TLD and HFA, demonstrating that bilingualism is not an impeding factor for language and cognitive development of children with HFA.

Conclusions: To conclude, our study demonstrates that (1) regardless of languages status (bilingual versus monolingual), children with HFA at risk for Language Impairment exhibit impaired syntax similarly to those reported in the literature for children with Developmental Language Disorder, and (2) syntactic difficulties in children with HFA are not attributed to deficient verbal memory.

53 **235.053** Pronoun Use in Monolingual and Bilingual Children with ASD

R. Novogrodsky[1] *and N. Meir*[2]*, (1)University of Haifa, Haifa, Israel, (2)Department of English Literature and Linguistics, Bar-Ilan University, Ramat*

Gan, Israel

Background:
Monolingual children with Autism Spectrum Disorder (ASD) show deficits in linguistic abilities that involve perspective-taking and pragmatic judgments[1]. For example, monolingual children with ASD have notorious problems with pronoun use[2]. In children with typical language development (TLD), pronoun use is related to syntactic knowledge, discourse-pragmatic knowledge, Theory of Mind (ToM) skills and Executive Functioning [3]. Little is known about the interface of ASD and bilingualism. Many parents of bilingual children with ASD are fearful of speaking their native language to their children, because they worried that dual-language exposure would confuse the children or exacerbate their impairments[4]. Moreover, parents receive advice from professionals to refrain from an additional language and to maintain a monolingual environment for children with ASD[5].

Objectives:

In the current study, we assessed pronoun production in monolingual and bilingual children with and without ASD and explored the relationship between pronoun use and children's ToM skills, Executive Functioning and complex syntax.

Methods:

Forty-five monolingual Hebrew-speaking children (28(18f/10m) with TLD and 17 (1f/16m) with ASD and 44 bilingual Russian-Hebrew-speaking children (30 (16f/14m) with TLD and 14 with ASD (3f/11m)) aged 4;6-9;2 participated. Bilingual children with and without ASD were raised in Russian-speaking families in Israel and spoke Russian as their Heritage Language and Hebrew as their Societal Language. Children with ASD received their diagnoses by a multidisciplinary team of specialists prior to the study, and it was verified using the Autism Diagnostic Observation Schedule (ADOS[6]) as part of the study assessment battery. All children scored within the norm on non-verbal IQ[7].

The pronoun elicitation task elicited third person pronouns in subject and object positions in Hebrew. In addition, we measured children's ToM skills; Executive Functioning (Inhibition and Verbal Working Memory), and complex syntax.

Results:

The results indicated an effect of Clinical Group, no effect of Language Status and no interaction between the two variables. The use of pronouns was lower in children with ASD as compare to their TLD peers. Children with ASD omitted pronouns more frequently in obligatory positions and/or produced more noun phrases instead of pronouns as compared to children with TLD. Importantly, bilingual children showed similar performance to their monolingual peers.

In the ASD group, pronoun use was associated with ToM skills and complex syntax, while no associations were detected between pronoun use and Executive Functioning measures. A further step-wise regression analysis showed that 39% of the variance of the pronouns use in children with ASD is explained by complex syntax, and 10% of the variance is explained by ToM skills.

Conclusions:

To conclude, the findings show that pronoun use is impaired in children with ASD, yet bilingualism is NOT an aggravating factor for children with ASD, which is reflected in the similar performance of bilingual and monolingual children with ASD. The core deficit of pronoun use in children with ASD is associated with their complex syntax and ToM difficulties.

54 **235.054** Access to Multiple Speaker Contexts Predicts Pronoun Acquisition and Use in ASD

***A. Fitch**[1], S. Arunachalam[2,3] and R. J. Luyster[4], (1)University of Connecticut, Somerville, MA, (2)Boston University, Boston, MA, (3)Communicative Sciences and Disorders, New York University, New York, NY, (4)Communication Sciences and Disorders, Emerson College, Boston, MA*

Background:
Children with ASD often display atypical patterns of pronoun development, including increased prevalence of pronoun reversals and avoidance relative to typically-developing peers[e.g.1]. Pronouns are difficult to acquire, in part, because of their shifting referents—*I* refers to myself only if I am the speaker. Contexts in which there are multiple speakers may thus be ideal for learning the meanings of personal pronouns: shifting referents for singulars (e.g. I, you) are more likely to be visible and easier to map[2,3]. Additionally, multiple speaker contexts are likely to provide more exposure to plural pronouns (e.g. we, us).

Objectives:

The goal of the study was to determine what role, if any, access to multiple speaker contexts play in the acquisition and proper use of personal pronouns in children with ASD.

Methods:

Participants were 119 caregivers of children with ASD (2;2 – 5;11, 102 male) who completed a survey about their child's language acquisition. Caregivers reported their child's language level (one word, phrase speech, or sentence level), pronoun use, and household environment. Pronoun questions asked about the age at which children acquired 21 personal pronouns and how well they use them now (correctly, errorful, or not at all). Household environment questions included the percentage of time they spent in the presence of two or more people, which we used as a proxy for time spent in multiple speaker contexts.

Results:

Acquisition

Principle component analysis was conducted on the age of acquisition (AoA) of all pronouns. Results yielded three components with eigenvalues >1 (75.6% of the variance explained). Components are best described as: singular first- and second-person pronouns (e.g. I, you), singular third-person pronouns (e.g. she, him), and plural pronouns (e.g. us, them). To determine the role of multiple speaker contexts on AoA, we conducted a series of linear regressions predicting component scores from multiple speaker context time and language level (see Table 1). Findings demonstrated that language level positively predicted scores on all three components (first/second: p <.001, third: p <.001, plural: p =.003). Multiple speaker contexts additionally predicted unique variance for plural pronouns (p = .018), but not first/second (p = .8) or third (p = .48).

Use

Point-biserial correlations were conducted to determine if access to multiple speaker contexts was related to current use (correct or errorful; those who had not yet acquired that pronoun were excluded from analysis). Access to multiple speaker contexts was positively related to the

correct use of first- and second- person pronouns: me (r = .343, p = .001), my (r = .222, p = .032), you (r = .244, p = .018), your (r = .227, p = .013), yours (r = .252, p = .006).

Conclusions:

Findings demonstrated that multiple speaker contexts play a positive role in the acquisition of personal pronouns for children with ASD. Specifically, multiple speaker contexts were related to the AoA of plural pronouns, and the correct use of first- and second- person pronouns. This finding has implications for pronoun-related interventions, as well as for theories of pronoun development more broadly.

55 **235.055** Refining the Scope of Language Impairment in Individuals with ASD through the Assessment of Complex Sentences

M. Stegenwallner-Schütz[1], *S. Kirst*[2], *I. Dziobek*[2] *and F. Adani*[1], *(1)University of Potsdam, Potsdam, Germany, (2)Berlin School of Mind and Brain, Humboldt-Universitaet zu Berlin, Berlin, Germany*

Background: Language is developing atypically in all individuals with ASD, although there is considerable variation in exactly which aspects of language are affected and whether this results in a Language Impairment(LI, Kjelgaard & Tager-Flusberg, 2001). Recent cross-linguistic experimental work has shown that an atypical development of complex sentence comprehension emerges in individuals with ASD (Durrleman et al., 2016; Prévost et al., 2017; Riches et al., 2011), which is often related to a history of (potentially undetected) LI (Modyanova et al., 2017). Object-initial sentences, i.e., sentences that alter the subject-verb-object default word order of German, can be disambiguated by morphological (i.e., case and/or number) marking. Case-marking on nouns was shown to enhance the processing of object-initial sentences in neurotypical children before number does, but the co-occurrence of both case and number supports processing abilities in children with LI (Stegenwallner-Schütz & Adani, 2018).

Objectives: We provide a fine-grained assessment of complex sentence processing abilities in individuals with ASD and an exploration of which morphological properties may alleviate their expected processing difficulties. Towards this end, we manipulated number- and case-marking on two types of object-initial sentences in German: Object-Verb-Subject (OVS, e.g., *The dog kicks the zebra* [English translation], in which *zebra* is interpreted as the agent of the action expressed by the verb *kick*) and Object-Relative Clauses (ORC, e.g., *Where is the dog that the zebra is kicking* [English translation; notice that number- and case-marking are not reported in the English translation]).

Methods: German-speaking individuals with ASD (N=26 [2 girls]; mean age: 11;10 [y;m]; age range: 6;10-15;3) and their neurotypical age-matched controls participated in a picture-selection task (OVS-study) and in a referent identification task (ORC-study). Test and filler sentences were presented auditorily and the participant had to select the target picture/referent. Based on a detailed battery of psycholinguistic standardized tests tapping into expressive/receptive vocabulary, morphology and syntax, we identified a subgroup of individuals with ASD with co-occurring LI.

Results: The accuracy results reveal an impaired comprehension of OVS sentences (proportion correct: 0.63, SE: 0.04) and of ORC (proportion correct: 0.25, SE: 0.05) by individuals with ASD with co-occurring LI, compared to neurotypical controls. While case-marking enhanced the accuracy of ORC (both in the ASD and the neurotypical groups), number-marking revealed a facilitative effect neither on OVS nor ORC in the ASD group. The performance by the group of individuals with ASD without LI and the neurotypical controls did not differ on any of the comparisons. The reported effects are significant at the statistical significance level of $p<0.05$.

Conclusions: OVS and ORC sentences are complex linguistic structures, whose correct comprehension appears to be vulnerable in individuals with ASD, particularly when this condition co-occurs with LI. The apparent lack of deployment of number-marking during OVS processing also qualifies as a risk factor, which is not attested in neurotypical development. In contrast, the sensitivity to case can be identified as one of their strengths. Our results highlight the effectiveness of psycholinguistic investigations in the identification of risk and protective factors during language development in ASD.

56 **235.056** Cross-Modal Coordination of Face-Directed Gaze and Emotional Speech Production in Adolescents with ASD

T. Sorensen[1], *E. Zane*[2], *T. Feng*[3], *S. Narayanan*[3] *and R. Grossman*[4], *(1)University of Southern California, Los Angeles, NE, (2)FACE Lab, Emerson College, FACE Lab, Boston, MA, (3)University of Southern California, Los Angeles, CA, (4)CSD, Emerson College, Boston, MA*

Background: The facial and vocal expressions of individuals with autism are often perceived as awkward (Grossman 2015, Faso et al. 2015, Sasson et al. 2017), which may be caused by atypical timing and synchrony of movements across face regions (Guha et al. 2016, Metallinou et al. 2013). Additionally, there are a range of findings for eyegaze to the face in ASD (Papagiannopoulou et al. 2014, Falck-Ytter & von Hofsten 2011). Despite an increased interest in cross-modal integration in ASD, there are no investigations to date into the relationship between speech production and emotional facial movements, nor whether face-directed gaze relates to facial-expression quality in ASD.

Objectives: In an emotional speech mimicry task, we predict that adolescents with ASD will make primarily lower-face movements to support speech production, but not make concurrent upper-face movements to express emotion. We also expect that adolescents who spend more time gazing at the face of a video model will produce more upper-face movements for emotional expressions.

Methods: Participants watched and mimicked videos of adolescents producing two-sentence combinations (a neutral sentence followed by an emotional one). We recorded acoustic measures of verbal speech (intensity, F0, etc.), facial motion capture (32 markers across the face), and eye-tracking data (dwell time to face) from 13 adolescents with ASD and 19 neurotypical (NT) adolescents. We used Granger causality to measure the strength of coordination between facial movements and acoustic measures: strong Granger causality indicates rigid speech-face dependence with few effective degrees of freedom, whereas weak Granger causality indicates independent control of the face and voice. We obtained Autism Quotient (AQ) scores as a continuous measure of autism features and used linear mixed effects models to analyze the relationship between AQ and (1) Granger causality between speech-face patterns and (2) face-directed gaze.

Results: Participants with more autistic features (i.e. high AQ scores) have greater cross-modal dependence than low-AQ adolescents ($\chi^2(7)=1541.9$, $p<0.05$). A linear mixed effects model with random slopes for AQ by motion capture marker demonstrates the effect of AQ is stronger for the lower face (lower cheek, mouth, chin) than for the upper face (eyes, eyebrows, forehead) ($U=595$, $p<0.05$).

AQ scores also interact with face-directed gaze. Specifically, the slope for net dwell time on any part of the face is steeper for children with high AQ (linear mixed effects model; all $p<0.05$): Heightened visual attention to the face results in greater speech-face dependence in high-AQ participants, but less dependence in low-AQ participants.

Conclusions: High-AQ adolescents have greater cross-modal dependence, suggesting they move all facial regions primarily for speech production

but not for additional emotional expressivity in an emotional-speech mimicry task. In contrast, low-AQ participants produce more facial feature movements not directly related to speech, particularly in the upper face (e.g. eyebrow raises), which can transmit emotional expressivity without being tied to the rhythm of lower-face speech movements. Contrary to our prediction, the difference between high- and low-AQ participants is *amplified* by greater visual attention to an emotional face.

57 **235.057** A Comparative Study of Verbal Autistic Children on Language Skills Using the CCC-2 - Brazilian Version

E. Furtado[1] *and F. R. Bó*[2]*, (1)University of Sao Paulo, Ribeirao Preto, Brazil, (2)Centro Integrado de Reabilitação, Hospital Estadual de Ribeirão Preto, Ribeirão Preto, Brazil*

Background: Social communication problems is a core group of symptoms for the diagnostic definition of autism spectrum disorders (ASD). In low or middle developed regions of the world, frequently it is difficult to find speech therapists and other speech specialists with adequate clinical experience in ASD, in order to provide screening or assessment of language problems or even for identify ASD children correctly. Consequently, caregivers self administered questionnaires or inventories for language symptoms could be an useful and practical way to perform screening for ASD in verbal competent children.

Objectives: To investigate comparatively the performance of CCC-2 on verbal ASD children in the subscales and global assessment for social communication problems and its potential for application as screening instrument for ASD

Methods: The study design was an observational, cross sectional, comparative case-control study design with two groups. The case group (N=20) was composed by verbal ASD children from four to sixteen years of age. The control group (N=20) was composed by typically developed children of the same age profile and sex distribution and free of behavioral or language problems. ASD children and their caregivers were recruited from the Child Psychiatry Outpatient Clinic of the University Hospital at the School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil. We use the Brazilian version of CCC-2 (*Children's Communicative Checklist – second edition),* originally developed by Bishop (1998) and translated from english to Brazilian portuguese by Costa and colleagues (2013). The diagnosis of ASD was performed according to the current DSM-5 (American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders – Fifth edition) criteria by a team of trained child psychiatrists, according to the standardized clinical protocol of the Child Psychiatric Outpatient Clinic.

Results: No statistically significant difference was found regarding socioeconomic variables as well regarding educational level of parents. The GCC (General Communication Composite) Standard score of the ASD group reached a lower mean value (M = 82.35; SD = 13.34) in comparison with the control group (M = 105.1; SD = 7.98). The difference of means was statistically significant (F = 42.83; p < 0.001). The ROC analysis identified a cutoff point for the GCC score of ≤ 95 with 85% sensitivity and 90% specificity (AUC = 0.936; p < 0.001). When using the GCC Percentile Rank, we found a mean score for the ASD group of 19.30 (SD = 19.63) and of 62.05 (SD = 18.50) for the control group. The difference of the mean GCC Percentile Ranks between the two groups was statistically significant (F = 50.25; p < 0.001). The ROC analysis for the GCC Percentile Rank identified a cutoff point at percentile ≤ 37, with 85% sensitivity and 90% specificity (AUC = 0.936; p < 0.001).

Conclusions: The results demonstrate a good discriminating performance of the CCC-2 Brazilian version for the screening and high suspicion for the identification of verbal ASD children.

58 **235.058** A New Approach for Assessing Social Communication in ASD: Elsa

M. Barokova[1] *and H. Tager-Flusberg*[2]*, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Psychological and Brain Sciences, Boston University, Boston, MA*

Background: Natural language samples can be a useful tool in the assessment of expressive language in ASD (Barokova & Tager-Flusberg, 2018; Tager-Flusberg et al., 2009). Expressive language is also central to social communication, which makes language sampling a great candidate for the evaluation of deficits in this domain – part of the core defining features of ASD. Yet, no study has examined the feasibility of using sample-derived measures in place of or as a complement to standardized assessments of communicative skills in ASD. Furthermore, sample-derived measures have been proposed to be good candidates for valid and reliable clinical outcome measures (Abbeduto, 2017; Barokova & Tager-Flusberg, 2018)

Objectives: We aimed to validate the utility of the *Eliciting Language Samples for Analysis* (ELSA) protocol for individuals with ASD as a tool for assessing social communication. We focused on the associations between ELSA-derived expressive language measures and scores on standardized assessments of communication and socialization – Vineland and SCQ.

Methods: We collected ELSA samples from 40 participants with ASD across a wide range of age, language ability, and symptom severity (Table-1). ELSAs consisted of activities with developmentally appropriate toys, eating a snack, watching a short movie, and a conversation about participants' interests (Barokova et al., 2017). All samples were coded by naïve coders in real-time using ELAN (Sloetjes & Wittenburg, 2008). Frequency of speech utterances and number of conversational turns per minute were extracted from the coded files. Participants' ASD diagnosis was confirmed with the administration of the ADOS. Vineland and SCQ questionnaires were collected from participants' parents.

Results: Frequency of utterances and number of conversational turns per minute were significantly correlated with the Vineland Communication Standard Score (for frequency: r_s **(38) = .592, *p* < .001, Figure-1;** and for turns: r_s **(38) = .595, *p* < .001**) and with the Vineland Standard Socialization Score (r_s **(38) = .514, *p* = .001** and r_s**(38) = .503, *p* = .001**). Frequency and conversational turns were strongly correlated with the SCQ Communication Subscore (r_s **(33) = .665, *p* < .001**, and r_s **(33) = .666, *p* < .001**) and moderately correlated with the SCQ Reciprocal Social Interaction Subscore, as well (r_s **(33) = .422, *p* = .011**, and r_s **(33) = .404, *p* = .016**).

Conclusions: The ELSA-derived expressive language measures were positively correlated with gold-standard measures of social communication, which provides preliminary support for the use of language sampling as an alternative method of assessment in this domain. These findings have laid the foundation for research focusing on the use of language sampling as a measure of autism symptoms that go beyond expressive language ability alone. Future work should examine the convergent and divergent validity of the frequency of utterances and conversational turn measures, as well as identify expressive language proxies for restricted interests (e.g., number of topics discussed) and repetitive behaviors (e.g., amount of verbal imitation).

59 **235.059** A Speech Generating Device Intervention with Peer Partners: Effects on Functional Communication of Preschoolers with

Autism

K. Bourque[1] *and H. Goldstein*[2]*, (1)Juniper Gardens Children's Project, Kansas City, KS, (2)Communication Sciences and Disorders, University of South Florida, Tampa, FL*

Background: Communication is the most targeted outcome of AAC interventions, with positive outcomes reported in studies that incorporate speech-generating devices for individuals with ASD. There is a lack of studies reporting interventions to improve communication with peers without disabilities. Our recent studies fill this void by reporting positive outcomes of integrating peer-mediated and SGD approaches on communication of preschoolers with ASD (Thiemann-Bourque et al., 2017; 2018).
Objectives:

To describe instructional peer training and SGD strategies documented to increase communication between children with ASD and peers, including generalization and maintenance of gains.

Methods: Effects were examined using a multiple-baseline design across six dyads (i.e., one child with ASD; one peer). We taught peers to be responsive partners using *Stay-Play-Talk with SGD* strategies (Thiemann-Bourque et al., 2017). To decrease time in baseline, the six dyads were split into three groups. Following a stable rate and no upward trend in communication measures, peers in the first group started treatment while baseline continued for the other two pairs. Peer training (PT) was conducted for 90 min, then the peers joined their buddy with ASD in 15-min classroom activities. The next pair then entered PT and began the weekly sessions; this was repeated until all peers were trained. Data was collected 2-3 times/week across baseline (range 4-10), treatment (range 20-31), generalization (6), and follow up (3) phases. Dependent measures included rates of child and peer communication acts, means (gestures, SGD, speech, and speech+SGD), and functions (request objects, request actions, comments, and request attention). Social validity was assessed by naïve judge's ratings of pre- and post-treatment video clips.

Results: Positive intervention effects for the children with ASD and peers were noted, and replicated across all six dyads. Across all dyads, children with ASD improved from a baseline average of 2 acts to 22 in treatment; peers improved from an average of 4 acts to 25 in treatment. Both partners generalized improvements (16 acts for focus; 16 acts for peers) and were able to maintain progress post-treatment (23 acts for focus; 25 acts for peers). Calculation of Tau-U revealed large effect sizes, with a combined Tau-U of .99 for the focus children and .94 for the peers. Treatment fidelity was 89% (average) for school staff and 83% for peers. Three children began to use different means including greater speech and speech+SGD; and three children used more gestures and SGD. Greatest changes were observed in functions to requests objects, followed by comments, then requests for actions with minimal changes in requesting attention. Social validity outcomes were positive, showing improved social ratings for children with ASD and peers.

Conclusions: Communication rates improved markedly for both partners, and the children with ASD used varied means following treatment with half beginning to use more speech. Future research is needed to examine strategies to increase other communicative means and functions that will maximize social success of minimally verbal children with ASD in inclusive environments.

60 **235.060** Abnormal Cry in Toddlers with Autism Spectrum Disorder: A Comparative Analysis of Acoustic Features of Cry in Clinical and Non-Clinical Populations.

V. E. Sanchez[1]*, M. Shukla*[2] *and A. S. Carter*[3]*, (1)Division of Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Psychology, University of Massachusetts Boston, Boston, MA, (3)University of Massachusetts Boston, Boston, MA*

Background: Preverbal vocalizations, e.g. crying and babbling, have been found to reflect characteristics of a child's target language, especially with regard to a language's prosodic (melodic) patterns (Boysson-Bardies et al. 1984; Mampe et al. 2009). Differences in prosody are one of the most common clinical features and among the earliest characteristics of Autism Spectrum Disorder (ASD) to be identified (Kanner, 1943; Dieh & Paul 2012). However, few studies have examined prosodic differences in vocalizations of toddlers with and without ASD (Sheinkopf et al., 2012; Venuti et al., 2012).
Objectives: This study was designed to investigate whether the cries of toddlers with ASD differ from the cries of their typically developing peers across four acoustic features of prosodic contours (duration, fundamental frequency (f_0), standard deviation of fundamental frequency, and peak frequency). It was hypothesized that the acoustic correlates of cry melodies of toddlers diagnosed with ASD would differ significantly from those of toddlers with typical development (TD) with the same native language.

Methods: As part of a larger study, seven toddlers with ASD (M_{age}=24.4 mo, SD=3.5) from monolingual English-speaking households were administered the ADOS-2 (Mod T) by research-reliable assessors, and the sessions were recorded and coded for crying. Previously published audio data for the TD group (n=13, M_{age}= 31 mo (SD=6)) were collected at home during tantrums with a LENA device (Green et al., 2012). Each cry was analyzed for four acoustic features (ASD, n=506 samples; TD, n=250); duration, fundamental frequency (f_0), standard deviation of fundamental frequency (SD f_0), and peak frequency.

Results: Independent sample T-Tests indicated that each of the four basic acoustic measures of cries were significantly different between groups (Table 1). Average duration was found to be shorter in the ASD group ($p=0.003$). Mean F_0 ($p<0.0001$) and SD f_0 ($p=0.01$) were found to be higher in the ASD group. Mean peak frequency was found to be lower for the ASD group ($p<0.0001$).

Conclusions: Each of the acoustic measures differed between the cries of children with ASD and the cries of children with TD in meaningful, predictable ways (Sheinkopf et al., 2012). Cries of children with ASD showed a higher mean fundamental, but also a lower peak frequency, meaning that the cries were higher in pitch overall, but were showed less modulation, which describes a flatter, less prosodically diverse cry. Higher average SD f_0 was found in the ASD group, indicating that the cries were more variable, thereby suggesting less structure. Overall, these results suggest that the ASD group did not follow the basic prosodic pattern of their native language, which can be analyzed by constructing and comparing average melody contours of cries from each group. Planned analyses include construction and comparison of average melody contours of cries from each group, which would graphically describe differences in the melodic structures of the cries.

61 **235.061** Acoustic-Perceptual and Quantitative Analysis of Grammatical Prosody in Adolescents with Autism

C. E. Gargan *and M. V. Andrianopoulos, Department of Communication Disorders, University of Massachusetts, Amherst, MA*

Background: Published empirical research is contradictory regarding the specific characteristics of atypical prosody among individuals with Autism Spectrum Disorder (ASD). It has been suggested that individuals with ASD have atypical pragmatic and affective prosodic abilities while grammatical prosodic abilities are relatively spared (Shriberg et al., 2001). However, there is some preliminary evidence that individuals with autism exhibit acoustic or perceptual differences in grammatical prosody (e.g., Grossman et al., 2010). Research is sparse regarding the specific features of grammatical prosodic abilities among individuals with ASD. It is important to reliably and validly identify and quantify grammatical prosodic features that contribute to the perception of "unnatural" speech of some individuals with ASD.
Objectives: This research addressed the following questions: 1) Do individuals with ASD perform significantly different on perceptual and acoustic measurements of expressive lexical stress and phrase stress tasks as compared to a TD comparison group?; 2) Do individuals with ASD perform significantly different on receptive lexical stress and phrase stress tasks as compared to TD controls?; 3) Do trained listeners who are blind to stimulus item and diagnostic category judge individuals with ASD as sounding more "unnatural" than their TD counterparts using a novel acoustic-perceptual rating scale to assess lexical and phrase stress?

Methods: A between-group study was conducted to investigate grammatical prosodic abilities among individuals with ASD (n=11; ages 13;11 to 19;11 years) in comparison to typically developing (TD) controls (n=11) matched for age, gender, and receptive language. Each group consisted of 7 males (63%) and 4 females (36%). Participants with ASD and their TD counterparts were monolingual English speakers. Four tasks from the Profiling Elements of Prosody in Speech-Communication 2015 (PEPS-C 2015) were administered to assess: 1) the perception and production of lexical stress in two-syllable words; and 2) the perception and production of a noun phrase versus a compound noun within short sentences. Receptive tasks required the participant to select a picture that corresponded with the utterance they heard from a recorded standardized test battery. Expressive tasks were rated by trained listeners using a set of predefined perceptual and acoustic measurements.

Results: The group of individuals with ASD performed significantly less accurate on the expressive Lexical Stress (p= .021) and Phrase Stress (p= .0001) subtests (PEPS-C-2015). Acoustic findings revealed significantly longer duration of utterances (p< .05) among the group with ASD. The individuals with ASD performed significantly less accurate on the receptive Lexical Stress (p= .001;) and Phrase Stress (p= .009) subtests on the PEPS-C (2015). Large effect sizes were evidenced (*Cohen's d* >1). Individuals with ASD were significantly more likely to be rated as sounding "unnatural" or "atypical" as compared to TD controls.

Conclusions: The outcomes of this investigation show that there are specific differences in the production of lexical stress and phrase stress that contribute to the perception of unnatural or atypical prosody among some individuals with ASD. Atypical prosody may contribute to communication and social impairments. The impact of language on prosody, its clinical implications, and directions for future research are enumerated.

62 **235.062** An Application of Generalizability Theory to Characterize Language Learning Interactions for Young Children with Autism in Their Inclusive Classroom

A. B. Ford *and L. D. Johnson, Educational Psychology, University of Minnesota, Minneapolis, MN*

Background:
For children with autism spectrum disorder (ASD), features of the disorder can impact the nature, frequency, and length of adult-child interactions important for language learning (Carpenter & Tomasello, 2000; Landa, 2007; Wetherby et al., 2004). Given the important role that interactions play in language learning for young children, it is important to examine the means by which inferences may be made about children's language learning environments. In other words, inferences about the nature, frequency, and length of interactions that produce clinical effects are based on researchers' systematic observation and sampling of certain behaviors for certain periods of time within certain settings (Irvin, Boyd, & Odom, 2015; Irvin, Hume, Boyd, McBee, & Odom, 2013; Sanders et al., 2016; Yoder, Lloyd, & Symons, 2018). The sampling approach relative to different facets of measurement (e.g., observers, occasions, contexts) contribute variability that may have a significant, yet often overlooked, impact on the inferences that may be made by researchers when interpreting their results (Webb, Shavelson, & Haertel, 2006).

Objectives:

Guided by generalizability theory (g-theory; Cronbach, Rajaratnam, & Gleser, 1963; Shavelson & Webb, 2006), the study objectives are to (a) describe methods for characterizing language learning environments of young children with ASD based on relevant measurement facets and (b) provide empirical guidance for conditions of measurement that should guide future investigations to optimize both the reliability of inferences and efficiency of data collection.

Methods:

Using systematic observation methods, video recordings of interactions between 10 children, ages 3- to 5-years-old with ASD, and adults in their inclusive preschool classrooms during exploratory play are being examined. Consistent with g-theory, two measurement facets were identified: occasions and observers. As such, 15-minute recordings for each participant are being gathered across four occasions within a three-week timespan. After ensuring 90% agreement across observers, each observer is coding each video for frequency and type of adult language behaviors (i.e.., open-ended questions, yes/no questions, choice questions, completion prompts, imitations, comments) and child communicative acts. The generalizability study is utilizing a *person x occasion x observer* random effects Analysis of Variance (ANOVA) model. A decision study will follow with levels of occasions and observers manipulated to determine the optimal conditions of measurement that lead to stable estimates of observed frequencies and types of adult behaviors and child communicative acts.

Results:

With the investigation underway, the researchers will present results of the generalizability study, displaying estimates of magnitude with which (a) variability in the person, (b) variability in the facets (i.e., occasions and observers), and (c) variability of the interaction of the person with the facets contribute to the observed measures of adult and child behaviors. Likewise, the researchers will present the results of the decision study, such that the impact of various levels of facets on error variance can be seen.

Conclusions:

The researchers will provide guidance on measurement conditions that are most relevant for researchers in interested in sampling language behaviors in inclusive preschool environments and provide recommendations for incorporating g-theory into investigations utilizing systematic observation methods.

63 **235.063** An Automated Measure of Conversational Semantic Coherence

J. R. Adams[1], *A. C. Salem*[2], *H. MacFarlane*[2], *S. Bedrick*[3], *E. Fombonne*[4] *and J. van Santen*[3], *(1)Computer Science, Oregon Health & Science University, Portland, OR, (2)Oregon Health & Science University, Portland, OR, (3)Pediatrics, Oregon Health & Science University, Portland, OR, (4)Psychiatry, Pediatrics & Behavioral Neurosciences, Oregon Health & Science University, Portland, OR*

Background: Complex conversational impairments in people with autism (focus on special interests or topically inappropriate responses) are well identified but their measurement requires time-consuming manual annotation of language samples. Natural Language Processing (NLP), and especially vector-based semantic methods, have shown promise to identify semantic difficulties in ASD on tasks such as semantic fluency and narrative retelling when compared to a clinician-annotated TD reference transcript. Whether or not such tools can establish language-based differences in conversational transcripts without recourse to a reference document remains to be established.
Objectives: Our goal was to develop a novel NLP measure of semantic coherence that could be employed with transcripts of conversational language in children. We hypothesized that semantic coherence, as measured by this method, would discriminate between children with or without ASD, and that more variability would be found in the group with ASD.

Methods: **Participants:** We used data from 70 subjects (38 ASD, 32 TD) age 5 to 8, all males, enrolled in a language study (ERPA). All participants were administered a battery of standardized diagnostic and neuropsychological tests, including the ADOS Module 3, the WPPSI-III, and WISC-IV. **Measures:** ADOS were recorded and subsequently transcribed verbatim using Praat software. The language output of each child during the emotion/conversation section was used in these analyses. **Analyses:** Transcripts were converted to vectors via application of a word2vec model trained on the Google News Corpus. Pairwise similarity across all subjects and a sample grand mean were first calculated. Using a leave-one-out algorithm a pseudo-value representing each subject's contribution to the grand mean was generated, and means of pseudo-values were then compared between the 2 clinical groups. Analyses were co-varied for non-verbal IQ (NVIQ), Mean length of utterance in morphemes (MLUM) and number of distinct word roots (NDR).

Results:

Statistically significant differences in mean of the pseudo-values between TD and ASD groups (Wilcoxon rank sum test, p = 0.007).

- TD subjects typically have a higher pseudo-value score suggesting that similarity scores of TD subjects are more similar to the overall group mean.
- Greater variance in the pseudo-values of the ASD group.
- Analysis of covariance suggests that none of NVIQ, MLUM, or NDR account for the difference between group means.

Conclusions:

The findings suggest that NLP methods can be effectively used to identify specific semantic difficulties that characterize children with ASD. The method is automated and does not require costly and time-consuming annotation by expert clinicians. Our results are preliminary and need to be replicated in larger samples, and older age groups. Likewise, we would need to replicate our findings in language samples collected in more natural ecological settings. Future developments of NLP methods might help to provide fine-grained differentiation of types of semantic divergence in a conversation or locate in a conversation the time and context when divergence from topics occur. Future improvements of NLP methodology may also yield new, cost-effective and sensitive outcome measures applicable to treatment research. Furthermore, more precise documentation of semantic impairments in ASD may inform new intervention strategies in language therapy.

64 **235.064** Are Variations in Narrative Language Reflected in Early Auditory Processing Via ABR?

K. Allen[1], *V. Tecoulesco*[2], *E. Skoe*[3] *and L. R. Naigles*[2], *(1)The University of Connecticut, Storrs, CT, (2)Psychological Sciences, University of Connecticut, Storrs, CT, (3)Speech Language Hearing Sciences, University of Connecticut, Storrs, CT*

Background: Autism Spectrum Disorder (ASD) is a developmental disorder affecting both social interaction and verbal communication (APA, 2013). Children with ASD demonstrate differences or delays in language development compared to typically developing (TD) children (Tek et al., 2013), as well as in aspects of brain development such as auditory brainstem response (ABR, Russo et al., 2008, Pillion et al. 2018). ABR is a measure of early auditory processing characterized by five waveforms occurring in various locations of the brainstem in response to a stimulus onset. Recent research has demonstrated that children with higher ABR stability show enhanced phonological and grammatical performance on experimental tests (Tecoulesco et al., 2018). Children with ASD also demonstrate challenges with narrative language, which seems less coherent and includes fewer causal connectors compared to TD peers (Baixuali et al., 2016). The current study investigates connections between measures of narrative language and concurrent ABR processing.
Objectives: The current study investigates how disturbances in early stages of auditory processing might account for variability in the narrative language of children with ASD, including lexical, discourse, and coherence measures.

Methods: Participants included twelve children with ASD; six have been completely coded. Their average age was 12.33 years (SD=3.01), average Matrices subtest score was 19.50 (SD=8.87), CELF scores were 36.67 (SD=6.31; FS) and 30.67 (SD=5.20; WC), and ADOS scores were 8.17 (SD=4.36). Children were assessed in their home; the narratives came from the ADOS tasks, including Objects, Cartoon, Tuesday storybook. Narratives were transcribed, and coded using CLAN. The Cartoon and Objects narratives were rated by seven naïve adults on story coherence, using a Likert scale (1 (easily followed) to 7 (very difficult to follow)). ABRs were recorded from scalp electrodes with a click stimulus (31.1/sec, 2000 trials) and a 40 millisecond "da" stimulus (10.9/sec, 6000 trials) presented at 80 dB SPL to the right ear. Wave V latency plus click and /da/ response stability (Fisher transformed Pearson's r-values), served as the primary dependent measures of sound encoding.

Results: Correlations performed between the ABR stability measures and language measures (total words, noun types, utterances, conjunctions, discourse markers) revealed consistently negative relationships: children with ASD who produced *more* of each of these measures in their narratives showed *lower* click and /da/ stability (-.981 < *r*s < -.823, *p*s < .01). No significant relationships emerged between the language measures and the ABR latency measures; however, the ratings of narrative coherence correlated marginally significantly and positively with click latency (r = .731, p = .099).

Conclusions: Significant relationships emerged between children with ASD's narrative language and their early auditory processing. The directionality of most of these relationships was surprising, as children who produced more varied words in a number of categories showed less

ABR stability. However, children whose narratives were rated as less coherent tended to have longer ABR latencies. Caution is needed before drawing conclusions because of small sample size as well as a limited number of language measures. Future analyses will include twice as many participants, plus additional grammatical measures from the narratives.

65 **235.065** Assessing Audio-Visual Integration in Speech in Minimally Verbal Young Children with Autism Spectrum Disorder

M. Kissine[1], *J. Bertels*[2], *N. Deconinck*[3], *G. Passeri*[4] *and G. Deliens*[1], *(1)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium, (2)Université libre de Bruxelles, Brussels, Belgium, (3)Paediatric neurology, Hôpital Universitaire des Enfants Reine Fabiola, Brussels, Belgium, (4)Child Psychiatry Service, Hôpital Universitaire des Enfants Reine Fabiola, Brussels, Belgium*

Background: Poor integration of speech sounds with the mouth mouvements likely contributes to language acquisition deficits in young children with autism spectrum disorder (ASD). However, currently existing evidence of multimodal integration deficit in autism is either limited to older high-functioning, verbal individuals or implements preferential gaze paradigms that are used in infant research, but, as we show, are not optimal to investigate pre-scholers.
Objectives: We designed a Reinforced Preferential Gaze paradigm that overcomes biaises in the previous research and allows to test multimodal integration in young, non-verbal children with ASD.

Methods: *Participants:* 31 non- or minimally verbal children with ASD (35–72 months) and 44 TD children (36–72 months)

Video stimuli are limited to the mouth region and consist of a 5 sec recording of 3 identical consonant-vowel syllables, so that three clear articulatory mouvements can be easily mapped on three salient acoustic events, associated with the consonant. In each trial, the *stimulus presentation phase* is followed by a 1 s *transition* blank screen, after which starts a visually attractive 3 s reward animation. see The position of the reward can be anticipated only based on temporal alignment between the video and the audio components of the stimuli: for half of the children in each group (TD or ASD), the reward consistently appeared on the side of the in-synch video (*Synchronous* version) and, for the other half, the reward consistently appeared on the side of the out-of-synch video (*Asynchronous* version). Consequently, anticipative gaze towards the location of the reward during the transition phase is indicative of the capacity of temporally bind the acoustic and the video signals. Each participant was exposed to 30 trials on a screen equipped with a Tobii X2-60 eye-tracker.

Two areas of interest (AOIs) were designed and kept constant across the stimuli and the transition phases: *Reward*, corresponding to the exact zone where the rewarded stimuli was displayed and *Non-reward*, corresponding to the exact zone where the non-rewarded stimuli was displayed. Together, these two AOIs corresponded to 8.86\% of the total area of the screen. A third AOI, *Other,* corresponded to the rest of the screen and was used for the analysis of the transition phase. Every 16 ms, and each AOI, we extracted eye-tracking data indicating whether this AOI was active or not.

Results: Stepwise multilevel regressions, with item-per-trial by item and by-participant random slopes were used to analyse fixation curves in the *stimuli* and *transition* phases. During stimuli presentation, children's gaze is mostly influenced by the periodic and salient mouth mouvement, independently of group or temporal alignment. Both groups demonstrated a clear preference for the Reward AOI during the first half of the transition period in both versions, viz. independently of whether the reward phase primed either the aligned or the misaligned video. Children with ASD exhibited a lower rate of fixations on the Reward AOIs, displaying lower sensitivity to audio-visual alignment.

Conclusions: Relative to traditional preferential gaze paradigms, our method offers a clearer window on young children with ASD's difficulties in audio-visual integration.

66 **235.066** Autistic Polyglots: An Analysis of the Language Experiences, Motivations, and Atypical Learning Profiles of Autistic Multilinguals

K. M. Nolte[1], ***B. G. Digard***[1], *A. Sorace*[2], *A. C. Stanfield*[3] *and S. Fletcher-Watson*[1], *(1)University of Edinburgh, Edinburgh, United Kingdom, (2)Department of Linguistics, University of Edinburgh, Edinburgh, United Kingdom, (3)University of Edinburgh, Edinburgh, United Kingdom of Great Britain and Northern Ireland*

Background: Autistic people can demonstrate skills that surpass neurotypical standards in various domains, including language. Some autistic people have difficulties with the acquisition of language, and display specific impaired linguistic processes such as mutism or pragmatic language impairments. However other autistic people successfully learn and use multiple languages. Specific enhanced linguistic skills such as hyperlexia, or learning skills such as memory and pattern recognition have been reported in autistic people. Still, the patterning of enhanced or impaired skills has not been consistently described, and a theoretical and empirical understanding of the ability of some autistic people to learn multiple languages is lacking. To date, case studies have only described savant autistic polyglots, but group studies of autistic multilinguals are scarce. Furthermore, no study has yet incorporated the accounts of autistic people describing their own experience as multilinguals.
Objectives: This study seeks to describe the factors contributing to the learning of multiple languages in multilingual autistic people. We complement quantitative data with a qualitative account of their internal motivations, and how they perceive the interplay between autism and multilingualism.

Methods: The Autism & Bilingualism Census (ABC) was an online survey designed for monolingual and multi-lingual autistic adults. The ABC included questions about demographics, language history, and open-ended questions to gather qualitative data on the way language learning and knowledge had influenced respondents' lives. A total of 297 autistic adults took part in the ABC, including 54 respondents knowing 4 languages or more. These 54 participants' answers to the demographic, language history, and open-ended questions were analyzed.

Results: Respondents (55.6% female) were aged between 18 and 64 (M=32.7 years, SD=9.8 years), 47 had a clinical diagnosis of autism and 7 were self-identified autistic. Twenty-six respondents listed 4 languages, 14 listed 5 languages, 14 listed 6 or more languages. For all their languages respondents reported a wide range of age of acquisition (AoA): for example, AoA of the 2ndlanguage (L2) ranged from 0 to 25 (M=5.9 years, SD=5.0). Respondents also reported a wide range of proficiency in all their languages: for example on the self-rating scale from 0="Not at all" to 8="Excellent", L2 proficiency ranged from 0.5 to 8 (M=5.2, SD=2.4). Autistic multilinguals' motivations include a predisposition for language acquisition and social factors, such as relationships and social skills. Respondents reported perceived benefits of multilingualism in several domains such as social skills, confidence, and opportunities. They also discussed the positive and negative effects of the atypical autistic learning processes (i.e. memory, pattern identification, increased focus) in relation to their language learning skills.

Conclusions: This is the first study reporting insights from autistic multilinguals regarding the relationship between autism and their language experiences, their motivations to learn languages, and their perceived benefits of being multilingual. This study highlights diversity in the language profiles of autistic multilinguals, and offers multiple leads to better support language learning opportunities for autistic people.

67 **235.067** Canonical Babbling in 9-Month-Old Infants Later Diagnosed with Autism Spectrum Disorder: A Naturalistic Evaluation of All-Day Recordings

S. S. Meera[1], *R. Pawar*[2], *K. V. Khuu*[3], *S. F. Warren*[4], *G. Cetin*[3], *V. Jagannath*[5], *M. Clements*[6], *D. V. Anderson*[7], *H. C. Hazlett*[8], *R. T. Schultz*[9], *A. Estes*[10], *S. R. Dager*[10], *L. Zwaigenbaum*[11], *K. Botteron*[12], *J. Parish-Morris*[13], *J. Pandey*[9], *T. St. John*[10], *M. Swanson*[8], *L. R. Watson*[14], *J. Piven*[15] *and .. The IBIS Network*[8], *(1)Carolina Institute of Developmental Disabilities, University of North Carolina at Chapel Hill, Carrboro, NC, (2)Georgia Institute of Technology, Atlanta, GA, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Speech-Language-Hearing: Sciences and Disorders, University of Kansas, Lawrence, KS, (5)University of South Florida, Tampa, FL, (6)Georgia Tech, Atlanta, GA, (7)Electrical and Computer Engineering, Georgia Tech, Atlanta, GA, (8)University of North Carolina, Chapel Hill, NC, (9)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (10)University of Washington, Seattle, WA, (11)University of Alberta, Edmonton, AB, Canada, (12)Washington University School of Medicine, St. Louis, MO, (13)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (14)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (15)*Co-Senior Authors, IBIS Network, University of North Carolina, Chapel Hill, NC*

Background: Canonical Babbling (CB) may serve as an early developmental marker in differentiating neurodevelopmental disorders (e.g. Belardi et al., 2017; Oller et al., 2010). However, research on vocalizations and CB in infants at high familial risk for autism spectrum disorder (ASD) is limited and conclusions are mixed (e.g. Northrup et al., 2015; Paul et al., 2011; Talbott et al., 2016). Previous studies have used short home videos to analyze CB (Patten et al., 2014; Paul et al., 2011). This may not be representative of an infant's abilities because infant volubility fluctuates throughout the day (Warren et al., 2010). Thus, in this study we used a novel method of selecting representative segments from full-day unobtrusive naturalistic recording using the Language Environmental Analysis (LENA^{TM}) to analyze CB in infants at high familial risk (HR) for ASD.
Objectives: To compare CB in 9-month-old HR infants diagnosed with ASD at 24 months (HR-ASD), without ASD (HR-Neg) and low risk infants (LR), using naturalistic day-long recordings.

Methods: A total of 72 (11 HR-ASD, 35 HR-Neg, 26 LR) 9-month-old infants contributed data as part of a larger, ongoing longitudinal study, the Infant Brain Imaging Study. Infants wore a LENA recorder for at least 1 full day (>8 hours). A study-specific algorithm parsed through the LENA files and compiled a 5-minute sample from high vocalization periods spread across the day. Two coders blind to subject diagnostic status coded these samples for canonical syllables (CS; consonant-vowel combination); IRR – 0.75, $p<0.001$. A Canonical Babbling Ratio (CBR) was computed, dividing total CS by total child speech-like vocalizations (ChV). Infants were assessed at either 9 or 12 months of age using the Mullen Scales for Early Learning.

Results: Across groups, infants did not differ by age, sex, number of hours of LENA recording, or parental education. The groups significantly differed on Mullen Receptive Language and Fine Motor scores at 9-12 months, but not on other Mullen subscales (Table 1). Mullen Non-verbal DQ, age, sex, data collection site and maternal education were included as covariates. Group differences in CBR were not significant, although the direction of effects was consistent with previous reports (meanCBR of HR-ASD < HR-Neg < LR; $F_{(58)} = 1.85$, $p=0.16$). This direction of differences was not explained by a similar pattern in ChV (Fig-1)

Conclusions: We found no significant differences between HR-ASD, HR-Neg, and LR infant CBRs at 9-12 months of age. Previously reported large effects have come from clinically ascertained samples of children diagnosed with ASD rather than from prospectively ascertained HR infants. HR infants may demonstrate more typical patterns of CB development as compared with clinically ascertained samples. We await larger samples to more fully examine these phenomena with greater power to detect potential differences. Despite the absence of statistically significant results, this study provides a framework for studying CB in infants at risk for ASD, as well as the relationship of CB to behavioral trajectories and outcomes.

68 **235.068** Charting the Impact of Bilingualism on Social and Communicative Development in Autistic Children

R. Davis[1], *S. Fletcher-Watson*[1], *A. Sorace*[2] *and H. Rabagliati*[1], *(1)University of Edinburgh, Edinburgh, United Kingdom, (2)Department of Linguistics, University of Edinburgh, Edinburgh, United Kingdom*

Background: There is a dearth of empirical literature addressing how bilingualism might impact upon those with autism. What limited literature exists can be summarised as follows: bilingual exposure is unlikely to lead to poorer development of language in children with ASD and could provide an advantage in social and communicative domains. However, many parents are still concerned about the potentially harmful effects of bilingualism on development. It is clear that rigorous quantitative designs capturing effects which extend beyond the linguistic domain are needed to elucidate these issues.
Objectives: The overall aim of this research is to explore how bilingualism impacts on cognitive and language development for children with autism and their families. Here, we focus on the relationship between bilingual language exposure and social cognition in children with and without autism, and the factors that mediate this relationship.

Methods: We are collecting data from autistic and neurotypical children aged 5-12 who are being raised in a bilingual environment. At the point of submission, we have enrolled 45 children in the study, of which 20 have an autism diagnosis. With a visit rate of 20 children per month, we will have complete and processed data for 50 autistic and 50 neurotypical children by the end of March 2019. These will be analysed for presentation at INSAR 2019.

At each visit, children complete a battery of social cognition tasks; The Theory of Mind Task Battery, a false-belief eye-tracking paradigm and a social preference eye-tracking task. Standardised IQ assessment and language measures are included in the test battery. Additionally, parents complete a number of relevant reports including the Theory of Mind Inventory and a Bilingual Language Experience Calculator.

Results: We anticipate that directly-observed and parent-report measures of social cognition will be highly correlated, and we will first run a principal components analysis to identify one or more latent variables representing social cognitive ability, or facets thereof.

Social cognitive ability will then be analysed as follows:

1) Mean differences between groups based on diagnostic status (autistic vs neurotypical), bilingual exposure (high versus low) and the interaction

term for these. We predict that autistic vs neurotypical group differences will be reduced when bilingual exposure is high.

2) Continuous relationship between bilingual exposure and social cognitive ability, taking account of IQ, language and diagnostic group.

Two-way ANCOVA's will be used to assess all interaction contrasts, followed by pairwise post hoc comparisons.

Conclusions: This study will elucidate the effects of bilingual exposure on social cognition in autistic and neurotypical children. This study takes a step towards exploring the question of whether bilingualism can provide a naturalistic opportunity to further develop social cognitive skills. The work has implications for future clinical practise and can contribute to an evidence base for parents to make an informed choice about bilingualism for their child.

69 **235.069** Communication Propels Growth in Early Speech Production for Young Children with Autism: A Mediation Model

J. Blume[1]*, K. Wittke*[2]*, L. R. Naigles*[3] *and A. Mastergeorge*[4]*, (1)Department of Human Development and Family Studies, Texas Tech University, Lubbock, TX, (2)University of Connecticut, Storms, CT, (3)Psychological Sciences, University of Connecticut, Storms, CT, (4)Texas Tech University, Lubbock, TX*

Background: Language abilities of children with autism spectrum disorders (ASD) are heterogenous (Tager-Flusberg, 2004), with delays in gesture production (Iverson & Wozniak, 2007) and joint attention (Wetherby et al., 2007) aligning with concurrent and subsequent language development deficits (Iverson & Goldin-Meadow, 2005; Luyster et al., 2008). Distinct cognitive and linguistic phenotypes have been defined in prior within-disorder comparisons of language (Wittke et al., 2017), informing anticipated patterns of later language development. However, the unique contributions of social communication elements in driving these differential patterns of language growth remain unclear.

Objectives: This study investigates the unique roles of social communication elements including emotion and eye gaze, communication, and gesture, in mediating growth in spoken language production between toddlerhood and pre-school to better inform anticipated developmental trajectories for children demonstrating specific patterns of ASD behaviors.

Methods: This study utilized a subset of secondary data originally collected through the Autism Phenome Project (APP, *N*=55, 42 male, mean age at initial visit=33.9 months, SD=5.5), a longitudinal study completed through the MIND Institute at the University of California-Davis. The APP intends to define clinically meaningful ASD subtypes based on behavioral and biological data, specifically evaluating children immediately following ASD diagnosis at age 24-40 months and again at follow-up evaluations completed approximately 3 years later. We performed simple linear regression analyses, using *Communication and Symbolic Behavior Scales, Developmental Profile* (CSBS-DP; Wetherby & Prizant, 2002) Behavior Sample Social Composite scores (see Table 1) at the age of diagnosis to predict growth in mean length of utterance (MLU) approximately 3 years later.

Results: Performance on the Social Composite partially mediated the positive relationship between MLU at toddler age and MLU at preschool age, driven by performance on the Communication scale above and beyond performance on the Gesture scale and Emotion and Eye Gaze scale (see Table 2 for detailed linear regression results). That is, total effect of MLU at toddler age on MLU three years later while controlling for Communication scale performance increased when this mediator was included in the model. When models included Gesture or Emotion and Eye Gaze scales alone, statistically significant mediation effects were not indicated.

Conclusions: These findings distinguish social communication factors including rate, behavior regulation, social interaction, and joint attention as key elements facilitating growth in MLU during the early language acquisition period from toddlerhood to preschool age. Communication behaviors may lead to increased turn-taking and engagement opportunities with peers, suggesting that MLU growth is more child-input dependent than behaviors which summon adult-input like gesture and emotion and eye gaze. Next analytic steps for this research endeavor include analyzing direct and indirect mediational pathways, and assessing changes in these pathways with this sample, as well as a larger sample, when additional social communication elements are incorporated. Further, subsequent studies should incorporate analysis of additional spontaneous speech elements and *Autism Diagnostic Observation Schedule* (ADOS-G; Lord et al., 1999) performance at both time points in order to identify unique, clinically meaningful phenotypes based on language form, language function, lexical diversity, and ASD-behavior severity.

70 **235.070** Comparing Parental Report to Standardized Assessment Scores in Communication

A. Kniola*, A. Shapiro, S. Char, N. Sheinberg and A. Farias, Mailman Segal Center for Human Development, Nova Southeastern University, Ft. Lauderdale, FL*

Background: Parent report is an important method of gathering developmental history in the evaluation of autism spectrum disorder. Additionally, diagnosis is thought to be more reliable and valid when using both parent report and evaluation findings. However, parent report may lack objectivity which is relevant when the child is being formally assessed for a developmental disability.

Objectives: It is hypothesized that parents will rate their children as being more proficient in communication skills on a parent-report measure than results indicate on the Verbal Skills scale of a cognitive functioning assessment. This discrepancy is expected based on the unique relationship between parents and their children and the resulting difference in communication parents have with their children compared to an individual with whom the children are less familiar.

Methods: Participants included 41 children (Males n=31, Females n=10) evaluated at a community-based developmental assessment clinic. Ages of participants ranged from 30 to 72 months (μ= 51.1 months) and they were assessed using the Vineland, Second Edition, Parent/Caregiver Rating Form (Vineland-II) and the Differential Ability Scales, Second Edition, Early Years Battery (DAS-II). The sample consisted of 35.1% Caucasian, 40.5% Hispanic, 21.6% Asian Americans, and 2.7% biracial participants. All participants were at-risk for autism spectrum disorder, as determined by a phone screening method. However, not all participants were ultimately diagnosed with autism spectrum disorder.

Results: As hypothesized, there was not a correlation (r= .294, p= .073) found between the subjects on the DAS-II Verbal Skills scale and the Vineland-2 Communication domain.

Conclusions: These results suggest that parents/caregivers may unintentionally inflate Vineland-II Communication scores due to the unique relationship between parents and their children. Additionally, the resulting difference in communication parents have with their children compared to an individual with whom the child is less familiar (e.g., the examiner) may serve to inflate scores. Such findings are crucial as they can help to determine how different sources of information should be considered in the evaluation process.

71 **235.071** Content Validity Testing of the Autism Classification System of Functioning: Social Communication (ACSF:SC) with Toddlers

and School-Aged Children with Autism

B. Di Rezze[1], *P. Rosenbaum*[2], *S. J. Gentles*[1], *C. Roncadin*[3], *L. Zwaigenbaum*[4], *M. J. C. Hidecker*[5], *S. Georgiades*[1], *O. Hlyva*[1] *and H. Viveiros*[6], *(1)McMaster University, Hamilton, ON, Canada, (2)CanChild Centre, McMaster University, Hamilton, ON, Canada, (3)Autism Spectrum Disorder Service, McMaster Children's Hospital - Hamilton Health Sciences, Hamilton, ON, Canada, (4)University of Alberta, Edmonton, AB, Canada, (5)Communication Disorders, University of Wyoming, Laramie, WY, (6)Pediatrics, McMaster University, Hamilton, ON, Canada*

Background:

The Autism Classification System of Functioning: Social Communication (ACSF:SC) is a strengths-based system that classifies 5 levels of social communication abilities of children with ASD. To date, the ACSF:SC has been developed and used with preschoolers (3-6 years), with whom it has undergone psychometric testing, the findings of which have been published (Di Rezze et al. 2016). The current study examines applicability, clarity and utility of the ACSF:SC across the full childhood age range, by consulting with parents of children with ASD and clinicians working closely with toddlers (24-36 months) and school-aged children (>6 years) with ASD.

Objectives:

To assess the content validity of the ACSF:SC with children ages 24-36 months, and over 6 years old, in order to test the usefulness of the ACSF:SC and examine its performance across this expanded age range.

Methods:

Qualitative methods were used to test ACSF:SC age expansions from the perspectives of parents and clinicians. We developed a user guide and conducted cognitive interviews and focus groups with parents of children (both toddler and school-aged) and clinicians working with children in this age range. Transcripts from interviews and focus groups were analyzed using qualitative content analysis.

Results: Ten parents and seventeen clinicians working with toddlers or school-aged children with ASD participated, and recommendations were provided for three categories: applicability, clarity and usability of the tool. **Applicability** captured respondents' observations on developmental appropriateness of the level descriptions, and their ability to "see" (recognize) an individual child fitting into one particular ACSF:SC level. Most found the ACSF:SC relevant, but in the toddler group we learned that it was important to consider the educational and emotional needs of parents of newly diagnosed children. **Clarity** captured respondents' understanding of the ACSF:SC, its explicit and underlying constructs, level descriptions and distinctions. Feedback on **usability** helped us to identify areas that needed to be more user-friendly.

Conclusions:

Through a variety of content validation processes, these results indicated that ACSF:SC constructs are seen to be applicable to both toddlers and school-aged children with ASD, as well as being understood by most parents. Several recommendations need to be considered before proceeding with its final revisions and field testing – both of which are currently underway. Next steps will involve revising the ACSF:SC and sharing it with international stakeholders (n=50), whose perspectives are currently being collected and analysed through an online survey on ACSF:SC revisions, based on this work. This work will be completed prior to this conference and integrated into the presentation.

72 **235.072** Contextual Differences in Gesture Production in Verbally Fluent Individuals with ASD

A. Muñoz Lavanderos[1], *A. Bagdasarov*[2], *Z. M. Dravis*[3], *L. Adeoye*[4], *B. Mahoney*[5], *J. Leung*[5], *A. Riiff*[3], *M. Cola*[3], *S. Plate*[3], *V. Petrulla*[3], *A. Faggen*[3], *K. Bassanello*[3], *A. Pomykacz*[6], *L. Bateman*[7], *J. Pandey*[3], *C. J. Zampella*[8], *J. Parish-Morris*[8], *E. S. Kim*[3], *R. T. Schultz*[3] *and* ***A. de Marchena***[5], *(1)University of Pennsylvania, Philadelphia, PA, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Center for Autism Research/CHOP, Phladelphia, PA, (5)University of the Sciences, Philadelphia, PA, (6)Children's Hospital of Philadelphia- Center for Autism Research, Philadelphia, PA, (7)The Center for Autism Research/CHOP, Philadelphia, PA, (8)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background:

Impairments in nonverbal communication, including co-speech hand gestures, are required for a diagnosis of autism spectrum disorder (ASD). Co-speech gestures serve a range of communicative functions, often measured by categorizing them into discrete types, e.g., *representational* gestures ("descriptives" on the ADOS, which depict visuospatial properties of referents), *interactive* gestures (which convey social functions such as emphasis or turn-taking), and *deictic* (pointing) gestures. Several studies have now shown that individuals with ASD select gesture types differently than controls, suggesting that they rely more on certain communicative features. In addition to differences in nonverbal communication, another hallmark feature of ASD is difficulty adjusting behavior to fit the specific context at hand. Very little research has examined if, and how, nonverbal communication strategies might change based on social/communicative context.

Objectives:

The objectives of this study were (1) to replicate the finding that individuals with ASD use gesture to fulfill different communicative functions, and (2) to determine whether contextual differences are associated with a change in how individuals with ASD gesture.

Methods:

Verbally fluent children and adults with ASD (n=39) and typically developing controls (TDC; n=14, see Table) were group-matched on age, gender, and full-scale IQ. An additional n=10 participants per group will be added to the dataset by INSAR 2019. Participants completed two controlled communicative tasks, designed to evoke spontaneous gestures (participants who did not produce any codable gestures were excluded from this dataset). In the "Cartoon" task, participants described a Looney Tunes cartoon, and in the "Box" task, participants described how a shape sorter toy worked. Gestures were coded according to the types described above, with the addition of *pantomime* gestures, which are representational gestures produced in the absence of speech.

Results:

Across groups, participants relied on different gesture types depending on the task, as evidenced by a significant Task*Type interaction (p=.03, η^2=.16), with the Cartoon task eliciting relatively more gestures conveying visuospatial content (i.e., representational and pantomime gestures). Participants with ASD produced fewer gestures overall (p=.007, η^2=.13) and spontaneously selected different gesture types than controls (Group*Type: p=.003, η^2=.24), with a large effect size (see Figure). The 3-way interaction of Group*Task*Type was not significant. To probe the Group*Type interaction, post-hoc t-tests revealed marginal group differences, suggesting that autistic participants used proportionally fewer interactive gestures (p=.11, Cohen's d=.46), and proportionally *more* pantomime gestures (p=.07, Cohen's d=.58).

Conclusions:

This study replicates previous work demonstrating that autistic individuals use gesture to fulfill different communicative functions than controls. Counter to our predictions, however, we found that participants with ASD *were* equally sensitive to the change in communicative context, and modified their gesture selection accordingly. Finally, we found that, across tasks, individuals with ASD were *more* likely to use "pantomime" gestures, in which they enacted their gesture in the absence of speech. On one hand, this finding reflects a weakness: reduced integration across verbal and nonverbal modalities. However, we also see this as a strength, in that participants identified an effective way to transmit information about the world.

73 **235.073** Creaky Voice in Adolescents with Autism Spectrum Disorder: An Acoustic, Quantitative Analysis

E. Weed[1]*, R. Fusaroli*[1]*, J. Mayo*[2] *and I. M. Eigsti*[3]*, (1)Aarhus University, Aarhus, Denmark, (2)University of Connecticut, West Hartford, CT, (3)Psychological Sciences, University of Connecticut, Storrs, CT*

Background: People with Autism Spectrum Disorder (ASD) have often been described as having unusual prosodic (e.g., "robotic", "flat", "monotone"), and vocal (e.g., "harsh", "nasal" and "hoarse") qualities to their speech, but there is little consensus on exactly how their speech differs from typical speech (McCann & Peppé, 2003). There is growing interest in using acoustic measures of speech to quantify these subjective impressions (Fusaroli et al., 2016), but nearly all studies to date examine traditional aspects of prosody, such as pitch and rhythm, and ignore voice quality.

Objectives: To investigate the accuracy, sensitivity, and specificity of acoustic measures of prosody in combination with measures of voice quality for diagnostic classification.

Methods: We analyzed speech data (8 sentences per participant) from 15 adolescents diagnosed with ASD (mean age = 14.4 years, SD = 1.48) with IQ scores in the typical range, and 15 adolescents with typical development (TD; mean age = 14.1 years, SD = 1.91); groups did not differ on chronological age or full-scale IQ. Participants in both the ASD and the TD groups demonstrated average to high average performance on standardized language measures (see Mayo, 2015, for details). We extracted acoustic features from the audio files using the *Covarep*(Degottex et al., 2014) toolbox for Matlab and custom Praat (Boersma & Weenink, 2001) scripts, and computed RQA (recurrence quantification analysis, a measure of temporal dynamics) features for voice creak using the R *nonlinearTSeries*package (Garcia, 2015). We built two logistic regression models. Model 1 incorporated acoustic measures of prosody previously employed in the literature (Fusaroli et al., 2016), as predictors of diagnosis: mean F0, standard deviation of F0, pause duration, and speech rate. Model 2 included the above, as well as measures of voice creak: mean creak, SD of creak, and a recurrence measure of creak (RATIO). All models were 10-fold cross-validated, and reported statistics are averaged over 1000 iterations.

Results: Model 1 (prosodic measures only) had an accuracy of 0.61 (CI: 0.60, 0.62), sensitivity of 0.57 (CI: 0.55, 0.59), and specificity of 0.66 (CI: 0.64, 0.67). Model 2 (prosodic and voice measures) had an accuracy of 0.71 (0.70, 0.72), sensitivity of 0.68 (CI: 0.66, 0.70) and specificity of 0.74 (CI: 0.72, 0.75). Adding the voice measures improved the model, even when taking the increased complexity of the model into consideration.

Conclusions: Qualitative descriptions of the speech of people with ASD often allude to characteristics that include both prosodic and voice-quality aspects, but quantitative studies to date focus on measures of prosody. Human raters are still substantially more effective at diagnostic classification on the basis of speech: expert clinicians displayed sensitivity of .86 and specificity of .86 in classifying these samples (Eigsti, Mayo and Simmons, INSAR 2016). However, it remains unclear which acoustic features clinicians base their judgments on. Our results extend previous findings, showing that measures of voice creak improve acoustic diagnostic models. In future work, we aim to systematically combine voice quality and prosody measures with the aim of informing speech language therapy and intervention.

74 **235.074** Evidence for Pronoun-Mapping Confusion in Children with ASD

E. Zane[1]*, S. Arunachalam*[2,3] *and R. J. Luyster*[4]*, (1)FACE Lab, Emerson College, FACE Lab, Boston, MA, (2)Boston University, Boston, MA, (3)Communicative Sciences and Disorders, New York University, New York, NY, (4)Communication Sciences and Disorders, Emerson College, Boston, MA*

Background:

"Pronoun reversals" – confusions between *you* and *I* – are believed to be produced more frequently by children with autism spectrum disorder (ASD)[1–3] than by typically developing (TD) children. This prevalence has been connected to social impairments in ASD, specifically to problems with self-other awareness[4] and perspective-taking[5]. However, a recent review of language-acquisition literature reveals that children with ASD show relative deficits in assigning meaning for nouns and relative strengths in morpho-syntax[7]. The authors conclude that "form is easy, [but] meaning is hard" for children with ASD.

If children with ASD struggle to assign meaning for even concrete nouns, reference for pronouns should be particularly baffling, since pronoun reference shifts between entities based on social and linguistic context. This should lead to pronoun-mapping errors beyond confusing *you* and *I*. For instance, a child might confuse *you* and *he*. And, if form is easier than meaning, children with ASD should make relatively fewer morpho-syntactic errors (e.g., "This is hims").

Objectives:

Using a caregiver survey, we tested whether children with ASD make more pronoun-mapping errors but fewer pronoun-form errors than their TD peers.

Methods:

We ask caregivers whether their child uses each of 16 pronouns, and if so, whether s/he always uses it correctly. If the child uses pronouns incorrectly, caregivers provide example errors. Caregivers of children with (N=119) and without (N=112) ASD participated. In the ASD group, children were significantly older (ASD *M*=53mos; TD *M*=31mos, $p<0.001$), and there was a higher proportion of males (86% vs. 71%, $c^2=6.21$, $p=0.02$). Proportions of children at different language levels (single-word-, phrase-, vs. sentence-level) did not differ significantly between groups ($c^2=2.33$, $p=0.31$).

Results:

We focused on children who use at least phrase-level speech, use at least two pronouns but do not always use them correctly (ASD N=67; TD N=62). We categorized caregivers' example errors as "mapping errors" (person, gender, number) and/or "form errors" (e.g. "Her is funny."). We used Fisher's Exact Tests to compare proportions of children who made each error type and found a significant difference in proportions of mapping errors (ASD 63%, TD 35%; p=0.003), but not form errors (ASD 19%, TD 29%; p=0.15). We then compared person, gender, number errors, separately. Children with ASD made more person errors (ASD 25%, TD 14%), but this difference was not significant (p=0.19). Of these, reversal errors made up a smaller proportion for the ASD group (ASD 76%, TD 89%). The ASD group made significantly more gender errors (ASD 42%, 23%; p=0.02). Only three children were reported making number errors; all were ASD.

Conclusions:

In accordance with the "form/meaning" hypothesis, a higher proportion of children with ASD make mapping errors than form errors, and significantly more of them make mapping errors than TD children do. The fact that gender and number errors are more prevalent in the ASD group shows that their erroneous use of pronouns is not limited to confusing features that distinguish self from other. Instead, children with ASD seem to have a hard time determining the appropriate meaning for all pronouns.

75 **235.075** Deficits in Understanding Perspective-Dependent Spatial Language By Older Children with ASD

E. Zane[1], *A. Ramakrishna*[2], *A. Krzyzanowicz*[3], *S. Narayanan*[4] *and R. Grossman*[5], *(1)FACE Lab, Emerson College, FACE Lab, Boston, MA, (2)University of Souther California, Los Angeles, CA, (3)SUNY Fredonia, Fredonia, NY, (4)University of Southern California, Los Angeles, CA, (5)CSD, Emerson College, Boston, MA*

Background:

The earliest reports on autism spectrum disorder (ASD) describe pronoun reversal errors, where individuals confuse *you* with *I*[1]. Subsequent research has suggested that such errors result from underlying deficits in perspective-taking in ASD[2–4]: specifically, that individuals do not understand others' perspectives and therefore cannot understand that the person referred to by *you* or *I* depends on who is speaking. If so, the same perspective-shifting deficit should then apply to spatial terms, like prepositions, since they can also be perspective dependent. For example, when two people are facing one another, the position "to the left" of one person is the opposite of "to the left" of the other.

Despite these parallels, there is limited research on spatial-language use in ASD[5], and, as far as we are aware, there is *no* research on their *interpretation* of such terms. If there is an underlying deficit in perspective-taking in ASD, it should affect both expressive and receptive spatial language.

Objectives:

We aim to determine whether children with ASD show relative weaknesses understanding perspective-dependent spatial language.

Methods:

Sixteen (16) older children and adolescents with ASD participated, along with 18 neurotypical (NT) peers. Groups were not significantly different in age (M ASD=13;5, M NT=13;7 p=0.86), sex (4 F ASD, 5 F NT, p=1), IQ (K-BIT 2[6], *M* ASD = 111, *M* NT = 111, p=0.95), and language (CELF-4[7] Core Language, *M* ASD = 106, *M* NT = 109, p = 0.68).

We presented 128 spatial arrays on a computer screen. In each, a doll is pictured in the middle of the screen, with four black shapes surrounding her (Figure 1). From trial to trial, the doll's position changes, so that she is facing different directions, but the shapes' positions are fixed.

At the beginning of each trial, participants hear a command in the "doll's voice", e.g. "Click on the shape above me". For half of the trials, the position of the object is described from the doll's perspective (e.g., "...on my left"), and for the other half, the shape's position is described from the participant's perspective (e.g., "...on your left").

Participants use a mouse to highlight and select the shape described.

Results:

We used a 2x2 repeated-measures ANOVA to measure the effect of Group (ASD vs. NT) and Perspective (Doll vs. Child) on shape-selection accuracy.

There was a significant interaction between Group and Perspective ($F_{(1,32)}$= 4.53, p=0.04), where children with ASD were less accurate at selecting a shape when the shape's position was described from the doll's perspective.

Conclusions:

Results show that older children and adolescents with ASD – even those with normal language scores – struggle to accurately interpret prepositions when they reflect another's perspective. Because prepositions are some of the most frequently used words in English, this presents a persistent problem during reciprocal conversation. Thus, we believe that language deficits in perspective-taking should be intervention targets for children with ASD, even for those who score within normal ranges on standardized language tests.

76 **235.076** Low-Verbal Investigatory Survey for Autism (LVIS) – an Initial Validation

E. Tenenbaum[1,2], *R. N. Jones*[3], *G. Righi*[3,4,5], *S. J. Sheinkopf*[3,5,6], *A. Naples*[7] *and I. M. Eigsti*[8], *(1)Duke Center for Autism and Brain Development, Durham, NC, (2)Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, (3)Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI, (4)E. P. Bradley Hospital, East Providence, RI, (5)Rhode Island Consortium for Autism Research and Treatment (RI-CART), East Providence, RI, (6)Brown Center for the Study of Children at Risk, Women and Infants Hospital, Providence, RI, (7)Child Study Center, Yale University School of Medicine, New Haven, CT, (8)Psychological Sciences, University of Connecticut, Storrs, CT*

Background: Approximately 30% of children with autism spectrum disorder (ASD) will be considered minimally verbal (MV) throughout their lifetime. However, we are unable to predict who is *preverbal* and who will *remain MV*. A tool for assessing communicative competence in MV children would allow us to increase our understanding of communicative trajectories. The current study explored the Low Verbal Investigatory Survey (LVIS), a 36-item parent-report measure designed to assess communicative capacity in MV children with ASD. The LVIS is easy to complete, and based specifically on language trajectories in ASD.

Objectives: To assess convergent and divergent validity of the LVIS in relation to gold-standard measures of language ability, and to assess the dimensionality and item characteristics of the LVIS.

Methods: Parents of 147 children (1 to 8 years) completed the LVIS. Sixty-four children had diagnoses of ASD [12 female; *M*(*SD*) age = 4.45(1.68) years], 28 had language or developmental delays [11 female; *M*(*SD*) age = 1.91(1.08)), and 55 were typically developing [21 female; *M*(*SD*) = 3.10(1.53)]. Scores were available on the Preschool Language Scales (PLS-5; Zimmerman et al., 2011) for 86 participants and on the Vineland Adaptive Behavior Scales (VABS-II; Sparrow, 2011) for 122 participants. Principal components analysis (PCA) with oblique rotation was used for data reduction. Pearson correlations assessed convergent and divergent validity with the PLS and VABS. Item Response Theory (IRT) was used to determine item characteristics.

Results: PCA analyses identified five factors (as indicated by scree plots and parallel analysis), which mapped onto: Language, Nonverbal Communication, Atypical Language, Loss of Skills, and Atypical Nonverbal Communication. A Communication Composite score was calculated as the sum of the Language and Nonverbal Communication scores. Convergent validity was demonstrated with significant correlations between the LVIS Communication Composite and PLS Receptive ($r(86) = .71$, $p < .01$) and Expressive Scores ($r(86) = .71$, $p < .01$), as well as VABS Communication Scores ($r(122) = .64$, $p < .01$). Divergent validity was demonstrated with significantly stronger correlations between the LVIS Communication Composite and Vineland Communication scores than with Socialization ($z = 2.38$, $p = .02$), Motor ($z = 4.33$, $p < .01$), or Daily Living Scores ($z = 2.66$, $p < .01$) (Figure 1). IRT models of the subscales indicated that these constructs were unidimensional and yielded informative item characteristic curves demonstrating the importance of joint attention for language development (Figure 2).

Conclusions: Results provide initial validation of the LVIS as a specific measure of communicative competence that captures multiple dimensions of communicative skills in the understudied population of MV children. Joint attention was demonstrated to be one of the most basic of nonverbal abilities, lending support to interventions targeting joint engagement as a critical skill for language development. The LVIS is designed to be short (< 10 minutes for completion); it requires no special equipment, and scoring requires no expertise. These data demonstrate that the LVIS is efficient and informative, and will be useful in research on early language development in ASD.

Poster Session
236 - Diagnostic, Behavioral, Sensory and Intellectual Screening and Assessment
11:30 AM - 1:30 PM - Room: 710

77 **236.077** The Abridged Version of the Autism-Spectrum Quotient in Chinese People with Autism

***C. Wang**, Nankai University, Tianjin, China*

Background: The Autism-Spectrum Quotient (AQ: Baron-Cohen et al. 2001) is among the most widely used scales assessing autistic traits in the general population. Hoekstra et al. (2011) reported that the 28-item abridged Version of the Autism-Spectrum Quotient (AQ-28) had high sensitivity and specificity which made the AQ-28 a useful alternative to the full 50-item version of AQ. Few studies have examined the psychometric properties of the 28 items among Chinese population.
Objectives: This study measured the distribution of autistic traits using AQ-28 in a big sample from Chinese people with autism spectrum disorders (ASD) and examined the measurement ability and convergent validity.

Methods: Total AQ-28 scores were collected from 6223 children and adults with ASD from all over China (except Tibet, Taiwan, Macau and Hong Kong), including 5073 ASD children (younger than 16 years old) (4255 males, M_{age}=8.7418,*SD*=3.4093, and 818 females, M_{age}=8.7083,*SD*=3.4567, Male: Female = 5:1) and 1150 ASD adults (older than 16 years old) (958 males, M_{age}=20.0120, *SD*=3.8738, and 192 females, M_{age}=20.4761,*SD*=4.6734, Male: Female = 5:1). 64.04% of the participants were recruited from urban areas, while 16.73% were living in suburbs and 19.22 % in rural areas. We examined the effects of groups (child and adult) and home areas (urban, suburb, rural) on AQ-28 total scores. The item severity and item discrimination was assessed using item response theory. In addition, we tested for sex differences in both groups. Besides, the caregivers of all the participants also filled a questionnaire about the characteristics of the people with ASD, comorbidities, service encounters, monthly cost for intervention/education and caregiver perceptions.

Results: The results showed that there was no gender difference in the ASD individuals on the AQ-28 scores but a correlation between age and AQ score was found (ASD children: M_{male}=77.9457,SD_{male}=10.6048, M_{female}=79.0880,SD_{female}=11.4374; ASD adults: M_{male}=76.1033, SD_{male}=11.0202, M_{female}=77.8750, SD_{female}=11.9456). In this study, 87.43% of the participants had received or were receiving various therapies/interventions, while 37.33% of people with ASD were in service centers, 42.68% were attending typical or special schools and 19.31% were staying at home, but only 41 participants (0.67%) got a job. It was found that participants' current status had significant correlation with AQ-28 scores.

Conclusions: This study confirms that AQ-28 has adequate validity to be used in health surveys as a measure of autistic traits.

78 **236.078** The Association between Parent-Reported Emotional/Behavioral Problems and the Modified Checklist for Autism in Toddlers

*K. L. Christopher[1], S. Bishop[2], L. Carpenter[3], Z. Warren[4] and **S. M. Kanne**[5], (1)University of Missouri, Columbia, MO, (2)University of California San Francisco, San Francisco, CA, (3)Medical University of South Carolina, Charleston, SC, (4)Vanderbilt University Medical Center, Nashville, TN, (5)Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO*

Background: Children with Autism Spectrum Disorders (ASD) have difficulties in the areas of social-communication and other restricted and repetitive behaviors. The assessment of these core symptoms may be complicated by the presence of other co-occurring emotional and behavior problems (EBPs), which can make differential diagnosis challenging. EBPs may include externalizing symptoms such as overactivity and aggression, as well as internalizing symptoms such as mood problems and anxiety. Studies have shown the presence of EBPs decrease the specificity of ASD screening and diagnostic instruments.
Objectives: This study assessed the impact of parent-reported EBPs on an often used autism screener, the Modified Checklist for Autism in Toddlers, Revised (MCHAT R/f). In addition, the study examined the potential benefit of combining EBP data with the MCHAT R/f data to improve screening accuracy.

Methods: Participants included 473 children, 1.5-5 years of age, referred to one of three sites for ASD-related concerns. EBPs were assessed via the Child Behavior Checklist (CBCL) and autism symptoms were screened with the parent-report MCHAT R/f in a subset (N = 290). Children were also

administered a full battery of diagnostic measures including the ADOS-2, with a final diagnosis assigned by a senior clinician.

Results: Overall, participants who were diagnosed with ASD had significantly lower externalizing EBPs compared to those who were not diagnosed with ASD (i.e., CBCL T scores - Externalizing [62.6 vs. 68.1]). Internalizing symptoms were not significantly different. Higher MCHAT-R/f scores (e.g., more ASD symptoms) and fewer CBCL- Externalizing symptoms were significantly predictive of an ASD diagnosis. MCHAT-R/f specificity was reduced if CBCL- Externalizing behaviors were present (i.e., from 44% to 27%). In addition, MCHAT-R/f Positive Predictive Value (PPV) was reduced from 86% to 71% if externalizing behaviors were present.

Conclusions: For toddlers referred for an ASD evaluation, parental report of significant EBPs, and in particular externalizing problems, often result in higher scores on an autism screening measure that may not be directly related to core autism symptoms (i.e., a false positive). Therefore, a combination of measures that assess EBPs and autism core symptoms will improve screening in this population. More specifically, results suggest that combining EBP findings from the CBCL with those of the M-CHAT R/f may improve the specificity of this instrument.

79 **236.079** The Brazilian Version of the ADOS: Translation, Cross-Cultural Adaptation and Semantic Equivalence for Brazilian Portuguese

*M. C. Teixeira[1], M. C. Pacífico[2], R. Lowenthal[3], C. Bosa[4], V. Namur[5], **M. M. Spaniol**[6] and C. S. de Paula[1], (1)Developmental Disorder Program, Universidade Presbiteriana Mackenzie, São Paulo, Brazil, (2)FMUSP, São Paulo, Brazil, (3)Santa Casa Hospital, Sao Paulo, Brazil, (4)Federal University of Rio Grande do Sul, Porto Alegre, Brazil, (5)Mackenzie Presbiterian University, São Paulo, Brazil, (6)Developmental Disorders Program, Mackenzie Presbiterian University, São Paulo, Brazil*

Background: Autism Spectrum Disorder (ASD) is a condition comprised of genetic and biological markers, but its diagnosis remains primarily clinical, based on behavioural measures which ideally rely on gold standard instruments, such as the ADOS. The ADOS has been translated, culturally adapted and standardized in numerous countries, but few of them in Latin America. After several years of work, the Brazilian version of the ADOS was recently concluded.

Objectives: In this study, our group researchers and clinicians aimed at translating and back-translating the ADOS to Brazilian Portuguese; to assess its cross-cultural semantic equivalence and to validate indicators of quality for the final version by analysing the inter-rater reliability of the ADOS scores.

Methods: This study had four stages: 1) Translation and back-translation; 2) Analysis of semantic equivalence; and 3) Pre-test to verify the agreement regarding the scoring procedure, between mental health specialists and a clinical specialist on the application and research with the ADOS. Permission to translate and conduct the cultural adaptation of the ADOS was obtained from the publishers of the instrument, Western Psychological Services.

Results: Results show good equivalence between the original ADOS version in English and the final version. A few semantic differences were found between the original version and the back-translation into English, although it did not interfere with the first translation into Portuguese or the final version. Limitations of this study include a small sample size, and related to that, the inter-rater reliability of the ADOS scores between the specialists and the ADOS clinician using the Kappa coefficient was equivalent for 7 out 10 areas.

Conclusions: The official Brazilian version of the ADOS will strengthen clinical and scientific research in ASD, preventing the use of unauthorized versions of the ADOS in Brazil.

80 **236.080** The Clinical Feasibility of Deconstructing Autism into a Pathogenetic Triad: Classification Results from a Case-Control Cohort

***D. Sarovic**[1,2], J. F. Schneiderman[2,3], N. Hadjikhani[1,4], B. Riaz[2,5], E. V. Orekhova[1,6], C. Gillberg[1] and S. Lundström[1], (1)Gillberg Neuropsychiatry Centre, Department of Psychiatry and Neurochemistry, Institute of Neuroscience and Physiology, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, (2)MedTech West, Gothenburg, Sweden, (3)Department of Clinical Neurophysiology, Institute of Neuroscience and Physiology, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, (4)MGH/ Martinos Center for Biomedical Imaging/ Harvard Medical School, Charlestown, MA, (5)Department of Clinical Neuroscience, Institute of Neuroscience and Physiology, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, (6)MEG-Center, Moscow University of Psychology and Education, Moscow, Russian Federation*

Background:

Several mechanisms have been shown to influence the risk and severity of autism. Autism can be understood as resulting from a triad of contributing factors: genetic vulnerability from common susceptibility variants influences the pervasive and normally distributed broader autism phenotype (BAP; operationalized as the Autism-Spectrum Quotient (AQ)); cognitive compensatory ability (operationalized as the working memory subscale (WMIQ) of the Wechsler Adult Intelligence Scale (WAIS)) alleviates social difficulties and allows for adaptive behaviors and learning; environmental risk factors (operationalized as Heart Rate Variability (HRV)) negatively influence brain development and cognitive compensatory ability. While the sheer number, heterogeneity, and variety of environmental factors make quantification difficult, we propose HRV as a candidate surrogate variable that may capture enough of an individual's history to be useful for diagnostic purposes.

Objectives:

Risk factors for autism have previously been theoretically discussed. However, a concrete and clinically relevant framework that can guide clinical reasoning has not been outlined. The objective of this study was to empirically validate the clinical feasibility of a pathogenetic triad by investigating its ability to classify a case-control cohort.

Methods:

20 neurotypical controls and 21 high-functioning individuals with autism (all adult males, age- and total IQ-matched) underwent neuropsychological testing using the WAIS and AQ, as well as ECG recording during a face-processing experimental paradigm of a magnetoencephalographic session. The inter-beat intervals from the ECG recordings were extracted and used to calculate the logarithm of the Cardiac Vagal Index (CVI), a measure of HRV. The AQ, WMIQ and CVI were plotted in 3D using Python Matplotlib to identify the plane of maximal separation between the groups. The principal component of the WMIQ and CVI for that orientation was found, and plotted against the AQ. A second-degree polynomial regressor was applied and the residual for each individual was calculated. Sensitivity, specificity, diagnostic odds ratio (DOR), and prevalence-corrected (at 1%) positive and negative predictive values were calculated. The residuals for each individual were used in a

Receiver Operator Characteristic, and the Area Under the Curve (AUC) was calculated.

Results:

It was found that classification of autism following deconstruction into a purported pathogenetic triad yielded high accuracy with a sensitivity of 90.5% and specificity of 90.0%. The DOR was 85.5 (lnDOR = 4.45, 95% CI [2.39-6.51]). The positive and negative predictive values were 0.084 and 0.999 respectively. The AUC was statistically significant at 0.963 ($p < 0.0005$, 95% CI [0.913-1.000], SE = 0.026).

Conclusions:

These results show the promise of deconstructing and operationalizing autism as a pathogenetic triad and its clinical feasibility in discriminating individuals with autism from neurotypical controls. A population-based study, with larger sample size, will be instrumental in proving the validity and clinical utility of the framework, as well as its specificity, as autism was the only patient group included. Strengths of the method include the simplicity, ubiquity and cheapness of the tests, as well as the short time needed for administration. If the high diagnostic accuracy were to be replicated, the method could easily be introduced into clinical work.

81 **236.081** The Effectiveness of Gold-Standard ASD Diagnostic Tools in Phelan-Mcdermid Syndrome

I. Giserman-Kiss[1], *D. Halpern*[1], *J. Zweifach*[1], *J. Foss-Feig*[1], *M. P. Trelles*[1], *M. L. Gorenstein*[1], *H. Voulgarakis*[1], *J. Weissman*[1], *E. Wilkinson*[1], *M. A. Rowe*[1], *J. Buxbaum*[2], *A. Kolevzon*[1] *and P. M. Siper*[1], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: Phelan-McDermid syndrome (PMS), also known as 22q13 deletion syndrome, is a rare neurodevelopmental disorder caused by loss of one functional copy of SHANK3 on the terminal end of chromosome 22q. Individuals diagnosed with PMS frequently demonstrate global development delay, intellectual disability of varying degrees, hypotonia, significant speech and language delays (including absent speech), and behaviors characteristic of autism spectrum disorder (ASD) (De Rubeis et al., 2018; Kolevzon et al., 2014; Soorya et al., 2013). Recent studies using gold-standard diagnostic instruments have revealed high rates of clinical ASD diagnoses in individuals with PMS, ranging from 69-84% (De Rubeis et al., 2018; Laura et al., 2018; Soorya et al., 2013). However, due to severe intellectual impairments, language delays, and repetitive behaviors seen in many individuals with PMS, a greater proportion of patients within this population exceed the cut-off scores on gold-standard diagnostic tools (i.e., Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview-Revised (ADI-R)) than actually go on to receive a diagnosis of the disorder (De Rubeis et al., 2018; Laura et al., 2018). Thus, due to complex developmental and behavioral profiles, careful integration of standardized assessment, caregiver report, and structured observations are necessary components of diagnostic evaluations of individuals with PMS.

Objectives: This study aimed to investigate the sensitivity and specificity of the ADOS-2 and ADI-R with regard to detecting ASD in a sample of children and adolescents with PMS who have intellectual disability and limited language abilities.

Methods: Thirty-six participants between 2 and 18 years old (mean age=8 years, 2 months, SD=53.4 months; 58% male) with PMS underwent comprehensive diagnostic evaluations. Participants were administered the ADOS-2 (Toddler Module: 6%; Module 1: 78%; Module 2: 17%) by a research-reliable clinician as well as a developmentally-appropriate assessment of cognitive functioning (Mullen Scales of Early Learning: 78%; Differential Ability Scales-II: 8%; Stanford-Binet-5: 14%). Developmental quotients (DQs) were calculated based on Mullen age equivalents. Participants' caregivers completed the Vineland Adaptive Behavior Scales-II (VABS-II) and the ADI-R with a research-reliable clinician. Consensus diagnoses of ASD accounted for test results, expert clinical judgment, and DSM-5 criteria.

Results: Cognitive assessment results revealed intellectual disability in all participants. Both the ADOS-2 and ADI-R (total scores) demonstrated high sensitivity in this population (100.0% and 82.8%, respectively); however, the specificity rate of both measures was poor (ADOS-2 specificity=28.6%; ADI-R specificity=57.1%). False positives on both measures had significantly higher IQs/DQs and VABS-II adaptive behavior composite scores than true positives ($p<.05$).

Conclusions: In a sample of children and adolescents with PMS, the ADOS-2 and ADI-R correctly identified ASD in most participants who ultimately received a clinical diagnosis. However, the rate at which the measures produced negative results for participants who did not receive clinical diagnoses was significantly lower than the specificity rates found in past studies of the measures with participants with idiopathic ASD (Lord et al., 1997; McCrimmon & Rostad, 2014). Thus, these tools must be used in conjunction with expert clinical judgement during diagnostic evaluations of individuals within this population.

82 **236.082** The Effects of Severity of Autism Symptoms on Developmental Trajectories

A. R. Borowy[1], *R. Kirchner*[2] *and K. M. Walton*[1], *(1)Nisonger Center, The Ohio State University, Columbus, OH, (2)The Ohio State University, Columbus, OH*

Background:

Children under the age of 3 years old who are experiencing developmental delays or disabilities are legally entitled to receipt of early intervention services, as mandated by Part C of the Individuals with Disabilities Education Act. Although little research has examined publicly available (Part C) early intervention services specifically, several studies have focused on efficacy of a variety of early-delivered programs for children with disabilities. This research suggests that a variety of outcomes (such as cognitive level, early nonverbal communication skills, and early social interaction skills) may relate to developmental growth over time in children receiving these services (Ben-Itzchak & Zachor 2007, Calandrella & Wilcox 2000, Harris & Handleman 2000). However, many potentially important factors that might predict developmental growth, such as symptoms of autism spectrum disorder, have not been explored in detail within a population of children receiving early intervention services.

Objectives:

This study aims to examine the effects of severity of autism symptoms, as measured by the parent rated Modified Checklist for Autism in Toddlers (M-CHAT) in the developmental trajectory of social skills, social communication, and adaptive behavior as measured by the Assessment, Evaluation, and Programming System (AEPS). Although it is anticipated that individuals with higher M-CHAT scores will have lower scores on the social communication, social, and adaptive behavior areas of the AEPS, little is known about the effect of M-CHAT scores on developmental

trajectory in these areas.

Methods:

Our sample includes 45 children ages 0-3 years enrolled in a center-based early intervention program between 2010 and 2017. Data was collected from review of children's educational records. We examined the relationship between scores on the M-CHAT (completed by the parent) and two time points (initial and a second time point between 2-9 months after initial) of the AEPS measures (completed by the teacher). We used regression models to predict growth on each AEPS domain using M-CHAT as a predictor variable and initial AEPS score, child age and gender, and time between AEPS assessments as covariates.

Results:

The overall regression models were not able to significantly predict growth on the social and social communication domains of the AEPS. However, there was a significant relationship between severity scores on the M-CHAT and the trajectory of adaptive behavior scores (β=-0.652, p=0.016).

Conclusions:

Surprisingly, M-CHAT scores did not predict gains over time in the social or social communication domains. We theorize that immersion of socialization within a group setting, as well as the emphasis on improving social and social communication skills for children who show heightened symptoms of autism, may buffer these areas of weakness for children with heightened ASD symptoms. However, adaptive skills that require more independence and complexity may not be focused on in group early intervention settings. It is our hope that this research will help improve early intervention services by increasing the understanding of the developmental trajectory of individuals receiving early intervention services, with specific implications on the need for adaptive skills intervention.

83 **236.083** The Experience of Getting a Neurodevelopmental Disorder Diagnosis: A Survey of Stakeholders

B. Afsharnejad[1], *N. Mullan*[2], *A. L. Finlay-Jones*[3], *A. J. Whitehouse*[4], *J. Wray*[5] *and K. Evans*[4,6], *(1)Autism Research Team, Telethon Kids Institute, Perth, Australia, (2)Telethon Kids Institute, Per, Western Australia, Australia, (3)Telethon Kids Institute, Perth, Western Australia, Australia, (4)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (5)State Child Development Service, Western Australia Department of Health, Perth, Western Australia, Australia, (6)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Bentley, Australia*

Background: Neurodevelopmental disorders (NDD) affect the brain and nervous system during early development. These disorders include attention deficit hyperactivity disorder, autism, fetal alcohol spectrum disorders and intellectual disability. The transdiagnostic approach suggests NDDs should be considered together, not in isolation. A transdiagnostic approach can make significant difference in understanding these disorders due to frequent overlap of signs, symptoms and diagnostic labels. Although the assessment and diagnostic experience has been studied individually for some NDDs, it is unclear if the assessment and diagnostic experiences of stakeholders (individuals diagnosed with a NDD, along with caregivers / family members and health professionals involved in their care) are similar or different across NDDs.
Objectives: This research project aimed to explore the NDD assessment and diagnostic experiences, from the stakeholder perspectives of individuals diagnosed with a NDD, their caregivers / family members and their health professionals.

Methods: An online survey designed specifically for this research project captured the assessment and diagnostic experiences of stakeholders across Australia. The survey included a general demographic section and tailored background questions for each of the three stakeholders groups: (1) individuals diagnosed with a NDD (n = 5); (2) caregivers / family members of an individual diagnosed with a NDD (n = 68); and (3) professionals involved in the assessment, diagnosis or care of individuals diagnosed with a NDD (n = 50). The survey concluded with an open-ended question seeking the stakeholders' view on how the process of assessing and diagnosing NDDs can be improved. A qualitative thematic data analysis approach, with the assistance of NVivo software, was used to identify themes from the qualitative survey responses from 113 stakeholders.

Results: The four main themes that emerged from the qualitative survey responses were process, support, health professionals and resources. Processes and clear pathways are needed where health professionals work collaboratively with one another, individuals undergoing assessment and caregivers / family members. Support during the assessment and diagnosis process was an expressed need to help individuals undergoing assessment and their caregivers / family members to navigate this very stressful time, in particular in relation to appraisal, emotional, informational and instrumental support. Health professionals with a lack of knowledge about some NDDs, or who miss early signs and symptoms, misdiagnose and do not identify comorbidities, were raised as concerns, all of which would be improved through the provision of more specialized training for health professionals in relation to the full range of NDDs. Finally, additional resources were deemed necessary to provide adequate trained health professionals to meet service requirements, integrate appropriate assessment tools into practice and provide financial support to allow individuals and caregivers / families to access assessment and diagnostic services within acceptable wait times.

Conclusions: The perspective of individuals, caregivers / families and health professionals, showed that across all NDDs the assessment and diagnosis process is often associated with a wide range of positive and negative emotions. Health professionals have the opportunity to implement solutions that may improve the diagnostic experience through addressing processes, supports, health professional training and resources.

84 **236.084** The Impact of Alexithymia on Autism Diagnostic Assessments

H. M. Hobson[1], *H. Westwood*[2], *J. Conway*[3], *F. S. McEwen*[4], *E. Colvert*[5], *C. Catmur*[6], *G. Bird*[3] *and F. Happé*[5], *(1)Department of Psychology, Social Work and Counselling, University of Greenwich, London, United Kingdom, (2)Royal Holloway, University of London, London, United Kingdom, (3)University of Oxford, Oxford, United Kingdom, (4)Biological and Experimental Psychology, Queen Mary University of London, London, United Kingdom, (5)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)Kings College London, London, United Kingdom*

Background: Alexithymia, a difficulty identifying and communicating one's own emotions, affects socio-emotional processes, such as emotion recognition and empathy. Indeed, research has highlighted several behavioural characteristics traditionally attributed to autism that have been demonstrated to be related to alexithymia. Given that many of these behaviours are assessed during autism assessments such as the Autism

Diagnostic Observation Schedule (ADOS), it is pertinent to examine the relationship between alexithymia and scores on autism diagnostic assessments.
Objectives: Our objective was to examine the association between alexithymia and ADOS scores. We examined 1) the impact of alexithymia on meeting the criteria for autism/ASD, 2) correlations between alexithymia and ADOS subscales, and 3) whether alexithymia predicted scores on specific ADOS items, selected a priori based on the literature.

Methods: We utilised two previous datasets for which both ADOS and alexithymia data were available. Participants included 96 women with anorexia, and 147 adolescents who were either high in autistic symptoms, or whose twin had high autistic symptoms. Both samples of participants completed the Toronto Alexithymia Scale (TAS-20), a self-report alexithymia measure. For the adolescent sample, parent-report alexithymia scores were also available (the Observer Alexithymia Scale). Current depression/anxiety symptoms were also measured: for the anorexia sample this was via the Hospital Anxiety and Depression Scale or the Moods and Feelings Questionnaire (depending on participant age), and for the adolescent sample this was via the Strengths and Difficulties Questionnaire.

Results: In the adolescent group, parent-reported (but not self-reported) alexithymia predicted autism/ASD diagnosis, correlated with both social affect and restricted and repetitive interests sub-scales, and predicted scores on a priori selected ADOS items. Fewer associations were observed in the anorexic sample, and most associations were removed once depression/anxiety symptoms were controlled for. Nonetheless, the presence of alexithymia predicted a near fourfold increase in the likelihood of meeting diagnostic criteria for autism/ASD in this sample.

Conclusions: Alexithymia does appear to show an association to ADOS scores, at the level of meeting the diagnostic threshold, ADOS subscales, and scores on specific items. The reduced associations in the anorexia sample could have arisen for a number of reasons. This includes the high level of depression and anxiety in this group potentially impacting on self-report alexithymia measures. Alternatively, this could be related to the gender and age of this group, as compared to the mostly male and younger adolescent group. This and future research have important implications for diagnostic practices, but also research practices in which ADOS assessments are considered the gold standard for inclusion in autism research.

85 **236.085** The Impact of DSM-5 Social Communication Disorder Diagnosis on Autism: Results from Two Systematic Literature Reviews and Meta-Analyses

ABSTRACT WITHDRAWN

Background: Social Communication Disorder (SCD) is a new behaviorally-defined developmental communication disorder diagnosis in the Fifth Edition of the Diagnostic and Statistical Manual (DSM-5). It was initially described as potentially capturing individuals with a DSM-IV, Text-Revised (DSM-IV-TR) diagnosis of autism, perhaps those with pervasive developmental disorder-not otherwise specified (PDD-NOS), who would no longer meet the more stringent DSM-5 ASD criteria. To date, limited studies have examined SCD, and its impact remains unknown.
Objectives: As part of two systematic literature reviews and meta-analyses, the first conducted prior to DSM-5 implementation and a recently completed five-year follow-up, we assessed the potential of an alternative diagnosis of SCD for individuals who met DSM-IV-TR but not DSM-5 autism spectrum disorder (ASD) diagnostic criteria.

Methods: We used the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines in conducting these reviews. We searched the literature for studies published between January 2011 and March 2013 (first review) and April 2013 and July 2018 (second review) that applied DSM-IV-TR and DSM-5 ASD criteria to study samples and, for those who did not meet DSM-5 ASD criteria, applied SCD criteria. Scientific rigor was rated using the Quality Appraisal of Reliability Studies. We pooled study data by extracting the number of individuals who met DSM-IV-TR ASD criteria but no longer met criteria for an ASD diagnosis under DSM-5 and, of those, the number who would alternatively meet SCD criteria. We estimated a pooled effect for the proportion of individuals meeting SCD criteria, and we investigated model heterogeneity and publication bias.

Results: Nine studies (four from the first review and five from the second review) representing data from 555 individuals assessed for SCD were included. Of these, 5 studies specifically examined ASD subtypes. There was no evidence of publication bias. While statistical significance was not achieved, the pooled effect suggests that less than one-third [28.8%; (95%CI 13.9-50.5), p=0.06] of those who met DSM-IV-TR but not DSM-5 ASD diagnosis would meet criteria for SCD. Heterogeneity was greater than expected by chance alone (Cochran's Q = 57.5, $p<0.001$, $I^2 = 86.1$). In studies which examined ASD subtypes, those with PDD-NOS (23 of 47 individuals; 49%) were less frequently captured by SCD compared to either Autistic Disorder or Asperger's Disorder.

Conclusions: Overall, SCD does not appear to capture the majority of those with ASD diagnosis using DSM-IV-TR but who no longer maintain their diagnosis under DSM-5. While subtype data are limited, SCD appears least likely to capture those with DSM-IV-TR PDD-NOS who do not meet DSM-5 ASD diagnostic criteria. The impact of SCD as a new, independent diagnosis from ASD, and its potential to serve as a gateway for services, are important areas for future research.

86 **236.086** The Misnomer of "High Functioning Autism": IQ Is a Weak Predictor of Functional Abilities at the Time of Diagnosis of Autism Spectrum Disorder

G. A. Alvares[1,2], *K. Bebbington*[1], *D. B. Cleary*[1], *K. Evans*[1,3], *E. J. Glasson*[1], *M. T. Maybery*[4], *S. Pillar*[1], *M. Uljarevic*[5], *K. J. Varcin*[1], *J. Wray*[6] *and A. J. Whitehouse*[1], *(1)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, QLD, Australia, (3)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Bentley, Australia, (4)School of Psychological Science, University of Western Australia, Perth, Australia, (5)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (6)State Child Development Service, Western Australia Department of Health, Perth, Western Australia, Australia*

Background:
'High functioning autism' is a term often used interchangeably for individuals with autism spectrum disorder (ASD) without an intellectual impairment (or Intellectual Disability, ID). Over time, this term has become synonymous with expectations of greater functional skills and long-term positive outcomes, despite contradictory clinical observations. Because an adaptive functioning assessment is not required for a diagnostic evaluation in many settings, it is often assumed that an individual's cognitive estimate (intelligence quotient, IQ), particularly those IQs that are

>70, approximate functional adaptive ability. While there has been some research investigating the relationship between IQ and adaptive functioning in ASD, very little has focused on individuals at the time of diagnosis. Understanding whether IQ is an appropriate proxy for adaptive functioning has important clinical implications for service provision and funding allocated for supports.

Objectives: This objective of this study was to investigate the relationship between adaptive behavior, IQ and age at diagnosis in ASD.

Methods: Participants part of an ongoing prospective register in Australia (The Western Australian Register for Autism Spectrum Disorder), notified by their diagnosing clinician(s) at the time of diagnosis. Established in 1999, the register currently contains details of more than 6000 cases, with information collected about diagnostic criteria met, co-occurring conditions, basic demographic data, and details of any diagnostic, cognitive, language and adaptive functioning assessments conducted. Cases were selected if they were ≤ 18 years at diagnosis, had a cognitive estimate and adaptive functioning scores recorded. This left a sample of n = 2222, which were then grouped by presence (n = 1039) or absence (n = 1183) of ID. Adaptive functioning was reported using the Vineland Adaptive Behavior Scales (VABS).

Results: As expected, VABS scores were significantly lower in the ID group, and IQ estimates significantly correlated with adaptive functioning scores across the whole sample. However, weaker sized correlation coefficients were observed between IQ and VABS in the group without ID, particularly for the Socialization subscale which fell below the threshold for statistical significance. Regression models suggested that IQ was a weak predictor of VABS composite and subscale scores after controlling for sex for children without ID. When comparing difference scores between IQ and VABS scores, the ID group's adaptive behavior estimates were close to reported IQs, while VABS scores fell significantly below IQs for children without ID. The gap between IQ and VABS scores increased with increasing age at diagnosis for all children.

Conclusions: These data indicate that estimates from IQ alone are an imprecise proxy for functional abilities when diagnosing ASD, particularly for those without ID. We argue that 'high functioning autism' is an inaccurate clinical descriptor when based solely on IQ and this term should be abandoned in research and clinical practice. We also recommend functional adaptive assessments be considered a key component of a comprehensive diagnostic evaluation, to facilitate more targeted service delivery and provision of adequate funding for the level of support and needs required on an individual basis.

87 **236.087** The Overlap of Autism Symptoms in Children with Williams Syndrome

R. Kirchner[1] *and K. M. Walton*[2]*, (1)The Ohio State University, Columbus, OH, (2)Nisonger Center, The Ohio State University, Columbus, OH*

Background: Williams syndrome (WS) is a neurodevelopmental disorder caused by a deletion of approximately 26 genes on chromosome 7 (7q11.23) (Peoples et al., 2000), and is commonly associated with hyper-sociability. However, despite this pattern of extreme friendliness, individuals with WS display an increased prevalence of autism spectrum disorder (ASD). Previous research investigating the presence of ASD symptoms in WS suggests that individuals with WS display elevations both on assessments measuring symptoms of autism (Lough et al., 2015) as well as gold-standard autism diagnostic assessments (Klein-Tasman, Phillips, Lord, Mervis, & Gallo, 2009).

Objectives: The objective of this study is to investigate the presence of behaviors associated with autism across different symptoms areas (as measured by the treatment scales of the Autism Spectrum Rating Scales; ASRS). Additionally, this study aims to investigate symptoms at the item level, to make recommendations as to which symptoms may best differentiate those with WS who have ASD from those who do not.

Methods**:** Parents (n=167) of children between 6 and 18 years of age completed survey data online as part of a larger study on ASD, Down syndrome, and WS. This poster aims to focus on the data from the ASD (n=39) and WS (n=45) groups. For this study, parents were asked to report child diagnoses and demographic information as well as complete an autism screener (Social Communication Questionnaire; SCQ) and a dimensional measure of autism symptoms (ASRS). An overall analysis was done to examine autism symptom elevation on the total score of the ASRS. Following this, children in the WS group were then divided into screen positive (n=20) and screen negative groups (n=25) based on whether or not they met the SCQ cut off score of 15.

Results: Overall, the WS group had an ASRS total score significantly higher than the mean score of 50 (M=65.24,SD=6.03), although this was significantly lower than the mean of the ASD group (M= 71.74, SD=5.04; ps<.001). Results comparing ASRS total scores showed that both the WS-screen negative and autism groups, and the WS-screen negative and WS-screen positive groups (ps<.001) were significantly different from one another. However, there was no difference between the autism and WS-screen positive groups. Further analyses using the eight treatment subscales of the ASRS revealed a similar pattern. Analyses at the item level revealed that questions relating to complex social skills (displaying interests in other's ideas, noticing social cues, understanding the point of view of others), as well as over-reactivity to loud noises may best differentiate these groups.

Conclusions: Results of this study further support previous research suggesting that individuals with WS exhibit elevated symptoms of autism. Although individuals with WS in this sample displayed significantly higher symptoms of autism (as demonstrated by the significantly higher ASRS total score), results suggest that measures such as the ASRS can differentiate between individuals with high vs. low symptoms of autism. Additionally, analyses at the item level suggest potential targets for symptom areas that may best differentiate those with WS who have ASD from those who do not.

88 **236.088** The Relationship of Intellectual Disability to Traditional and Distinct Anxiety Presentations in Children with ASD

C. M. Kerns[1]*, B. Winder-Patel*[2]*, M. Solomon*[3]*, A. M. Iosif*[4]*, S. Gam*[5]*, B. Heath*[6] *and D. G. Amaral*[6]*, (1)University of British Columbia, Vancouver, BC, Canada, (2)MIND Institute, University of California, Davis, Sacramento, CA, (3)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA, (4)Public Health Sciences, University of California Davis, Davis, CA, (5)UC Davis MIND Institute, Sacramento, CA, (6)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA*

Background:

Research suggests that children with ASD present with "traditional," anxiety disorders (e.g., specific phobia, generalized, separation, and social anxiety) as well as distinct forms of anxiety, such as fears of change and idiosyncratic phobias (e.g., fear of gloves). A prior study found that traditional and distinct anxieties can be reliably differentiated and that traditional, but not distinct, anxiety symptoms are positively associated with language ability in verbal children on the spectrum. Yet, rates of traditional and distinct symptoms have not been compared in children with

ASD with and without intellectual disability (ID).

Objectives:

Research suggests that children with ASD present with "traditional," anxiety (e.g., specific phobia, generalized, separation, and social anxiety) as well as distinct forms of anxiety, such as fears of change and idiosyncratic phobias (e.g., fear of gloves). A prior study found that traditional and distinct anxieties can be reliably differentiated, and that traditional, but not distinct, anxiety symptoms are positively associated with language ability in verbal children on the spectrum (Kerns et al., 2014). Yet, rates of traditional and distinct symptoms have not been compared in children with ASD with and without intellectual disability (ID).

Methods:

63 youth with ASD (ages 9–13 years: *M*=11.08, SD=1.82; 78% male; 44% with ID) were part of the middle childhood follow-up of a rigorous longitudinal study of biological and behavioral correlates of ASD known as the Autism Phenome Project (APP). Anxiety symptoms were assessed via the Anxiety Disorders Interview Schedule–Parent/Autism Spectrum Addendum (ADIS/ASA), a semi-structured interview validated to assess 10 types of traditional and distinct anxiety in ASD. The highest traditional and distinct clinical severity ratings (CSR; Range 0-8, 4 = cut-off for impairment) were used to categorize each child's anxiety presentation and assess concordance with the report of anxiety symptoms exceeding clinical cut-offs on brief parent-report measures, including the CBCL, MASC, and SCARED.

Results: Per the ADIS/ASA, 68% of total children presented with impairing anxiety (CSR ≥ 4), including: 22% traditional anxiety only, 19% distinct anxiety only, and 27% with both. Rates of impairing distinct anxiety (ID 45% v. No ID 46%) and traditional anxiety (ID 39% v. No ID 60%) were not significantly different in children with, versus without, ID. Yet, though children without ID presented with varied traditional anxiety disorders (phobia 49%, generalized anxiety 26%, social anxiety 14%, separation anxiety 11%), those with ID had only phobia (36%) and OCD (4%). In contrast, both children with and without ID presented with distinct anxieties, including social confusion fears (10%, 9%), idiosyncratic phobia (14%, 14%), fears of change (14%, 23%), and worries about special interests (3%, 11%). Brief parent-report measures had limited sensitivity in the sample, particularly amongst those with ID (Table 1).

Conclusions: This study provides further evidence of both traditional and distinct presentations of impairing anxiety in youth with ASD and suggests that brief parent measures lack sensitivity. Anxiety may be missed in youth with ASD when the content of their worries/fears varies from traditional conceptualizations or when their cognitive and their language abilities are impaired.

89 **236.089** The Reliability and Validity of the Social Responsiveness Scale to Screen for Autism Spectrum Disorder in Vietnamese Children

*P. Hong Nguyen[1], M. E. Ocansey[2], M. Miller[3], D. T. K. Le[4], **R. J. Schmidt**[5] and E. Prado[2], (1)Thai Nguyen University of Pharmacy and Medicine, Thai Nguyen, DC, Viet Nam, (2)Program in International and Community Nutrition, University of California Davis, Davis, CA, (3)University of California, Davis, MIND Institute, Sacramento, CA, (4)Thai Nguyen University of Pharmacy and Medicine, Thai Nguyen, Viet Nam, (5)Public Health Sciences, University of California Davis, Davis, CA*

Background:

The Social Responsiveness Scale (SRS) has been validated in high income countries, but not yet in low and middle-income countries.

Objectives:

We assessed the reliability and validity of a Vietnamese-translated SRS to screen for autism spectrum disorder (ASD).

Methods:

We used a 3-phase study in 173 Vietnamese caretakers and their children (ages 4-9 years) that piloted, reliability tested, and validated the translated SRS.

Results:

We found that the translated and culturally adapted Vietnamese SRS demonstrates high reliability (0.82–0.83), validity (0.88–0.89), sensitivity (93%) and specificity (98%) for identification of children with ASD in Vietnam. The optimal cutoff was 60 for both total raw scores and T-scores. Both SRS long and short forms performed adequately in screening for children with ASD.

Conclusions:

Access to validated screening measures is limited in low and middle-income countries. The translated and culturally adapted Vietnamese SRS showed good reliability, validity, and sensitivity for identification of children with ASD in Vietnam. Future studies should examine the utility of culture-specific norms.

90 **236.090** The Systematic Observation of Red Flags for Autism in the First Year of Life for Infants at Risk

***M. Pileggi**[1], N. Brane[1], J. Bradshaw[2] and A. Wetherby[3], (1)Marcus Autism Center, Atlanta, GA, (2)Department of Psychology, University of South Carolina, Columbia, SC, (3)Florida State University Autism Institute, Tallahassee, FL*

Background: Studies focused on high-risk (HR) siblings of children with ASD demonstrate that core ASD symptoms can be detected as early as 12 months (Bryson, et. al, 2008; Watson et. al, 2013; Zwaigenbaum et. al, 2005), highlighting the opportunity for earlier screening. The Systematic Observation for Red Flags (SORF/Cite) is an observational screening tool based on DSM-5 diagnostic criteria designed to quantify presence of ASD symptoms. The SORF has been validated to differentiate 16-24 month-olds with ASD from those with developmental delay and typical development (Dow et al., 2017). Given the pressing need for earlier detection, the current study examined utility of the SORF among 12-month-old HR infants.

Objectives: In a prospective, longitudinal study of infant siblings, we examined: 1) sensitivity and specificity of the SORF at 12-months for predicting ASD at 24-months, and 2) associations between 12-month SORF performance and 24-month phenotypic outcome

Methods: Participants included 122 infants seen for communication, developmental and social-behavioral assessment at 12 and 24-months of age. Participants were either HR (N=45,) or low-risk infants (LR; N=77). The Communication and Symbolic Behavior Scales-DP Behavior Sample (Wetherby & Prizant, 2002) and the Mullen Scales of Early Learning (Mullen, 1995) were administered at 12-months. The SORF was coded via video

review of the CSBS and provides a measure of ASD symptoms (represented as a score and total number of red flags) across two domains: Social Communication and Social Interaction (SC) and Restricted Repetitive Behaviors (RRB). At 24-months, participants received a diagnostic evaluation that included the CSBS, Mullen, ADOS-2, and clinician best estimate diagnosis.

Results: See results in Table 1 and 2. 12-month-olds later diagnosed with ASD scored significantly higher than TD infants on the SORF SC domain, RRB domain, and overall composite. Infants with ASD also had significantly more SC and total red flags (RFs), with the difference in RRB RFs approaching significance. Highest sensitivity and specificity was observed for the SORF Composite with a cutoff of 18, which correctly identified 24 of 31 ASD infants, yielding a sensitivity of .77 and specificity of .76. Optimal cutoff for SORF Total RFs was 7, with 20 of 31 infants having 7 or more RFs at 12 months, yielding a sensitivity of.65 and specificity of.75. The SORF composite score and SC domain score at 12-months were both highly correlated with ADOS-2 CSS and verbal and nonverbal skills at 24-months.

Conclusions: Our results show that 12-month-olds later diagnosed with ASD exhibited significantly greater SORF total and SC domain scores compared to TD-infants. Additionally, SORF Composite cutoff of 18 resulted in higher sensitivity and specificity than SORF red flags cutoff of 7. SORF RRB scores were less associated with ASD when considered in isolation, in line with other research showing RRBs unfold over time and are quite subtle in the first year (Zwaigenbaum et. al, 2015, Bryson et. al 2008). The high sensitivity and specificity of the SORF at 12-months highlights the need for 12-month screening studies that include larger samples of both high-risk and community-based infants.

91 **236.091** Toddlers with Tuberous Sclerosis Complex with Comorbid Autism Spectrum Disorder at High Risk for Adaptive Behavior Delay By 36 Months.

D. A. Pearson[1], *S. S. Hashmi*[1], *H. Northrup*[1], *D. A. Krueger*[2], *A. W. Byars*[2], *D. S. Murray*[2,3], *M. E. Williams*[4], *S. E. O'Kelley*[5], *E. Hanson*[6], *N. Bing*[2], *B. Kent*[2], *R. Mansour*[1] *and M. Sahin*[6], *(1)McGovern Medical School, Univ. TX Health Sci Cntr-Houston, Houston, TX, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Autism Speaks, Boston, MA, (4)Univ. of Southern California/Children's Hosp. of Los Angeles, Los Angeles, CA, (5)University of Alabama at Birmingham, Birmingham, AL, (6)Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background:
Infants born with TSC have a 40-50% risk for developing Autism Spectrum Disorder (ASD), a condition strongly associated with deficits in adaptive behavior development. Previous investigations have noted that children with TSC are at high risk for intellectual and adaptive deficits (e.g., Kopp et al., 2008), and that significant declines in adaptive function occur over time in individuals with TSC (van Eeghen et al, 2011). Although concerns with adaptive behavior dysfunction has been noted in TSC, little is known about the relationship between adaptive function and ASD in very young children (e.g., toddlers) with TSC

Objectives:

In this study, we compare developmental trajectories in adaptive behavior between age 18 and 36 months in toddlers with TSC, to determine if a diagnosis of ASD is associated with a higher risk over time for adaptive deficits.

Methods:

Sample was composed of toddlers who had completed their 36-month TACERN project evaluation. The ASD group consisted of 19 toddlers (15 boys, mean age= 36.5 mo., mean MSEL=53.3). The non-ASD group consisted of 60 toddlers (30 boys, mean age= 36.5 mo., mean MSEL= 85.3). Adaptive function was assessed using the Vineland Adaptive Behavior Scales, 2nd Ed., with parents serving as informants. Time-series analysis techniques (in which each child's development is tracked over time) were used to compare the developmental trajectories in VABS-II domains standard scores between 18 and 36 months in the two groups.

Results:

At 18 months, the VABS-II scores were lower in TSC+ASD compared to non-ASD (p<0.001). From 18 months to 24 months, the trajectories of adaptive development remained steady in both groups (p>0.05). However, between 24 and 36 months, significant group differences emerged in developmental trajectories (p<0.01). Toddlers with TSC+ASD demonstrated significant standard score decreases in Communication (-8.5), Daily Living Skills (-15.9), Socialization (-13.5), and the Adaptive Behavior Composite (-13.2) (p<0.05 for all). In contrast, for non-ASD group, standard scores decreased by 2.1, 4.4, 2.7 and 7.9--none of which was significant. Examination of subdomain raw scores suggested that while both groups gained new skills between 24 and 36 months, the rate of acquisition of new adaptive skills was much slower in the TSC+ASD group.

Conclusions:

Given that adaptive deficits are associated with suboptimal developmental outcomes, the declining trajectories of adaptive skill development in TSC+ASD suggests that by 36 months, toddlers with TSC+ASD are at significantly higher risk for suboptimal outcomes—similar to ASD-related adaptive concerns seen in the general pediatric population.

92 **236.092** Training Pediatricians to Implement Autism-Specific Screening Tools: A Review of the Literature

R. E. Murray[1] *and E. E. Barton*[2], *(1)Hope Autism & Behavioral Health Services, LLC, Nashville, TN, (2)Special Education, Vanderbilt University, Nashville, TN*

Background: The American Academy of Pediatrics recommends using an autism-specific screening tool for all young children at primary care well visits. Screening can detect risk of Autism Spectrum Disorder (ASD) in young children whose parents and pediatrician may not have developmental concerns. The identification of children with or at-risk for ASD increases their access to early intervention services, which helps ameliorate skill deficits associated with Autism. Recent studies indicate pediatricians use autism-specific screening tools infrequently. Some research has been conducted to determine whether providing training to primary care providers increases screening practices; however, evidence-based practices for training pediatricians to conduct ASD-screenings have not been identified. We conducted a review of the research on training primary care providers (e.g., pediatricians) to conduct ASD-screenings with young children and their families. This information can be used to advance research, policy, and practice.
Objectives: The purpose of this review was to systematically review the research on training primary care providers to conduct ASD screenings including challenges related to their use and describe the findings.

Methods: Our literature search included terms for participants (pediatrician* OR doctor* OR physician* OR clinic* OR primary care), intervention

(professional development OR training* OR workshop* OR course OR teaching), and outcome (screen* OR diagnos* OR intervention* OR ADOS* OR M-CHAT* OR Autis*). Article screening was conducted in three steps: title screening, abstract screening, and full-text screening. Two coders extracted data related to population, design, independent variable characteristics, and study outcomes. All studies were evaluated using Cochrane's Risk of Bias tool.

Results: Few studies reported characteristics of participants. Five of the 12 studies reported inclusion criteria for providers. Most studies reported the setting; all reported on-site training. >50% of the studies reported objectives; they included goals related to knowledge/education and practice improvement. A variety of screening tools were used across studies. 75% of the studies reported an increase in the use of the screening tools following training. 66% included surveys, which reported increases in provider confidence and likelihood to use the tool. Knowledge consistently increased while the resulting referral rates varied by study and age group. All studies were rated as having a high risk of bias.

Conclusions: Overall, there is a lack of high-quality research in this area. Few research groups have conducted studies examining the effect of training primary care providers to implement Autism-specific screening tools. Methodological details in several studies were insufficient for replication. Furthermore, several studies included more than one training method, making it difficult to determine which parts of the training package were effective. Several directions for future research are suggested. Component analyses should be conducted to determine the most effective parts of training. Future studies should be held to higher rigor standards and work to decrease bias. Additionally, given changes in provider confidence, knowledge, and practice were observed, future research should investigate the cause of the increase in screenings. Finally, given the limited availability of resources for evaluations and early intervention, future research should investigate the costs and benefits associated with universal screening for Autism.

93 **236.093** Understanding the Diagnostic Process of Autism Spectrum Disorder in Females: The Role of Initial Diagnosis and Comorbidities

A. Aitken[1], *C. Song*[2] *and C. A. McMorris*[3], *(1)School and Applied Child Psychology, University of Calgary, Calgary, AB, Canada, (2)University of Calgary, Calgary, AB, Canada, (3)Werklund School of Education, University of Calgary, Calgary, AB, Canada*

Background: To ensure early intervention, it is important that children with autism spectrum disorder (ASD) receive a diagnosis as early as possible, as identifying and diagnosing ASD early can improve an individual's quality of life and reduce social, emotional, and behavioural problems (Bargiela, Steward, & Mandy, 2016). ASD can be diagnosed as young as two years of age; however, there are many children that do not receive a diagnosis until school age, defined here as five years of age and older (Pringle et al., 2012; Hiller, Young, & Weber, 2015). It has been suggested that the heterogeneity of symptoms and the presence of comorbid mental and physical health disorders can contribute to a late diagnosis (McMorris et al., 2013). Sex also contributes to late diagnosis, as females typically receive a diagnosis later than males (Duvekot et al., 2017; Hiller, Young, & Weber, 2016). Inconsistencies in the current literature have lead to equivocal conclusions related to the role of sex in children receiving a late diagnosis of ASD. Thus, it is unclear if females experience more instability in their diagnostic process than males.
Objectives: Given the inconsistencies in the existing literature, the primary objective of this study is to determine how sex impacts the diagnostic process of females with ASD. In particular, the study will first investigate if females, compared to males, have *more* instability in their diagnostic process, as indicated by a) taking longer to receive their ASD diagnosis; and b) receiving numerous initial diagnoses prior to their ASD diagnosis. A secondary aim of the study is to determine whether the existence of co-occurring mental health disorders may impact these sex differences in the diagnostic process.

Methods: Caregivers of children 18 years of age or younger, and who have a primary diagnosis of ASD are asked to complete a questionnaire that collects information about: 1) demographic information (i.e. age and sex); 2) initial diagnosis; and 3) multiple diagnoses and comorbid psychiatric or health conditions. Participants are recruited through: 1) autism-specific community agencies in Calgary, Alberta, who support children; 2) the University of Calgary external research page; 3) Facebook ASD support groups; and 4) the ASD Diagnostic Clinic at Alberta Health Services.

Results: We currently have 18 male and 14 female participants, and anticipate 35 males and 35 females by Spring 2019. Descriptive statistics will be conducted for all variables, including frequencies, means, standard deviations, and ranges. To answer the aforementioned research questions/aims, multiple regression models will be used.

Conclusions: Understanding whether sex impacts the process of receiving an ASD diagnosis can inform diagnostic tools for clinicians to determine early signs for diagnosis, particularly in females. The importance of determining sex differences in the first diagnosis a child receives can provide information as to whether clinicians are misdiagnosing females at a higher rate than males. These findings will aid health practitioners in their awareness of early ASD symptoms in both sexes, developing community outreach and intervention programs, and ultimately improve outcomes for these children and their families.

94 **236.094** Use of the CHILD Behavior Checklist 11/2–5 As a Screening Tool to Identify High-Risk Siblings Who Require Clinical Assessment

F. Apicella[1], *V. Costanzo*[1], *N. Chericoni*[1], *R. Lasala*[2], *F. Muratori*[3], *M. Prosperi*[1], *R. Tancredi*[4], *A. Mancini*[5] *and M. L. Scattoni*[6], *(1)IRCCS Fondazione Stella Maris, Calambrone (Pisa), Italy, (2)IRCCS Fondazione Stella Maris, Calambrone, Italy, (3)Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, (4)IRCCS Stella Maris Foundation, Calambrone (Pisa), Italy, (5)Stella Maris Foundation IRCCS, Pisa, Italy, (6)Research Coordination and Support Service, Istituto Superiore di Sanità, Rome, Italy*

Background:
Younger siblings of children with autism spectrum disorder (ASD) are at higher risk of developing ASD themselves, therefore their surveillance by community health providers is pivotal in order to determine whether they need referral for further assessments. A variety of standardized tools and screening instruments have been developed to inform clinical decision-making. However, early identification is complex, especially in children who may show sub-clinical ASD symptoms or other developmental problems due to a familial genetic risk.

Objectives:

This study aimed to investigate the utility of a parent completed questionnaire - the Child Behavior Checklist (CBCL 11/2–5) - in identifying toddlers who require further specialist assessment, in a population of siblings at genetic risk for ASD.

Methods:

CBCL profiles of 40 toddlers (18 mos.) at genetic risk for ASD, recruited through a surveillance programme, were compared with those of 40 toddlers with no familiarity for ASD (18-24 mos.) recruited through local kindergartens. Toddlers in the high-risk group underwent clinical assessment with the Autism Diagnostic Observation Schedule -ADOS and a best estimate diagnosis was obtained, in accordance with DSM-5 criteria (Outcomes: 9 ASD; 31 no-ASD). Scores on the CBCL questionnaire were compared within the sibling group, to evaluate possible differences between siblings with and without an ASD diagnosis and correlated with the ADOS clinical assessment (ADOS total score).

Results:

As a group, siblings at risk for ASD did not present significant differences in their CBCL profiles in comparison with the TD group. Subtyping the sibling group on the basis of the clinical diagnosis enabled us to observe that 5 of the CBCL scales significantly differentiated siblings with an ASD outcome from siblings with a familial risk but no ASD outcome ($p < .05$): Somatic Complaints, Withdrawn, Attention Problems, Internalizing Problems and Autism Spectrum Problems. Indeed, higher scores on these scales were positively correlated with higher ADOS total scores ($p < .05$) and an outcome of ASD as estimated by clinical judgement ($p < .05$).

Conclusions:

These preliminary findings suggest the utility of the CBCL scales, in particular, of 5 scales (Somatic Complaints, Withdrawn, Internalizing, Attention problems, and Autism Spectrum Problems) in identifying siblings at genetic risk for ASD who need further specialist assessment for ASD, as early as 18 months of life.

95 **236.095** Using a Portable Eye-Tracking Device to Measure Social Impairment in Children with Autism Spectrum Disorder

E. Wilkinson[1], *F. Barrientos Porras*[2], *M. Zimic*[2], *R. Gilman*[3], *M. A. Rowe*[1], *P. M. Siper*[1], *A. Kolevzon*[1] *and M. P. Trelles*[1], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Universidad Peruana Cayetano Heredia, Lima, Peru, (3)Johns Hopkins University, Baltimore, MD*

Background: Autism spectrum disorder (ASD) is a neurodevelopmental condition affecting 1 in 68 children and carrying a public health burden of $69 billion per year. Available ASD treatments are reliant on early and accurate identification. Expert clinicians can reliably diagnosed ASD by age two; nonetheless, research has found that a diagnosis of ASD for underserved and minority populations can be delayed several years despite parental concerns. Using eye-tracking measures, visual attention in ASD has been the focus of extensive research as an early and quantifiable marker of the disease. Indeed, diminished visual social attention and atypical non-social engagement have been correlated with increased ASD symptomatology.

Objectives: The overall objective of this study is to evaluate the utility of a tablet-based eye tracking paradigm to asses social and non-social engagement in children with ASD as a diagnostic aid in community settings. We will also examine the relationship between gaze preference to social and non-social scenes with measures of social impairment, cognitive and adaptive functioning.

Methods: Twelve children with ASD, and 11 age-matched typically developing (TD) controls were included in this study. Children with ASD were diagnosed based on psychiatric evaluation, DSM-5 criteria, and the ADOS-2. All participants received measures of cognitive function. In addition, children with ASD were administered the Vineland Adaptive Behavior Scale- 2nd edition (VABS-2). All participants completed the eye-tracking paradigm, which consists of a 50 second video in which a social scene and a non-social scene are displayed side-by-side. The algorithm measures time spent looking at: (1) social scene, (2) non-social scene, (3) distraction (i.e. middle of the screen, outside screen frame). A subset of TD and ASD participants (n=11) completed the Social Responsiveness Scale 2nd Edition (SRS-2).

Results: Gaze preference for the *social scene* was significantly higher for the TD group as compared to ASD participants (ASD: M=16.58, SD=12.2; TD: M=33.55, SD=16.36; p=0.01). There was no difference in time spent looking at the *non-social scene* (ASD: M=18.63, SD=13.01; TD: M=13.01, SD=11.27; p=0.317) or the *distraction* condition (ASD: M=64.75 SD=19.72; TD: M=52.88, SD=21.94; p=0.223). Gaze preference towards the *social scene* was not correlated with the adaptive behavior composite on the VABS-2 ($r = 0.108$, $p = 0.505$) or with full IQ scores ($r = 0.293$, $p=0.197$). SRS-2 total scores and time spent looking at the *social scene* had a negative relationship approaching significance ($r=-0.592$, $p = 0.055$).

Conclusions: Consistent with the existing literature, we found that children with ASD spent significantly less time looking at the *social scene* as compared to their TD peers. Importantly, gaze preference was not impacted by measures of cognitive or adaptive functioning. Interestingly, our results suggest that social impairment as measured by the SRS-2 is inversely correlated with gaze preference towards the social scene, suggesting that the eye-tracking paradigm might be sensitive social functioning in children with ASD and, as such, useful as a measure of treatment response. Overall, these results highlight the utility of the application and warrant continued larger-scale investigation.

96 **236.096** Using the Social Responsiveness Scale–Short Form to Assess ASD Characteristics in Children with Dup15q Syndrome

C. DiStefano[1], *C. Hyde*[2] *and S. Jeste*[3], *(1)University of California Los Angeles, Los Angeles, CA, (2)Semel Institute, UCLA Medical Center, Los Angeles, CA, (3)University of California, Los Angeles, Los Angeles, CA*

Background: The Social Responsiveness Scale (SRS) is a quantitative measure of autism symptoms, which is widely used in studies of autism risk and phenotypic characterization of associated genetic syndromes. Due to concerns over the vulnerability of the SRS to non-ASD traits such as cognitive and language abilities, Sturm and colleagues (2017) developed a short form SRS, using item response theory to identify the least vulnerable items. The resultant 16-item short form was unidimensional and un-biased by language or non-verbal cognitive ability. In order to further evaluate the performance of the SRS short form in children with cognitive and language impairment, we examined the SRS scores of children with duplications of 15q11.2-q13.1 (dup15q syndrome), which is one of the most common copy number variants associated with ASD and intellectual disability (ID). Dup15q syndrome is characterized social communication deficits, cognitive and language impairment, hypotonia, motor impairment, and epilepsy (Battaglia etal., 2010). These widespread and significant impairments present a challenge to accurate measurement of ASD characteristics.

Objectives: 1) Examine the association of short-form SRS scores with verbal and non-verbal cognitive ability, and other measures of ASD characteristics (SCQ, ADOS) in children with dup15q syndrome, 2) compare these associations in children with dup15q syndrome and age and IQ-matched children with idiopathic ASD and ID.

Methods: Participants included 31 children with dup15q syndrome (3-14 years; IQ *M(SD)* 35(22)), and an age and IQ-matched group of children with

idiopathic ASD (*N*=18). Participants were assessed using the Autism Diagnostic Observation Schedule (ADOS) and cognitive/developmental assessment (Mullen Scales of Early Learning or Differential Ability Scales). Parents completed the SRS and Social Communication Questionnaire (SCQ). The SRS was scored with original long form T-scores and revised short form totals.

Results: In children with dup15q syndrome, both long and short form SRS scores were negatively associated with verbal IQ (*r*=-.61, *p*<.001; *r*=-.42, *p*=.02, respectively), and non-verbal IQ (*r*=-.7, *p*<.001; *r*=-.46, *p*=.009). Long and short form SRS scores showed moderate positive association with ADOS severity scores (*r*=.62, *p*=.004; *r*=.56, *p*.01) and SCQ scores (*r*=.69, *p*=.003; *r*=.57, *p*=.02). In contrast, neither long nor short form SRS scores were associated with verbal or non-verbal IQ in the ASD+ID group, but did show the expected positive association with SCQ and ADOS scores (*r*-values .65-.7, *p*-values .008-.02).

Conclusions: SRS short form scores did not show an association with language or cognitive abilities in children with ASD+ID, consistent with the results from Sturm and colleagues. However, in children with dup15q syndrome, SRS short form scores were negatively correlated with language and cognitive scores, albeit with reduced correlations strength. Encouragingly, SRS short form did show the expected positive association with other measures of ASD characteristics in the dup15q sample. In children with dup15q, the short form SRS represents an improvement over the long form in terms of reduced relationship to non-ASD characteristics, but was not independent of those characteristics as in the ASD+ID sample. The SRS short form should be interpreted with caution when used in genetic syndromes with a high degree of impairment across domains.

97 **236.097** Utility of the M-CHAT-R for Identifying Autism and/or Developmental Disorder in a Representative Community Sample at the 18-Month Pediatric Visit

R. A. Sturner[1,2], *B. J. Howard*[3,4], *L. Stewart*[5,6], *S. M. Attar*[4], *P. E. Bergmann*[7] *and K. Bet*[4], *(1)Pediatrics, Center for Promotion of Child Development through Primary Care, Baltimore, MD, (2)Pediatrics, Johns Hopkins U School of Medicine, Baltimore, MD, (3)Pediatrics, The Johns Hopkins U Sch. of Medicine, Baltimore, MD, (4)Total Child Health, Baltimore, MD, (5)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (6)Center for Promotion of Child Development through Primary Care, Baltimore, MD, (7)ForesightLogic, Shoreview, MN*

Background:
Autism screening is recommended by the AAP at both 18 and 24-month check-up visits (2006) and M-CHAT-R/F is the most popular screen. However, a USPSTF report (2015) did not recommend universal autism screening, citing inadequate data about current screening tool accuracy, specifically lack of information on children screened negative. Studies suggest that the Positive Predictive Validity of the M-CHAT is lower at 18 months than at 24 months, even with the required follow-up interview (Pandey, 2008) (Sturner, 2017). However, it has been argued that almost all false positive M-CHAT-R/F screens have alternative clinical value in detecting children with developmental disorder (Robins, 2013).

Objectives:

To determine the predictive utility of the M-CHAT-R with Follow Up Interview (M-CHAT-R/F) for concurrent autism and developmental diagnoses in a community pediatric sample at 18 months, including children screening negative.

Methods:

Parents of 11,878 children completed the M-CHAT-R at 18-month pediatric visits (16-20 mo.) via an online system (CHADIS). Children with positive screens (96) and age and practice matched controls (314) were recruited. All children had diagnostic evaluations using the ADOS-2 Toddler Version and Mullen tests with clinical impression of autism considered to be a positive for autism. Developmental disorder was defined as the typical criteria for early intervention services (score >1 ½ SD below the mean on two or more subscales or > 2SD on a single subscale).

Results:

The M-CHAT-R/F had significantly lower sensitivity (0.35 vs 0.73) compared to M-CHAT-R with significantly higher specificity (0.89 vs 0.64) but positive predictive value (PPV) tended to be low (0.37) and not significantly different than M-CHAT-R (0.27), and negative predictive value did not differ (0.88 vs 0.93). 51% of the MCHAT-R/F false positives were developmental delay (DD) positives. However, MCHAT-R/F correctly identified only 19% of the developmental screen (ASQ-3) false negatives as true positives for delay. When the entire group of autism +/or DD (Table 2) is considered slightly more than half are identified by the combination of MCHAT-R/F + ASQ (sensitivity 0.53). Addition of the Follow Up to M-CHAT-R+ ASQ lowers sensitivity (0.75 to 0.53) and NPV (0.80 to 0.74) but increases specificity (0.63 to 0.81) and PPV (0.55 to 0.61).

Conclusions:

We cannot assume that children 16-20 months old passing the M-CHAT-R/F are unlikely to have an autism diagnosis. The low sensitivity to the presence of autism was without the intended balancing benefit of increase in positive predictive value, the rationale for requiring a follow-up interview. If referral for developmental delay in addition to referral for autism is considered desirable, false positives are infrequent. However, the clinical utility of the recommended procedure (M-CHAT-R/F) false positives is considerably less if only children missed by a developmental screen are considered.

98 **236.098** Utility of the Screening Tool for Autism in Two-Year-Olds (STAT) to Detect Autism in Toddlers before 24 Months of Age in Taiwan: A Longitudinal Study

C. C. Wu[1] *and C. H. Chiang*[2], *(1)Department of Psychology, Kaohsiung Medical University , Kaohsiung, Taiwan (Province of China), (2)Department of Psychology, National Chengchi University, Taipei City, Taiwan*

Background:
Autism spectrum disorder (ASD) is thought as an innate developmental disorder. Over past decade, some studies reported that prevalence of ASD has increased markedly. However, compared to Western countries, the prevalence of ASD in Taiwan is lower. There are a few reasons that cause the differences of the prevalence, such as stigma in Chinese culture, policy of government etc. Previous studies reported that early intervention improved outcomes for toddlers with ASD. The benefits of early intervention highlighted the importance of earlier identification of toddlers with ASD. Knowing the importance of early identification, the American Academy of Pediatrics (AAP) has recommended that all infants receive universal screening for autism less than 24 months old (Johnson et al., 2007).

Objectives:

The purpose of the longitudinal study is to examine the predictive validity of the Screening Tool for Autism in Two-Year-Olds (STAT; Stone et al.,

2008) as a screening tool for detecting ASD in toddlers before 24 months of age in hospital-based clinical sample. The STAT is a 12 items interactive autism-specific screening tool, including four behavioral domains: play (2 items), requesting (2 items), joint attention (4 items) and imitation (4 items).

Methods:

There were 139 toddlers between 16 to 24 months (Time 1) participated the study and all toddlers were recruited from the teaching hospital in Chia-Yi area. 18 months after the assessment at Time 1, participants were invited for re-assessment and finally diagnosis. There were 119 children between 35 to 46 months (Time 2) received follow-up assessment. The average length of time between the initial and follow-up assessment s was 18.64 months (SD = 1.09). Finally, there are 57 children with ASD and 62 children with developmental delay (DD).

Results:

Using receiver operating characteristics (ROC), 2.25-2.75 was the optimal range of the total of the STAT as cut-off at Time 1. Using cutoff score of 2.25, the sensitivity was .88, and the specificity was .73. In addition, the positive predictive value (PPV) was 74.6%, while the negative predictive value (NPV) was 86.5%. Using cutoff score of 2.50, the sensitivity was .86, and the specificity was.81, the PPV was 80.3%, and the NPV was 86.2%. Using cutoff score of 2.75, the sensitivity was .74, and the specificity was.88, the PPV was 85.7%, and the NPV was 78.6%. The AUC was .87 at Time 1. Using ROC, 1.25-1.50 was the optimal range of the total of the STAT as cut-off at Time 2. Using cutoff score of 1.25, the sensitivity was .86, and the specificity was .71, the PPV was 73.1%, and the NPV was 84.6%. Using cutoff score of 1.50, the sensitivity was .70, and the specificity was.79, the PPV was 75.5%, and the NPV was 74.2%. The AUC was .82 at Time 2.

Conclusions:

The results of this study revealed that STAT showed high predicative validity for detecting ASD in toddlers before 24 months of age. This study indicated that the STAT is a promising good tool to differentiate the toddlers with ASD and toddlers with DD.

99 **236.099** Validation of a CBCL/6-18 ASD-Scale: Differentiation of Youths with ASD from Comparison Groups

***K. S. Ellison**, P. J. Castagna and T. E. Davis, Department of Psychology, Louisiana State University, Baton Rouge, LA*

Background: Broadband measures have been used to identify youth at risk for Autism Spectrum Disorder (ASD), including the *Childhood Behavior Checklist/6-18 (CBCL/6-18).* Only one study has created a 9-item ASD-scale utilizing items from *CBCL/6-18* to differentiate children with ASD from comparison groups (Ooi et al., 2010). However, its validity has not been examined

Objectives: This study investigated differences among children with ASD, Social Anxiety Disorder (SAD), Specific Phobia (SP), and those having no diagnoses (NODX) on the eight *CBCL/6-18* syndrome scales. The 9-item ASD-scale was examined to determine its ability to differentiate the ASD group from the other groups.

Methods: Nine youths with ASD (8 male; *M=9.66* years-old), 9 with SAD (4 male; *M=10.22* years-old), 9 with SP (5 male; *M=9.22* years-old), and 9 with NODX (7 male; *M=12.78* years-old) were included as part of a larger IRB-approved study. Diagnoses were confirmed by the *Childhood Autism Rating Scale, Second Edition (CARS-2)* and the *Anxiety Disorders Interview Schedule (ADIS-IV-C/P).* Full-Scale IQ was measured using the *WISC-V* (ASD *M*=94.00, *SD*=13.83; SAD *M*=99.67, *SD*=10.61; SP *M*=101.67, *SD*=7.97; NODX *M*=103.44, *SD*=8.03). The *CBCL/6-18* was completed by the primary caretaker. Consent/assent was obtained.

Results: A one-way MANOVA was run to determine the effect of diagnosis on the eight *CBCL/6-18* syndrome scales. The differences between diagnosis on the combined dependent variables was significant, $F(24, 73)=2.05$, $p=.01$; Wilks' $\Lambda=.23$. Follow-up univariate ANOVAs showed that Anxious/Depressed ($F(3, 32)=3.30$, $p=.03$), Social Problems ($F(3, 32)=5.82$, $p<.001$), and Aggressive Behavior ($F(3, 32)=6.17$, $p<.001$), scales were statistically significantly different between groups. Games-Howell post-hoc tests showed that the ASD group had significantly higher mean scores on Anxious/Depressed ($p=.04$), Social Problems ($p=.03$) and Aggressive Behavior ($p=.03$) than the NODX group and higher Social Problems ($p=.04$) than the SAD group. Cronbach's alpha was computed for the ASD-scale, for each group separately and the full sample. Surprisingly, ASD group had poor internal consistency (.43); when one item was removed (*#66. Repeats acts over and over*) it improved to .61. Acceptable internal consistency was found for the SP (.91), NODX (.77) groups and the full sample (.79). Three logistic regressions were used to test the ability of the ASD-scale to differentiate the ASD group from the comparison groups. All logistic regression analyses yielded significant results ($p<.05$), with variance accounted for by the ASD-scale ranging from 28.3% (ASD vs. SP) to 84% (ASD vs. NODX). Overall prediction success rates at 83.3% (sensitivity 88.9%, specificity 77.8%) for the ASD vs. SAD and SP groups, and an overall predication success rate of 88.9% for ASD vs. NODX.

Conclusions: The *CBCL/6-18* may be used in differentiating children with ASD from those with other disorders. High scores on the ASD-scale identified the majority of children in the ASD group, especially compared to the SAD and SP groups; low scores identified the majority of children being contrasted with the ASD group. Future research should address the limitations of the current study specifically, the small sample size, in order to determine if the internal consistency and predictive utility of the scale can be improved.

100 **236.100** Validity of the Autism Diagnostic Observation Schedule-2 (ADOS-2) in South Korean Toddlers and Preschoolers with ASD from 12-47 Months of Age

***K. S. Lee**[1], S. Jung[2], H. R. Thomas[3] and S. H. Kim[4], (1)Rehabilitation, Hanshin University, Seoul, Korea, Republic of (South), (2)Sewon Infant Child Development Center, Seoul, Korea, Republic of (South), (3)Psychiatry, Weill Cornell Medical College, White Plains, NY, (4)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY*

Background: The gold-standard diagnostic measure, the Autism Diagnostic Observation Schedule-2 (ADOS-2; Lord et al., 2014), has shown strong diagnostic validity in individuals with ASD, including young children from 12 to 47 months of age (Luyster et al., 2009; Gotham et al., 2007). However, the studies of the diagnostic validity of the ADOS have been limited to samples obtained from the Western countries, limiting the evidence for the valid use of the ADOS in the Eastern countries, although initial attempts have been made recently to examine its validity in Chinese (Sun et al., 2015) and Indian (Rudra et al., 2014) children with ASD. A recent translation of the ADOS-2 in Korean (2017) has increased the use of the ADOS in South Korea significantly for both research and clinical purposes, which highlights the urgent need to examine the validity of the ADOS for South Korean children.

Objectives: To provide the initial validity of the ADOS Toddler Module and Module 1-2 in South Korean toddlers and preschoolers.

Methods: The ADOS-2 was administered by a research team led by a research reliable clinician to 143 children clinically referred for ASD (68 children with ASD, 39 with non-spectrum (NS) disorders [e.g., developmental delays]), and 36 typically developing (TD) children recruited as a comparison group in a metropolitan area of South Korea. The mean age was 33.1 months (SD=9.1) and a mean nonverbal IQ, 81.5 (SD=25.1). Fifty-six children received the Toddler Module, 67 children, Module 1, and 20 children, Module 2. Algorithm and item scores were compared based on the ANOVAs for the ASD vs. NS/TD groups. Sensitivity and specificity using the ADOS algorithm cutoffs ("ASD cutoffs"; Lord et al., 2014) for each Module and age/language group were computed for the ASD vs. NS/TD diagnostic comparisons. Correlations (Pearson's *r*) between algorithm totals and developmental factors (e.g., nonverbal mental age, chronological age) were computed to examine the effects of these factors on the measurement of autism symptom severity.

Results: The ASD group showed significantly higher ADOS algorithm totals, and social affect and repetitive and restricted behavior (RRB) domain scores across all Modules ($p<0.05$) compared to the NS/TD groups. Likewise, the ASD group scored significantly higher on the majority of item scores on the diagnostic algorithms across all Modules, with the greatest variability in Toddler Module ($p<0.05$). Sensitivities were excellent, ranging from 94% to 100% across different Modules. Specificities varied more, ranging from 75% (Module 1, Few to No Words algorithm) to 100% (Module 2). Algorithm totals had mild-to-moderate correlations with NVMA and age (range=r=0.1 to 0.5).

Conclusions: The current study demonstrates promising, initial evidence for the diagnostic validity of the ADOS-2 for clinically ascertained, South Korean toddlers and preschoolers with ASD from 1-4 years of age. Results suggest that the ADOS-2 could be validly implemented as a diagnostic tool by highly trained clinicians, with minimal cultural adaptations, in research and clinical settings for South Korean children. This study is one of the first steps in current efforts for the cross-cultural validation of the ADOS-2 in non-Western countries.

101 **236.101** Variation between Clinician and Parent Report Outcomes Following a Trial of Pivotal Response Treatment

E. A. DeLucia[1], *A. Pomales*[1], *R. L. Gruen*[1], *L. L. Booth*[1] *and P. E. Ventola*[2], *(1)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background:
Assessment of autism spectrum disorder (ASD) symptom severity is an area of great clinical importance. Reliable measures of ASD symptom severity and change in symptom severity over time are necessary to quantify treatment response, yet there is no strong consensus in the literature of the best way to measure change in symptom severity (Bolte & Diehl, 2013). Two common methods of assessing change in symptom severity are parent-reported questionnaires and clinician-administered assessments. However, the literature is mixed as to the relationship between parent and clinician reports of ASD symptom severity as measures of treatment response (Stone, Hoffman, Levis & Ousley, 1994; Murray, Mayes & Smith, 2011).

Objectives:

The present study aimed to explore agreement between parent and clinician report of ASD symptom severity before and after Pivotal Response Treatment (PRT).

Methods:

The study sample consisted of 41 children ages 4-9 who were diagnosed with ASD. Participants received 16 weeks of PRT. All participants received a diagnostic and clinical characterization battery before and after treatment. Measures administered at pre-PRT and post-PRT included the Autism Diagnostic Observation Schedule (ADOS) and Social Responsiveness Scale – II Parent Report Form (SRS-II). Paired-samples t-tests were used to examine change in measures of ASD symptom severity. Pearson correlations were then used to examine the association between parent-rated and clinician-rated measures of symptom severity.

Results:

Paired-samples t-tests confirmed our previous findings of improvement in ASD symptom severity as reported by parents on the SRS-II (pre-PRT t-score M=73.95, post-PRT t-score M=68.32,$p<.001$) and as reported by clinicians on the ADOS Calibrated Severity Score (CSS; pre-PRT M=7.65, post-PRT M=6.90, $p=.037$). Pearson correlations between the change in SRS-II and the change in ADOS CSS revealed no correlation in symptom change on the two measures ($r=-.115$,$p=.503$). Furthermore, there was no significant correlation between the SRS-II and the ADOS CSS at pre-treatment or post-treatment time points (pre-PRT $r=-.220$,$p=.185$, post-PRT $r=.109$, $p=.505$). Additional Pearson correlations were run between all ADOS and SRS-II subscales, and no significant correlations were found. When controlling for gender, age, and IQ, partial correlations between the change in SRS-II and ADOS CSS remained insignificant.

Conclusions:

As a group, children improved in social communication skills following PRT; however, there was heterogeneity in treatment response. Improvement as measured by the ADOS did not relate to improvement as reported by parents on the SRS-II. This indicates that although PRT facilitated social communication skills in the sample as a whole, it may have an effect in heterogenous ways at the individual level. The ADOS tends to assess core social communication skills as well as understanding and insight, whereas the SRS-II measures skills related to social communication in naturalistic contexts. These results underscore the need for collecting outcome information from multiple informants across a variety of settings to obtain an accurate understanding of treatment response. Future studies should examine the relationship between other measures of treatment response and consider additional methods of quantifying social communication change.

102 **236.102** Visual Scanning Preferences of Low-Birth-Weight Preterm

ABSTRACT WITHDRAWN

Background: Visual scanning studies of preterm infants are still limited and contributions are relevant to establish their typical eye gaze pattern, aiming for the identification of early impairments, and ASD screening
Objectives: to evaluate time fixation in social and non-social figures and percentage of preterm that looked to the images.

Methods: cross-sectional study, with 31 preterm, eye gaze evaluated at 6 months of corrected age.Inclusion criteria: toddlers of six months of corrected age, of both sexs, born before 37 weeks of gestation and birth-weight equal or below 20000g, followed up at a multidisciplinary outpatient clinic for preterm infants.Exclusion criteria: genetic syndrome and/or presence of a major motor, visual or hearing deficiency, according

to the diagnosis recorded in the children's histories by the multiprofessional team that accompanied the children after their discharge from the neonatal unit. Preterm were evaluated with eye-tracking Mirametrix S2 Eye Tracker (version 2.0.0.057, Mirametrix Research Inc., 2011) with Mirametrix Viewer software (made in Canada) and 17 inches monitor. Six boards with social and non-social figures were projected in a screen computer each one for 5 seconds, successively, evaluating time and percentage of preterm that looked to each board. Socioeconomic data, clinical evolution during the hospitalization period in the neonatal intensive care unit and perinatal clinical data were collected from the charts .M-CHAT questionnaire was answered at 18 months of corrected age by the sample. This study complies with the guiding policies and principles for experimental procedures endorsed by the National Institutes of Health.

Results: The study sample was composed of 31 preterm with birth-weight equal to or below 2000g, 12 (38.7%) male. The mean gestational age at birth was 30.7 ± 2.7 weeks (24 to 35 weeks), the mean birth weight was 1362 ± 363 g (655 to 2000 g), Mother's age at birth was 28.2 ± 6.0 years and 73.9% belonged to socioeconomic class C (average income between U$500 and U$2000). None of the preterm had siblings with ASD diagnosis. Preterm showed bigger visual fixation time in social figures, if compared to non-social ones, regardless to the social figure position in the board. Similar percentage of preterm looked either to social or non-social figures, to social figures with direct or indirect look, and to the eyes or mouth of the social figure. No preterm was screened positively with M-CHAT

Conclusions: At 6 months of corrected age, preterm show capacity of eye gaze in eye-tracking test, preferring social figures, suggesting that this tool can be useful as another screening ASD instrument.

103 **236.103** What Are the Differences between Parent-Reported Autism Concerns on the M-CHAT-R/F and Clinical ADOS-2 Results?: Findings from a Sample of Ethnically Diverse, Low Income Families

J. L. Kuhn[1], *E. Hickey*[2], *S. Broder-Fingert*[2,3] *and E. Feinberg*[3,4], *(1)Pediatrics, Boston Medical Center, Boston, MA, (2)Boston Medical Center, Boston, MA, (3)Boston University School of Medicine, Boston, MA, (4)Boston University School of Public Health, Boston, MA*

Background: To detect autism spectrum disorder (ASD) in as many cases and as early as possible, the American Academy of Pediatrics recommends universal ASD-specific screening at 18- and 24-months. Pediatricians widely screen for ASD with the Modified Checklist for Autism in Toddlers Revised with Follow-Up (M-CHAT-R/F), a parent questionnaire with 20 binary items. Some research indicates sensitivity of the M-CHAT-R/F at rates up to 91%; however, in other studies the validity has been questioned for children who have: (a) families with lower socio-economic status, (b) varying symptom expression, such as females, and (c) ethnic minority group status. Understanding the areas of discrepancy and agreement on parent-report and gold-standard assessment (i.e., ADOS-2) is critical for informed recommendations on the M-CHAT-R/F's practical utility.

Objectives: To explore the relationship between parent-indicated concerns for ASD on the M-CHAT-R/F and corresponding gold standard assessment within a sample of ethnically diverse, low-income families.

Methods: Data were collected about 148 toddlers who had positive MCHAT-R/F screens in primary care and diagnostic assessment including ADOS-2 administration in specialty care. Participating parents, toddlers, and clinical sites were from a larger randomized controlled trial of Family Navigation across three U.S. cities. Two trained clinicians independently mapped M-CHAT-R/F items onto the ADOS-2 scoring system, based on measured ASD symptoms that corresponded across both assessments. Inter-rater agreement was 85%. The M-CHAT-R/F positive predictive value (PPV) in relation to ASD diagnostic resolution was calculated. Across toddlers with and without ASD, parent-indicated M-CHAT-R/F and clinician indicated ADOS-2 results were tabulated. Proportions of clinicians and parents with concordant present or absent concerns (i.e., positive predictive and negative predictive values) and with disagreement across corresponding items (i.e., false positive and false negative rates) were calculated.

Results: The participating toddlers were 73% male, 59.4% born in the U.S., and primarily from ethnic minority groups. The majority of parents had graduated high school, enrolled in social service programs, and received public insurance. Eighty-two of 148 toddlers met ASD diagnostic criteria, yielding an M-CHAT-R/F PPV of 0.55, which is within the range of its published performance characteristics. When a skill was indicated as a concern on the ADOS-2, the highest rate of M-CHAT-R/F-ADOS-2 agreement was on pretend play, pointing to ask for help, and imitating. In contrast, low agreement was identified on ratings of children's shared enjoyment and intonation. High false negative rates (i.e., absent M-CHAT-R/F item concern and present corresponding ADOS-2 item concern) occurred on pointing, imitation, response to name, and unusual finger movements. High false positive rates (i.e., present M-CHAT-R/F item concern and absent corresponding ADOS-2 item concern) occurred on responding to pointing and not requesting parents' attention.

Conclusions: In the context of research indicating poor M-CHAT-R validity for samples of ethnic minority and low SES children, this study identified specific areas that may contribute to a high level of inaccurate screens. Further exploration of parent-related factors (e.g., expectations of children, interpretation of items) and assessment-related factors (e.g., specificity of skill, wording of item, cultural bias) is recommended to explain the underlying causes of these findings.

104 **236.104** What Is the Optimal Structure of the Autism Phenotype: A Comprehensive Comparison of Dimensional, Categorical, and Hybrid Models

H. Kim[1], *C. M. Keifer*[1], *C. Rodriguez-seijas*[1], *N. R. Eaton*[2], *M. D. Lerner*[2] *and K. Gadow*[1], *(1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY*

Background:

While initially conceptualized as a categorical construct, recent years have seen an emergence in clinical, research, and popular discourse about a continuous (dimensional) "autism spectrum." More recently, a compelling new possibility has emerged that integrates both categorical and dimensional representations of ASD symptoms (i.e., hybrid model). Nevertheless, there was still a debate about how to best conceptualize ASD phenotypic symptom structure, with multiple categorical, dimensional, and categorical-dimensional hybrid models showing varying degrees of support (Frazier et al., 2012; Georgiades et al., 2007; James et al., 2016). Given this, adjudicating between these proposed structures of ASD symptoms is essential for effective diagnostic classification in the context of research as well as clinical practice.

Objectives:

We sought to delineate the optimal structure of the observable ASD symptom phenotype by comprehensively comparing categorical, dimensional,

and categorical-dimensional hybrid models in two large, diverse samples of youth with and without ASD.

Methods:

The primary study sample comprised 3,825 youth, who were consecutive referrals to a university developmental disabilities clinic or a child psychiatric outpatient clinic. We analyzed the ASD symptom rating scale from the parent-report version of the Child and Adolescent Symptom Inventory-4R. A series of latent class analyses (LCA), exploratory and confirmatory factor analyses (EFA and CFA, respectively), and factor mixture analyses (FMA) were compared. Further, including only individuals whose ASD diagnoses were available, we conducted another subset of analyses where we further specified the three following category-based models: (a) diagnostically-driven categorization, (b) empirically-driven categorization, and (c) *DSM-5*-based-categorization. We also conducted a full replication analysis using a separate large heterogeneous and geographically diverse sample of clinic referrals (*N*=2,503).

Results:

Overall results indicated that the ASD symptom phenotype was best conceptualized as multi-dimensional rather than categorical (either diagnostically-based categories or empirically-based categories) or as a categorical-dimensional hybrid (Figure 1). ASD symptoms were best characterized as falling along three dimensions (i.e., social interaction, communication, and repetitive behavior). The results of the replication analysis were virtually identical to those of the analyses conducted using the primary dataset, supporting: (a) the superiority of the 3-factor dimensional model of ASD symptoms (Table 1-1), (b) the same top five models (Table 1-1), and (c) that the best fitting models for each approach were almost identical across the two subsets (i.e., the primary and replication analyses) of analyses (Table 1-2).

Conclusions:

In sum, our findings are consistent with the notions that ASD traits are widely distributed among the general population of clinic referrals; there are three core domains of symptoms (social, communication, repetitive behavior); and diagnostic models including their associated symptom clusters are better conceptualized as dimensional. Clinically, these results challenge traditional conceptualizations of *autism*, *spectrum*, and *disorder*, and have important implications for differential diagnosis and trans-diagnostic models of pathogenesis.

105 **236.105** A Paradigm for Engaging Underrepresented Communities in Autism Research

T. M. Girolamo[1], *M. L. Rice*[1] *and S. F. Warren*[2], *(1)Child Language Doctoral Program, University of Kansas, Lawrence, KS, (2)Speech-Language-Hearing: Sciences and Disorders, University of Kansas, Lawrence, KS*

Background: Racial/ethnic minorities, individuals of low socioeconomic status (SES), and individuals with extensive special education needs are underrepresented in autism research. Community-based methods, as well as proactive and reactive recruitment methods, have been shown to be effective at engaging racial/ethnic minorities in research. To our knowledge, these methods have not been used for engaging minority adolescents and young adults of low SES with extensive special education needs in behavioral autism research.

Objectives: This pilot study tested the efficacy of a community- and participant-centered paradigm for recruiting and retaining minority adolescents and young adults of low SES with extensive special education needs in behavioral autism research.

Methods: The NYC Department of Education and the University of Kansas IRBs approved this study. A community- and participant-centered paradigm was implemented over a four-month period. The first author partnered with a community organization to recruit participants. Participants attended a Title I school requiring a diagnosis of ASD. Most students are racial/ethnic minorities and qualify for free lunch. The school consists of self-contained classes with a maximum class size of 6 - 12 students.

Recruitment included proactive and reactive strategies. In addition to disseminating information on a flyer, the first author made repeated visits to the recruitment site to distribute/collect flyers and provided individual consultation on the research process to participants and their families.

Formal recruitment and assessment happened in a single session at a time and place selected by participants' families outside of school. Each session required 10 minutes for assent and informed consent, and 60 minutes for assessment. Participants and their families were compensated $20 and $40, respectively.

Results: The paradigm was effective. 12 of 80 (15%) potential participants returned consent-to-contact forms, 10 of 12 (83%) were successfully contacted, and 10 of 10 (100%) were formally recruited and retained. All participants were male, racial and/or ethnic minorities, and adolescents or young adults (100%). The paradigm was costly in terms of time. Assessment and recruitment required 30 hours and 20 hours respectively, or 5 hours per participant. Most of this time was spent traveling to the research sites.

Conclusions: This study demonstrated the efficacy of a community- and participant-centered paradigm to engage racial/ethnic minority adolescents and young adults of low SES with extensive special education needs in behavioral autism research. Findings suggest when barriers to participation are removed, it is feasible to engage underrepresented communities in autism research. Further work is needed to learn how to make this paradigm efficient, sustainable, and scalable.

106 **237.106** Parent Behavior Associated with the Development of Emotional Self Regulation for Children with Autism in a Diverse

Sample

A. C. Laurent[1], *K. Gorman*[1] *and J. H. Fede*[2], *(1)Psychology, University of Rhode Island, Kingston, RI, (2)College of Pharmacy, University of Rhode Island, Kingston, RI*

Background: Emotional self-regulation (ESR) challenges are well documented in the developmental profiles of children with autism (Samson, et al, 2014). The development of child ESR is influenced by parent behaviors during daily interactions. Children diagnosed with autism have significant social communicative and sensory processing differences which potentially impact parent behaviors (Laurent & Gorman, 2018). Limited evidence suggests that children of color may be diagnosed later than their white peers, and that parents of color may engage in different parenting behaviors (ADDM, 2012). As such, exploring the relationship between autism specific child behavioral characteristics and parents behaviors among a diverse sample associated with supporting ESR is warranted.

Objectives: To examine the association between behavior of young children diagnosed with autism and their parents' behaviors as a function of race/ethnicity.

Methods: Participants were 37 children diagnosed with autism and a parent. Child age ranged between 30-48 months (*M*=40.86, *SD*=5.75). Participants were diverse: 32.4% identified as families of color; 19% of the children were female. Employing a cross sectional design, we observed parent-child dyads in their homes during naturalistic routines: free play, social communication (SC) assessment, and snack. Observations were video recorded for subsequent coding using combined event/time sampling procedures. Parent behaviors included physical engaging and helping, language-based engaging and helping, redirection/distraction, vocal comfort, physical comfort, language-based comfort, emotional following, and active ignoring. Children's SC abilities were assessed using the Communication Symbolic Behavior Scales- Developmental Profile (Wetherby & Prizant, 2002)and their sensory processing (SP) abilities were assessed using the Sensory Processing Measure – Preschool Home form (Ecker & Parham, 2010). Parents completed a demographic questionnaire.

Results: Compared to children of color, White children scored higher on SC ($t(35)=2.06$, $p<.05$) and lower on the SP measure ($t(35) =-2.62$, $p<.05$) indicating overall fewer SC and SP challenges. Parents engaged in all of the behaviors associated with ESR development during the observations but to varying degrees (Laurent & Gorman, 2018). Parents of color used redirection/distraction significantly more often than White parents during the combined observation ($t(35)=-2.547$, $p<.05$) and the CSBS DP assessment condition ($t(35)=-2.382$, $p<.05$). Additionally, parents of color used language and helping behavior significantly less often than White parents during free play ($t(35)=2.425$, $p<.05$). However, after controlling for child SC ability, differences were no longer significant (Tables 1 & 2). No other differences were observed.

Conclusions: In this sample, children of color demonstrated more significant delays in SC and SP than the White children in our study. When the child SC delays were controlled for, differences in parenting behaviors were no longer significant. This suggests that parents engage in responsive parenting practices based on their child's developmental level rather than factors related to race and ethnicity. No differences based on sex of the child were noted.Future research within culturally diverse populations is warranted to further understand racial/ethnic group differences that we observed in relation to both child characteristics and parent behavior. These findings have potential implications for informing parent coaching interventions aimed at supporting the development of child ESR.

107 **237.107** Physiological Responses to the Emotions of Others in Infants with a Family History of ASD

T. Bazelmans[1], *T. Charman*[2], *M. H. Johnson*[3], *E. J. Jones*[4] *and &. the BASIS Team*[5], *(1)King's College London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (4)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (5)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom*

Background: Although symptoms associated with Autism Spectrum Disorder (ASD) do not emerge until the second year of life, differences in attention regulation have been observed in infancy. Additionally, studies have reported differences in physiological measures, such as heart rate (HR). During a calm state, some studies report higher HR and smaller HR responses to social stimuli in ASD compared to typically developing children.

Objectives: In this study HR is compared between infants with an older sibling with ASD (ASD-sib) and those without a family history of ASD (control-sib) in response to non-social stimuli and social, emotional stimuli. Additionally, groups are compared on the amount of HR deceleration during the videos, as an indicator of attentional engagement.

Methods: Data is from the 5, 10 and 14-month visits of the longitudinal British Autism Study of Infant Siblings (BASIS; www.basisnetwork.org). Ninety-three ASD-sibs (52 males) and 28 control-sibs (17 males) had HR data available for at least one visit. HR was measured continuously during an eye-tracking paradigm including a non-social wildlife video (N-S), Happy video and Sad video. At the end of the paradigm, infants either saw the N-S video (5 months) or a neutral social video. 'Baseline HR was the median of 5 pre-stimulus beats. Average HR during deceleration was calculated as: HR during video when lower than baseline - baseline. Multilevel mixed models were compared using log-likelihood test. Variables were added in the order age, condition, group, condition-by-group interaction.

Results: There was an effect of age (B = -.05, p <.001) and condition on HR (p <.001), but no group (p =.373) or interaction (p =.112) effect. Data at each visit showed that HR was lowest during N-S at 5 months, but during Happy at 14 months. For HR deceleration, there was an effect of age (B =.002, p =.008) and condition (p <.001), but not of group (p =.358) or the interaction (p =.680). HR deceleration was largest during Happy and last N-S video at 5 months, but during Sad at 14 months. Looking more specifically at the change in HR deceleration over development showed that with age, children increased their HR deceleration to the Sad video only. Additionally, cross-lagged models showed bidirectional associations between parent-reported language skills and HR/HR deceleration.

Conclusions: Despite previously reported differences in physiological activity at baseline or in response to social stimuli in children with ASD, ASD-sibs do not show differences in HR during infancy compared to the control-sib group. Moreover, groups did not differ in HR deceleration, suggesting similar amounts of attention allocation in both groups. With age, infants show increased HR deceleration to the sad stimulus. This finding contributes to the literature suggesting that infants can discriminate between emotions around 5 months, although emotion recognition and regulation are still developing. Moreover, early language skills play a role in physiological adaption to social information and vice versa. Following-up which children in the ASD-sib group go on to have ASD can further elucidate whether children with ASD already show differences in autonomic activity in infancy.

108 **237.108** Potential Gender Differences in Non-Verbal and Verbal Communication Among High-Risk and Low-Risk Infant Groups

C. E. Freden[1], *A. R. Neal-Beevers*[1], *A. C. Dowd*[1] *and B. G. Davidson*[2], *(1)The University of Texas at Austin, Austin, TX, (2)Pediatrics, University of Miami Miller School of Medicine, Miami, FL*

Background:

Throughout their lifetime, females may master non-verbal communication more adeptly than males (Briton & Hall, 1995), such that high-functioning females may "camouflage" their social deficits and receive a late ASD diagnosis (Lai et al., 2017). While gender differences in ASD have been examined in older children, adolescents, and adults (Hull et al., 2017), little research has explored potential gender differences in non-verbal and verbal communication in the context of high-risk (HR) versus low-risk (LR) infant development.

Objectives:

The objective of this study was to examine within risk status gender differences and within gender risk status differences in non-verbal and verbal communication at 12, 15, and 18 months in infants who are at HR and LR for ASD.

Methods:

These analyses used secondary data from two cohorts of LR (n=43) and HR (n=39) infant participants from two longitudinal studies. Nonverbal communication skills were measured using the Early Social Communication Scales (ESCS; Mundy et. al, 2013) at 12, 15, and 18 months, yielding frequency information on initiating joint attention (IJA), initiating behavioral regulation (IBR), and percent correct scores for responding to joint attention (RJA; number of trials in which a child correctly follows the examiner's point). Verbal communication was measured using the MacArthur-Bates Communicative Development Inventory (MCDI; Fenson et al., 2007) at 12 and 15 months. Descriptive statistics and One-Way ANOVAS were calculated.

Results:

The results of the ANOVAs comparing gender differences within each risk group yielded no significant differences for IJA, IBR, or MCDI scores between LR males and females at any age or for IJA, RJA, IBR, or MCDI scores between HR males and females at any age. However, a significant difference was found for RJA at 15 months between LR males and females, with LR females outscoring LR males. Comparing risk status group differences within each gender, no significant differences were found for IJA or IBR between LR and HR females or IJA between LR and HR males. However, significant differences were found for RJA at 18 months and MCDI Phrase Speech Comprehension (Percentile Score) at 15 months between HR and LR females, with LR females outscoring HR females. Furthermore, significant differences were found for IBR at 12 months, RJA at 18 months, and MCDI Vocabulary Comprehension at 15 months between HR and LR males, with LR males outscoring HR males.

Conclusions:

These analyses suggest that, within the context of a particular risk group, gender differences in non-verbal and verbal communication may not be observable at 12 and 15 months; they may not emerge until later in development when communication skills are more advanced. These analyses show that within the same gender, HR individuals scored lower in some realms of non-verbal and verbal communication than their LR counterparts, starting as early as 12 months of age. Thus, infants who are at HR for ASD, but not yet diagnosed with ASD, may be distinguishable from LR infants of the same gender, implicating a potential for future diagnosis or possession of a broader autism phenotype.

109 **237.109** Predictors of Initiation of Early Intervention Services Prior to Positive Screen for Autism Spectrum Disorder in Young Children

K. E. Wallis[1], ***W. Guthrie***[2], *A. Bennett*[3], *M. Gerdes*[3], *S. E. Levy*[4], *D. S. Mandell*[5] *and J. S. Miller*[2], *(1)The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)Children's Hospital of Philadelphia, Philadelphia, PA, (4)Division of Developmental and Behavioral Pediatrics, Center for Autism Research, Children's Hospital of Philadelphia; Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, (5)Center for Mental Health, University of Pennsylvania, Philadelphia, PA*

Background: Early intervention (EI) for autism spectrum disorder (ASD) can lead to improved outcomes.[1-3] To improve early identification of and treatment for ASD, the American Academy of Pediatrics recommends developmental surveillance and ASD-specific screening in primary care. Referrals to EI can be initiated before final diagnoses are made, and the EI system can facilitate diagnosis and access to targeted ASD interventions, if indicated. However, minority children are less likely to be represented in EI,[4] and are more likely to be diagnosed with ASD at a later age.[5] We examined whether disparities in early initiation of EI exist, even before a child screens positive for ASD, which may contribute to disparities in ASD identification.

Objectives: To examine whether socio-demographic factors are related to early initiation of EI before a child screens positive for ASD.

Methods: Universal ASD screening was implemented in a large, academic primary care network using the Modified CHecklist of Autism in Toddlers (M-CHAT).[6] We identified all children aged 16-30 months who screened positive on the M-CHAT between 2013 and 2016 during a well-child visit, and who had also completed a general developmental screen (n=2,884). Data were extracted directly from the electronic health record, including results of screening, socio-demographic characteristics, documented diagnoses, and prior EI initiation. Prior EI initiation was defined as patient having been previously referred to EI (regardless of outcome of evaluation) or already receiving EI, according to provider documentation during the visit in which M-CHAT was positive. Manual chart review for a random subsample of 10% of charts was conducted to confirm data accuracy, with >90% agreement for manually and digitally extracted data. A priori hypotheses stated that socio-demographic factors would predict early EI initiation. Therefore, multivariable logistic regression models included all socio-demographic factors (child age, ethnicity, race, sex, insurance, and language spoken at home) simultaneously to assess factors associated with prior EI initiation. Diagnoses made prior to visit with positive M-CHAT were enumerated.

Results: Among children who screened positive on the M-CHAT (n=2884), 26.4% of children (n=762) had prior EI initiation, with a median age of 19 months. Children with prior EI initiation were more likely to be white race (p<.001), older (p= .002), Hispanic ethnicity (p<.01), and have only English spoken at home (p=.02). Insurance status and child sex were not statistically significantly associated with prior EI enrollment. Diagnoses given prior to positive M-CHAT among those with early EI initiation are presented in table 2.

Conclusions: For some children who later go on to screen positive for ASD, developmental surveillance results in successful early initiation of EI. However, prior to a first positive M-CHAT, racial and socio-economic disparities already exist in initiating EI services, demonstrating that not all children uniformly benefit from early developmental surveillance and EI initiation. This may preclude them from ASD diagnostic and intervention

services accessible through EI. Recognizing the early clinical and socio-demographic factors that drive early EI initiation may help providers equitably perform developmental surveillance and initiate EI, with the ultimate goal of improving ASD identification and outcomes.

110 **237.110** Prospective Associations between Anger and Later Internalizing Symptoms in Young Children with ASD

***K. K. Powell**, Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Early negative emotionality is a risk factor for later difficulties in the general population, including internalizing symptoms and anxiety (Dougherty et al., 2015; Hernandez et al., 2015). Although intensity of anger in response to real-world challenges in toddlers with ASD was found to be greater than that of TD and DD peers (Macari et al., 2018), little is known about prospective relationships between anger and later internalizing symptoms including anxiety, which affect a large proportion of preschool- and school-age children with ASD (Gadow et al., 2004; Simonoff et al., 2008). The present study aims to address these gaps in knowledge.
Objectives: To examine the association between directly-observed and parent-reported anger in the second year and internalizing symptoms including anxiety at age 3.

Methods: Participants included 94 toddlers (Time1: M_{age}=22mo, range: 13-30mo; Time2: M_{age}=39mo, range: 33-47mo): 53 ASD and 41 typically-developing (TD). At Time1, anger was assessed both via parent report (ECBQ-Frustration) and directly (Laboratory Temperament Assessment Battery (Lab-TAB; Goldsmith & Rothbart, 1999). Intensity of emotional expression of anger (iEE-Anger) across facial and vocal channels was coded during three Lab-TAB episodes designed to elicit anger. At Time2, parents completed the Early Childhood Inventory (ECI-4; Internalizing composite) and the Preschool Anxiety Scales-Revised (PAS-R; Generalized Anxiety score).

Results: In the ASD group, Time1 iEE-Anger was correlated with the PAS-R Generalized Anxiety score at Time2 (r(30)=.377, p=.04), while iEE-Anger did not predict either Time2 measure in the TD group. Parent-reported ECBQ Frustration at Time1 in the ASD group was significantly and positively associated with PAS-R Generalized Anxiety (r(53)=.401, p=.003). In contrast, parent-reported ECBQ Frustration in the TD group was significantly associated with the ECI-Internalizing composite (r(41)=.550, p<.0001) but not with anxiety.

Conclusions:

This study suggests a significant role for anger in the development of anxiety and internalizing symptoms. Results indicated that expression of anger at age 2 measured both directly and via parent report predicted psychopathology a year later. In the ASD group, both directly-assessed and parent-reported anger at age 2 were associated with later generalized anxiety symptoms. This contrasted with TD toddlers, for whom parent-reported anger predicted later internalizing symptoms. Taken together, these preliminary results indicate that anger in toddlerhood is related to later anxiety in toddlers with ASD, but for TD children anger predicts a range of internalizing symptoms. Furthermore, prospective relationships suggested that pathways to these vulnerabilities may not be the same in children with TD and ASD. The data highlight the importance of a multi-method approach in understanding the development of internalizing symptoms and anxiety in young children with ASD.

111 **237.111** Prospective Associations between Anger and Later Internalizing Symptoms in Young Children with ASD.

***K. K. Powell**[1], K. Joseph[1], F. E. Kane-Grade[2], H. Neiderman[1], K. Villarreal[1], C. D. Gershman[1], C. Nutor[1], N. Powell[1], E. Yhang[1], S. Fontenelle[1], T. Tsang[1], A. Vernetti[1], K. Chawarska[1] and S. Macari[1], (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Boston Children's Hospital Labs of Cognitive Neuroscience, Boston, MA*

Background: Early negative emotionality is a risk factor for later difficulties in the general population, including internalizing symptoms and anxiety (Dougherty et al., 2015; Hernandez et al., 2015). Although intensity of anger in response to real-world challenges in toddlers with ASD was found to be greater than that of typically-developing (TD) and DD peers (Macari et al., 2018), little is known about prospective relationships between anger and later internalizing symptoms including anxiety, which affect a large proportion of preschool- and school-age children with ASD (Gadow et al., 2004; Simonoff et al., 2008). The present study aims to address these gaps in knowledge.
Objectives: To examine the association between directly-observed and parent-reported anger in the second year and internalizing symptoms including anxiety at age 3 in children with and without ASD.

Methods: Participants included 94 toddlers (Time1: M_{age}=22mo, range: 13-30mo; Time2: $M_{age=}$39mo, range: 33-47mo): 53 ASD and 41 TD. At Time1, frequency of anger was assessed via parent report (Early Childhood Behavior Questionnaire (ECBQ), Frustration scale) and intensity of anger was assessed directly (Laboratory Temperament Assessment Battery (Lab-TAB; Goldsmith & Rothbart, 1999). Intensity of emotional expression of anger (iEE-Anger) across facial and vocal channels was coded during three Lab-TAB episodes designed to elicit anger. At Time2, parents completed the Early Childhood Inventory (ECI-4; Internalizing composite) and the Preschool Anxiety Scales-Revised (PAS-R; Generalized Anxiety score).

Results: In the ASD group, Time1 iEE-Anger was correlated with the PAS-R Generalized Anxiety score at Time2 (r(30)=.377, p=.040), while iEE-Anger did not predict either Time2 measure in the TD group. Parent-reported ECBQ Frustration at Time1 in the ASD group was positively associated with PAS-R Generalized Anxiety (r(53)=.401, p=.003). In contrast, parent-reported ECBQ Frustration in the TD group predicted ECI-Internalizing composite scores (r(41)=.550, p<.0001) but did not predict anxiety.

Conclusions: This study suggests a significant role for anger in the development of anxiety and internalizing symptoms. Results indicated that expression of anger at age 2 measured both directly and via parent report predicted psychopathology a year later. In the ASD group, both directly-assessed intensity and parent-reported frequency of anger at age 2 were associated with later generalized anxiety symptoms. This contrasted with TD toddlers, for whom parent-reported frequency of anger predicted later internalizing symptoms. Taken together, these preliminary results indicate that frequency and intensity of anger in toddlerhood is related to later anxiety in toddlers with ASD, but for TD children, frequency of anger instead predicts a range of internalizing symptoms. Thus, prospective relationships indicate that pathways to these affective and behavioral vulnerabilities may not be the same in children with TD and ASD. The data highlight the importance of a multi-method approach in understanding the development of internalizing symptoms and anxiety in young children with ASD.

112 **237.112** Reciprocal Associations between Language Ability and Social Functioning Development over a Two-Year Period in Young Pre-Verbal Children with Autism Spectrum Disorder

***D. Oosting**, A. Eisenhower and A. S. Carter, University of Massachusetts Boston, Boston, MA*

Background: Extant research involving young children with ASD has examined developmental trajectories of language ability and social functioning separately, with little focus on relations between these domains across early childhood (Bennett et al., 2015). Pre-verbal young children with ASD are of particular clinical relevance, given that greater language abilities at school entry have been shown to predict positive long-term adjustment in language and social functioning (Tager-Flusberg & Kasari, 2013). Since attention to and engagement with social contexts is necessary for language development, and growing language skills can facilitate further social engagement, examining reciprocal relations between social and language functioning in early development among pre-verbal children with ASD could inform intervention efforts. Further, more optimal nonverbal cognitive functioning, autism symptom severity, and joint attention skills have been associated with gains in both language ability and social functioning (Anderson et al., 2007, 2009; Thurm et al., 2007).
Objectives: We examined reciprocal associations between language ability and social functioning in a sample of young pre-verbal children with ASD over a two-year period. Moderating effects of baseline nonverbal cognitive functioning, initiation of and response to joint attention, and autism symptom severity on these associations were explored.

Methods: Participants were 90 pre-verbal children (21 girls) with ASD confirmed at two assessments: 1) 18 to 33 months of age (T1: M = 28 ± 4 months) and 2) 29 to 51 months (T2: M = 41 ± 4 months). Fifty-six children were assessed one year after T2 (T3: 43 to 66 months; M = 52 ± 5 months). Missing T3 data was imputed for 34 children. Pre-verbal status was defined at T1 by *t*-scores below 30 on the Mullen Scales of Early Learning (Mullen) expressive language scale, corresponding to the "Very Low" descriptive category. Nonverbal cognitive functioning was derived from T1 Mullen Visual Reception and Fine Motor subscales. Social functioning was assessed with the original parent-report Vineland Adaptive Behavior Socialization scale. Autism symptom severity was measured with T1 Autism Diagnostic Observation Schedule algorithm total score. Initiation and response to joint attention was assessed with T1 Early Social Communication Scales. Multi-group cross-lagged panel analyses examined reciprocal associations between language ability and social functioning and potential moderators.

Results: Cross-lagged panel analyses revealed significant within-time correlations and within-domain autoregressive paths over time. All added reciprocal paths were significant (Fig. 1). Nonverbal cognitive functioning moderated T1 to T2 and T2 to T3 autoregressive language paths (Fig. 2a). Autism symptom severity moderated T2 to T3 autoregressive language and social functioning paths (Fig. 2b). Joint attention indices did not moderate.

Conclusions: For young pre-verbal children with ASD, language ability and social functioning appear to exert concurrent and cascading reciprocal developmental influences. Nonverbal cognitive functioning and autism symptom severity change the magnitude of these relations (Ellis Weismer & Kover, 2015). Findings support potential amplification of intervention effects from simultaneous targeting of language and social domains for this population. Increased attention to nonverbal cognitive functioning and autism symptom severity in intervention research may also inform targeted intervention approaches for young pre-verbal children with ASD.

113 **237.113** Relationship between Child Dysregulation and Parenting Stress Scores in Toddlers with ASD

A. J. Schlink[1], *L. M. Baczewski*[1], *Y. de Nocker*[2], *J. Yang*[3], *A. Gulsrud*[2] *and C. Kasari*[4], *(1)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (3)Department of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (4)University of California, Los Angeles, Los Angeles, CA*

Background:
Parents of children with ASD are known to experience levels of stress significantly higher than those experienced by parents of children with other disabilities (Osborne, McHugh, Saunders, & Reed, 2008). Child challenging behaviors are also shown to be correlated with these parent stress levels, wherein more challenging behaviors are associated with greater parent stress (Lecavalier, Leone, & Wiltz, 2005). However, it is unclear what specific aspects of child behavior are most predictive of parent stress among a sample of parents who have a toddler at risk for ASD or recently-diagnosed with ASD.

Objectives:

The present study aimed to: (1) establish whether there is an association between parent perceptions of discrete child behaviors (as measured by the Infant-Toddler Social and Emotional Assessment (ITSEA)) and parenting stress (as measured by the Parenting Stress Index (PSI)) (2) to determine the relationship between significant ITSEA subdomain scores and PSI subdomain scores controlling for demographic characteristics.

Methods:

This study is a secondary analysis of an RCT of toddlers at-risk for ASD (N=86 parent-child dyads; Kasari, et al., 2015). Parents completed the ITSEA and the PSI prior to beginning a caregiver mediated intervention study. This study reports on baseline associations only. The ITSEA has four subdomains including: Externalizing problems, Internalizing problems, Dysregulation and Competence. The PSI assesses stress in the parent-child system based on three categories: child-related, parent-related, and total stress. Analyses first included, bivariate correlations to determine the associations between ITSEA and PSI subdomain raw scores at baseline. Significant correlations between subdomain scores informed the subsequent predictors within the multiple regression models. Next, three regression analyses determined which ITSEA subdomains significantly predicted each PSI subdomain. This analysis controlled for autism severity (as measured by ADOS Clinical Severity Scores), IQ (Mullen developmental quotient), treatment assignment, age, and gender. Insignificant predictors were excluded from presented analyses.

Results:

All four ITSEA subscale scores externalizing, internalizing, dysregulation, and competence significantly correlated with the PSI child subdomain scores as well as the PSI total stress subdomain scores. The ITSEA dysregulation and externalizing subscale scores significantly correlated with the PSI parent subdomain scores (see table 1 for full matrix). In pursuit of the second objective, PSI total stress and parent domain scores were each uniquely predicted by ITSEA dysregulation scores (β=0.44, *p*=.002; β=0.39, *p*=.001). Additionally, PSI child domain was significantly predicted by both ITSEA dysregulation (β=0.33, *p*=.01) and competence (β=-0.32, *p*=.006) subscale scores.

Conclusions:

Child dysregulation is a behavior that strongly predicts parents' stress across all domains of the PSI, highlighting the need to address these behaviors in behavioral intervention studies. Consistent with previous findings (see Davis & Carter, 2008), impairments in child social relatedness (as measured by competence domain of ITSEA) also produced high-levels of parent stress in this sample. These findings suggest that intervention studies may find it useful to explicitly target parent stress and integrate tools to help manage child dysregulation.

114 **237.114** Respiratory Sinus Arrhythmia Predicts Fear Longitudinally in Infants and Children with FXS, ASD, and Typical Development

C. J. Black[1], *A. L. Hogan*[1], *K. D. Smith*[1] *and J. E. Roberts*[2], *(1)Department of Psychology, University of South Carolina, Columbia, SC, (2)Psychology, University of South Carolina, Columbia, SC*

Background:

Fragile X syndrome (FXS) is a neurodevelopmental disorder characterized by intellectual disability, inattention, and increased likelihood of maladaptive behaviors (Bailey et al., 2008). Further, it is the most common genetic cause of autism spectrum disorder (ASD; Cohen et al., 2005). Both FXS and ASD have high rates of comorbid anxiety disorders which often are not diagnosed until later in life (Cordeiro et al., 2010; Kessler et al., 2005). However, prodromal signs of anxiety can be observed in infants and young children across typical and atypical development. In typically developing (TD) children, atypical respiratory sinus arrhythmia (RSA), an index of parasympathetic nervous system function, and elevated fear are known to predict later anxiety (Viana et al., 2017). The relationship between early RSA and fear has not been examined in young children with FXS or ASD despite the high risk for anxiety in both groups.

Objectives:

The objective of the current study is to examine whether baseline RSA predicts fear across infancy and early childhood in FXS and ASD as well as TD controls. Further, we aim to determine whether the relationship between RSA and fear is different across groups.

Methods:

Participants included 36 children with FXS (10 [27.8%] female), 28 children with ASD (2 [6.9%] female), and 37 TD children (7 [18.9%] female). Participants were tested several times between 4 and 117 months of age, for a total of 276 observations (FXS *n*=116; ASD *n*=29; TD*n*=131). Baseline RSA was extracted using CardioBatch (University of Illinois at Chicago). Fear was measured via parent-report temperament questionnaires; specifically, the Fear subscales from the Infant Behavior Questionnaire-Revised (<18 months), Early Childhood Behavior Questionnaire (18-36 months), and the Childhood Behavior Questionnaire (>36 months) (Gartstein & Rothbart, 2003; Putnam, Gartstein, & Rothbart, 2006; Rothbart, et al., 2001; respectively).

Results: Univariate analysis of covariance controlling for age and sex revealed no difference between groups for fear ($F(1,276) = 0.249$, $p = .780$) and baseline RSA ($F(1,276) = 2.187$, $p = .114$). To examine the relationship between RSA and fear across early childhood, a linear mixed model was employed with baseline RSA, age, group, and an RSA by group interaction entered as predictors of fear. There were significant main effects of age ($F(1,271) = 14.386$, $B = -0.014$, $p < .001$) and baseline RSA ($F(1,271) = 7.975$, $B = -0.23$, $p = .005$). The main effect of group ($F(1,271) = 3.516$, $B = -0.839$, $p = .062$) and the interaction of group by RSA ($F(1,171) = 2.888$, $B = 0.137$, $p = .090$) were both non-significant.

Conclusions: Results indicate that higher baseline RSA is related to lower fear across all groups, suggesting that the physiological mechanisms associated with fear may be similar across typical and atypical development. Early physiological dysregulation and temperamental fear are risk markers for later anxiety in TD children, so interventions targeting the physiological dysregulation and/or temperamental fear may be effective in prevention. Given similar relationships between physiology and fear across groups, interventions known to be effective in TD groups could potentially be applied to both FXS and ASD.

115 **237.115** Sexual Dimorphism of Social-Emotional Development in Toddlers

L. C. Shuffrey[1], *M. Potter*[2], *P. E. Springer*[3], *T. N. Ochoa*[4], *N. H. Brito*[5], *H. J. Odendaal*[6] *and W. P. Fifer*[1], *(1)Division of Developmental Neuroscience, Columbia University Medical Center, New York, NY, (2)Obstetrics and Gynaecology, Stellenbosch University, Bellville, South Africa, (3)Paediatrics & Child Health, Stellenbosch University, Cape Town, South Africa, (4)New York State Psychiatric Institute, New York, NY, (5)Department of Applied Psychology, New York University, New York, NY, (6)Obstetrics and Gynaecology, Stellenbosch University, Cape Town, South Africa*

Background: The increasing prevalence of developmental disorders such as autism spectrum disorder (ASD) and the effectiveness of early intervention services in improving long-term outcomes for affected individuals highlights the necessity in identifying early risk factors and biological markers for atypical neurodevelopment. In children without neurodevelopmental concerns, there is a developmental increase in high-frequency neural oscillations (Beta and Gamma) and a developmental decrease in low-frequency neural oscillations (Delta and Theta). Although there is significant heterogeneity in prior studies, relative to neurotypical populations, infants at-risk for developmental disorders often exhibit lower levels of high-frequency oscillations and higher levels of low-frequency oscillations. Specifically, EEG studies of *awake* infants at-risk for autism have found: reduced frontal power and higher alpha power at 3 months and lower spectral power across all frequencies at 6 months whereas other studies suggest high-risk infants demonstrate different developmental trajectories in neural oscillations than their low-risk peers. Objectives: To identify associations between electrocortical spectral power during infant natural sleep and subsequent social-emotional development in toddlers.

Methods: Participants included in the present analysis consisted of infants initially enrolled in the Safe Passage Study with follow-up assessments currently underway. The sample consisted of 203 infants (116 males/87 females; gestational age at birth *M*: 39.4 weeks, SD: 1.1 weeks) from the Western Cape Province of South Africa who had both neonatal EEG and developmental assessments at ~3 years of age. Neonatal EEG was recorded during sleep in the supine position using EGI's (GEM) 28-lead net for approximately thirty minutes. Average electrocortical power was computed in 10 frequency bands (Delta 1-3 Hz; Theta 4-6 & 7-9 Hz; Alpha: 10-12 Hz, Beta: 13-15, 16-18, & 19-21 Hz, Low-Gamma: 22-24 & 25-36 Hz, Gamma: 37-48 Hz) and 12 brain regions (left and right: frontal-polar, frontal, central, parietal, temporal, & occipital) separately within active (REM) and quiet (slow wave) sleep. The Brief Infant-Toddler Social and Emotional Assessment (BITSEA) was administered at 3 years of age (*M*: 37.0 months, SD: 2.6 months). Multiple regressions were run to predict social-emotional development from neonatal EEG power with prenatal exposures, gestational age at birth, and hours of life as covariates. Secondary sex specific analyses were also computed.

Results: In active sleep, increased Alpha, Beta, and Low-Gamma EEG power in the left temporal, right temporal, and left-frontal regions were associated with *increased* socioemotional problems on the BITSEA, ($F(1, 196) = 2.33 - 2.92$, p's = .000 - .01. Sex specific analyses revealed increased Delta, Theta, and Alpha EEG power during quiet sleep in the left temporal, frontal, and frontal polar regions were associated with *increased* socioemotional problems in males only, ($F(1, 111) = 4.49 – 6.37$, p's = .000 - .01. Conversely for females, increased Delta, Theta, and Alpha EEG power in the right frontal and central regions were associated with *increased* socioemotional competence scores, ($F(1, 82) = 1.18$, p's = .000 - .01 (Figure 1).

Conclusions: Our results demonstrate sexual dimorphism of EEG brain markers at birth associated with subsequent socioemotional development in toddlers.

116 **237.116** Temperament Variability Among Socio-Demographic and Clinical Subgroups of Children with Autism Spectrum Disorder in the Study to Explore Early Development

B. Barger[1], *E. Moody*[2], *S. Rosenberg*[3] *and L. Wiggins*[4], *(1)Georgia State University, Atlanta, GA, (2)University of Colorado, Denver, Aurora, CO, (3)University of Colorado Anschutz Medical Campus, Aurora, CO, (4)Centers for Disease Control and Prevention, Atlanta, GA*

Background: The proposed factor structure of the Behavioral Style Questionnaire (BSQ) is not supported in children with autism spectrum disorder (ASD), for whom a 10-factor solution may be best. It is unknown whether socio-demographic and clinical variables are associated with expression of these 10 factors among children with ASD.

Objectives: To compare socio-demographic and clinical subgroups of children with ASD on alternative BSQ temperament factors.

Methods: Data were collected in the Study to Explore Early Development-Phase I (SEED1). SEED1 is a case-control study funded by the Centers for Disease Control and Prevention and conducted at multiple sites throughout the U.S. (catchment areas in CA, CO, GA, MD, NC and PA). Children with ASD were recruited through developmental disability service organizations and were aged 2-5 years at time of enrollment. Clinicians confirmed ASD status with the Autism Diagnostic Observation Schedule and Autism Diagnostic Interview Revised. BSQ data were obtained via caregiver self-administered questionnaire.

Revised BSQ (BSQ–R) Bartlett factor scores were developed via exploratory factor analysis (*M*=0; *SD*=1): (1) *Maladaptivity* (e.g., "bothered by changes"), (2) *Environmental Sensitivity* (e.g., "sensitive to noises"), *(3) Quiet Persistence* ("practices [to mastery]"), *(4) Social Inattention* (e.g., "does not acknowledge [when called]"), *(5) Social Approach* (e.g., "approaches [unknown children]"), (6) *Activity* (e.g., "[frequently] runs"), (7) *Crying, (8) Rhythmicity* (e.g., "hungry at dinner"), (9) *Food Openness* (e.g., "tries new foods"), and (10) *Negative Social* (e.g., "complains about friends").

Maladaptivity, Quiet Persistence, Social Approach, Crying, Rhythmicity, *Food Openness,* and *Negative Social* were non-parametrically distributed. ANOVA and T-tests compared groups for parametric factors; Friedman ANOVAs and Wilcoxon Rank Sums compared groups for non-parametric factors.

Socio-demographic subgroups were sex (male/female), maternal race (White/Black/Other), maternal ethnicity (Hispanic/non-Hispanic), and maternal education (high school or less /some college or college degree/advanced degree). Clinical subgroups were intellectual disability (ID; no/yes) defined as a Mullen Scales of Early Learning Early Language Composite Score < 70, and nonverbal status (no/yes) measured by the Social Communication Questionnaire.

Results: White mothers reported more problems with *Maladaptivity, Social Inattention,* and *Food Openness* in their child with ASD than did Black or Other race mothers; Black mothers reported more problems with *Crying* than did White or Other race mothers. Hispanic mothers reported more problems with *Food Openness* than did non-Hispanic mothers. Mothers with HS education reported more problems with *Quiet Persistence* but fewer problems with *Crying* than did those with more education. Children with ASD and ID had more problems with *Environmental Sensitivity, Quiet Persistence, Rhythmicity, Food Openness,* and *Activity* and fewer problems with *Negative Social* than those without ID. Non-verbal children with ASD had more problems with *Negative Social* and fewer problems with *Environmental Sensitivity, Quiet Persistence, Social Approach,* and *Rhythmicity* than did verbal children with ASD. All reported differences are significant at $p < .05$.

Conclusions: Socio-demographic and clinical variables are associated with BSQ-R scores for children with ASD. Future research is needed to better understand these associations and the resultant impact on family functioning.

117 **237.117** Testability in Young Autistic Children: A Descriptive Longitudinal Study Comparing Conventional and Strength-Based Assessment.

D. Girard[1], *A. Girard-Bossé*[2], *T. Drob*[2], *P. Bayati*[3] *and I. Soulieres*[1], *(1)Psychology, University of Quebec in Montreal, Montréal, QC, Canada, (2)Psychology, University of Montreal, Montreal, QC, Canada, (3)University of Montreal, Montreal, QC, Canada*

Background: DSM-5 autism spectrum (AS) disorder diagnosis is often done early in childhood and must specify whether there is an accompanying intellectual disability (APA, 2013). However, conventional intellectual assessment at such an early age bears many challenges and may not accurately represent the potential of young autistic children, whose developmental paths are highly atypical. For example, many autistic children are considered as having intellectual delay at preschool age when assessed with conventional tests. However, many of them will no longer exhibit an intellectual delay or disability at school age.

Objectives: We first wanted to describe testability at the age of diagnosis (T0) and a year later (T1) in a group of young AS and typically developing (TD) children using WPPSI-IV as conventional assessment and Raven Coloured Progressive Matrices (RCPM) as strength-based assessment. Second, we wanted to determine the proportion of AS and TD children with scores in the intellectual delay range (QI<70 or percentile rank<=2%) when assessed with WPPSI-IV compared with RCPM.

Methods: At T0, 100 children (50AS; 50 NT) aged 30-70 months (mean 54 months) were tested with both WPPSI-IV and RCPM. Data collection for T1(one year after T0) is still ongoing, but 46 children (20AS; 26NT) have already completed T1 with the same two tests. Of these, 38 children (12AS; 26 NT) were able to complete all tests at both time points. Both groups are matched on age at both time points (ps>.05).

Results: At T0, all 50 TD children who attempted to complete WPPSI-IV and RCPM were able to complete both tests. The 26 TD children who were called back a year later were also all able to complete both tests. Out of the 50 AS children who were tested at baseline (T0), 58% (29/50) were able to complete WPPSI-IV whereas 66% (33/50) were able to complete RCPM. A year later (T1) testability of AS increases for both tests as 75% (15/20) were able to complete WPPSI-IV and RCPM. Also, the proportion of AS children with scores in the intellectual delay range (IQ<70 or percentile rank<=2%) is higher when using WPPSI-IV [14% (7/50)] compared to RCPM [2% (1/50)] at T0. A year later, this percentage decreases to 10% (2/20) using WPPSI-IV and to 0% (0/20) using RCPM in the AS group. Linear regression analyses are planned to determine whether performance on WPPSI-IV and on RCPM could predict the evolution of cognitive potential, operationalised as change between WPPSI-IV standard score at T0 and T1.

Conclusions: In the AS group, the performance and ability to complete WPPSI-IV increases a year after baseline, as children get older. Also, administration conditions specific to RCPM seem to favour AS children in their comprehension and compliance to the test relative to WPPSI-IV. Thus, a strength-based approach could help bypass some challenges of assessing young AS children at the age of diagnosis. Our results also suggest that assessing AS children at such an early age is difficult and that waiting until school age to assess their cognitive potential could help

increase their testability.

118 **237.118** The Broader Autism Phenotype in the First Two Years: Maternal Reports and Play Behaviors

A. M. Kellerman *and A. J. Schwichtenberg, Purdue University, West Lafayette, IN*

Background: In families raising a child with an autism spectrum disorder (ASD), younger siblings are at elevated risks for ASD, and other developmental concerns including subclinical ASD features, often called the Broader Autism Phenotype (BAP). In adults and children aged 3 years or older, self- or parent-report questionnaires are often used to characterize the BAP. For children under 3, clinical judgments and standardized developmental assessments typically inform impressions of the BAP. Recent work has expanded our understanding of the BAP in early childhood by documenting observed dyadic social difficulties as early as 15 months of age. However, less is known about maternal reports of BAP-aligned social difficulties in young children and how that may inform their play interactions.

Objectives: Within this study we expand our developmental understanding of the BAP in early childhood by examining (1) maternal reports of social communication difficulties in their children, compared to typically developing peers, and (2) if reported social difficulties inform mothers' approaches to play, within a social context.

Methods: As part of a prospective study, dyads were recruited from families with at least one older child with ASD (high-risk group, n = 36), and families with no history of ASD (low-risk group, n = 38). During laboratory visits at 12, 15, 18, and 24 months of age children completed a series of standardized assessments and a mother-child play interaction. At each visit, child socialization and communication skills were mother-reported via the Vineland Adaptive Behavior Scales (VABS). Play interactions were rated with the Joint Engagement Rating Inventory (JERI). Between 24 and 36 months, children completed an outcome visit and, following previously established criteria, children were assigned to BAP (n = 22) and TYP (n = 52) groups.

Results: A series of ANCOVAS were conducted, with terms for infant sex and maternal education as covariates, and revealed significant group differences on select standardized measures and indices of play from 12 to 24 months of age. Group comparisons revealed differences between the BAP and TYP outcome groups by 24 months in mother-reported socialization, $F(1, 68) = 4.22$, $p = .04$, partial $\eta 2 = .06$, and communication $F(1, 68) = 5.71$, $p = .02$, partial $\eta 2 = .08$. By 15 months, mothers in the BAP group exhibited less symbol highlighting, $F(1, 30) = 5.71$, $p = .02$, partial $\eta 2 = .17$, and following-in, $F(1, 30) = 5.33$, $p = .03$, partial $\eta 2 = .17$. Mothers in the BAP group also exhibited more affective communication by 12 months, $F(1, 24) = 5.85$, $p = .03$, partial $\eta 2 = .23$. These results were not consistent across visits (Figure 1).

Conclusions: Overall, this study provides detailed information on early social interactions in the BAP, which may inform intervention and differential diagnosis efforts. By examining group differences across four time-points, the current study demonstrates that distinct patterns exist between BAP and TYP. Recognizing the increasing demand for parent-mediated elevated-risk interventions, these findings highlight several social constructs through which interventions may promote optimal development in children developing at risk.

119 **237.119** The Development of Pretend Play in Very Young Children with Autism Spectrum Disorder (ASD)

C. Dissanayake*, M. Chaudry and J. Barbaro, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia*

Background: Our ability to identify and diagnose ASD in toddlerhood allows study of critical developmental phenomenon such as the emergence of pretend play. However, there remains little understanding of the very early development of pretence abilities in ASD compared to children without ASD, and whether individual differences make some children with ASD more likely to have intact pretend play. Longitudinal studies are needed to examine causal factors in the early emergence and development of pretence. While it is well established that pretence and cognition are interrelated, there remains no evidence on whether this relationship is bidirectional or unidirectional in children with ASD.

Objectives: We examined the development of spontaneous pretend play in children with ASD compared to children with Developmental and/or Language Delay (DD/LD) from 24- to 48-months of age. A further aim was to investigate whether the relationship between pretend play and cognition (verbal and non-verbal) was bidirectional within the ASD group using longitudinal data.

Methods: The participants comprised 48 children with ASD and 20 children with DD/LD who were assessed at both 24- and 48-months. All children were assessed with the Mullen Scales of Early Learning (MSEL) at each age, with the target group being significantly lower on Verbal Mental age (VMA), Non-VMA and overall Developmental Quotient compared to the DD/LD group at both 24- and 48-months. Spontaneous pretend play was coded continuously (frequency and duration) off videotapes by a coder blind to group status when participants were 24- and 48-months of age.

Results: Very little pretence was observed at 24-months in both groups. A two way repeated measures ANOVA indicated a significant increase in spontaneous pretend play in both groups over time, with no group differences at either 24- or 48-months.

Significant concurrent and cross-lag correlations were found between cognition (age equivalent scores on visual reception, fine motor, expressive language and receptive language) and spontaneous pretend play at 24-and 48-months in the ASD group. Hierarchical multiple regression showed that pretend play at 24-months did not significantly predict pretend play at 48-months. With the addition of the cognitive variables, the model significantly predicted pretend play at 48-months, accounting for 27.4 % of the variance. The cognitive variables, on their own, predicted 20.6% of the variance. However, pretend play at 24-months was not a significant predictor of verbal or non-verbal cognition at 48-months, indicating a unidirectional relationship between cognition and pretend play in young children with ASD.

Conclusions: Our findings indicate that young mixed ability children with ASD engaged in equivalent levels of spontaneous pretend play at 24- and 48-months compared to DD/LD children, despite having significantly lower cognitive abilities overall. The findings support previous work with older and more able children with ASD indicating they can engage in pretend play even when it is not elicited; these findings, together, support neither a competence nor performance deficit in pretence in ASD. The findings also suggest that cognitive abilities facilitate the development of early pretend play in children with ASD and that this relationship is unidirectional.

120 **237.120** The Emergence of Early Signs for Autism Spectrum Disorder in Babies at High Risk and Its Relationship with Later Trajectories of Symptom Severity

M. Franchini[1]*, L. Zwaigenbaum*[2]*, E. Duku*[3]*, V. Armstrong*[4]*, J. A. Brian*[5]*, S. E. Bryson*[6]*, N. Garon*[7]*, W. Roberts*[8]*, C. Roncadin*[9]*, L. A. Sacrey*[10] *and I. M. Smith*[11]*, (1)Dalhousie University / IWK Health Centre, Halifax, NS, Canada, (2)University of Alberta, Edmonton, AB, Canada, (3)McMaster University,*

Hamilton, ON, Canada, (4)IWK Health Centre / Dalhousie University, Halifax, NS, Canada, (5)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (6)Dalhousie University, Halifax, NS, Canada, (7)Mount Allison University, Sackville, NB, Canada, (8)isand, Toronto, ON, Canada, (9)Autism Spectrum Disorder Service, McMaster Children's Hospital - Hamilton Health Sciences, Hamilton, ON, Canada, (10)Autism Research Centre, Edmonton, AB, CANADA, (11)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA

Background:
How early signs for autism spectrum disorder (ASD) emerge is currently unknown. The Autism Observation Scale for Infant (AOSI) represents an elegant solution to the prospective observation of the emergence of ASD symptoms in high risk infants. Within this study, we longitudinally assessed infant siblings of children with ASD from 6 to 18 months of age using the AOSI. We followed up the expression of their symptomology using the Autism Diagnostic Observation Schedule (ADOS), collected from 18 months to 5-7 years in the same children. We derived distinctive trajectories of early signs of ASD in infancy, and we observed the conditional probability that those trajectories had on the later trajectories of symptom severity.

Objectives:

The primary goal of the current research was to define, in children at high risk, the relationship between how early signs for ASD emerge and the expression of symptom severity later in life.

Methods:

The sample was composed of 499 high risk siblings (281 males), of whom 128 received an ASD diagnosis in a blinded assessment at 36 months. We used group-based trajectory models (GBTM) to derive trajectories of early signs for ASD measured at 6, 9, 12, 15 and 18 months of age using the AOSI. Using the same statistical model, we derived symptom severity trajectory groups from the ADOS at 18, 24, 36-42, and 60-84 months. We examined the proportions of children within each trajectory group, and analyzed the conditional probability of switching from a distinctive AOSI trajectory to a later ADOS trajectory.

Results:

Analysis revealed three distinctive trajectory groups for early signs measured with the AOSI and three distinctive trajectories for symptom severity measured with the ADOS (Low, Intermediate and Increasing trajectory groups for each). Pairwise comparisons between trajectory groups for quadratic slope and intercept estimates revealed significant differences for all comparisons (all $p < .001$) for both analyses. As expected, children with an ASD diagnosis were more likely to be in the trajectory groups with the highest scores on both the AOSI and ADOS. Furthermore, children in the Low trajectory group from the AOSI had an 80.2% chance to continue in the Low ADOS trajectory group, 67.5% of the children stayed in the Intermediate trajectory group as measured with both scales and 77.3% remained in the High trajectory group. Importantly, no children from the Low AOSI trajectory group were in the Increasing ADOS trajectory group in later childhood.

Conclusions:

Our results confirm substantial heterogeneity in the early emergence of ASD symptomatology in children at high risk for ASD. Moreover, we have shown how the emergence of signs of ASD in infancy is highly predictive of the later patterns of symptomatology. These results have strong clinical implications, supporting the need to screen infants at high risk for ASD repeatedly and to monitor closely how early signs of ASD appear, as this can be highly indicative of the clinical course. The AOSI shows good potential as an early assessment of ASD symptoms.

121 **237.121** The Predictive Value of Early Temperament and Sensory Features for Cognitive Development and Early Symptoms of Autism Spectrum Disorder in Preterm Children

***F. Vlaeminck**, J. Vermeirsch, P. Warreyn and H. Roeyers, Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: There is accumulating evidence that temperament and sensory processing differs between children at high risk for autism spectrum disorder (ASD) who do and do not develop ASD. A study by Garon et al. (2018) suggests that temperament, particularly Effortful Control at 24 months, plays a role in predicting later ASD symptoms. In addition, Wolff et al. (2018) reported cross-sectional associations between sensory experiences and restricted and repetitive behavior (RRB). However, research on this matter focused mainly on high-risk siblings. Yet, preterm children are another important high-risk group for developing ASD (Agrawal et al., 2018). It could be hypothesized that also in these children, temperament and sensory features may be of predictive value for cognitive development or symptoms of ASD. Pérez-Pereira et al. (2015) for example, reported that extroverted temperament predicted better language outcome in a group of preterm children.
Objectives: This study explored the predictive value of early temperament and sensory features for cognitive development and ASD symptomatology at 36 months in a group of preterm children.

Methods: Participants were 45 children born before 30 weeks of gestation (21 girls). At the corrected ages of 10, 18 and 24 months, sensory features and temperament were assessed using the Infant/Toddler Sensory Profile (ITSP) and the Infant Behavior Questionnaire (IBQ) or Early Childhood Behavior Questionnaire (ECBQ). Mullen Scales of Early Learning, ADOS-2 and the Social Responsiveness Scale (SRS) were administered at 36 months.

Results: Linear regressions were performed to predict ADOS_RRB, ADOS_SA (social affect), SRS_RRB, SRS_SCI (social communication and interaction) and Developmental Index (DI) of the Mullen at 36 months, using the measures of temperament and sensory-related features at 10, 18 and 24 months. More sensory avoiding as measured with the ITSP_24 predicted lower Mullen_DI scores ($F(1,40) = 4.172$, $p = .048$, $R^2 = 0.094$) and higher SRS_RRB scores ($F(1,43) = 8.361$, $p = .006$, $R^2 = 0.163$). Higher ADOS_RRB scores were predicted by less sensory seeking as assessed with the ITSP_24 ($F(1,43) = 6.527$, $p = .014$, $R^2 = 0.132$). A lower score on low registration on the ITSP_10 was predictive for more social problems on the SRS_SCI ($F(1,43) = 12.508$, $p = .001$, $R^2 = 0.225$). Temperament and sensory features did not have any predictive effect on ADOS_SA scores.

Conclusions: This study indicates that sensory processing is predictive for cognitive development and early ASD symptoms in preterm children, especially at 24 months. Concerning RRB, the ITSP was predictive for both parent-report (SRS) and observational measures (ADOS-2). It is possible that children avoid stimuli because of oversensitivity and develop RRB's to cope with this oversensitivity, or that children who already have specific interests, are less tempted to process other stimuli. As for the social-communicative aspects of ASD, only parent-report (SRS) was predicted by sensory features. Children who registrate less of their environment, possibly miss attempts to social interaction from others, have less learning experiences, and may develop less optimal social skills. In this study, early temperament does not seem to be of predictive value for

ASD symptomatology or cognitive development.

122 **237.122** The Rapid Interactive Autism Screening Test in Toddlers: Further Validation and Generalization

R. Choueiri[1], *M. Ravi*[2] *and W. Robsky*[2], *(1)University of Massachusetts Memorial Children's Medical Center, North Worcester, MA, (2)UMass Children's Hospital, Worcester, MA*

Background: Preliminary results from the Rapid Interactive Screening Test for Autism in Toddlers (RITA-T) pilot study supported the validity of the test in screening for autism spectrum disorders (ASD) in a highly controlled research environment. Further testing is needed to determine if the results can be replicated among a broader, more diverse population.
Objectives: To generalize and evaluate the effectiveness of the RITA-T, a new level 2 screening assessment for ASD in diverse populations. This study is further designed to determine the optimal cut-off score for use in screening ASD and thus improve referrals to tertiary care centers.

Methods: The RITA-T consists of nine activities that evaluate the participant's social, communication, and interaction skills. Use of language and verbal commands is limited to simple phrases intended to direct the participant's attention and does not rely on the participant's need to interpret complex commands that may be limited by vocabulary.

Four Early Intervention (EI) providers from the THOM EI program in Worcester, MA were trained on the RITA-T**.** The test was administered to 81 toddlers from diverse ethnic and racial backgrounds. From this group, 70 toddlers had a positive MCHAT-R (Modified Checklist for Autism in Toddlers- Revised) or other behavioral concerns for ASD. After screening with the RITA-T, toddlers were then referred to a diagnostic team that administered the Autism Diagnostic Observation Schedule-2 (ADOS-2) and the Mullen Scales of Early Learning (MSEL). A final clinical diagnosis was made as ASD or non-ASD based on testing and clinical presentation. Eleven toddlers were referred by EI after being evaluated as low risk of ASD. Clinical diagnosis was made based on the results of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) , MCHAT-R, and Batelle Developmental Inventory. Each participant's RITA-T score was compared to their final clinical diagnosis and ADOS-2 diagnosis to evaluate the validity of the RITA-T and determine the optimal cut-off score.

Results: Eighty-one toddlers (78% male) were evaluated. The age of the participants ranged from 18 to 35 months (mean age 27.3 months). The study population was 58% white, 20% Hispanic, 15% African-American, and 7% Asian. Of those, 57 (70.4%) were diagnosed with ASD and 24 (29.6%) were diagnosed as non-ASD. Optimal cutoff score for the RITA-T was determined to be 12(PPV = 0.93, NPV = 0.95). Those with a score lower than 12 were considered low risk for ASD. Patients with a score from 12 to 16 were considered to be intermediate risk requiring further evaluation, whereas those with scores higher than 16 were most likely high risk for ASD.

Conclusions: Training and administration of the RITA-T is generalizable, and results support its validity and correlation with clinical diagnoses. Cut-off score was further refined. Further testing will evaluate the effectiveness of the RITA-T screening in those 12- 18 months.

123 **237.123** The Relationship between Parent Responsiveness and Early Language Development in Children at Elevated Likelihood for ASD

J. Artis[1], *L. R. Watson*[2] *and E. Crais*[2], *(1)University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: Parent verbal responsiveness has been associated with later expressive and receptive language skills of children diagnosed with autism spectrum disorder (ASD) (McDuffie & Yoder, 2010; Perryman et al., 2013). However, less is known about the predictive relationship between the nonverbal and verbal responsiveness of parents of infants at elevated likelihood of ASD (EL-ASD) and their later language skills.
Objectives: This study aims to determine if nonverbal and/or verbal parent responsiveness are predictive of later receptive and expressive language skills of children at EL-ASD.

Methods: This study used extant data of 87 children who were identified as at EL-ASD at the age of 12 months based on their scores on the First Year Inventory 2.0 (FYIv2.0). These children were participants in a randomized controlled trial that tested the efficacy of a parent-mediated intervention. The Mullen Scales of Early Learning Receptive and Expressive Language Scales were used to assess the language skills of the children at infancy (13-15 months) and toddlerhood (22-25 months). An interval coding system (adapted from Yoder et al., 2009) was used to measure parent responsiveness within unstructured play. Hierarchical linear regressions were performed to determine if parent responsiveness accounted for unique variance in toddler language scores above the infant language scores and intervention group assignment. A parsimonious model was chosen based on the variables that were significantly associated with the toddler language scores.

Results: The first order correlations revealed that infant receptive language and parent verbal responsiveness to infants (i.e., proportion of intervals in which parents provided verbal responses with or without physical responses), but not nonverbal responsiveness (i.e., proportion of intervals in which parents provided physical responses with or without verbal responses), were significantly correlated with toddler receptive language. A linear regression model that included the infant receptive language scores and controlled for the study group assignment accounted for 22.65% of the variance in the toddler receptive language scores. Parent verbal responsiveness was then added to the model, and was a significant predictor, explaining an additional 14.52% of the variance in toddler receptive language (R^2 = 0.37, F (3,79) = 15.58, p<0.01).

Infant receptive and expressive language scores and parent verbal (but not nonverbal) responsiveness to infants all had significant first order correlations with toddler expressive language scores. A linear regression model that included receptive and expressive language scores of infants and study group assignment explained 36.71% of the variance in toddler expressive language scores. When parent verbal responsiveness was added to the model, it was a significant predictor, accounting for an additional 5.7% of the variance in toddler expressive language (R^2 = 0.42, F (4,78) = 14.33, p<0.01).

Conclusions: Our findings agree with previous research on the benefits of early parent verbal responsiveness for later language development, extending findings to children at EL-ASD. These results demonstrate the need for parents to provide verbal input that follows into their child's focus of attention in order to assist in the development of language skills in these children.

124 **237.124** The Relationship between Maternal Linguistic Input and Language Development in Children with ASD and Dld

H. L. Fipp-Rosenfield, *M. K. Jones and M. Roberts, Communication Sciences and Disorders, Northwestern University, Evanston, IL*

Background: Quantity and diversity of maternal linguistic input are related to child language outcomes. However, less is known about maternal and child characteristics that may impact this relationship in children with ASD. Current research suggests that in children with ASD, quantity and diversity of maternal linguistic input impacts child language skills (Fusaroli et al., 2018). In typically developing children, maternal socioeconomic status (SES) relates to maternal language input, which impacts child language outcomes (Hart & Risley, 1995). The impact of SES on maternal linguistic input in children with ASD is not well studied. Child characteristics, such as social communication deficits inherent to ASD, may be an important factor to consider (Arunachalam & Luyster, 2018). By comparing children with ASD to children with developmental language disorder (DLD) we are able to examine the unique impact that social communication difficulties, above and beyond language delays, may have on maternal language input.

Objectives: The current study aims to (1) examine the relationship between mother's use of language type (number of unique words), token (frequency of words) and type/token ratio (TTR) and child's use of language type, token, and type/token ratio (2) investigate differences in maternal linguistic input based on SES (3) to examine the extent to which ASD status moderates the relationship between maternal input and child language.

Methods: The current study included 184 mother-child dyads: 111 children with ASD (M=2.77 years, SD= .53) and 73 children with DLD (M=2.66 years, SD=.50). 10 minute mother-child interactions using a standardized set of toys were transcribed and analyzed using SALT (Systematic Analysis of Language Transcripts; Miller & Iglesias, 2008). From the transcription, type, token and TTR of total words, adjectives, nouns, prepositions, and verbs were analyzed for both the mother and child. Mothers completed a questionnaire indicating their household income. Income status was defined as follows: low income $0-$25,000, middle income $25,001-$100,000, high income greater than $100,000.

Results: We computed pearson correlations to determine the relationship between maternal input and children's lexical diversity across both populations (see Table 1). We used two-sample t-test to examine the differences in maternal input based on household income (Table 2). Linear regressions revealed that ASD status moderates the relationship between maternal language measures and children's language measures for preposition token ($F(1, 180) = 4.745$, $p < .05$) and preposition TTR ($F(1, 180) = 7.284$ $p < .05$).

Conclusions: This research highlights the importance of investigating maternal and child characteristics that may impact the relationship between maternal linguistic input and language development in children with ASD. Future research should include longitudinal approaches to investigate the relationship between maternal linguistic input and later child language outcomes to examine the extent to which types of linguistic input change base on the child's developmental level. Further research is necessary to characterize the differences in maternal linguistic input based on SES in children with communication disorders. It is essential to continue to investigate the extent to which social communication deficits may moderate the relationship between input and children language levels.

125 **237.125** The Relationship between Maternal Infant-Directed Speech and Infant Attention during the First Year

A. J. Woolard[1], *T. Armstrong*[2], *T. Benders*[3], *A. E. Lane*[4], *F. Karayanidis*[5], *V. Murphy*[6] *and L. E. Campbell*[7], *(1)University of Newcastle, Australia, Callaghan, Australia, (2)University of Newcastle, Newcastle, Australia, (3)Linguistics, Macquarie University, Sydney, Australia, (4)University of Newcastle, Callaghan, Australia, (5)Psychology, University of Newcastle, Australia, Callaghan, Australia, (6)Medicine and Public Health, University of Newcastle, Australia, Callaghan, Australia, (7)School of Psychology, University of Newcastle, Newcastle, Australia*

Background: Mothers use infant-directed speech (IDS) when talking to their infants. IDS is highly effective in regulating infant attention. The most salient aspects of IDS during the first year, when attention development is occurring rapidly, are prosodic characteristics. In particular, pitch contours are highly informative for infants and contribute to attention regulation. Children with autism spectrum disorder (autism) may experience difficulties with attention regulation, impacting schooling and social interactions. IDS is known to be associated with infant attention during interactions with others, however, little is known about the relationship between IDS and the development of attention over time. The present study examined the relationship between maternal pitch contours in early infancy and infant attention at one year of age.

Objectives: The aim of this study was to explore whether the pitch contours used by mothers during IDS with their 6-month-old infants were related to the infant's attention at 12 months, as indexed by the First Year Inventory (FYI; Reznick, Baranek, Reavis & Crais, 2007).

Methods: 21 mother-infant dyads participated in a 15-minute recorded interaction at infant age of 6 months. Infant attention was then assessed using the FYI at 12 months of age. The FYI has been adapted to assess infant attention including: responding to social attention, initiating social attention, and non-social sensory attention. A total of 3,714 pitch contours were extracted from audio collected during interactions and classified into contour types (rising, bell, sinusoidal, u-shaped, slowly-falling, rapidly-falling, and complex). Pearson's or Spearman's product moment correlations were used to determine the relationship between maternal pitch contours at 6 months of age and infant attention scores on the FYI at 12 months of age.

Results: Bell, sinusoidal and u-shaped (BSU) contours were combined to create one contour type as they have shown to be highly related in the literature. Infant scores on 'responding to social attention' were strongly associated with BSU contours ($r_s(21) = -.62$, $p=.003$), and rising contours ($r_s(21) = .62$, $p=.003$). Mothers who used less BSU and more rising contours with their infants at 6 months of age scored their infants more poorly on social attention scores at 12 months of age.

Conclusions: These results suggest that maternal pitch contours used with infants at six months of age are related to parent-reported infant attention at 12 months. In particular, mothers who used more BSU contours, which are thought to maintain infant attention, reported that their infants were more responsive to social attention at 12 months. Conversely, mothers who used more rising contours, which are typically used to attain infant attention when an infant is not attending, reported that their infants were less responsive to social attention at 12 months. As poorer attention is a common symptom of autism, the link between maternal use of IDS and at-risk groups needs to be explored further.

126 **237.126** The Relationship between Pitch Contours in Infant-Directed Speech and Infant Risk for Autism

A. J. Woolard[1], *A. E. Lane*[2], *T. Benders*[3], *L. E. Campbell*[4], *V. Murphy*[5], *L. Korostenski*[6], *F. Karayanidis*[7], *S. J. Lane*[8], *D. Barker*[9], *C. A. Mallise*[10], *O. Whalen*[1] *and J. Mattes*[9], *(1)University of Newcastle, Australia, Callaghan, Australia, (2)University of Newcastle, Callaghan, Australia, (3)Linguistics, Macquarie University, Sydney, Australia, (4)School of Psychology, University of Newcastle, Newcastle, Australia, (5)Medicine and Public Health, University of Newcastle, Australia, Callaghan, Australia, (6)John Hunter Children's Hospital, Newcastle, Australia, (7)Psychology, University of Newcastle, Australia, Callaghan, Australia, (8)Occupational Therapy, University of Newcastle, Newcastle, Australia, (9)University of Newcastle, Newcastle, Australia, (10)The University of Newcastle, Callaghan, Australia*

Background: Early mother-infant interactions comprise the sensory environment experienced by infants and mediate early development. A fundamental component of mother-infant interactions is maternal infant-directed speech (IDS), which is the unique speech register universally used when interacting with infants. IDS facilitates infant language learning and socio-communicative development via its prosodic characteristics, vis a vis pitch contours. There is little research, however, investigating how pitch contours associated with IDS are used with infants at-risk of or displaying issues with socio-communicative and language development or sensory regulation, such as those at-risk of Autism Spectrum Disorder (autism).

Objectives: The aim of this study was to characterise the utterances and pitch contours used by mothers when interacting with their infants at high-risk for autism compared to mothers of infants at low-risk for autism.

Methods: 18 mothers and their 12-month-old infants (12 male, 6 female) were participants in studies of early child development from three cohorts. Mother-infant dyads participated in a 15-minute recorded interaction. Infant risk for autism was assessed using the observer-rated Autism Detection in Early Childhood assessment (ADEC; Young, 2007) and the parent-report First Year Inventory (FYI; Reznick, Baranek, Reavis & Crais, 2007). Eight infants were assessed as at-risk for autism. A total of 5429 maternal pitch contours were extracted from the interactions and classified into contour types (rising, bell-shaped, sinusoidal, u-shaped, slowly-falling, rapid, flat and complex). Pearson product-moment correlations were performed to determine correlations between maternal pitch contour use and infant risk for autism.

Results: Mothers of clinically high-risk infants spoke less overall, with an average of 260.9 utterances during the interaction, compared to 334.2 spoken by mothers of low-risk infants. As infant risk on the parent-report FYI increased, mothers spoke fewer utterances (r=-.576, N=18, p=.01) and used fewer rising (r=-.586, N=18, p=.01), sinusoidal (r=-.636, N=18, p=.005), more complex (r=.584, N=18, p=.01) and more rapid (r=.526, N=18, p=.03) contours. As infant risk on the observer-rated ADEC increased, mothers spoke fewer utterances (r=-.631, N=18, p=.02), and used fewer flat shaped contours (r=-.679, N=18, p=.01) but more u-shaped contours (r=.619, N=18, p=.02).

Conclusions: These preliminary data suggest that mothers of high risk infants use different patterns of IDS than mothers of low risk infants. Further assessment of maternal IDS patterns from early infancy through the end of the first year of life in high and low risk infants is warranted to identify at what stage IDS patterns deviate between groups.

127 **237.127** The Relationship between Walking and Language Development Is Disrupted in Infants with Autism Spectrum Disorder

L. A. Wang[1,2], *L. D. Yankowitz*[1], *W. Guthrie*[3], *J. Parish-Morris*[1], *J. Pandey*[1], *K. Botteron*[4], *S. R. Dager*[5], *J. N. Constantino*[4], *A. Estes*[5], *H. C. Hazlett*[6], *L. Zwaigenbaum*[7], *J. Pruett*[4], *N. Marrus*[4], *J. Piven*[8] *and R. T. Schultz*[1], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Department of Psychology, University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)Washington University School of Medicine, St. Louis, MO, (5)University of Washington, Seattle, WA, (6)University of North Carolina, Chapel Hill, NC, (7)University of Alberta, Edmonton, AB, Canada, (8)*Co-Senior Authors, IBIS Network, University of North Carolina, Chapel Hill, NC*

Background: Learning to walk is a critical point of change for communicative development. Walking onset is associated with subsequent increases in communication skills in typically developing (TD) infants, independent of age (Walle & Campos, 2014). This may be due to increased opportunities for social communication afforded by walking, or to other shared factors (e.g., epigenetic causes). A recent study found that infants later diagnosed with autism spectrum disorder (ASD; N=15) did not exhibit the same increased language growth after walking onset as their non-ASD peers (West et al., 2017).

Objectives: The present study uses a larger sample to (1) determine whether the relationship between walking ability and subsequent rate of language development is significantly attenuated in infants with ASD, and (2) assess whether walking ability is related to growth in language skills specifically or in nonverbal cognitive skills as well.

Methods: 156 low-risk (LR) siblings of TD children and 361 high-risk (HR) siblings of children with ASD were tested at 12 and 24 months (m) of age as part of the Infant Brain Imaging Study. Based on ASD status and Mullen Scales of Early Learning language scores at 24m, HR infants were assigned to the ASD (HR-ASD; N=80), language delayed (HR-LD; N=34), or no diagnosis (HR-ND, N=247) group. 14 LR infants with atypical outcomes (LD, N=11; ASD, N=3) were excluded from analysis. To measure walking ability at 12m, a novel composite comprised of Mullen and Vineland Adaptive Behavior Scales-II items indexing walking-related behaviors was calculated (Cronbach's α=.9). Separate mixed effects models were run predicting Mullen expressive language (EL), receptive language (RL), and visual reception (VR) raw scores including age, walking score, and a 4-level factor for group (reference=LR) as fixed effects, all interactions, and random intercepts. In these models, the age-by-walking score interaction represents the relationship between walking ability and growth in Mullen scores in the LR group, while each 3-way interaction reflects the difference in this relationship between a particular HR group and the LR group.

Results: The interaction between age and walking score was significant in the model for EL (β=0.20, p=.03), confirming that better walking was associated with increased EL growth for LR infants (Figure 1). The effect of walking scores on EL growth was significantly attenuated in the HR-ASD group compared to the LR group (β=-0.13, p=.04) and was marginally attenuated in the HR-LD group compared to the LR group (β=-0.09, p=.08). No other three-way interactions were significant for EL. No interactions including walking score were significant for RL or VR; thus, walking ability was only associated with EL development.

Conclusions: For LR infants, better walking ability at 12m was associated with greater subsequent gains in EL. Only the HR-ASD group displayed a statistically different relationship between walking ability and EL growth relative to the LR group, though this effect was trending in the smaller HR-LD group. Importantly, walking ability was related only to EL and not RL or VR growth, suggesting that walking is specifically related to EL rather than to cognitive maturation more broadly.

128 **237.128** Validation of Rapid Interactive Screening Test for Autism in Toddlers (RITA-T) in a Chinese Population

X. Kong[1], *M. Koh*[2] *and J. Kong*[3], *(1)Massachusetts General Hospital, Boston, MA, (2)Radiology, Massachusetts general hospital, Charlestown, MA, (3)MGH, MA, MA*

Background:

A growing body of evidence confirms that early diagnosis and intervention significantly impact the prognosis of individuals with Autism Spectrum Disorder (ASD). The average age for diagnosis is currently around 3-4 years, but many ASD individuals start to show signs as early as infancy.

Development of an easily applied early detection tool and screening test has become imperative and has drawn a great amount of attention in recent years.

Objectives:

The Rapid Interactive screening Test for Autism in Toddlers (RITA-T, published in 2015) is a recently developed test for early ASD detection. However, its feasibility and variation in sensitivity have never been assessed in an Asian population. The aim of this study is to evaluate this new screening method on children with an ethnically or culturally Chinese background and propose improvements and modifications to benefit more children at high risk for ASD.

Methods:

In this ongoing study, 14 Chinese children (age range from 1.5 to 4, average 2.7) living in the US were recruited. All participants met the following inclusion criteria: 1) aged 1-6 years old; 2) parents or teacher recommend further examination based on their observation or a preliminary screening; 3) Younger sibling of ASD individuals; 4) higher risk population based on survey, with established perinatal risk factor.

Results:

Preliminary analysis showed a significant correlation between the ADOS score and RITA-T score (Spearman's correlation, rho = 0.72, p =0.004). Based on the ADOS assessment, 13 children were diagnosed with ASD. With a cut line of 16 (RITA-T score), we found a sensitivity of 82% and specificity of 33%. We also administered an eye tracking test with a paradigm developed in our lab; the data analysis is still ongoing.

Conclusions:

Our preliminary results provided important proof-of-concept information on early screening using RITA-T, which may serve as a basis for further investigations.

Poster Session

11:30 AM - 1:30 PM - Room: 710

129 **238.129** Francophone Students with Autistic Spectrum Conditions: What Do They Have to Say Regarding Their School Inclusion Experiences?

M. Aubineau[1] *and T. Blicharska*[2]*, (1)Université de Toulouse, Toulouse, France, (2)Psychology, University of Toulouse Jean Jaurès, Toulouse, France*

Background: Recently, an increasing number of students diagnosed with high functioning autistic spectrum conditions (HFASC) were able to attend mainstream high schools in both France and Quebec. Despite international studies and governmental recommendations to involve directly youth with HFASC in research, their own perspective has rarely been taken into account in francophone research settings.
Objectives: Grounded in an ecological approach where participants are acknowledged as experts and knowledge co producers, our work aims at understanding how they cope with mainstream education in high schools.

Methods: 26 teenagers with HFASC (13-17) and their parents collaborated in this research, in France (n=17) and in Quebec (n=9). This study examines qualitative data from semi-structured interviews with the teenagers in the light of descriptive analyses of two questionnaires that they completed: the *Friendship Qualities Scale* (FQS) and the *Self-Perception Profile for Adolescents* (SPPA).

Results: ***Questionnaire analysis.*** Cluster analysis identified three profiles of friendship representation (FQS), mainly distinguished by two dimensions: companionship and help/aid from a friend. Three dimensions (social acceptance, close friends and physical appearance) differentiate self-perception into a 4-group typology (SPPA). Moreover, social skills training support (individual or group sessions) were positively correlated with more confident friendship and self-representations. ***Thematic analysis.*** Managing sensory overload in the school setting (N=20), perceived immature behaviors and bullying from peers (N=19) and fatigue resulting from to important workload (N=15) are identified as the main obstacles for their wellbeing in high school. On the contrary, being included in an intensive or international academic program (N=7), being driven by a passion or a clear objective (N>15) and having a friend in the school environment (N=11) appear to be important enablers for a successful inclusion. In France, the benefits *vs* limits of the teaching assistant's presence in class (between 12 to 20 hours per week) need to be examined more closely, from the perspective of specific challenges for self-esteem and autonomy. Although strongly dependent of peers' representations, the autistic identity is generally well lived and accepted, especially outside of high school (N>18). Finally, differences between France and Quebec in access to health services and school systems appear to have little impact on adolescents' well-being but raise a number of questions regarding provision support access inequalities for certain families, considering the frequent use of private services in France.

Conclusions: When France and Quebec just released their new national plans for autism, transition from adolescence to adult life will constitute one of the major challenges for youth with HFASC in the next few years and has to be anticipated as soon as possible. This preparation would allow the adolescents to gain autonomy and practical skills to better understand their needs and strengths and allow them to speak for themselves in a professional environment. Finally, our work highlights the interest for Francophone research and society to move from a deficit-led approach to a neurodiversity paradigm, promoting empowerment of individuals and considering ASC as a valuable contribution to human diversity.

130 **238.130** Friendship and Victimisation in Children with Autism Spectrum Disorder in Support Mainstream Secondary Schools - a Mixed Method Analysis

A. Jones Bartoli[1]*, I. Dale*[2]*, Y. Dyer*[3]*, P. F. Heaton*[4] *and D. May*[5]*, (1)Goldsmiths, University of London, London, United Kingdom of Great Britain and Northern Ireland, (2)The National Autistic Society, Sheffield, United Kingdom, (3)National Autistic Society, London, United Kingdom, (4)Psychology, Goldsmiths College, University of London, London, United Kingdom, (5)National Autistic Society, London, United Kingdom of Great Britain and Northern Ireland*

Background: School-age children with autism are reported to have poorer well-being outcomes than their mainstream peers (Begeer et al., 2017). Despite research consistently indicating that children with autism are less likely to be socially included than their mainstream peers (Adams et al., 2014; Little, 2001), there is little research exploring the experiences of friendships and victimisation in autistic students in school.
Objectives: To compare well-being and social outcomes of students with and without autism attending mainstream secondary schools with an autism support base.

Methods: A mixed-methods approach was used to explore well-being and experiences of friendships and bullying of 27 young people with autism and 33 typically developing children. Groups were matched in terms of gender ratios and by age (mean age= 12 years, 1 month; SD = 0.69).

Self-report questionnaires included the Subjective Happiness Scale (Lyubomirsky & Lepper, 1999); Self-Report Coping Scale (Causey & Dubow, 1992); and the self-report Strengths and Difficulties Questionnaire (SDQ; Goodman, 2001). Qualitative information was gathered adapting interview items from module three of the Autism Diagnostic Observation Schedule (Lord et al., 2000; as per Rowley et al., 2012).

Results: Regression analyses were conducted to examine how far coping styles and sources of support predicted well-being. Analyses revealed no interaction between Autism/comparison groups and impact of coping styles on SDQ total problem score or happiness, so both groups are considered together (regression statistics, SDQ: Adj r2 =.15, p =.005; Happiness: Adj r2 =.23, p <.001). An Internalising style of coping predicted increased difficulties (β =.35, p =.002). Statistically significant predictors of happiness were using a Problem Solving style of coping, a positive predictor (β = .44, p <.001), and Internalising style of coping, which negatively predicted happiness (β = -.25, p =.02). Sources of social support did not predict either well-being outcome.

We also examined the qualitative and quantitative information collected about friendships, bullying and social support. There are no differences between the groups on the incidences of bullying (p =.15), but students with autism were statistically less likely to use peers and close friends for support (p=.01 and p=.001 respectively). Examination of the interview data indicated greater variance in the understanding and experience of friendships amongst students with autism compared to mainstream peers, and incidences of bullying were more likely to be focused on characteristics related to autism than the range of focus for mainstream children (e.g. appearance, accent, "that person bullies everyone").

Conclusions: These findings suggests that all students, not only those with autism, would benefit from support in developing a more problem-focused style of coping with difficulties. Autistic students do have sources of social support, but are less likely to rely on similar-aged peers. This may be related to the variability we observed in understanding and experience of friendship. We suggest that better understanding the factors underpinning this variability will be an important avenue for future research, allowing schools to better target support for students who may be vulnerable to more significant social difficulties.

131 **238.131** Full Inclusion for Children with Autism in Preschool

***S. A. Yoon**, Child and Adolescent Hospital, Seoul National Univ. Hospital, Seoul, Korea, Republic of (South)*

Background: Many children with ASD spend inordinate amounts of time alone pursuing repetitive and unimaginative activities during free play time in preschool. Moreover they are lack of social communicative skills. Recently inclusive preschool settings have been increased in Korea for children with ASD and their peers are performed a role in play by fostering opportunities for modeling to them.
Objectives: The purpose of this study is to investigate the perceptions and attitudes of early childhood education teachers in inclusive settings, difficulties and needs of special education teachers, and positive and negative effects of children with autism and typical peers.

Methods: This study employs a qualitative research methodology which included participant observation and the in-depth interview with typical peers, general education teachers, special education teachers and parents.

Results: Carefully selected for this study were five integrated preschool. Using thematic content analysis, the positive and negative perceptions, attitudes, appropriateness and readiness of inclusive settings are categorized into sub-themes.

Conclusions: 4 main themes were selected: general teacher's mind and insight towards full inclusion, peer's playing with ASD, uses of special interests for children with ASD, interdisciplinary team approach

132 **238.132** Reading Comprehension in the First Year of Schooling for Verbal Students Diagnosed with Autism Spectrum Disorder

***J. M. Paynter**[1] and M. Westerveld[2], (1)School of Applied Psychology, Griffith University, Southport, Australia, (2)Allied Health, Griffith University, Southport, Australia*

Background: Students diagnosed with autism spectrum disorder (ASD) are at risk of persistent reading difficulties, particularly reading comprehension, with challenges reported in over 50% of students. Early literacy skills are strong predictors of later reading success in children without a diagnosis of ASD. To date however, limited research has investigated early literacy skills in children diagnosed with ASD and whether they are significant predictors of later reading success.
Objectives: Using the Simple View of Reading (Gough & Tunmer, 1986) as a guiding framework, we assessed the reading comprehension skills of children diagnosed with ASD in their first year of schooling and investigated 1) the concurrent links between reading comprehension and reading accuracy; 2) the concurrent links between reading comprehension and listening comprehension; 3) the links between school-age performance on reading comprehension and pre-school ability on listening comprehension, vocabulary, and print concepts (i.e. print and word awareness).

Methods: Students diagnosed with ASD were first assessed at Time 1 during pre-school (n = 57, mean age = 57.61 months, SD = 5.73) and again at Time 2 following entry to their first year of formal education (n = 41, mean age = 73.37, SD = 4.54). At time 1 all participants had their ASD diagnosis verified, could speak in short-phrases, and were able to sit and attend for at least brief periods to complete assessments. At each time point a battery of assessment measures was completed, including at Time 1: listening (story) comprehension (Profile of Oral Narrative Ability [PONA]), vocabulary (Peabody Picture Vocabulary Test-4), and print and word awareness (Phonological Awareness Literacy Screening - PreK); at time 2, reading comprehension and reading accuracy (York Assessment of Reading for Comprehension) and listening comprehension (PONA).

Results: In the first year of formal schooling, 21 of the 41 were able to accurately read two grade-level short passages. Of these 21, 38.1% performed within expected limits on the comprehension component. For the 21 students who completed the comprehension task, reading comprehension was significantly linked with reading accuracy with a medium effect, r = .44, p = .048. Reading comprehension was significantly linked to listening comprehension with a large effect, r = .83, p < .001. School-age performance on reading comprehension was significantly linked to pre-school

ability on listening comprehension (r = .69, p = .001), vocabulary (r = .78, p < .001), and print concepts (r = .47, p = .03) with medium to large effects.

Conclusions: Only 38% of the participants showed age-appropriate reading comprehension skills in their first year of schooling**.** As expected, reading comprehension showed strong correlations with both reading accuracy and listening comprehension skills, consistent with the Simple View of Reading. Finally, pre-school vocabulary knowledge and story comprehension skills significantly linked with later reading comprehension skills. Taken together these results indicate that reading difficulties may be detected prior to, and in, the early years of schooling for children diagnosed with ASD. This highlights the potential for early assessment and targeted intervention to support later reading success for students diagnosed with ASD.

133 **238.133** How Do Children with Autism Spectrum Disorder Understand What They Read?

T. Sorenson Duncan[1]*, K. Manasi*[2]*, S. H. Deacon*[2] *and I. M. Smith*[3]*, (1)Pediatrics / Psychology and Neuroscience, Dalhousie University / IWK Health Centre, Halifax, NS, Canada, (2)Psychology and Neuroscience, Dalhousie University, Halifax, NS, Canada, (3)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA*

Background: Extracting information from written material is a pillar of academic success. For most children with ASD, making sense of what they read – reading comprehension – is a noted area of challenge. To support these children's academic progress, we must understand the component skills contributing to their reading comprehension. Research suggests that children with ASD draw on two broad skills: word reading, the ability to identify words, and oral language, used to attach meaning to these words. Children with ASD tend to have advanced word reading abilities relative to their levels of reading comprehension, which when marked is referred to as hyperlexia. This raises questions about the relative importance of each component skill in the reading comprehension of children with ASD.

Objectives: This study seeks to improve our understanding of the mechanisms by which children with ASD understand what they read. Specifically, this study asks, what are the relations between reading comprehension and (a) word reading, (b) oral language, and (c) component skills of oral language for children with ASD?

Methods: In this systematic literature review, we searched four major databases, using *autis**, *child**, *reading*, *literacy*, and *academic achievement* as search terms. Studies were selected that included both reading comprehension and word reading measures from school-aged, monolingual English-speaking children with ASD. A meta-analysis was then conducted using 27 studies with data from 1018 children.

Results: Descriptive Statistics. These studies reported a wide range of word reading and reading comprehension abilities. Average standard scores for word reading ranged from 82.29-109.05, and for reading comprehension from 74.3-107.59. Consistent with a hyperlexic profile, in all but one study, the average word reading score was greater than that for reading comprehension, with the mean difference ranging from -4.84 to 29.9.

Results: Meta-analysis. Similar mean correlations were found between reading comprehension and (a) word reading (*M r*=0.685 [0.574-0.771], n=27 studies), and (b) oral language (*M r*=0.653 [0.579-0.716], n=24). Among the components of oral language skills, relations were also similar between reading comprehension and (a) vocabulary (*M r*=0.709 [0.563-0.811], n=9), and (b) sentence-level abilities (*M r*=0.701 [0.580-0.791], n=5).

Conclusions: Our results demonstrate that word reading and oral language are essential to reading comprehension for children with ASD. This finding may seem surprising given the noted hyperlexic profile of some children with ASD, which at its extreme suggests word reading in the absence of understanding. However, many assertions about reading comprehension are based on group comparisons between children with and without ASD. In our view, oral language has been over-emphasized in understanding reading comprehension because children with ASD often show more marked difference in this area. By looking within samples of children with ASD, and not only in relation to children with typical development, this study reveals key insights as to the relation between both component skills, word reading and oral language, and reading comprehension for these children. In sum, this study provides a necessary foundation for further studies of the mechanisms that underlie reading comprehension for children with ASD.

134 **238.134** How Do Educators Use Evidence-Based Practices with Students with ASD?

P. LaCava*, Rhode Island College, Providence, RI*

Background: The search for effective practices in autism spectrum disorders (ASD) has been an ongoing initiative for families and professionals alike (Simpson, 2005). While scientifically based research has been promoted since the 1960s, a push for the use of evidence-based practices (EBP) has only been targeted more recently (Odom et al., 2005). Groups such as the National Professional Development Center (Wong et al., 2014) have published critical reports on EBP, including the identification of EBP and practice guidelines. Despite these advances there still exits a research to practice gap (Parson et al., 2013). The overall objective of this research is to explore educators' understanding and use of EBP in schools.

Objectives: The objectives of this study include:

1. identify educator knowledge, opinions and attitudes about EBP
2. describe the practices educators use
3. identify barriers to using EBP
4. identify professional development needs
5. understand how educators make EBP decisions
6. pilot an EBP process tool

Methods: This multi-phase study takes place in a northeastern U.S. state and includes qualitative and quantitative methods. Phase 1, which is currently underway, includes interviews, a questionnaire, and implementation of a pilot EBP process. The questionnaire is used to identity participant demographics, educational level, ASD training, etc. Interviews are used to understand what EBP are used and how educators make EBP decisions. Member checks are used to confirm validity. Participants are also interviewed at their school before, during and after they use the pilot EBP process to gather information about the tool's validity. This tool guides educators to choose, use and evaluate EBP. Participants were recruited through autism related email list serves and must work with at least one student with ASD to be included.

Phase 2 begins in 2019 and is an online questionnaire to survey educators. Phase 1 data will help guide the construction of the questionnaire

which include sections on: participant demographics, understanding/attitudes/opinions of EBP, practices used, training and professional development.

Phase 3 which will be implemented in 2020 uses focus groups, observations and other qualitative methods to gain rich insights about ASD practice in schools as a follow up to the previous two phases.

Results: Educators have been recruited who work with students with ASD from early childhood to young adult levels. Current results indicate that professionals are using a range of eclectic practices, but most were unaware of free EBP resources (e.g., the AFIRM Modules). Some participants noted they don't use some practices with fidelity and that their school/district has limited resources to support them. To date, most participants have stated they like the pilot EBP process tool and that it is helpful for them to think about EBP and use practices with fidelity. Final results will be shared at the INSAR meeting.

Conclusions: Initial implications include the need for more specific EBP training as well as school district level coaching and infrastructure to support educators. Basic dissemination of the NPDC and other EBP work needs to be done. Final conclusions will be made after all data are collected prior to the INSAR meeting.

135 **238.135** How Do Evidence Based Practices Inform an Evidence Based Practice in Psychology Child-Centered and Teacher Coaching Intervention?

K. Pinkman[1], *L. A. Ruble*[2], *M. Adams*[2] *and J. H. McGrew*[3], *(1)Department of Educational School and Counseling Psychology, University of Kentucky, Lexington, KY, (2)University of Kentucky, Lexington, KY, (3)Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN*

Background: When applied within a school setting, the American Psychological Association's Evidence Based Practice in Psychology (EBPP) Framework proposes that optimal clinical decision-making should emerge from a consideration of the overlapping features of the evidence-based practice, student/family preferences and strengths, and classroom teacher resources and needs (American Psychological Association Presidential Task Force on Evidence-Based Practice, 2006). A challenge faced by clinicians, parents, and classroom teachers is how best to integrate EBP's within the personalized context outlined in an EBPP framework. The Collaborative Model for Promoting Competence and Success (COMPASS) is a student-centered, teacher coaching framework based on the EBPP approach (McGrew, Ruble, & Smith, 2015; effect size range 1.1-20).COMPASS is comprised of an initial parent-teacher consultation with a focus on obtaining a shared, holistic understanding of the student with ASD at home and school from those most familiar with the student. Three student goals are identified falling within social, communication, and learning skills domains.

Objectives: To identify what EBP's are present in the intervention plans of an EBPP-informed intervention such as COMPASS. To determine the frequency that each EBP is used in the different domains and which were utilized most. To identify what EBP's are common across learning domains of social, communication, and learning skills.

Methods: Twenty-nine sets of teaching plans targeting three goal domains (social, communication, and learning skills) were evaluated for young students with ASD (age range: 3-8 years). **Procedure.** An initial codebook providing definitions and examples of the 27 EBPs was developed using descriptions from the National Professional Development Center for ASD report on EBPs for students with ASD (Wong et al., 2014). The initial codebook was reviewed and refined for accuracy and clarity by a set of three coders before a final version was approved. The final codebook was then applied to determine what EBPs appear in each section of the teaching plan. EBPs were rated as either present (1) or absent (0). Frequency was calculated by summing the number of occurrences of the EBP within each goal domain and across goal domains to determine which EBPs intersect across domains. **Interrater Reliability:** Two coders independently coded 20% of the teaching plans and 87% reliability was achieved.

Results: Twenty-two of the 27 EBP's (81%) were utilized in at least one teaching plan. Within the social domain, 6 EBPs were utilized on average and the most frequent EBP was peer-mediated instruction (27/29 plans). For the learning/work domain, 5 EBPs were used on average and the most frequently used EBP was visual support (VS) (24/29). For the communication domain, 6 EBPs were used on average and the most frequently occurring EBPs were VS and prompting (20/29). Across domainsthe most frequently occurring EBPs were reinforcement and prompting.

Conclusions: COMPASS teaching plans utilized most of the 27 EBP's within the 29 teaching plans coded. Teaching plans include a variety of EBP's and those most frequently included within domains were peer-mediated instruction and intervention, visual supports, and prompting. Across domains reinforcement and prompting were used most frequently.

136 **238.136** Integrating Family Concerns in School Transition Preparation for Diploma-Track Youth with Autism Spectrum Disorder

J. Chen*, G. I. Orsmond and E. S. Cohn, Department of Occupational Therapy, Boston University, Boston, MA*

Background: In the United States, federal mandates require that parents and transition-age students (14-22 years old) receiving special education services be involved in the decision-making process regarding education and service plans. However, research suggests that families and students may not be meaningfully involved in the process. In particular, students with autism spectrum disorder (ASD) are the least likely to attend or provide input in their annual meetings (i.e., Individualized Education Program meetings), compared to students with other disabilities. Researchers also document that parents of youth with ASD have concerns for their student's adult future, and are dissatisfied with transition preparation and services. Due to their academic successes, youth with ASD who are primarily included in general education, and will receive a high school diploma, may be particularly understudied or inadequately supported in preparing for life after high school. Thus, there is a need for further exploration of how schools are currently addressing the needs and concerns of families of transition-age students with ASD graduating with their same-age peers.

Objectives: The goal of this exploratory analysis was to examine the Individualized Education Programs (IEPs) of 20 students with ASD from their last year of high school, in order to: (a) describe the parent and student concerns and annual goals documented in IEPs; and (b) explore whether families' concerns are integrated in students' annual goals and objectives.

Methods: IEPs were collected directly from families or schools, as part of a longitudinal study with parents and students with ASD graduating with a high school diploma within a year. Content analysis was conducted to systematically code and classify concerns and annual goals/objectives. Additional analyses were completed to examine the congruence between concerns and goals for each individual student. Table 1 provides coding examples. We then explored patterns across all students regarding how families' concerns were being addressed in students' annual goals.

Results: Parent and student concerns and annual goals focused on a wide range of domains, such as high school academics, organization skills,

and life skills (e.g., money management, community mobility). However, in numerous cases, student and parent concerns did not align. Further, families' concerns were often not entirely addressed in the annual goals. For example, one family stated concerns about the student's academics, social/communication with peers, emotional well-being, and transition to college; however, her annual goals only addressed emotion management and strategies to complete academic work.

Conclusions: These analyses provide insight into the types of concerns and annual goals documented for diploma-track youth with ASD. Further, the findings suggest a misalignment between families' concerns and annual goals, intended to direct students' special education supports and services for the year. These findings suggest that schools may have different priorities than families. Overall, the findings highlight the need for future research on how the decision-making process in developing priorities for annual goals is occurring in practice, and moreover how family perspectives are considered in developing transition plans for high school students with ASD.

137 **238.137** Intersections between Racial Biases and Implicit and Explicit Stigma Towards Autism in Two Cultural Contexts within the United States.

R. Obeid[1], *J. Bailey Bisson*[2], *A. Cosenza*[3], *A. J. Harrison*[4], *F. James*[5], *S. Saade*[6] *and K. Gillespie-Lynch*[7], *(1)Department of Psychological Sciences, Case Western Reserve University, Cleveland, OH, (2)Clemson University, Clemson, SC, (3)College of Staten Island, City University of New York, Staten Island, NY, (4)Educational Psychology, University of Georgia, Athens, GA, (5)Psychology, College of Staten Island, City University of New York, Staten Island, NY, (6)American University of Beirut, Beirut, Lebanon, (7)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY*

Background: Disparities in access to care and stigma negatively impact autistic individuals (Durkin et al., 2010; Gray, 2002). Disparities in access to care may constitute a form of structural stigma, or "cultural norms and institutional policies that constrain the opportunities, resources, and wellbeing of the stigmatized" (Hatzenbeuler & Link, 2014, p. 2). Racial biases in autism identification have been documented among clinicians and educators (Beeger et al., 2009). Ethnic minorities are less likely to be diagnosed with autism and are diagnosed later than white children (Valicenti-McDermott et al., 2012). Black children in the US are often misclassified with conduct disorder (CD; Mandell et al., 2007). To the best of our knowledge, no prior study has examined implicit biases in autism identification.
Objectives: To examine implicit and explicit biases in autism identification among college students at two universities within the US (New York and Georgia).

We hypothesized that participants would:

1. Express heightened explicit and implicit stigma towards CD relative to ASD.
2. Be more likely to implicitly associate black children with CD rather than ASD while associating white children with ASD over CD.

Methods:

Participants (N = 510) were recruited from public universities in NY (n = 381; Female: 264, Mean Age:19.37; White: 37%) and Georgia (n = 129; Female:105, Mean Age: 20.17; White: 80%). Participants evaluated two vignettes depicting a child with ASD or CD after being randomly assigned to view either a photo of an African-American or a European-American male child (CAFE Set; LoBue, 2014; Figure 1).

Participants rated explicit stigma towards the children in the vignettes using an adapted Social Distance Scale (Bogardus, 1933), in addition to a measure of explicit racism (Symbolic Racism Scale; Henry & Sears, 2002). Participants also qualitatively evaluated the children's condition (Figure 1). We created two Implicit Association Tests (IATs): "Disability Valence" and "Racial Bias." (Figure 2).

Results:

Regardless of race depicted, participants reported heightened explicit stigma towards CD (M=21.63, SD=5.37) compared to ASD (M=11.15, SD=4.17), t(509)=40.05, p<.001 and did not differ in their accuracy in describing the child's condition as ASD (African-American vignette: 75.6%; European-American vignette: 72.8%) or CD (African-American vignette: 53.5%; European-American vignette: 62.4%). Participants were more likely to implicitly associate good words with ASD and bad words with CD (M=.270, SD=.29), t(498)=20.83, p<.001, and to associate European-American images with ASD and African-American images with CD (M= -.064, SD=.29), t(483)= -4.82, p<.001. No associations were observed between social distance and performance on the IATs. Racism *was* associated with racial bias in NY (r = -.11, p = .04) but not Georgia (r = -.09, p = .33).

Conclusions: This evidence of implicit but *not* explicit racial bias in autism identification among non-specialists, in conjunction with prior research demonstrating that checklists fail to avert misclassification of ethnic minorities by specialists (Burke et al., 2015), suggests that implicit biases contribute to disparities in access to autism care. Future research should evaluate whether implicit attitudes contribute to diagnostic and policy decisions by specialists to clarify contributions of implicit stigma to structural stigma.

138 **238.138** Intolerance of Uncertainty and Anxiety in Children and Youth with Autism Spectrum Disorder

R. J. Pagaling[1], *J. Baraskewich*[2] *and C. A. McMorris*[2], *(1)Educational Psychology, University of Calgary, Calgary, AB, Canada, (2)Werklund School of Education, University of Calgary, Calgary, AB, Canada*

Background: Anxiety is common in individuals with Autism Spectrum Disorders (ASD) and is estimated to occur in about 40% of youth with ASD (van Steensel et al., 2011). Individuals with ASD exhibit two types of anxiety: 1) traditional anxiety disorders that are consistent with the DSM-5 (e.g., social anxiety disorder, specific phobia); and 2) atypical anxiety disorders that are unique to ASD (e.g., other social anxiety, idiosyncratic phobia, fear of change) (Kerns et al., 2011). Intolerance of uncertainty (IU) is one cognitive process implicated in the development and maintenance of anxiety in ASD (Boulter et al., 2014). However, few studies have examined this relationship.
Objectives: The current study will examine: 1) the relationship between IU and atypical and typical anxiety disorders, and 2) IU and anxiety symptom severity in children and youth with ASD. It is hypothesized that IU will be strongly positively associated with atypical anxiety symptoms, as well as severity of anxiety in children and youth with ASD.

Methods: Twenty-five youth aged 8 to 14 with ASD will participate in the present project. Typical and atypical anxiety symptoms will be assessed using the Anxiety Scale for Children with Autism (Rodgers et al., 2016) and The Anxiety Disorders Interview Schedule – Autism Addendum (Kerns, et al., 2014). IU will be measured using The Intolerance of Uncertainty Scale (Comer et al., 2009). Data collection is partially complete (n=18), with

completion expected in Winter 2019. Regression analyses will be conducted to investigate the research questions.

Results: Preliminary analysis showed a significant relationship between child-reported IU and type of anxiety in children with ASD. Additionally, a strong positive relationship was found between total IU, IU subscale prospective anxiety, and anxiety severity. It is anticipated that parent-reported IU will be strongly positively associated with the atypical anxiety symptoms and anxiety severity.

Conclusions: The current study provides further support that children with ASD may exhibit avoidant responses when faced with uncertainty. Findings from the current study will provide valuable insight into the role of IU in applying and facilitating proper interventions to help children and youth cope with their feelings of uncertainty, which in turn may decrease anxiety symptoms.

139 **238.139** Jasper in the Classroom: Preschool Teacher Experiences Integrating Autism Intervention in Lausd Classroom Curriculum

N. Muldoon[1]*, L. Hughart*[1]*, J. Panganiban*[2] *and C. Kasari*[1]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)Semel Institute, University of California Los Angeles, Los Angeles, CA*

Background: JASPER (Joint Attention Symbolic Play Engagement and Regulation) is an evidence-based social communication intervention for children with autism spectrum disorder (ASD) (Kasari et al, 2006). Past research has examined a train-the-teacher model for JASPER in Preschool for All Learners (PALs) teachers in Los Angeles Unified School District (LAUSD) (Lawton & Kasari, 2012). The present JASPER in the Classroom pilot explores the experiences and feedback of teachers regarding their experiences learning and implementing JASPER within the classroom setting.
Objectives: To gain insight into the experiences of LAUSD PALs teachers who were trained to use JASPER strategies for implementation into their daily classroom curriculum.

Methods: Following the completion of the JASPER in the Classroom study, PALs teachers who received extensive training in JASPER were asked to share their experiences as participants (n=10). Teacher interviews consisted of 10 questions prompting for their feedback and were conducted and recorded via Zoom, a web call software. Recorded interviews were later transcribed and coded by two research assistants. Common themes were coded from the responses and prominent themes emerged following a consensus check. All themes were categorized and tallied. Five of the 10 questions were selected for analysis based on relevancy to the present study.

Results: Of the five selected questions, one to four prominent themes emerged per question. Of the ten teachers (n=10), 7 expressed feeling overwhelmed while initially learning JASPER strategies, while 3 expressed initial ease. When asked to report the most useful strategies learned, joint attention gestures (n=7) and language strategies (n=7) were reported to be the most useful, followed by modeling (n=4) and behavioral regulation gestures (n=3). Eight teachers reported that they will use all strategies, while 2 responded that there was one specific strategy they do not plan to employ. All 10 teachers found implementation of JASPER to be feasible in the classroom — three expressed that live-coaching is a necessary aspect of making it feasible, and three thought that having paraprofessionals coached would make it even more feasible. In terms of unprompted comments made, 7 said the strategies are generalizable throughout the day, 7 expressed that JASPER helped them in setting student goals, 5 saw visible improvements in students, and 3 said the strategies are generalizable to all students.

Conclusions: Coding common themes from interviews with PALS teachers revealed promising results of integrating the JASPER intervention within PALs classroom curriculum (n=10). While teachers expressed feeling initially overwhelmed, all found implementation of JASPER to be feasible within the classroom setting and reported they would continue the use of JASPER strategies post-study. These interviews revealed promising results of integrating JASPER intervention directly within the PALs curriculum — rather than requiring teachers to set aside classroom time to implement the intervention — which may potentially lead to an increase in social communication among students with ASD and other related disorders. This feedback regarding different aspects of learning JASPER and implementing it into the curriculum can inform similar studies moving forward, and will allow teachers to be an integral part of this process.

140 **238.140** Latent Change Score Analysis of Writing Development over 12 Months in School-Age Children with Autism Spectrum Disorder

M. C. Zajic[1]*, R. Grimm*[1]*, N. S. McIntyre*[2] *and P. Mundy*[3]*, (1)University of Virginia, Charlottesville, VA, (2)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)University of California at Davis, Sacramento, CA*

Background: Children with autism spectrum disorder (ASD) experience challenges with literacy development, commonly demonstrating challenges with lower-order (i.e., transcription) and higher-order (i.e., text generation) writing abilities. These difficulties have often been explored cross sectionally, but no studies have investigated the writing abilities of children with ASD using multiple time points.
Objectives: 1) To examine change in writing across two time points spaced roughly 12 months apart and 2) to explore predictors of change in writing abilities.

Methods: Seventy-two children with ASD participated in this study (Table 1). Children were aged 9-17 at the first time point (T1) and 10-18 at the second time point (T2). Time points were spaced roughly 12 months apart for all participants. Community diagnoses of ASD were confirmed with the ADOS-2. Cognitive ability (FIQ) was measured with the WASI-II, and all participants fell within the borderline to above average ranges. Writing performance was assessed using the Test of Written Language, 4th Edition (TOWL-4), a narrative writing task where participants generate a story about a provided picture. Participants received different but equivalent forms at T1 and T2. Responses were scored for Contextual Conventions (CC; lower-order writing abilities) and Story Composition (SC; higher-order writing abilities). Word count (WC) was also recorded. Two trained research assistants scored all writing samples and demonstrated excellent interrater reliability on a sample subset (n = 34; αs > .90).

Latent change score models (LCSM) were used to examine change and predictors of change between time points. LCSMs model change between two time points as a latent change factor and allow for assessing the average change between time points, the variance in the change factor (the extent to which individuals differ in change over time), and the extent to which change is proportional at T2 based on T1 (and other predictors).

Results: See Table 2 for estimates and p values. All LCSMs were run using Mplus 7.3. Participants demonstrated significant change in CC and WC but not SC. Additionally, participants showed similar amounts of change for CC and WC but varied for SC. T1 CC and SC negatively predicted latent change (i.e., participants who initially scored lower at T1 improved at T2), but T1 WC showed no association to T2. Adding additional predictors showed CC and SC remained negatively predictive, FIQ positively predicted CC but not SC, and age and ADOS-2 were not predictive for either. For WC, no predictors significantly predicted latent change.

Conclusions: Findings demonstrate that children with ASD make distinct changes in their writing abilities across 12 months. Participants showed more change in lower-order writing abilities (i.e., CC and WC) compared to higher-order writing abilities (i.e., SC). However, while initial lower-order and higher-order abilities predicted later change, initial WC did not predict later change. This provides potential further support to the graphomotor challenges experienced by children with ASD. Furthermore, FIQ appeared to positively influence growth for SC but not for CC or WC. Findings suggest further research is needed to understand the developmental trajectories of writing development in children with ASD.

141 **238.141** National Clearinghouse on Autism Evidence & Practice (NCAEP): Updating a Large Scale Systematic Review of Behavioral Interventions for Children and Youth with ASD

K. Hume[1], *J. R. Steinbrenner*[1], *S. Odom*[1], *B. Tomaszewski*[1], *K. L. Morin*[2], *S. W. Nowell*[3], *M. Savage*[4], *N. S. McIntyre*[5], *S. Szendrey*[6] *and S. Yucesoy Ozkan*[7], *(1)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)University of North Carolina, Chapel Hill, Chapel Hill, NC, (3)University of North Carolina - Chapel Hill, Chapel Hill, NC, (4)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Carrboro, NC, (5)University of California at Davis, Davis, CA, (6)Allied Health, University of North Carolina, Chapel Hill, NC, (7)Frank Porter Graham Child Development Institute, Chapel Hill, NC*

Background: The National Professional Development Center on ASD (NPDC) completed a review of literature published between 1990-2011 and identified 27 evidence-based practices (EBPs) for individuals with ASD from birth through age 21. These findings have had a broad impact on the field since their publication in 2015 (e.g. seminal manuscript cited over 750 times; online AFIRM modules with over 60,000 users that support the use of each practice; identified by IACC as one of the top 20 scientific advances in ASD research). These findings are dated, however, and the National Clearinghouse on Autism Evidence and Practice (NCAEP) is conducting an updated review of the literature and new findings related to the identification of EBPs will be available for IMFAR 2019.

Objectives: The objectives of this session are to (1) identify new practices that have met the criteria for identification as an evidence based practice, (2) identify for whom they are effective (including race, ethnicity, and nationality data of study participants) and (3) identify for what outcomes the practices have an effect.

Methods: The NCAEP team used the same search strategy as the 1990-2011 systematic review, for peer-reviewed articles using variations of the terms (1) autism(e.g., ASD, Asperger) and (2) intervention (e.g., treatment, program, education). The inclusion criteria are experimental or quasi-experimental studies (single-case design and group design) that examine a behavioral, educational, or developmental (i.e., non-medical) intervention for individuals with ASD from birth through 22 years old. The following steps were completed for the systematic review: (1) search of 9 databases, (2) deduplication of search results, (3) title/abstract review (NCAEP team), (4) full-text review for inclusion (NCAEP team), (5) quality review, determination of effects, and preliminary data extraction (NCAEP trained external reviewers), and (6) consensus decision for quality and presence of effects as needed (NCAEP team). The NCAEP team is currently in the process, of reviewing and finalizing the data extraction, which is combining the information about effects, interventions, outcomes, and participants across the 1990-2011 and 2012-2017 reviews.

Results: The 2012-2017 review started with over 61,000 articles in the initial search. Currently, 640 articles have met quality criteria. See the PRISMA chart in Figure 1 for additional details about the numbers of articles during each phase of the review. Preliminary participant data indicates that more studies include 6-11.9 year-olds (56.9%) and 3-5.9 year-olds (44.6%) participants, with fewer studies including 12-14.9 year-olds (27.2%), 15-18 year-olds (18.8%), and the fewest studies including children under 3 years old (9%) and 19-22 year-olds (6%) . Also, only about 30% of included articles report race, ethnicity or nationality data. Early data shows that social (39.5%) and communication (21.0%) domains are the most common intervention targets.

Conclusions: The updated systematic review of behavioral and developmental interventions is an important step to continue to move research and practice forward to improve outcomes for children and youth with ASD. New evidence will likely shift current practice categories (e.g.technology based interventions), identify new EBPs, and provide additional data related to the efficacy of interventions for diverse populations.

142 **238.142** Online Learning: A Good Fit for Students with Autism?

S. H. Hedges*, Special Education, Appalachian State University, Boone, NC*

Background: Adolescents with autism are heavy users of technology for entertainment. What is not well known is how they use it to support learning. Online learning may be a way for these students to take courses in subject areas of interest that may not be available in their local high school, thus helping to prepare them for life after high school. It could also be a way to ease high school graduates with autism into post-secondary education. However, there is a void in the literature on the experiences of online learning of individuals with autism. Taking courses from the comfort of a quiet classroom dedicated to online learning, which is offered in many high schools today, or even from home, may be another way to help adolescents with autism more effectively transition to higher education and/or careers of interest.

Objectives: The purpose of this study was to explore the experiences and perspectives of secondary students with autism with online learning.

Methods: This study used a paper survey with 275 high school students with autism from 30 high schools spread across 3 states in the US. The majority of participants were male (87%), white (72%), without intellectual disability (93%), and on track to graduate high school with a regular diploma (100%).

Results: This study found that while only 27% of participants had an online learning experience, 52% indicated they were favorably disposed to taking online courses in the future. Of those students who had an online experience, the majority found it beneficial mostly due to their ability to control the amount of time they needed to learn. The majority (55%) said they liked learning online because they could take as little or as much time as they needed to work on the course and almost half (48%) indicated they liked it because they could work on it on their own schedule. Regarding the reduction in social interaction through online learning, only 19% said they liked online courses because they did not have to interact with the teacher and 18% because they did not have to interact with other students. Most participants took courses in subjects related to science and math.

Conclusions: Many students with autism who have experienced online learning find it beneficial for the control it gives them over when and the amount of time they devote to the learning. Reducing social interactions by taking online classes was less important. Online learning has the potential to help young adults with autism to ease into higher education or to fill gaps in their knowledge as they transition to adulthood. It can

also allow them to take courses more specific to their interests.

143 **238.143** Parent and Teacher Reports of Internalizing Symptoms in Children and Adolescents with ASD: Implications for School Placement

M. M. McNeel[1], *A. M. Slaughter*[1], *E. R. Jellinek*[1], *K. H. Erps*[1], *J. S. Benoit*[1], *R. P. Goin-Kochel*[2] *and S. S. Mire*[3], *(1)University of Houston, Houston, TX, (2)Baylor College of Medicine, Houston, TX, (3)Psychological, Health, & Learning Sciences, University of Houston, Houston, TX*

Background: Children with autism spectrum disorder (ASD) often experience comorbid internalizing symptoms, such anxiety and depression. Students with ASD may require school-based services to mitigate effects of internalizing symptoms on daily school functioning and long-term educational outcomes. This information about children's and adolescents' emotional, behavioral, and social functioning is most useful for determining impairment and needs—including school-based supports and placements—when gathered from different informants (i.e. parents, teachers). However, differences between parent and teacher ratings of youth internalizing symptoms (INT) are common, and the effect of such differences upon school-based placement for students with ASD is unclear. Understanding how parents' and teachers' reports of internalizing symptoms affect school services is critical to improving school-based support for students with ASD.

Objectives: To (a) compare parent and teacher ratings of INT; (b) identify differences in INT for students in various school-based placements; and (c) explore parent and teacher ratings of INT as potential predictors of school-based placement.

Methods: Data were analyzed from the Simons Simplex Collection (SSC v15.0) and included 591 youths with ASD (age: range=6-17yrs, *M*=10.22, *SD*=3.09). Paired t-tests were used to compare parents' Child Behavior Check List (CBCL) and teachers' Teacher Report Form (TRF) scores on the Internalizing Composite (INT) and the three INT subscales (Somatic Complaints [SOM], Withdrawn [WTH], Anxious/Depressed [ANX/DEP]). These comparisons were then made across three school-based placement groups: 100% general education (No SpEd; *n*=221), mixed general and special education (Some SpEd; *n*=202), 100% special education (All SpEd; *n*=168). Forthcoming multinomial logistic regression analyses will permit identification of how these scores may predict school-based placement into one of these three groups.

Results: Overall, significant differences emerged between parent and teacher scores on SOM (CBCL *M*=56.55, SD=6.99; TRF *M*=53.96, *SD*=6.02), *t*(591)=7.4, *p*<.001, and WTH (CBCL *M*=62.54, SD=8.79; TRF *M*=60.51, SD=7.85), *t*(591)=5.07, *p*<.001. Among the No SpEd and Some SpEd groups, teacher and parent SOM and WTH scores differed but INT and ANX/DEP did not. However, for the All Spec group, statistically significant differences emerged between CBCL (*M*=55.63, *SD*=6.15) and TRF (*M*=58.02, *SD*=7.39) ANX/DEP t-scores, *t*(168)=-3.75, *p*<.001.

Conclusions: Overall, our findings suggest that reports of youth internalizing symptoms with ASD are nuanced in terms of the *informant* (i.e., parent vs. teacher) and *types* of internalizing symptoms (i.e., somatic complaints, withdrawn, anxious/depressed). Moreover, parent and teacher ratings of internalizing symptoms varied depending on school-based placement. These findings suggest that differences in parent and teacher ratings of internalizing symptoms—which affect multiple facets of school-based functioning for students with ASD—may impact school-based placement. This study underscores the need to utilize multi-informant data regarding internalizing symptoms so appropriate support is in place for school-age children and adolescents with ASD.

144 **238.144** Proactive Planning for Evidence-Based Practices in Schools:

B. Ventenilla[1], *M. Melgarejo*[2] *and J. Suhrheinrich*[3], *(1)Special Education, San Diego State Universtiy, San Diego, CA, (2)Education, San Diego State University, San Diego, CA, (3)San Diego State University, San Diego, CA*

Background:

Schools are the primary service sector in which individuals with autism spectrum disorder (ASD) receive care. Although the use of evidence-based practices (EBPs) is mandated in schools (Individuals with Disabilities Education Improvement Act [IDEA] 2004; No Child Left Behind 2001), and school districts are required to provide resources and funding to support the implementation of EBPs; that is not always the case in practice. Districts sometimes fail to provide resources to comply with IDEA standards (Yell, Katsiyannis, Drasgow, & Herbst, 2003), suggesting that sometimes they adopt a reactive strategy (correctly implement EBPs only after an IDEA violation), rather than using IDEA as a framework for effective EBP implementation. Understanding factors related to proactive planning for EBP implementation may support more effective implementation.

Objectives:

To evaluate the factors related to school district use of proactive strategies to support EBP implementation.

Methods:

Thirty members from the California Autism Professional Training and Information Network (CAPTAIN), representing multiple school districts from across the state, participated in a total of six focus groups. Participants were asked to select a program for students with ASD that their district was currently implementing or had recently implemented, and to describe the implementation process.

Audio recordings of the focus group sessions were transcribed and independently coded by research associates, and inter-rater reliability was assessed by comparing coding and discussing discrepancies to arrive at agreement. N*Vivo qualitative software was used to identify themes across participants.

Results:

Participants reported that some districts provide resources to select and implement interventions based on student needs, whereas others do so reactively (e.g., after due process and litigation, or when an escalated situation occurs)(See Table 1). Proactive strategies that emerged include (1) as the number of students with ASD increases, districts provide training and resources to support EBP implementation for students with ASD (2) participants working with the district or SELPA receive a grant to fund programs, (3) districts working with CAPTAIN, an agency that supports the understanding and use of EBPs for individuals affected by ASD, (4) districts identifying student needs in general. Reactive strategies that emerged include (1) interventions being selected because of due process or litigation, (2) students being placed in non-public schools, as districts pay for non-public school tuition if they cannot offer a Free and Appropriate Public Education, (3) participants provide support for a teacher in an escalated situation involving a student with ASD, due to the lack of teacher training. Participants also shared their thoughts on why proactive strategies are not consistently implemented in their districts, and reported that while implementation of proactive strategies would require more

effort and money initially, it is cost-effective in the long run.

Conclusions:

This may give insight on how to allocate resources to proactively address student needs by appropriately selecting and implementing EBPs and prevent reactively addressing student needs after problematic situations occur. Future research should evaluate the differences between schools or districts that act proactively or reactively when providing for student needs.

145 **238.145** Quality of Life of Students with Autism Spectrum Disorder Compared to Typically Developing Students Attending Colleges in the American Northeast

N. Bianculli[1], *L. O. Lavoura*[1], *O. Ghoneim*[1] *and C. C. Mann*[2], *(1)School of Pharmacy and Physician Assistant Studies, University of Saint Joseph, Hartford, CT, (2)Department of Counseling and Applied Behavior Analysis, University of Saint Joseph, West Hartford, CT*

Background:

Autism Spectrum Disorder (ASD) is characterized as a developmental disorder that negatively impacts social functioning (American Psychiatric Association, 2013). As a result, navigating college can present a particular challenge for individuals with ASD relative to their typically developing peers. Approximately 17% of the 50,000 youth diagnosed with ASD who leave high school every year in the United States attend a 4-year college or university (Roux, Shattuck, Rast, Rava, & Anderson, 2015). Though more students with ASD are entering college, reviews of attrition and graduation records found that the completion rate for these students is 79.5% (Roux et al, p 46), a full 10 points lower than college-students with other disabilities. While efforts have been made to identify specific variables that may be impacting the experiences of American college students with ASD, (e.g., Gobbo & Shmulsky, 2014;) few researchers have explored the first-hand accounts of college students with ASD regarding their experiences in college. At this time, one study has been published comparing the experiences of British students with ASD to that of their neurotypical peers (Gurbuz, Hanley, & Riby, 2018). Such an evaluation has not been conducted at an American institution.

Objectives:

This study sought to compare self-reported quality of life (QoL) of students diagnosed with ASD enrolled in degree programs in the Northeastern United States with that of their neurotypical peers using an online questionnaire designed to collect both qualitative and quantitative data.

Methods:

A 68 item (17 demographics, 43 Likert-scale, and 7 open-ended) online questionnaire (adapted from Gurbuz et al.) was distributed to 42 Colleges and Universities in the Northeastern United States with dedicated support programs for students with ASD. Institutional Review Boards approved the study at all participating institutions prior to distribution of the questionnaire. Potential participants were invited to take part anonymously

Results:

981 students participated in the study (20 students with ASD). Among all participants, 78.5% were undergraduate, 15.7% Master's students, and 5.7% Doctorate students. Majority of participants were full time students (85.7%), female (74.2), Caucasian (63.2%), and single (51.1%). For participants with ASD, 35% were diagnosed less than age 5, 90% were diagnosed with a healthcare provider, and 65% report disclosing their diagnosis to their institution. The complete data analysis (i.e., Principal Component Analysis applied to the Likert-scale items to assess the factor structure of the data) will be presented at the meeting.

Conclusions:

Preliminary results of this study have important implications for institutions seeking to better support students with ASD. Further, results suggest not only differences in the college experiences of individuals with ASD, but items related to campus and academic support services also highlight areas of strength and opportunities for improvement relative to supporting this population.

146 **238.146** Read (and talk) with Me: Book Reading Interactions between Children with Autism Spectrum Disorder (ASD) and Their Caregivers.

V. Fleury[1] *and A. B. Ford*[2], *(1)School of Teacher Education, Florida State University, Tallahassee, FL, (2)Educational Psychology, University of Minnesota, Minneapolis, MN*

Background: Professionals advocate for early literacy instruction to be intentionally included in early intervention programming. This targeted instruction is particularly pertinent for children with ASD who are at increased risk for reading difficulties due to social communication deficits that are characteristic of the disorder. Caregivers are instrumental in supporting their children's literacy and oral language development. Reading aloud to children, often referred to as shared reading, has been repeatedly shown to relate to literacy outcomes.

Objectives: The primary aim of this exploratory investigation is to identify malleable factors associated with children's participation in shared reading with their caregiver. We will present our most recent findings from this project with the goal of: (1) describing and comparing shared reading between caregivers and their children with ASD and caregivers and their children with typical development (TD) and (2) evaluating the role of book selection on children's participation and adults' external reading behaviors.

Methods: A total of 37 parents and their preschool children (n = 17 with ASD; n = 20 with TD) participated in this study. Members of the research team recorded caregivers and their children reading nine books together (i.e., 3 familiar, 3 non-fiction, 3 fiction). Caregivers were instructed to read as they would typically. Researchers coded adult and child external reading behaviors (e.g., comments, questions outside of the text, responses) during shared readings.

Results: Our analyses revealed group differences in reading interactions. Caregivers of children with ASD generally talked more during readings than parents of children with TD (F (1, 35) = 5.59, p =.02, partial eta squared = .138). However, children with ASD demonstrated lower rates of responding to caregiver questions and comments compared to children with TD (F (1, 35) = 4.13, p =.050, partial eta squared = .106).

We also explored relationships between book genre (i.e., non-fiction, fiction, familiar) on external reading behaviors. We found a main effect of book genre on caregiver talk, with caregivers talking more during non-fiction books compared to other genres (Wilk's Lambda = .52, F (2, 34) = 16.01, p = <.001, partial eta squared .49). Children with ASD responded more frequently to questions posed during familiar books compared to either non-fiction or fiction books (χ^2 (2, n = 17) = 14.94, p = .001). The interaction between book genre and rates of responding was not significant

for children with TD (χ^2 (2, n = 20) = 1.30, p = .52).

Conclusions: These preliminary findings suggest that caregiver-child interactions during shared reading is qualitatively and quantitatively different for children with ASD and those with TD. Book reading interactions between caregivers and their children with ASD are generally driven by the adult reader. Moreover, many children with ASD may need support in responding to caregiver questions. These findings have potential implications for researchers as they develop shared reading interventions for this population. Malleable factors, such as book genre and caregiver external talk, could serve as the target for intervention efforts.

147 **238.147** Growing up with Autism: What Do We Know? Where Do We Need to Go?

V. Fleury[1], *P. Chaxiong*[2], *J. Gunderson*[3] *and S. Intepe*[4], *(1)School of Teacher Education, Florida State University, Tallahassee, FL, (2)Educational Psychology, University of Minnesota, Minneapolis, MN, (3)University of Minnesota, Minneapolis, MN, (4)Florida State University, Tallahassee, FL*

Background: The quantity and quality of research on autism spectrum disorder (ASD) has grown dramatically over the past few decades. Multiple workgroups have conducted systematic reviews of autism intervention research to identify effective interventions and discriminate new and promising approaches from the deceptive and improbable. The majority of autism intervention research included in these reviews, however, is focused on early intervention and early childhood development (Wong et al., 2014). In recent years, funding agencies and scholars have called for researchers to broaden their scope to address the needs of adolescents and adults with ASD (IES Request for Applications, 2014).
Objectives: The primary research aims are as follows: (1) to evaluate the extent to which the field is responding to this call of broadening research efforts to include adolescents and adults with ASD; and (2) to describe the type of research being conducted and outcomes of interest.

Methods: We conducted a systematic scoping review of empirical research published between 2008-2017 that included at least one individual with ASD age 12 or older. The research team created a protocol that detailed study inclusion criteria, search terms, and appropriate library search databases. Studies were initially screened for inclusion based on a title and abstract review; studies that met eligibility were then subjected to full-text review. The following variables were extracted for each included study: date of publication; study type (e.g., intervention; descriptive); participant ages; primary intervention outcome/study variables.

Results: We will present our results in adherence with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). The initial search revealed 2182 studies. Approximately 25% of these studies (n = 529) met criteria to be included in the review. Descriptive analysis of publication dates shows a consistent increase in the number of published empirical studies from 2008 to 2017 that include adolescents or adults with ASD. A total of 27 studies published in 2008 met inclusion criteria compared to 122 studies in 2017. Data on the nature and type of studies is forthcoming.

Conclusions: Our data suggest that the field is responding to the need to broaden research efforts to include adolescents and adults with ASD. The intent of this scoping review was to provide a broad overview of the current state of our empirical knowledge for this population. These findings may inform researchers as to specific areas of need that remain under addressed in the current body of literature. It is important to note that we evaluated these studies primarily for content. Evaluation of methodological quality of studies was beyond the scope of the current review but will be needed if the goal is to identify specific evidence-based practices for this population. This review should be viewed as a launching point for follow up meta-analytic studies in which researchers attend to methodological rigor as part of their evaluation process.

148 **238.148** Reading Skills in Children and Adolescents with ASD

M. B. McClain *and C. R. Haverkamp, Psychology, Utah State University, Logan, UT*

Background: There is a limited amount of research on ASD and academic functioning (Keen, Webster, & Ridley, 2016). A review of intervention literature specific to children with ASD conducted by Wong and colleagues (2015) found that only 12 percent of the reviewed articles emphasized academic outcomes. Achievement profiles within this population vary (Assouline, Nicpon, & Dockery, 2012), but many individuals with ASD experience academic difficulties, including those who have cognitive abilities in the average range (Estes et al., 2011; Kim, Bal, & Lord, 2018). Reading skills are particularly variable in children with ASD (Nation, Clark, Wright, & Williams, 2006), but research suggests that reading comprehension skills tend to be more impaired than reading fluency within this population (e.g., Mayes & Calhoun, 2008; McIntyre et al., 2017; Whitby & Mancil, 2009). McIntyre and colleagues (2017) found that in a sample of children with ASD, ADHD, and TD, 55%, 33%, and 11%, performed 1 standard deviation or greater below the mean on a standardized measure of reading comprehension, respectively. Assessing reading skills during psychological and psychoeducational evaluations for all students with ASD is important, as it will assist with important educational and school-based intervention planning.

Objectives: Research suggests that several neurocognitive and language abilities play a role in reading deficits in children with ASD (e.g., May et al., 2013; McIntyre et al., 2017; Sansosti et al., 2013). Additional research is needed to more comprehensively understand these relationships. Moreover, given the importance of measuring reading skills in children with ASD, examining how consistently primary standardized assessment tools measure reading skills within this population is needed. The current study preliminarily explores the following research questions: (1) What are the neurocognitive and language correlates associated with reading skills in children with ASD in comparison to individuals without ASD (with and without reading difficulties)?, and (2) is there any variance in reading skill performance across three commonly used standardized assessments in children with ASD?

Methods: Data collection will commence January 2019. Participants in the current study will be children with ASD, specific learning disability (SLD), or TD children between the ages of 6 and 17 and their parents/caregivers and teachers. Child participants will complete a hearing screening, the CELF-5, WISC-V, GORT-5, and reading subtests of the WJ-IV ACH, WIAT-III, and KTEA-3. Children's parents and teachers will complete the ASRS, BRIEF-2, and Conners-3.

Results: For this presentation, descriptive data will be presented. If there have been sufficient participants, repeated measures regression or multilevel modeling (MLM) will be used.

Conclusions: The current presentation will highlight preliminary neurocognitive and language correlates of reading performance for children with ASD and children without ASD (with and without reading difficulties) and discuss the similarities and differences in reading performances across these groups as measured by commonly used standardized achievement tests. The importance of measuring reading performance in youth with ASD, understanding factors that may influence reading skills in this population, and clinical and educational implications will be addressed.

149 **238.149** Relationship between Food Selectivity and Sensory Hyper-Responsivity in Children with Autism Spectrum Disorder: A Qualitative Study

Y. Wang[1], *R. Ohshima*[2], *K. Matsushima*[3], *Y. Yamamura*[4] *and M. Ide*[1], *(1)Department of Rehabilitation for Brain Functions, Research Institute of National Rehabilitation Center for Persons with Disabilities, Tokorozawa, Saitama, Japan, (2)Department of Psychological Counseling, Faculty of Human Sciences, Mejiro University, Shinjuku-ku, Tokyo, Japan, (3)Department of Human Health Science, Graduate School of Medicine and Faculty of Medicine, Kyoto University, Kyoto, Japan, (4)Department of Elementary Education, Faculty of Education, Teikyo University, Itabashi-ku, Tokyo, Japan*

Background: Sensory hyper-responsivity is one of a major symptomatic condition in individuals with autism spectrum disorders (Marco et al., 2011). This symptom appears in various types of modalities and have been suggested to associate food selectivity (Cermak et al., 2010). Children with ASD are overly selective in their eating patterns that they are lack of food variety in intaking flesh fruits and vegetables especially in their earlier developmental stage (Emond et al., 2015). Whereas several studies that examined relationship between sensory hyper-responsivity and food selectivity by quantitative investigation using several questionnaires, little is known about its neurophysiological basis.

Objectives: To obtain more information with regard to the influence of sensory hyper-responsivity on food selectivity in children with ASD, we conducted a study applying a qualitative KJ method which is generally accepted in language data analysis.

Methods: Four children with ASD (7 ~ 14 year-olds male, respectively) and their mothers were participated. The mother answered the Short Sensory Profile (SSP; Tomcheck & Dunn, 2007) which evaluate the severity of hyper- / hypo-responsivity. Three out of four children were over 1 or 2 standard deviation of the standardized mean both in the total score (62, 87, 125 / maximum of 190) and sub-category of Taste / Smell Sensitivity (6, 6, 20 / maximum of 20). Thus, we defined them as 'High sensitivity type' relative to a child defined as 'Low sensitivity type'. Semi-structured interview (30 ~ 50 min) was performed using a guideline which we had developed. We heard "favorite foods" and "disliking foods" as well as those texture and other sensory features for the children and mothers. The authors classified the foods according to that the children are favorite or disliking, and made categories following semantic similarities after putting labels as to speech contents.

Results: We mainly focused on differences between High and Low sensitivity types. We found 3 categories and 8 sub-categories in High sensitivity types (Figure 1). "Difficulty of chewing and swallowing" was related with pickiness to avoid foods that is not easy to eat and bite. "Hyper-responsivity to food texture" was related with avoiding foods' textures and shapes which influence easiness to swallow. They disliked sticky, dry, limp textures of the foods. The category involved preference to eat dark taste. Avoiding of intaking of flesh fruits and vegetables was found. "Atypical picky to food appearance" involved hesitating to eat from foods' appearance. In contrast, Low sensitivity type tended to prefer to weak tastes' foods and flesh vegetables. Influence of visual appearance of foods did not be reported.

Conclusions:Our qualitative study demonstrated that food selectivity is constructed several factors which are shared with all children with ASD having high sensory hyper-responsivity. The result that both "difficulty of chewing and swallowing" and "Hyper-responsivity to food texture" contributed food selectivity was seemed to derived from sensory abnormalities when taking the foods. Chewing and swallowing can be done functioning various nerves in the swallowing reflex. The current study suggested that sensory and motor disabilities might be underlying in food selectivity.

150 **238.150** Resilience in the First Year of College for Students with ASD

M. Pizzano[1] *and C. Kasari*[2], *(1)Education, University of California, Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA*

Background: Adjustment in the first year of postsecondary education is challenging for all students, but those with autism spectrum disorder (ASD) and other learning disabilities experience greater psychosocial and academic difficulties (HERI, 2011). Knowledge about the college experience of those with ASD is increasing (e.g. Gelbar, et al., 2014), but little is known about factors contributing to the success of these students. Resilience has been referred to as adjustment and adaptation to college with optimal outcomes in grades, and mental health (Hartley, 2011). Objectives: The current study will examine predictors of adjustment of individuals with ASD, ADHD/LD, or no disability in their freshman year of college.

Methods: This secondary analysis looked at the nationally representative sample of college students who completed both the Cooperative Institutional Research Program (CIRP) Freshman Survey at the start of and the Your First College Year Survey at the end of their 2016-2017 academic year (n=9493). Respondents were divided into three groups: self-report of learning disability (LD), or attention deficit hyperactivity disorder (ADHD) (n=483), having ASD (n=23) or reporting no learning issues (n=4275). Regression models were applied to each group to identify predictors of adjustment. Individual survey items were combined to create the predictors of social support, high school scores, service access, study habits, and family resources. Items were combined into the outcome variables of academic performance, and overall satisfaction.

Results: Regression models were run for each group on each outcome with bonferonni correction for multiple posthoc tests. For the group with **no learning issues**, significant predictors were **1)** good academic study habits for improved mental health (b=0.20, p<0.00) and better academic performance (b=0.74, p<0.00), **2)** higher ratings of social support for improved mental health scores (b=0.02, p<0.01), and **3)** higher high school test scores for better academic performance (b=0.74, p<0.00). For those **ADHD and/or LD**, significant predictors were **1)** better study habits for, improved mental health scores (b=0.22, p<0.00) and better academic performance (b=0.84, p<0.00), and **2)** higher high school test scores and for better academic performance (b=0.14, p<0.00). For those with **ASD**, the significant predictor was **1)** better study habits for better academic performance (b=0.93, p<0.02).

Conclusions: For the no learning issues group, academic study skills predicted both academic success and optimal mental health in the first year, with social support and high school test scores playing additional roles. The ADHD/LD group had similar predictors of academic study skills and high school test scores. However, for those with ASD, neither social support nor test scores played a role in first year resilience, with the only factor being academic study habits. Results suggest that all students benefit most from support in academic study habits and that resources may need to be directed towards building this important skill. Further investigation with a larger group of students with ASD is warranted.

151 **238.151** Response Differences on the Minecraft Writing Assessment: Comparisons between Children with Autism Spectrum Disorder, Children with Attention-Deficit/Hyperactivity Disorder, and Typically Developing Children

S. Wilson[1]*, M. C. Zajic*[1] *and P. Mundy*[2]*, (1)University of Virginia, Charlottesville, VA, (2)University of California at Davis, Sacramento, CA*

Background: Children with autism spectrum disorder (ASD) demonstrate broad challenges with transcription and text generation. Recent studies have shown that these challenges are related to difficulties with language, social communication, and executive functions. The Minecraft Writing Assessment (MWA) was designed to explore writing challenges in children with ASD compared to children with attention-deficit/hyperactivity disorder (ADHD) or typical development (TD). Preliminary findings have shown group differences on word production but have not explored potential relationships between broader task performance and text production across groups.
Objectives: 1) To examine group differences in response style to the prompt, audience awareness, and items recalled during video recall or writing; 2) to compare relationships between word production with item recall during video recall and writing.

Methods: A total of 132 (66 with HFASD, 29 with ADHD, and 37 TD) children participated who were matched on age (M=14, SD=2.24). Both clinical groups were matched on FIQ. ASD diagnoses were confirmed using the ADOS-2, and ADHD diagnoses were confirmed using the Conners-3. All participants completed the experimenter-designed MWA that included a questionnaire about Minecraft, watching and recalling items from a short two-minute gameplay video, and a ten-minute writing prompt where participants either handwrote or typed a story about the video to a specific audience (a peer their own age who had never played Minecraft). Writing samples were counted for words and were coded as either being written in a narrative or a descriptive style. Audience awareness was coded dichotomously for including at least one comment/detail intended for someone unaware of Minecraft. Item recall was coded for 35 items across seven categories for immediate video recall and inclusion in writing sample (Table 1). All categories were also scored dichotomously for whether a child recalled any item within a given category (Table 2).

Results: Groups did not differ on response style (67-85% wrote descriptively) or audience awareness (28-36% addressed an audience; Table 1). Groups differed on item inclusion, with ASD and ADHD performing lowest on total item inclusion (Table 1). Children with ASD or ADHD often performed lowest for recall during video or writing for items remembered per category (Table 1) and for any items were recalled per category (Table 2). ASD showed a moderate relationship between word count and item inclusion (r=.46, p<.0005) but not video recall (r=.23, p=.07). ADHD showed a moderate relationship with word count and both video recall and item inclusion (rs=.60-.61, ps<.001). Both were unrelated for TD, though prior findings suggested this was due to less variability in observed word count. Partial correlations with FIQ demonstrated similar findings across groups.

Conclusions: Groups responded similarly to the prompt, but children with ASD demonstrated specific difficulties with item recall, particularly with children with ASD showing more prominent gaps in recall categories compared to children with ADHD or TD children. Children with ADHD showed a more consistent relationship compared to children with ASD between recall and inclusion of items with word count. These findings offer insights into potential predictors associated with writing difficulties in children with ASD.

152 **238.152** Self-Directed Video Prompting: Promoting Rapidity of Skill Acquisition and Independence across Settings

G. Yakubova[1]*, L. Leibowitz*[2]*, B. L. Baer*[1]*, N. Halawani*[3] *and L. Lestremau*[2]*, (1)University of Maryland, College Park, MD, (2)Ivymount School and Programs, Rockville, MD, (3)Special Education, University of Jeddah, Jeddah, Saudi Arabia*

Background: Achieving independence across a variety of post-school settings is critical for students with ASD. With post-school outcomes of students with ASD being very low compared to peers without disabilities and challenges students with ASD encounter in daily life, the need to examine strategies that contribute to independence in completing vocational, daily living, and functional tasks is important. One strategy that could be a game-changer and could bridge the skills gap is technology. Video prompting (VP) is one such practice that has been found effective in teaching skills to students with ASD. The presentation describes the results of the study that examined the effects of point-of-view VP with least-

to-most prompting (LMP) system on the rapidity of students' vocational skill acquisition. While many studies examined the use of VP in teaching students with ASD, studies that examined the effects of VP on teaching vocational skills were limited. Further this presentation shares the strategy for decreasing the need for extensive job coaching and shifting adult prompting to self-prompting using technology.
Objectives: The purpose of this study was to examine the effects of point-of-view VP with LMP system on the rapidity of skill acquisition of two students with ASD and two students with ID when working on school-based job tasks with process steps that required students to pay attention to the process of task completion rather than the functional step itself.

Methods: A multiple probe across students design of SCRD (Horner & Baer, 1978) was used to identify the effects of a VP and LMP intervention on students' skill acquisition during a vocational task**.** Four students with ASD and ID participated in the study. Visual analysis and effect size calculations (Tau-U) were used to analyze data, as is recommended for SCRD data, to determine the existence and magnitude of a causal relation between the intervention and outcome (Kratochwill et al., 2013).

Results: Each of the four students showed significant increases in skill acquisition between the baseline and intervention phases (see Table 1 and Figure 1). The weighted average Tau-U resulted in 1.0, demonstrating a strong effect of the intervention between baseline and both the intervention phase and VP-only phase. The Tau-U effect with 90% confidence intervals was between 0.7695 and 1.

Conclusions: The VP and LMP as a combined intervention is effective in improving vocational skills of students with both ASD and ID. Given the versatility of this method, and the ease with which it can be created and personalized, VP and LMP can be used by educators to teach a variety of skills to students with ASD. Upon skill acquisition, students can use VP as a self-prompting support and fade it as necessary for completion of various tasks without relying on adult prompts. This method can also be used throughout one's life in a variety of settings due to the versatility and portability of the strategy.

153 **238.153** Sleep Problems and School Functioning in Adolescents with ASD

I. Schouwenaars[1]*, M. Magnee*[1]*, C. van Bennekom*[2]*, H. M. Geurts*[3] *and J. P. Teunisse*[1]*, (1)HAN University of Applied Sciences, Nijmegen, Netherlands, (2)R&D, Heliomare, Wijk aan Zee, Netherlands, (3)University of Amsterdam, Amsterdam, Netherlands*

Background:
Sleep problems are common in adolescents with ASD (Cortesi, Giannotti, Ivanenko, & Johnson, 2010), with reported percentages of up to 88% (Hodge, Carollo, Lewin, Hoffman, & Sweeney, 2014). While a growing number of studies show that sleep problems during adolescence have a major impact on school functioning in typically developing adolescents (e.g. Dewald, Meijer, Oort, Kerkhof, & Bögels, 2010; Curcio et al., 2006; Pagel, Forister, & Kwiatkowki, 2007), the relationship between sleep problems and school functioning in adolescent with ASD is not yet clear. The majority of these studies have used subjective measurements of sleep, which are known to have a poor reliability compared with objective sleep measures (like actigraphy). Subjective sleep measurements are important to establish sleep quality, however, objective measurements can't be ignored (Goelema, 2018). Therefore, both objective and subjective sleep measurements are included to investigate the relationship between sleep and school functioning in adolescents with ASD.

Objectives:

The objective of the present study is to identify the most relevant features of objective and subjective sleep variables in relation to school functioning in adolescents with ASD.

Methods:

In a repeated measures design (daily measurements over a period of three weeks) 20 adolescents with ASD and sleep problems were assessed on self-reported measures of sleep and school functioning by means of a webapp. The adolescents completed a sleep diary with questions about sleep onset latency (SOL), number of awakenings, wake time after sleep onset (WASO), total sleep time (TST), sleep quality, napping, last night's activities, electronic media-use and caffeine use. At the end of each day they completed questions about their school functioning (mood, concentration, stress, fatigue, mental effort and physical exercise). Also one of their parents and a teacher completed questions about the adolescents' functioning. Additionally, in ten adolescents, sleep was measured with a sleep tracker (Elan, Philips ©) throughout the study period. The Elan obtains reflective, green-spectrum photoplethysmography (PPG) data from the wrist and acceleration data (ACC) using an internal 3D accelerometer. Variables used from the Elan device are: SOL, (TST), WASO, number of awakenings and sleep efficiency (SE).

Data were analyzed with network analysis level to explore the relationships between aspects of sleep and school functioning. Network analysis is a new and promising analysis to establish a network representing the relations between directly measured variables (nodes), which can be performed on individual and group level (Costantini et al., 2015; Epskamp, Waldorp, Mõttus, & Borsboom, 2018). In total, the network contains 17 nodes: TST, SOL, WASO, number of awakenings (measured with the Elan and self-reported), sleep quality, mood, fatigue, stress, concentration, electronic media-use and caffeine use, physical exercise and mental effort (self-reported). Three separate network analyses with the same 17 nodes (at group and individual level) are performed: 1) aspects of sleep and school functioning measured by adolescents, 2) aspects of sleep and school functioning measured by parents and 3) aspects of sleep and school functioning measured by teachers.

Results: Results will be presented at the conference.

Conclusions: Conclusions will be presented at the conference.

154 **238.154** Steam Education to Empowerment Autistic Children: Exploration of an Project-Based Methodology with Reverse Inclusion

M. Baquerizo*, M. Hurtado and B. Lucero, Turing: science, technology and neurodiversity, Lima, Peru*

Background: Different studies show that individuals with an autism spectrum condition (ASC) tend to gravitate towards the fields of science, technology, engineering, art and mathematics (STEAM). The approach in childhood to these fields, not only can enhance the talent, also facilitate the development of social and communication skills. **Objectives:** We describe the vision of our approach and the exploration of a project-based methodology with reverse inclusion.Methods: This methodology was applied in workshops to groups of children between 8 and 15 years old, especially related to robotics, electronics and programming. Data were obtained from a participant observation and analyzed qualitatively.
Results: It is important that the groups conform according to interests, and the activities around the project are structured to the maximum, the roles must be defined according to the complexity of the activity and the characteristics of each child. It is convenient to include other activities

not structured to facilitate the generalization of social and communication skills. The inclusion of neurotypical children and autistic facilitators is very positive. **Conclusions:** Our project-based methodology with reverse inclusion It seems to be useful for STEAM education in ASC, this type of approach can to bridge the gap in social inclusion of autism community in developing countries.

155 **238.155** The Academic Background of Teachers Working in Specialized Classes with Adolescents Who Have Autism Spectrum Disorder

***M. Bessette**, Psychology, Université du Québec à Montréal, Montreal, QC, Canada*

Background: In Quebec, a majority of students with autism spectrum disorder [ASD] are educated in specialized classes within a mainstream school. Their teachers usually have an academic background in special education, but they are not equally prepared to work with children with ASD. In addition, the teaching profession requires a constant actualization of knowledge and skills and teachers must always adapt to the numerous changes that will occur during their career. However, unfavorable conditions to a thoughtful approach towards their professional development still exist. Moreover, researchers found insufficient data demonstrating empirically the efficiency of professional development on students learning.

Objectives: This study, which is financed by the Social Sciences and Humanities Research Council and is part of a larger research project, aims to compare 1) the initial training and the continuing education and training of teachers working in specialized classes with adolescents who have autism spectrum disorder and 2) their needs for further continuing education and training.

Methods: The participants consisted of fifteen teachers (fourteen women and one man) working in specialized classes with six to ten adolescents with autism spectrum disorder. Each participant took part in a semi-structured interview based on an interview grid and a questionnaire regarding their sociodemographic and occupational characteristics. The teachers' training was subjected to an exploratory and descriptive analysis, with transcripts of the teachers' comments coded in two Excel files.

Results: The teachers' initial training is homogeneous, most of them holding a bachelor's degree in Special education. The teachers' continuing education and training is very heterogeneous in both quantity and quality. Furthermore, many trainings followed by teachers are not research-based. The teachers' needs are also large and varied.

Conclusions: The continuing education and training of teachers working with adolescents who have ASD must be oriented and recognized by a board that would implement obligatory guidelines for professional development. And, to ensure their quality, trainings should only be provided by renowned experts certified by this board. Moreover, according to research, supervision is the best form of training for professional development. Therefore, teachers should have the opportunity to be supervised by qualified professionals.

156 **238.156** The Classroom Environment and Engagement of Australian Students with Autism Spectrum Disorder As Reported By Their Teachers

***M. Clark**[1], D. Adams[1], M. Westerveld[2] and J. Roberts[3], (1)Graduate Institute of Educational Research, Griffith University, Brisbane, Australia, (2)Allied Health, Griffith University, Southport, Australia, (3)Graduate Intitute of Educational Research, Griffith University, Meadowbrook, Australia*

Background:

Despite an increase in inclusive education, there is little research investigating teachers' experiences of educating students on the autism spectrum. To date, few studies have described the use of classroom supports for students on the autism spectrum, and studies have yet to compare the instructional material used in the classroom and the engagement of students on the autism spectrum compared to their classmates.

Objectives:

The current study explored the classroom practices of Australian teachers working with students on the autism spectrum. The classroom supports implemented to facilitate learning of students on the autism spectrum were investigated here. Teacher reported engagement in classroom activities and the frequency of instructional material use were compared for students on the autism spectrum and the remainder of the class.

Methods:

Eighty-seven classroom teachers involved in the Longitudinal Study of Australian Children with Autism (LASA) completed a questionnaire pack reporting on student behaviours, and engagement and teaching practices. Teachers selected the accommodations and supports they provided to students in their class on the autism spectrum to indicate those that were most frequently used in support of learning. Frequency of student engagement in classroom activities and the frequency of instructional material use were both coded on a 3-point scale (0- never or rarely, 1-sometimes, 2-often) for students on the autism spectrum specifically and for the remainder of the class.

Results:

Modified or alternate tests, slower paced instructions and allowing more time to complete tasks were the most common modifications made in the classroom to support the learning of students on the autism spectrum. Teacher reported student engagement differed in many ways for students on the spectrum when compared to their classmates. Students on the spectrum required significantly more individual instruction from the classroom teacher ($Z=-2.98$, $p=.003$), or individual instruction from another adult ($Z=-2.83$, $p=.005$). In contrast, the remainder of the class were more likely to listen to whole class instructions ($Z=-2.33$, $p=.020$) and were significantly more likely to engage in classroom discussions by responding to questions ($Z=-3.12$, $p=.002$) than students on the spectrum. According to teachers, students' performance on portfolio tasks and student attitude/behaviour were important when determining the grades of the class as a whole and the performance of students on the spectrum. However, performance relative to a set standard ($Z=-2.82$, $p=.005$), performance relative to the rest of the class ($Z=-2.82$, $p=.005$) and homework ($Z=-3.31$, $p=.001$) were endorsed as significantly more important when determining the grades of the whole class and less important when evaluating the grades of their students on the spectrum specifically. There were no significant differences in the teacher reported use of instructional materials to support the learning of students on the autism spectrum compared to their classmates, with similar instructional materials used class wide.

Conclusions:

The results from this study have important implications for schools and teachers supporting children on the autism spectrum, within the school environment.

157 **238.157** The Effects of Background Noise on Reading in Children with Autism Spectrum Disorder

C. R. Haverkamp *and M. B. McClain, Psychology, Utah State University, Logan, UT*

Background: Commonplace noises in classrooms may result in unfavorable listening environments that negatively affect student learning, including reading skills (Klatte et al., 2010; Maxwell & Evans, 2000). Little is known about how noisy classroom environments impact students with ASD with regard to academic performance. Previous research indicates that individuals with ASD are more at-risk for difficulties with reading (Brown et al., 2013) and attention problems (Leyfer et al., 2006; Mayes & Calhoun, 2007), which could be further impacted by noisy environments. In a recent pilot study (McClain et al., in review), researchers found that children with ASD evidenced significantly lower reading comprehension skills than TD children. However, with background noise, this difference was nonsignificant. Further research is needed to explore the effects of multiple background noises on reading skills in children with ASD.
Objectives:

The current project has the following objectives:

1. To determine differences in reading fluency performance across various background noises for children with ASD.
2. To determine differences in reading comprehension performance across various background noises in children with ASD.
3. To determine differences between children with ASD and TD children in reading fluency performance across various background noises.
4. To determine differences between children with ASD and TD children in reading comprehension performance across various background noises.

Methods:

Participants

Currently, participants in the present study are children diagnosed with ASD (*n*=3) and typically developing children (*n*=13) between the ages of 6 and 12. Children with ASD are identified by parent report and scores on the Autism Spectrum Rating Scale (Goldstein & Naglieri, 2013). Of note, data collection is ongoing. It is anticipated that a minimum of 20 children with ASD and 40 TD children will be included in the final analyses.

Procedures

Participants attended two clinic visits. At clinic visit one, participants completed the WISC-V, a brief language and hearing screening, and the GORT-5 (Form A) while their caregivers completed a demographic questionnaire and three rating forms (i.e., ASRS, BRIEF-P, and Conners-3P). During clinic visit two, participants were administered four reading fluency and comprehension curriculum-based measurements (CBMs) in four different conditions: (1) Quiet, (2) One-Person Talker, (3) Classroom Noise, and (4) White Noise. Participants completed these conditions in an audiologic sound-treated testing booth to ensure extraneous noises were minimized.

Results: Performance on reading fluency and comprehension CBMs are the dependent variables. Reading fluency is measured by percent words read correct and percent of errors made per minute. Reading comprehension is measured by percent comprehension questions answered correctly. The researchers will use multilevel models to determine differences in reading fluency and comprehension between experimental groups and background noises.

Conclusions: While data collection is ongoing, results from an initial pilot study indicate differences in reading fluency and comprehension performance across groups and sound conditions. No specific predictions are included due to the study's exploratory nature. However, findings may help education professionals and parents provide ideal work environments in the school and home settings for children with ASD.

158 **238.158** The Endrew Decision's Impact on the Education of Students with Autism: Implications for School Practice and Policy

S. Hurwitz*, Special Education, Indiana University, Bloomington, IN*

Background: Learners with autism, like all students with disabilities, are entitled to receive a free appropriate public education (FAPE), a component of the Individuals with Disabilities Education Act (IDEA). Historically, the *free* and *public* components have been fairly straightforward; however, the *appropriate* aspect has been at the center of contentious lawsuits. In 2017, the U.S. Supreme Court provided guidance regarding what constitutes an appropriate education for students with disabilities in *Endrew v. Douglas County*. The *Endrew* case centered around a student with autism, and we use it to discuss how the ruling will impact the education of students with autism and to offer recommendations for practice and policy.
Objectives: This study helps education researchers, school leaders, teachers, and families to understand the legal background of special education law and how *Endrew* may alter it going forward.

Methods: We analyze the legal history of the educational benefit standard prior to *Endrew,* and discuss the split in the lower courts that led to the Supreme Court hearing this case. Examining both sides, we debate whether *Endrew* is the educational "game changer" that disability advocates hope it will be.

Results: We make recommendations for schools and education policy in light of the fact that Endrew's family received tuition reimbursement for the specialized (ABA-based) private school that they enrolled him in after he failed to make progress at his local public school. After the ruling, more families may request placement in similar private or charter schools. We find that the decision may not alter the educational approach for students with autism who are progressing alongside their peers. On the other hand, it elevates academic and functional expectations for students who, like Endrew, are placed in self-contained classrooms or are not making grade-level progress.

Conclusions: We provide a list of suggestions for schools: Schools should prioritize behavior management in order to facilitate academic and functional progress at school; IEP goals should be ambitious and measurable to ensure that students are making annual progress; teachers should be trained in evidence-based practices that work for students with autism. There may be an increase in the number of families requesting evidence-based practices, like ABA, from the public school system, and/or placement in alternative settings like specialized charter and private schools.

159 **238.159** The Friendship LAB Social Skills Program for Students with ASD in a Community Setting: A PILOT Study

C. A. Waugh*, Applied Psychology and Human Development, Ontario Institute for Studies in Education, University of Toronto, Toronto, ON, Canada*

Background: The ability to effortlessly and instantaneously modulate to another's perspective, which emerges early in typical development, is a hallmark deficit in Autism Spectrum Disorders (ASD). Among the consequences of this deficit is the reported disparity of friendship among individuals with ASD. Given the contribution of friendship to social and academic outcomes fostering healthy peer relationships is of great importance. Although the need to prioritize social skills development in ASD treatments is not a new notion (Klin & Volkmar, 2000), the urgency of this need has not translated into readily available educational programs to be used in community settings. Previous research suggests that The Friendship Lab is effective in improving social skills and increasing social engagement among children with ASD and may be implemented in the community (Waugh & Peskin, 2015).

Objectives: The present study examines the extent to which social responsiveness and peer relationships improve following the completion of The Friendship Lab program offered in a community setting.

Methods: Thirteen children (10 males and 3 females) with high-functioning ASD, 11-12 years of age (*M* = 11.6, SD = 0.26), participated in this study. Nine weeks of concurrent classes were held for children and their caregivers. The children received instruction via PowerPoint lessons using comic strips to depict social scenarios. Lessons were followed by game play and weekly homework assignments, including hosting playdates, were given. The Social Responsiveness Scale (SRS; Constantino, 2002) was used as an outcome measure immediately at the conclusion of the intervention. Each child and caregiver were also interviewed prior to intervention and then again at a six-month post intervention.

Results: Two-tailed pairwise *t*-tests (pre- and post-intervention) revealed that following participation, children improved significantly on total SRS scores, *p* =.01. They also showed significant improvement on the SRS Social Communication Interaction Index of the SRS, *p* =.02. Although not specifically targeted, improvements were also found on the SRS subtest of Restricted Interests and Stereotypical Behaviours, p =.16. Anecdotally, children appeared to enjoy participation and group leaders reported ease in delivering the manualized curriculum. Parents reported that their children appeared more confident and willing to take initiative in social interactions following participation. At 6 months post-intervention, all families reported having hosted at least one playdate during the previous two months (*M* =6.6, SD=11.76). Children also reported significant increases in their number of friends *p*=.02.

Conclusions: Results indicate that children participating in the Friendship Lab improved in their social responsiveness and peer relationships after having participated in the program. The findings of this pilot study suggest that this social skills intervention can be effectively delivered in a community setting.

160 **238.160** The Impact of Attention on Reading in Adolescents with Autism Spectrum Disorder

C. Archambault[1], *D. Tullo*[2] *and A. Bertone*[2], *(1)Department of Education and Counselling Psychology, McGill University, Montreal, QC, Canada, (2)McGill University, Montreal, QC, Canada*

Background: Research suggests that attention plays an important role in the development of reading skills even after controlling for other known predictors of reading such as general cognitive functioning (IQ; e.g., Rabiner & Coie, 2000) and receptive language skills (e.g., Cain & Bignell, 2013). Most research examining the relationship between attention and reading has been conducted with either typically developing (TD) children (e.g., Dally, 2006; Rabiner & Coie, 2000), or with individuals with Attention-Deficit Hyperactivity Disorder (ADHD) and/or reading disorders (e.g., Kibby et al., 2014; Stern & Shalev, 2013). Less research has been conducted with students with Autism Spectrum Disorder (ASD). The few studies that have examined the relationship between attention and reading in ASD samples suggest that word reading skills are associated with sustained attention (May et. al, 2013; Mayes and Calhoun, 2007). For TD populations, sustained attention has been more strongly associated with reading comprehension skills (e.g., Arrington et al., 2014).

Objectives: The aim of the present study was to examine the relationship between sustained attention and two specific reading abilities; word reading skills and reading comprehension. In addition, we examined if sustained attention adds to the prediction of word reading and reading comprehension above and beyond two other known predictors of reading; IQ and receptive language skills.

Methods: The study included 22 adolescents (M_{age} = 14.3 years old) recruited from a school providing services to students with special education needs presenting with a primary diagnosis of ASD. Most participants had below average general cognitive functioning (M_{FSIQ}= 62.3, *SD*= 22), as defined by the full-scale IQ of the WASI-II (Wechsler, 2011). Attention was measured using the d' score of the Conners' Continuous Performance Test 3rd Edition (CPT 3; Conners, 2014), a computerized attention task. Reading performance was assessed on the Word Reading and Reading Comprehension subtests of the Wechsler Individual Achievement Test-Third Edition (WIAT-III; Wechsler, 2009). Receptive language skills were assessed on the Listening Comprehension subtest of the WIAT-III.

Results: Word Reading scores were not significantly correlated with any predictors (FSIQ, listening comprehension performance, attention). Reading Comprehension scores were correlated with FSIQ (*r*= .43, *p*<.05), attention (*r*=-.76[1], *p*<.01), and listening comprehension (*r*=.70, *p*<.01). A multiple regression analysis was conducted with Reading Comprehension as the outcome measure and the three predictors as the independent variables. The predictors explained 72.8% of the variance in reading comprehension (R^2 =.73, F(3,16)=14.28, *p*<.01). Listening comprehension (β = .44, *p*<.05) and attention (β = .44, *p*<.05) were significant predictors of reading comprehension in the regression but FSIQ was not.

[1] On the CPT-3, a greater score indicates a poorer performance.

Conclusions: Our results suggest that for adolescents with ASD and lower than average cognitive functioning, sustained attention and receptive language skills both play a significant role in reading comprehension. A better understanding of the cognitive factors influencing reading achievement could have a number of implications regarding how reading difficulties in students with ASD can be remediated, such as targeting attention to remediate reading difficulties in students who do not respond to traditional reading interventions.

161 **238.161** The Impact of an Inclusive Pre-College Program on Preparation for Higher Education for Students with ASD

B. Freedman *and W. Garton, Center for Disabilities Studies, University of Delaware, Newark, DE*

Background: Challenges for students with autism in college include difficulty with social communication and adjustment to changing support structures, as well as challenges with day-to-day problem-solving (Dentes & Koles, 2012). The difficulties in transitioning from high school to college contribute to these problems, since students are often not provided with explicit instruction on the systems changes and new skills required to be successful in a higher education setting (Cai & Richdale, 2016). Despite the challenges that persist for college students with ASD, specific supports designed for students with ASD are uncommon and unproven (Gelbar, 2016). Since 2015, the University of Delaware has offered

high school students with disabilities a higher education preparation experience through an inclusive pre-college program. This presentation examines a subset of students diagnosed with Autism Spectrum Disorder and the effects of program participation on readiness for post-secondary education.
Objectives: Explore the impact of a pre-college program for high school students with autism:

- Identify trends in changes to an assessment of learning strategies
- Share student reflections on growth from the program
- Describe post-program changes for the student

Methods: Students received instruction in self-advocacy, social-communication and study skills through two primary interventions: 1) a three-credit, lecture-based course called Metacognitive Strategies, which emphasizes requisite academic and independent skills for college; and 2) academic coaching, an interpersonal process which has been found to be effective in enhancing student success (Mitchell & Topf, 2016). Following completion of the five-week program, students receive follow-up support through individualized and group meetings. A case study approach will be used to describe four previous students with ASD who participated in the pre-college program. Demographic characteristics, including academic profile and high school-based supports pre- and post-program will be shared. Changes in individual standard scores and percentiles on the Learning & Study Strategies Inventory (LASSI; Weinstein, Palmer, & Acee, 2016) will be presented. Educational achievement (e.g., grades in college-level courses) will be described, as well as changes to supports post-program.

Results: Each of the four students exhibited an increase on the study skills assessment and described greater confidence in college. Common themes among students included similarities in gains on LASSI (e.g., subscales in Attitude, Concentration, Time Management), and student reflections on changes from the program (e.g., greater confidence in pursuing college; increased ability to self-advocate). All four students successfully passed both college-level courses in the program. Students advocated for changes to their IEP/504 post-program in order to mirror accommodations more similar to college. This included one student advocating for a reduction in support from paraprofessional services.

Conclusions: Authentic higher education experiences in preparation for college entry shows significant promise for students with ASD. Students participating in a pre-college program showed an increase in study skills, expressed greater confidence in their ability to succeed and knowledge of how to be successful in higher education. The implementation of college-based accommodations and practice navigating higher education systems serves as an opportunity for the student to explore best-fit accommodations and authentically utilize them before enrolling in undergraduate courses as a college freshman.

162 **238.162** The Quality of IEP Goals for Students with ASD in 60 High Schools

L. J. Hall[1], *B. Tomaszewski*[2], *B. Kraemer*[1], *K. L. Morin*[3], *K. Hume*[2] *and S. Odom*[2], *(1)Special Education, San Diego State University, San Diego, CA, (2)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)University of North Carolina, Chapel Hill, Chapel Hill, NC*

Background:
Individual Education Plans are the foundation upon which the educational experience of students with disabilities is built, with annual goals at the heart of the document. In order to measure student progress, it is imperative that these goals and objectives are measurable and linked to assessments. This presentation summarizes an analysis of the quality of IEP goals written for students with ASD from 60 high schools prior to intervention in each of the four domains focused on in a RCT study entitled, the Center on Secondary Education for Students with Autism (CSESA).
Objectives:

- Describe the quality of IEP goals for students with ASD in total and for each of the 4 CSESA domains including: a) if they were written for one target b) if antecedent conditions are clear, c) if they are observable and measurable and d) if mastery criteria are included.
- Determine if there is a significant difference in the quality of goals written for students in a diploma seeking compared with an alternative program.
- Describe the percentage of goals with accompanying data and the amount of time spent coaching educators to write high quality goals.

Methods:
Prior to any intervention, the CSESA research team collected information on the existence and quality of goals written in each of four areas (academic, social, transition, & independence and behavior) for high school students from 60 high schools in three states totaling 1442 goals. Information about the use of data for monitoring progress was obtained.
The goals written for students in the diploma seeking programs (57% of the total) and those in a modified program (43% of the total) were compared across quality features using a chi-square analysis.
Results:

- Only 61% of the goals were taken from the student's IEP written from those already written to address one of the four content areas targeted. The domain with the highest number of goals was academics and the lowest number was transition. Only 25% of the total goals met the criteria for high quality in all areas. The most goals meeting the full quality criteria were Academic (30%), and the least high quality goals addressed Social (18%) competence (see Table 1).
- The chi-square tests revealed that there was a significant difference between programs, with students in the modified program having a higher number of goals that had a single target selected, χ^2 (1, N = 385) = 5.63 p = .020, antecedent conditions clear, χ^2 (1, N = 384) = 9.31, p = .002, the target skill/behavior observable and measureable, χ^2 (1, N = 384) = 6.61, p = .010, and having met mastery criterion, χ^2 (1, N = 385) = 9.04, p = .003.
- Only 13% of all IEP goals written had accompanying data to support baseline performance.

Conclusions:
Professional development is needed to improve the quality of the IEP goals written for high school students with ASD, especially in the social

domain, and for students who are diploma bound and completing their education in general education settings.

163 **238.163** The Relationship between Turn Taking and Joint Attention in Interactions between Caregivers and Young Children with Autism

***K. Lee**, S. Safran and H. Schertz, Indiana University, Bloomington, IN*

Background:
It has been theorized that turn taking, defined as simple back-and-forth exchanges, is foundational to joint attention (Schertz, Odom, Baggett, & Sideris, 2018; Mundy, 2016). Turn-taking sequences may be used to convey instrumental or social intent. While turn taking may be foundational to joint attention, studies that distinguish social and instrumental turn-taking functions and their relationship to joint attention are limited.

Objectives:

The study sought to analyze the strength and direction of the relationship between turn taking (i.e. social and instrumental) and joint attention. We hypothesized that social turn taking would be positively correlated to responding to and initiating joint attention, and that instrumental turn taking would not.

Methods:

This research utilized pre-existing video data of 20 toddlers with autism from the Joint Attention Mediated Learning (JAML) intervention study (Schertz et al., 2018), which was designed to help toddlers with autism learn social preverbal communication (i.e. joint attention) through caregiver-child interaction. Spearman's (1904) Rank-Order Correlation Coefficient was employed to determine the strength and direction of the relationship between social turn taking and instrumental turn taking with joint attention. Instrumental Turn Taking (ITT), Social Turn Taking (STT), Responding to Joint Attention (RJA), and Initiating Joint Attention (IJA) were measured using a video observational coding system. The STT, RJA, and IJA measures from the Precursors of Joint Attention Measure coding manual (Schertz, Horn, Lee, & Mitchell, 2018b) were used. An ITT measure was added to the coding criteria for the present study. A primary observer coded a total of 120, 10-minute videos (six per participant) for observances of variables, and a secondary observer coded 25% of the videos. The mean percent agreement (and ranges) of interobserver agreement for ITT were 93.47% (76-100%), 95.22% (71-100%) for STT, 98.31% (88-100%) for RJA, and 99.15% (95-100%) for IJA.

Results:

Correlational analysis revealed a significant positive relationship between instances of STT and RJA, (18) = .481, $p < .05$, one-tailed. In addition, there was a significant positive relationship between instances of STT and IJA, (18) = .622, $p < .00$, one-tailed. In other words, there were tendencies for participants who showed more STT to also show more RJA and IJA. The coefficient of determination (was calculated and indicated that 23.13% of the variance in STT is shared with RJA and 38.68% of the variance in STT is shared with IJA. Correlational analysis revealed no significant relationship between ITT and RJA, (18) = .337, $p = .07$, one-tailed, and between ITT and IJA, (18) = .161, $p = .24$, one-tailed.

Conclusions:

The current study identified a positive relationship between social turn taking and both joint attention variables and no relationship between instrumental turn taking and either joint attention variable. While not causal, these findings may support the theory that social turn taking, a simple form of dyadic engagement, is foundational to triadic joint attention, a more complex form of engagement. A larger sample size is needed for future investigation for a more rigorous examination to validate the hypothesis.

164 **238.164** There's No "One-Size-Fits-All" Approach: How Future Faculty Plan to Teach Autistic College Students

***B. R. Nachman**, University of Wisconsin-Madison, Madison, WI*

Background: Higher education institutions are experiencing increased enrollments of autistic college students, as White, Ollendick, and Bray (2011) estimate that up to approximately two percent of college students may meet the criteria for autism. Faculty who are ill prepared to effectively teach autistic college students may undermine students' academic success, as opposed to capitalize on their interests and strengths (Austin & Peña, 2017). We must shift our attention toward supporting future faculty (e.g., faculty-aspiring graduate students and postdocs), though there is an absence of literature on educating them about autistic college students. Consequently, this study illuminates the possibilities of reaching future faculty who prioritize designing inclusive classroom experiences.
Objectives: The purpose of this mixed methods evaluation study is to examine both the efficacy of an online autism-centered unit of an "Inclusive Teaching" course – focused on inclusivity, equity, and cultural diversity issues – as well as future faculty readiness to teach autistic college students. In particular, the research questions were threefold: 1) How do course unit activities promote future faculty understandings of autistic college students and Universal Design principles?"; 2) How do future faculty describe characteristics of autistic college students?; 3) How do future faculty self-report their comfort, knowledge, and preparation to teach autistic college students?

Methods: This study, following a mixed methods evaluation design, gathered data from participants via three sources: surveys with Likert-scale and open-ended questions (distributed before, immediately after, and six months following the autism unit); written responses to vignettes (prompting participants to note how classroom context influences teaching techniques); and interviews (conducted one month and seven months after the course concluded). I utilized Dedoose to conduct open coding and structural coding for each of the interviews, vignettes, and open-ended survey questions, clustering similar themes into categories. I also conducted descriptive statistics of the quantitative data, marking participants' changes in comfort, knowledge, and preparation. I mixed findings across the qualitative and quantitative strands through comparing participants' descriptions of their autism comfort, knowledge, and preparation with how they answered Likert-scale questions on similar topics.

Results: Three themes surfaced, each related to the individual research questions. First, participants found vignettes as helpful in recognizing and addressing various manifestations of autism in college students, drawing on anecdotes in guiding their planned teaching techniques, such as developing inclusive group work assignments. Second, participants described autism as impacting individuals across the lifespan, compared to their previous understandings of this as a "childhood disorder." Thus, future faculty shared examples of how they can support autistic students' individualized needs in navigating college. Third, based on survey data, participants exhibited growth in their level of comfort, knowledge, and preparation to teach autistic college students, noting how engagement in the course unit elevated their confidence in meeting students' capabilities for academic success.

Conclusions: Training future faculty about autistic college students appears effective in boosting future faculty preparation, comfort, and knowledge of this student population. Additionally, this course unit provided them with an outlet to learn about, experiment with, and reflect on their inclusive teaching techniques.

165 **238.165** Training Academy: Supporting Educational Personnel to Train Their Staff in ASD

ABSTRACT WITHDRAWN

Background:
Education professionals rarely receive specialized training in autism. This study further evaluated a new Training Academy to support existing school personnel to train their own staff. Following a successful pilot study (IMFAR, 2017), this abstract now reports the full results of our developed training model. Participants attended the Training Academy as a collaborative cohort. The cohort received training materials and in-vivo practice sessions, prior to delivery of each training. Participants were required to provide their own school staff with 3 trainings: ASD for a general audience; ASD specific to paraprofessionals; ASD specific to speech, social work and O.T.

Objectives:

This study investigated the effectiveness of the Academy model to increase education professionals competence in delivering training to their staff. Two consecutive cohorts were utilized. The study addressed:

- educator change in competence of training skills gained across the training period
- the relationship of educators self-efficacy to outcome
- the relationship of educator self-efficacy to professional experience prior to training

Methods:

Participating educators (n= 29) who attended the Academy completed a structured questionnaire pre and post training.

The questionnaire emphasized key aspects of training competencies. Three sections described a training scenario related to (i) general ASD knowledge, (ii) paraprofessional competencies (iii) related services competencies. The final questionnaire had 12 questions; maximum score, 72.

In addition, the participants completed the ASSET, a self-report measure to assess self efficacy in ASD specific skills (Ruble et al.,2013).

Results:

1. i) T-test revealed that there was a significant ($p<.01$) increase in competence scores pre and post training academy for each type of training provided (general ASD, paraprofessional, related services).
2. ii) ASSET scores were divided by the mean to create high and low self efficacy groups. To compare group performance pre and post training, scores were entered into a repeated measures multivariate analysis of variance, with time (pre, post) as the within subjects repeated measure and group (high, low SE) as the between factor.

There was no significant group by time interaction effects.

iii) To determine the effect of prior experience on educator self-efficacy, data was entered in a logistic regression model with group membership (high and low self-efficacy) as the dependent variable, and lifetime number of ASD students, educational level, and years teaching as covariates. There were no significant effects of professional experience predicting self-efficacy group membership.

Conclusions:

These results indicate the effectiveness of our training program. By attending the training, educators increased their confidence in their ability to train the autism curriculum to their staff. Educators in both the low and high self-efficacy groups increased their training competence scores over the training period. Furthermore, educators' self-efficacy for training competencies appeared to have little relationship to their prior professional experience, experience with autism or their educational level. This has important implications for training educational professionals. Even professionals who have many years experience, or who have taught many students with ASD, can increase their own training competence by attending an intensive training. The Training Academy is now being provided to professionals in subsequent cohorts.

166 **238.166** Utah Neurodiversity Workforce Program (UNWP): A Higher Education Consortium to Deliver an Education-to-Employment System

V. D'Astous[1], *C. Wright*[2], *A. V. Kirby*[3], *M. Diener*[2], *S. D. Wright*[4] *and N. Warren*[1], *(1)FCS, University of Utah, SLC, UT, (2)University of Utah, Salt Lake City, UT, (3)University of Utah College of Health, Salt Lake City, UT, (4)Nursing, University of Utah, SLC, UT*

Background: UNWP is a state-wide participant-oriented research (POR) program with active involvement by autists to create a comprehensive (unwp.utah.edu) education-to-employment pathway for neurodiverse individuals across Utah. The research is based on interviews with students with autism, parents, staff and faculty (N=62) in higher education indicating the need for specialized services for neurodiverse students. UNWP collaborates with high schools, community and industry partners and is funded by the Governor's Office of Economic Development to improve post secondary entry/completion and employment rates for individuals with ASD.
Objectives: To implement and evaluate the educational pathway including: 1) Increase in higher education success for neurodiverse students; 2) Inter-institutional collaboration of resources from post-secondary sites; and 3) improvement of employment outcomes between the employment needs of Utah's growth industries and the untapped pool of skilled neurodiverse individuals.

Methods: Participant-oriented research involving autists in all areas of program development, implementation, and evaluation of the pathway model.

Results: Year 1 included awareness training to 200 higher education faculty/staff. The program received strong evaluations indicating importance of increasing awareness of neurodiversity. Embedding this model into existing student support services infrastructure of institutions of higher education and vocational-tech schools both ensures its success and enhances existing multi-collaborative relationships. For example, partnering

with Student Career Services, we tapped into their industry partners to provide work-based learning opportunities based on individual student interests and talents. UNWP also increased their staff awareness of the strengths and challenges of this student population and how to best support them in achieving meaningful employment. Awareness trainings to 100 managers and employees in the tech industry and WBL experiences with students with ASD have initiated discussions with HR on how current hiring procedures are creating barriers for this population. Another benefit is that managers began to think more deeply about leveraging the talents of all employees through greater sensitivity to diversity based on evaluations. Seventeen students participated in technology industry work-based learning with 2 students successfully placed in competitive full-time positions. Year 2 is a replication of the model to 3 statewide higher education institutions and is currently underway. This presentation will be a discuss of lessons learned in this participant-oriented research model.

Conclusions: The strength in the development of the UNWP pathway model has been the inclusion of autists in all aspects of development and implementation. Autists are active participants in the development of all educational materials and trainings. This POR research and program development details the scope of the issue, highlighting the challenges and barriers for these students, the benefits that they could contribute to unfilled jobs in the tech industry, and demonstrates how this pathway can be scaled to address this problem state-wide. From this participant-oriented research we have created a state-wide, collaborative, inter-institutional network to meet industry needs. Based on the program development and successful academic, community and industry partnerships, UNWP offers a high rate of return-on-investment. Our pathway model has promising potential for replication across the states and in other international communities.

167 **238.167** Developing a Participatory Autism Training through Collaboration with Autistic College Students and Non-Autistic High School Students

K. Gillespie-Lynch[1], *N. Tricarico*[2], *P. Bongiovanni*[3], *W. Pinkava*[2], *B. Kofner*[4], *A. Hernandez*[5], *X. Rosario*[5], *L. Reinoso*[5], *A. Ainsworth*[5], *M. Pajovic*[6], *J. Irizarry*[5], *A. J. Harrison*[7] *and N. Alcantra*[5], *(1)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY, (2)College of Staten Island, City University of New York, Staten Island, NY, (3)CUNY, Staten Island, NY, (4)CUNY, NY, NY, (5)Pelham Lab High School, Bronx, NY, (6)John Jay, Manhattan, NY, (7)Educational Psychology, University of Georgia, Athens, GA*

Background: Autistic people are negatively impacted by misconceptions about and stigma towards autism (Botha et al., 2018). Participation in a brief online autism training was associated with reduced stigma towards and increased knowledge about autism among college students internationally (Gillespie-Lynch et al., 2015; Obeid et al., 2015; Someki et al., 2018). Past research suggests that modifying autism stigma among adolescent boys is challenging (Staniland & Bryne, 2013); an intensive autism training was associated with improved behavioral intentions among adolescent girls (Ranson & Bryne, 2014). Autistic people may be able to use their autism expertise to improve autism trainings (Gillespie-Lynch et al., 2017).

Objectives: A participatory team composed primarily of autistic college students and non-autistic high school students developed, evaluated and iteratively revised an autism training to increase its potential to ameliorate stigma towards and misconceptions about autism.

Methods: Three autistic (and one non-autistic) college students and seven non-autistic high school students helped adapt an autism training by making concepts/assessments more accessible and adding videos wherein autistic college students shared their insights. High school students in the Bronx (18 female, 35 male) completed a pre-test (assessing demographics, stigma (social distance scale; Bogardus, 1933), and autism knowledge (adapted from prior knowledge measures; Stone, 1987, Harrison, 2017), an in-person autism training delivered by high school students, and a post-test (identical to the pre-test with space for open-ended feedback). While 43.4% of the high school students completed the post-test immediately after the training, 56.6% did the post-test a week later due to limited class time. After evaluating data from the high school students, we revised the training/assessments and administered them online to NYC college students (289 female, 142 male) who completed pre-tests (α social distance= .91; α = autism knowledge = .79) and post-tests immediately before and after the training.

Results: Among high school students participating in an early adaptation of the training, repeated measures ANOVAs with gender and time of post-testing as between subjects variables revealed no changes in stigma associated with training (p =.89) but improvements in knowledge, F (1,48) =4.58, p=.04. Among college students participating in the revised training, improvements in both stigma, F(1, 429) = 61.42, and knowledge were observed, F(1, 429) = 139.48, ps< .001. Females reported lower stigma and higher knowledge (ps < .001) and enhanced improvement in knowledge relative to males (p = .02). Open-ended feedback was overwhelmingly positive, e.g., "I honestly enjoyed this very much, the videos were excellent. I wanted to add that this really opened my eyes to what I would actually like to do with my life:)"

Conclusions: Participation in an initial participatory training adaptation was associated with improved knowledge but *not* improved stigma among primarily male high school students. Participation in a longer revised training (with more videos and opportunities for interactive engagement) led to improved knowledge *and* stigma among primarily female college students. In future research, we will use an identical participatory training with high school and college students to evaluate associations between developmental stage, gender and responsiveness to anti-stigma training.

Poster Session
239 - Emotion
11:30 AM - 1:30 PM - Room: 710

168 **239.168** Topography and Correlates of Emotional Response in Psychiatrically Hospitalized Children and Adolescents with ASD

J. B. Northrup[1], *J. Golt*[2], *J. Montrenes*[3], *J. Vezzoli*[2], *D. C. Cumpanasoiu*[4], *C. Peura*[5], *B. J. Taylor*[6], *M. S. Goodwin*[4], *M. Siegel*[7] *and C. A. Mazefsky*[8], *(1)University of Pittsburgh, Pittsburgh, PA, (2)University of Pittsburgh Medical Center, Pittsburgh, PA, (3)University of Pittsburgh School of Medicine, Pittsburgh, PA, (4)Northeastern University, Boston, MA, (5)Spring Harbor Hospital, Westbrook, ME, (6)Psychiatry, Maine Medical Center Research Institute, Portland, ME, (7)Maine Medical Center - Tufts School of Medicine, Westbrook, ME, (8)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA*

Background: Poor emotion regulation (ER) in individuals with ASD contributes to the high rates of co-morbid psychiatric and behavioral problems, psychotropic medication prescription, and psychiatric hospitalizations. While research on ER in ASD has increased recently, it has mostly relied on questionnaire data from higher functioning individuals or structured tasks in very young children. We lack understanding of the topography and

correlates of poor ER in more severely affected older children and adolescents who require intensive treatment for serious emotional and behavioral disturbance.

Objectives: The present study assessed emotional response to distressing tasks in youth with ASD during psychiatric hospitalizations. We: 1) Describe behavioral and affective responses to tasks, and 2) Analyze relations between individual differences in functioning and autism severity and response to tasks.

Methods: Participants include 112 children and adolescents from the Autism Inpatient Collection (AIC) who were administered a subset of modified paradigms from the Laboratory Temperament Assessment Battery (Lab-TAB) designed to elicit negative affect. Participants represented the full spectrum of intellectual and functional abilities (see Table 1 for participant characteristics).

Affect (valence and intensity) and behavioral response (BR; e.g. inappropriate behavior, aggression) were coded in 10 second intervals from videotapes of assessments. The following variables were calculated from coded data: proportion of intervals with negative response (negative affect or BR), mean intensity of negative response [from 1 (mild) to 5 (highly negative)], average length (i.e. number of intervals) of negative response, range of affect [from -3 (highly negative) to +3 (highly positive)], and negative lability (i.e. proportion of intervals with large negative changes in affect [≥ 3 unit changes] from previous interval).

Results: Table 2 displays descriptive statistics for the six variables describing affect and BR in the initial baseline period (prior to distressing tasks) and during the task portions of the Lab-TAB assessment. As can be seen in the table, mean intensity of negative response, length of response, and range of affect were significantly higher during tasks than baseline.

Furthermore, children with lower adaptive functioning displayed more intense and longer negative responses and more negative lability. Individuals administered ADOS Module 1 (non-verbal/single words) showed more frequent, more intense, longer, and more labile negative responses than individuals administered Module 2 (phrase speech), 3 (fluent speech, child), or 4 (fluent speech, adolescent/adult). Interestingly, despite this relation to verbal ability, negative response variables were largely unrelated to non-verbal IQ and ADOS severity score, with the exception that lower IQ participants displayed higher negative lability.

Conclusions: This is the first study to empirically examine emotional response in children and adolescents with ASD and severe emotional and behavioral problems across the full spectrum of functioning. Results indicate huge variability in response to frustrating tasks that appears to be related, in part, to adaptive functioning and communication abilities. Results highlight the importance of examining ER in non-verbal and severely affected individuals.

169 **239.169** Alexithymia Is Associated with Impaired Interoceptive Accuracy but Not Interoceptive Signal Perception in ASD and Other Populations

D. A. Trevisan*, M. R. Altschuler, A. Bagdasarov, C. Carlos, S. Duan, E. Hamo, S. Kala, M. L. McNair, T. C. Parker, D. Stahl, T. Winkelman, M. Zhou and J. McPartland, Child Study Center, Yale University School of Medicine, New Haven, CT*

Background:

Alexithymia, a condition characterized by difficulties identifying and describing one's own emotions, has high co-occurrence with ASD and other disorders (Bird & Cook, 2013). Prior research is mixed, with studies demonstrating that alexithymia is associated with both heightened (Scarpazza et al., 2015) and reduced (Herbert et al., 2011) perception of interoceptive signals (i.e., internal bodily cues and sensations). Both heightened and reduced signal perception can be maladaptive; the former leading to poor modulation of interoceptive signals, and the latter leading to inadequate detection of interoceptive signals. Maintaining healthy bodily and emotional functioning requires "accuracy" in discriminating interoceptive signals and associating those signals with specific feelings or physiological states (e.g., hungry, nauseous, or angry). Delineating the mechanisms that underlie alexithymia is critical for understanding shared psychophysiological risk factors for various disorders and for considering treatments for alexithymia.

Objectives:

To conduct a meta-analysis to determine the extent to which various facets of interoceptive ability and alexithymia are related, and to determine the methodological factors and sample characteristics that account for heterogeneity among studies.

Methods:

Meta-analysis aggregated effects from all empirical studies reporting a statistical association between interoceptive ability and alexithymia across typically developing and disordered populations. Interoceptive ability was conceptualized into subjective and objective dimensions aligning with orientation to and ability to discriminate/specify bodily cues: 1) Objective Signal Perception—the ability to perceive and track bodily processes, such as one's own heartbeat, 2) Subjective Signal Perception—self-reported awareness of bodily cues, and 3) Interoceptive Accuracy —self-reported ability to discriminate bodily cues or associate them with feelings or physiological states. Moderating effects of Diagnosis —typically developing, ASD, and eating disordered–were also examined.

Results:

A random effects model revealed a summary effect size across all 55 independent samples (total N = 6246) of r=-.161, p=.004, indicating that interoceptive ability is associated with lower alexithymia across studies. Analyzing facets of interoceptive ability separately, neither Objective Signal Perception nor Subjective Signal Perception (r=.033, df=28, p=.514), was significantly related to alexithymia (r=.080, df=13, p=.352). However, Interoceptive Accuracy was related to lower alexithymia (r=-.452, df=18, p<.001). Combining all subgroups, Diagnosis significantly moderated effect size strength $Q_B(2)$=18.61,p<.001. While interoceptive ability was not significantly related to alexithymia in typically developing samples (r=-.024, df=37, p=.616), it was related to lower alexithymia in ASD (r=-.501, df=5 p=.006) and eating disordered samples (r=-.493, df=6, p<.001).

Conclusions:

Reduced interoceptive ability is associated with alexithymia across studies, and this effect is driven by reduced Interoceptive Accuracy but not Objective or Subjective Interoceptive Signal Perception. This finding clarifies confusion in the literature and improves conceptual understanding of the alexithymia construct. We propose that ASD may be associated with both hypo and hyper-perception of interoceptive cues (negating statistically significant associations between Signal Perception and alexithymia), but that impaired Interoceptive Accuracy accounts for higher alexithymia in ASD and other disorders. The moderator analysis suggests that the mechanisms contributing to alexithymia may differ according to diagnosis, such that interoceptive deficits underlie alexithymia in ASD and eating disorders but not in the general population.

170 **239.170** Basic and Self-Conscious Emotional Experiences Recounted By Children with and without Autism Spectrum Disorder

I. Misiunaite[1], *D. Davidson*[2], *E. Hilvert*[3], *M. Giordano*[2], *K. Miniscalco*[1] *and A. Winning*[1], *(1)Loyola University Chicago, Chicago, IL, (2)Psychology, Loyola University Chicago, Chicago, IL, (3)Loyola University, Chicago, IL*

Background:

The ability to reflect on one's emotional experiences is central to effective social and interpersonal life. Studies have shown that children with Autism Spectrum Disorder (ASD) struggle with recounting more complex emotions, but not basic emotions (Losh & Capps, 2006). This is important because complex emotions, especially self-conscious emotions (e.g., guilt, pride), facilitate social relationships and societal norms.

Objectives:

Using a detailed linguistic coding scheme, the purpose of this study was to evaluate children's personal recounting of specific basic and self-conscious emotional experiences in contrast to studies that have examined general categories of emotions. Relations between ASD symptomatology, Theory of Mind (ToM) abilities, receptive vocabulary, and recounting of emotions were also assessed.

Methods:

Twenty-three children with ASD and 38 neurotypical (NT) children participated, and were tested following IRB approval and appropriate consent procedures. See Table 1 for participant characteristics (e.g., SRS-2, CARS-2, FSIQ, ToM, etc). Children were asked to recount two experiences of each basic (i.e., happy, fear, sad), and self-conscious emotion (i.e., pride, embarrassment, guilt). Responses were audio-recorded, and then transcribed and coded by two raters. Each response was coded for appropriateness of the content (0-3), length in number of clauses, and number of prompts needed to elicit a response.

Results:

Children with ASD provided less appropriate content in recounting experiences of pride, embarrassment, and guilt than NT children. However, no significant differences were found between children with and without ASD when recounting experiences of basic emotions. In terms of number of clauses, children with ASD produced briefer descriptions of emotional experiences pertaining to embarrassment and guilt than NT children. Across both types of emotions, children with ASD needed more prompts in order to elicit examples of the emotions than NT children. However, this was qualified by the fact that for some emotions (i.e., guilt), children with ASD were more likely to simply not give a response, and therefore we did not continue with prompting. In children with ASD, social functioning (SRS-2) predicted the number of prompts needed to elicit sad, embarrassing, and guilty recounts, as well as the number of clauses in their recount of embarrassing experiences. ToM predicted the appropriateness of the content for sad and pride recounts, and the number of clauses for sad experiences but only for children with ASD. For NT children, vocabulary ability predicted appropriateness of the content for fear and pride recounts.

Conclusions:

Our findings show that children with ASD were on par with their NT peers in recounting experiences of basic emotions. However, for self-conscious emotions, children with ASD showed less appropriate content and, in some cases, briefer responses. Children with ASD also needed more prompting in eliciting emotional experiences than NT children. There was some evidence that social functioning and ToM were predictive of the performance of children with ASD, whereas only vocabulary predicted performance for NT children and only for a subset of emotions. Many emotion training programs focus exclusively on basic emotions. Our results suggest that it may be more beneficial if programs focus on self-conscious emotions.

171 **239.171** Cognitive Emotion Regulation in Autism

A. N. Ruigrok[1], *S. Griffiths*[1], *R. Holt*[1], *G. Renouf*[1], *M. C. Lai*[2] *and S. Baron-Cohen*[3], *(1)University of Cambridge, Cambridge, United Kingdom, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom*

Background: Autism is a heterogeneous neurodevelopmental condition. Co-occurring mental health conditions such as depression are more prevalent amongst autistic individuals. These conditions show sex/gender differences in prevalence in the neurotypical (NT) population, with more women being diagnosed with depression. Having heightened autistic traits, but not an autism diagnosis, has also been related to a higher rate of depression, and cognitive emotion regulation (CER) strategies have been shown to influence depressive symptomatology. Bruggink and colleagues (2016, Research in Autism Spectrum Disorders) found that autistic individuals used more "Other Blame" and less "Positive Reappraisal" CER techniques than NT individuals, as measured by the CER Questionnaire (CERQ). However, differences in sex/gender or influence of autistic traits were not measured.

Objectives: To test for group and sex/gender differences in CER strategies between autistic and NT adults. We hypothesise that (1) the autism group and the high autistic trait group use more negative coping strategies and less positive CER strategies than the low autistic trait NT group and (2) any sex/gender differences would be attenuated in the autism group.

Methods: Participants were recruited through the Cambridge Autism Research Database (CARD) and included 854 individuals who completed the CERQ, Autism Spectrum Quotient (AQ) and the Patient Health Questionnaire (PHQ-9), a depression symptom questionnaire. Participants were divided into three groups based on diagnosis and AQ score (high > 26): 172 autistic males, 51 high-AQ NT males; 60 low-AQ NT males; 212 autistic females; 120 high-AQ NT females; and 239 low-AQ NT females. NT participants included did not suspect an autism diagnosis. All participants were matched on gender assigned at birth and gender currently identified.

Results: Two MANCOVAs were run to test for overall difference in adaptive or maladaptive strategy use. Alpha level was set at .025 to correct for multiple comparisons. Factorial ANCOVAs were done to examine group and sex/gender differences in strategy use (False Discovery Rate corrected within adaptive or maladaptive strategies). Bonferroni corrected pairwise-t-tests were used to test for group differences within single strategies. No group-by-sex/gender interactions were found in use of CER strategies. Across group, sex differences were found on "Other-Blame", with men tending to use this strategy more often than women. Group differences were found on 7 of the 9 subscales of the CERQ, after controlling for age and depression scores. The autism and high-AQ groups scored higher on depression symptoms and employed negative coping strategies ("Self-blame", "Catastrophizing") more often and positive styles ("Positive Refocusing", "Refocus on Planning", "Positive Reappraisal", "Putting things into Perspective") less often than the low-AQ NT group.

Conclusions: Autistic and high-AQ individuals show higher levels of depression symptomatology and use more negative coping styles, and less

positive coping styles than low-AQ NT individuals, even after controlling for group differences in depression scores. Future research will examine if use of CER strategies, or if differences general wellbeing, life events and alexithymia moderate or mediate depressive symptomatology. If CER styles mediate or moderate depression in these groups, targeting CER use may be a helpful avenue for therapy.

172 **239.172** Dealing with Distress: Cognitive Correlates of Coping Strategies in Young Children with ASD

*H. Tokadjian[1,2], **C. E. McCormick**[3] and S. J. Sheinkopf[2,4], (1)Rhode Island Consortium for Autism Research and Treatment (RI-CART), Bradley Hospital, East Providence, RI, (2)Brown Center for the Study of Children at Risk, Women and Infants Hospital, Providence, RI, (3)Purdue University, West Lafayette, IN, (4)Rhode Island Consortium for Autism Research and Treatment (RI-CART), East Providence, RI*

Background: Individuals with Autism Spectrum Disorder (ASD) have difficulty establishing effective emotion regulation skills and consequently experience behavior problems (Sofronoff et al. 2007). Common coping strategies identified in literature on typical development are described as constructive/goal-oriented, venting, and passive/avoidance, and have shown both direct and indirect effects on positive and negative outcomes (Eisenberg et al., 1993; Blair et al., 2004). Although there is some evidence to support the relation between cognitive ability and the regulation of emotions (Mazefsky et al., 2013), research is limited in addressing how specific elements of cognitive functioning impact coping behaviors.
Objectives: The aim of this study was to compare types of coping strategies used in a heterogeneous sample of children with ASD, and explore the way in which varying levels of IQ may influence their use of coping strategies.

Methods: Participants were 83 children, 48 with ASD and 35 typically developing controls (age range 2–7; *M*= 4.23 years, *SD*= 1.15, 77% male). IQ was assessed using the Stanford Binet-5. The ASD participants were split into two subgroups based on expressive language: low verbal (up to basic phrase speech; N =33) and high verbal (verbally fluent; N = 15). Participants were presented with a series of tasks that were designed to be frustrating (e.g. toy with a broken part). Coping strategies during these tasks were coded as: instrumental, avoidance, aggression, disruption, venting, social-monitoring, and support-seeking (Eisenberg et al., 1993; Marcelo & Yates, 2014).

Results: The strategies were summed to create three composite variables of positive strategies (instrumental, social-monitoring, and support-seeking), negative strategies (aggression, disruption, and venting), and avoidant strategies (avoidance; Jahromi et al., 2012; Zantinge et al., 2017). There was a significant difference in coping strategies based on group ($F(6, 156)=10.24$, $p< .001$). The ASD low verbal group used less positive strategies compared to the ASD high verbal and typically developing groups ($p< .001$). The ASD low verbal group used more negative strategies compared to the typically developing group ($p=.047$). In addition to the group differences, moderation analyses within the ASD group revealed a significant two-way interaction between non-verbal IQ and high versus low verbal ability ($\beta=-.432$, $p=.043$). Higher non-verbal IQ scores predicted greater use of positive coping strategies for the low verbal ASD group (*simple slope*= -0.02, $p=.008$). There were no significant interactions between verbal or full scale IQ and verbal ability predicting positive, negative or avoidant coping strategies.

Conclusions: Children with ASD and low verbal ability displayed fewer positive coping strategies during frustrating events compared to their peers. However, within this group higher non-verbal ability was associated with more positive coping strategies. Thus, non-verbal cognitive functioning may have a protective effect, supporting the expression of constructive coping strategies. This suggest that individuals who appear to be significantly impaired can demonstrate effective coping when undergoing challenging situations. These findings are important for continuing to explore the mechanism by which stressful experiences influence behavior and what factors may or may not lead to more positive outcomes in children with ASD.

173 **239.173** Degree of Emotional Openness of Mothers with Children with Autism Spectrum Disorder

***A. Lampron**, N. Poirier and N. Moussa, Psychology, Université du Québec à Montréal, Montréal, QC, Canada*

Background: Emotional openness refers to the access of someone's own emotional experience, to certain characteristics that can describe our emotional experience (e.g., the tendency to be open, accessibility and apprehension of information that emotions provide), to a long-term and evolving openness (e.g., greater access to emotions) and ultimately social outcomes (e.g., emotional exchanges in interpersonal relationships). The model of emotional openness allows us to evaluate the different emotional processes perceived in a person and the coherence between them (Reicherts, Genoud and Zimmermann, 2012). This model is based on five central dimensions: the cognitive and conceptual representation of emotions (REPCOG), the communication of emotions (COMEMO), the perception of internal emotional indicators (PERINT) and external (PEREXT) and the regulation of emotions (REGEMO) (Reicherts, Genoud and Zimmermann, 2012). An additional dimension is added to the model, the normative restrictions of affectivity (Reicherts, Genoud and Zimmermann, 2012).
Objectives: The purpose of this study is to explore the dimensions of emotional openness in mothers with children with Autism Spectrum Disorder (ASD).

Methods: Forty-seven Quebec mothers of children with ASD participated in this study. Mothers are aged between 28 and 51 years old. The average age of mothers is 38 years old. The Emotional Opening Dimensions (DOE-36) questionnaire (Reicherts, 1997, 2007) is used to assess the degree of emotional openness of mothers.

Results: Mean and standard deviations for the six dimensions of emotional openness are presented (Table 1). The weakest dimension is the normative restrictions of emotional openness whereas the highest dimension is the cognitive and conceptual representation of emotions. Correlations between the different dimensions of emotional openness are analyzed. The initial model of emotional openness is presented by including the different correlations found in the sample (Figure 1). Associations between the dimensions of emotional openness, the age of the mother, and the gender of the child were made. The age of the mother is positively and significantly associated with the cognitive and conceptual representation of emotions (r = 0.328 *), but with no other dimension of emotional openness. The gender of the child is negatively and significantly associated with the perception of external emotional indicators (z = -1.974 *) and the normative restrictions of emotional openness (z = -2.097 *). Thus, mothers with a male child have a lower score on the perception of external emotional indicators (m = 3.36) than mothers with a female child (m = 4.10). Also, mothers with a male child have a lower score on normative restrictions of emotional openness (m = 2.90) than mothers with one female child (m = 3.80).

Conclusions: This study highlights the profile of the emotional openness of mothers with children with ASD. Specific interventions can also be put in place to work on the weaknesses of the emotional openness of these mothers.

174 **239.174** Development of a Visual Autistic Identity and Emotions Scale

A. Riccio[1], *J. Delos Santos*[2], *S. K. Kapp*[3], *A. Jordan*[4], *D. S. Smith*[5], *D. DeNigris*[6] *and K. Gillespie-Lynch*[7], *(1)Department of Psychology, The Graduate Center, City University of New York (CUNY), New York, NY, (2)Hunter College, City University of New York, New York, NY, (3)University of Exeter, Exeter, United Kingdom, (4)CUNY, Staten Island, NY, (5)College of Staten Island, CUNY, Staten Island, NY, (6)Psychology & Counseling, Fairleigh Dickinson University, Madison, NJ, (7)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY*

Background: Non-speaking individuals and those historically labeled as "low-functioning" have rarely been included in research on perceptions of autism (Jones et al., 2013; Sequenzia, 2017). The prevailing use of "high/low-functioning" to qualify autism, groupings rejected by self-advocates as inaccurate and offensive, reduces the complexities and abilities of autistic people (Endow, 2015; Kenny et al., 2016). Due to marginalization of these groups, the ways non-speaking people experience autistic identity is not represented in the current literature. Measures using alternate modes of communication are needed to reach more autistic individuals so they may share their experiences. In the current study, we adapted a visual measure widely-used to assess emotions, the Self-Assessment Manikin (SAM; Bradley & Lang, 1994), composed of scales representing valence, arousal and control, to develop a visual autism identity scale.

Objectives: To create and evaluate a novel visual measure of autistic identity comprised of picture-based representations of core aspects of the lived experience of autism, identified by autistic members of our research team, and associated emotion rating scales.

Methods: A participatory team of 5 autistic and 4 non-autistic researchers iteratively developed an adapted version of the SAM (Figure 1), drawn by an autistic co-author, and a list of core aspects of the lived experience of autism (Table 1). Adaptation of the SAM was guided by an evaluation of the original SAM wherein autistic teenagers (n=15) and autistic (n=16) and non-autistic (n=148) college students were asked "What do you think these pictures are measuring?" Responses were qualitatively coded after researchers obtained reliability. We are currently evaluating the psychometric properties of the full scale by having autistic adolescents and college students rate each aspect of the lived experience of autism and relating responses to the RAADS-14 (Eriksson et al., 2013).

Results: Autistic and non-autistic participants exhibited pronounced difficulties interpreting the widely used SAM emotion scales. The scale for valence was most often understood, with 81% of autistic/93% of non-autistic participants correctly interpreting the scale. In contrast, only 19% of autistic/28% of non-autistic participants correctly identified the arousal scale. Many participants instead described hunger or physical pain (52% autistic, 39% non-autistic). Similarly, only 6% of autistic/16% of non-autistic participants correctly identified the control scale. Most interpreted the scale as body size or height (84% autistic, 65% non-autistic). By attending to the types of errors participants made with the original SAM, the participatory group developed 4 emotion rating scales (Figure 1): valence (sad to happy), anxiety (calm to anxious), pride (shameful to prideful), and energy level (depleted to energetic), as well as a visual measure of centrality to self.

Conclusions: Findings highlight that an emotion rating scale that is very widely used (5644 citations) is confusing for autistic and non-autistic youth. Measures of emotion that are developed in a participatory manner, with many opportunities for people to provide open-ended interpretations and careful validation, are clearly needed. After validating our autistic identity scale, we will use it with autistic people across the spectrum to gain a fuller understanding of autistic experience and identity.

175 **239.175** Double Dissociation in Amygdala and Insula to an Auditory "Looming" Threat Task

A. N. Bennion[1], *D. N. Top*[2], *K. Smith*[2], *C. A. Larson*[3], *C. Rich*[2], *T. White*[2] *and M. South*[4], *(1)Psychology, Brigham Young University, Provo, UT, (2)Brigham Young University, Provo, UT, (3)Neuroscience, Brigham Young University, Provo, UT, (4)Psychology & Neuroscience, Brigham Young University, Provo, UT*

Background: Understanding the mechanisms that underlie anxiety in autism is a critical task for experimental and clinical research. Previous studies have shown atypical fear conditioning response in autistic samples. However, because fear conditioning requires learning, other processes potentially complicate the interpretation of results. Neuroimaging studies of auditory "looming" have shown amygdala activation in response to sounds that appear to be coming "toward" the person in contrast to neutral or to "receding" sounds. We proposed using a looming task to investigate neural fear response without the need for any contingency learning.

Objectives: A multi-method study of auditory looming and receding in young autistic adults. We hypothesized typical fear response (e.g., amygdala and insula) in the autism sample compared to neurotypical young adults, suggesting that other factors underlie atypical fear conditioning and elevated anxiety in autism.

Methods: 25 AUT and 31 age and ability matched neurotypical (NT) young adults listened to sounds that get progressively louder (looming) or quieter (receding) while undergoing fMRI scans. The auditory stimuli consisted of pulsed tones of 2000ms duration and a 1kHz carrier frequency that were amplitude-modulated with a smoothed square wave envelope of 5Hz. The 2000ms sound sweeps were multiplied with an exponential function to obtain sound pressure level changes of 15dB (rising intensity sound, 70-85dB; falling intensity sound, 85-70dB; constant intensity sound, 77dB). Stimuli were presented bilaterally. All analyses were corrected for multiple comparisons using family-wise error correction.

Results: There was a main effect for group in left amygdala activation, NT>AUT (F=14.35; p=0.008) but no main effect for sound condition or group x condition interaction. There was a main effect for condition in bilateral insula, looming > receding (right: F=58.19; p=0.000; left: F=51.55; p=0.000) and a main effect for group for right insula, in the opposite direction, AUT > NT (F=39.53; p=0.000), but no group x condition interaction.

Conclusions: While we initially hypothesized that task response would not differ between groups, these and other data coming into our lab suggest a story of "physiological inflexibility" in which a restricted range of psychophysiological response in autism may contribute to frequent outbursts, meltdowns, or crippling anxiety. The neural response to threat differs between autism and neurotypical samples even when no learning is required, and may contribute to higher-order symptoms of anxiety that are so frequent in autism.

176 **239.176** Examining How Children with and without ASD Extract Emotion from Prosody

N. E. Scheerer[1], *F. Shafai*[2], *R. A. Stevenson*[3] *and G. Iarocci*[1], *(1)Simon Fraser University, Burnaby, BC, Canada, (2)The University of Western Ontario, London, ON, Canada, (3)Western University, London, ON, Canada*

Background:
Individuals with Autism Spectrum Disorder (ASD) have difficulty perceiving and expressing emotions. Since prosodic changes in speech (i.e. changes in intonation, stress, rhythm, etc.) are crucial for extracting information about the emotional state of the speaker, an inability to perceive and interpret these prosodic changes may lead to impairments in social communication.

Objectives:

Previous work investigating individuals with ASD's ability to identify the affective intentions conveyed by changes in speech prosody have been complicated by the fact that experimental stimuli often carry affective value in both their prosodic and their semantic content. The objective of this study was to use non-verbal affective sound-clips to determine whether children with ASD have difficulty extracting affect from changes in prosody. This research also explored whether a difficulty extracting affective intent from changes in prosody may be related to social competence.

Methods:

Children with (n=26) and without (n=26) ASD between the ages of 6 and 13 years listened to short non-verbal affective sound-clips and were required to match the emotion expressed in the noise burst to either an emotional face, or an emotion word. Affect bursts were obtained from the Montreal Affect Voices database, while faces were obtained from the Karolinska Directed Emotional Faces database. The Multidimensional Social Competence Scale (MSCS) parent report was used to measure social competence.

Results:

A 2 (Stimulus type: Face, Word) by 2 (ASD: Yes, No) repeated measures analysis of variance was conducted on matching accuracy. There was a main effect of stimulus type, $F(1,50)= 71.10$, $p< .001$, $n^2= .587$, as accuracy was higher when affect bursts were matched to words (M= 84.86, SE= 1.30), relative to faces (M= 73.24, SE= 1.30). The stimulus type by group interaction was also significant, $F(1,50)= 4.630$, $p= .036$, $n^2= .085$, as children with, (M= 84.78, SE= 1.84), and without, (M= 84.94, SE= 1.84), ASD performed similarly when matching the affective sound-clips to words, but the children with ASD, (M= 70.19, SE= 1.84), were less accurate than children without ASD, (M= 76.28, SE= 1.84), when matching the affective sound-clips to faces. Accordingly, MSCS scores were positively correlated with face, ($r(50)= .281$, $p= .048$), but not word, ($r(50)= .023$, $p= .874$), matching accuracy.

Conclusions:

Children with and without ASD accurately matched affective noise bursts to emotion words, suggesting children with ASD can accurately extract the affective meaning conveyed by changes in prosody. Children with ASD were less accurate at matching the noise bursts to the emotional faces, suggesting that children with ASD struggle to make use of this information in a social context. Given that affect-face matching accuracy was correlated with social competence, the inability to integrate social information derived from a speaker's voice and face may interfere with effective social communication. Future research will explore whether this difficulty reflects a difficulty in extracting the affective meaning from faces, or whether it may represent a difficulty integrating emotional information from multiple modalities.

177 **239.177** Exploring Emotional Regulations Strategies Used By Adolescents with Autism and Mild Intellectual Disability: A Preliminary Study

A. L. Gardner[1,2], *B. Ratcliffe*[3,4] *and M. Wong*[3], *(1)The Children's Hospital Westmead, Sydney Children's Hospitals Network, Westmead, Australia, (2)Graduate School of Research, Western Sydney University, Parramatta, Australia, (3)The Children's Hospital at Westmead, Sydney Children's Hospitals Network, Westmead, Australia, (4)School of Social Sciences and Psychology, Western Sydney University, Bankstown, Australia*

Background: Prevalence rates in Australia currently estimate that one in 70 young Australians are on the autism spectrum. Over 70% of Autistic people will have a co-occurring intellectual disability, and an equal number will also suffer from mental illness. Yet currently we know little about why, or how to better protect this vulnerable population. Autistic adolescents with Intellectual Disability (ID) have significantly higher rates of mental health disorders than their typically developing peers. Studies of the general population have linked poor emotional regulation (ER) to mental health problems. Researchers have suggested that emotional dysregulation may be a core difficulty for many people with autism. But there is dearth of research exploring the development of emotional regulation skills in Autistic adolescents with ID.
Objectives: The primary aim of this mixed method study was to investigate which adaptive ER strategies were being used successfully by Autistic adolescents with Mild ID. The secondary aim was to explore the emotional regulation strategies (both adaptive and maladaptive) being used in times of sadness, anger and anxiety.

Methods: Three focus groups were conducted with 22 key informants (parents, teachers and allied health professionals) with extensive experience supporting Autistic adolescents with ID. Quantitative data was analyzed for percentages and trends and converged with a content and thematic analysis of the qualitative data.

Results: Reports indicated that across the emotions of sad, anger and worry, numerous ER strategies are being successfully implemented by this population. Autistic Adolescents with Mild ID are reported to use a range of adaptive ER strategies, however the most commonly used strategies often involved distraction or a change of physical state, rather than engaging cognitive strategies, such as reappraisal. Adaptive ER strategies were reported to be more effective when the adolescent is displaying a lower level of emotional intensity. When emotions are at a high level of intensity, cognitive ER strategies become ineffective, with an adult carer / parent assuming responsibility for regulating the adolescents' emotions. Parents reported less child direct self-regulation strategies and more parent guided regulation or re-direction strategies.

Conclusions: This study provides an insight into the difficulty that Autistic adolescents have in being able to control their emotions. The study also suggests that compared to their typically developing peers, this population demonstrates less ability to self-regulate and greater reliance on being regulated by others. Co-regulation strategies, which are the stepping stone for typical development, also seem to be limited across all contexts. Outcomes from this study provide the first insights into EC in Autistic adolescents with ID and have implications for future clinical intervention models. Findings from this study are being used to inform an adolescent and Mild ID adaptation of the first autism specific, evidence and emotion-based intervention, Westmead Feelings Program. The results have formed highlighted the need for a greater focus on emotion coaching for parents, teachers and professionals.

178 **239.178** Feasibility of Measuring Physiological Reactivity in More Severely Affected Youth with Autism in a Psychiatric Inpatient Setting

D. C. Cumpanasoiu[1], *J. Heathers*[1], *J. B. Northrup*[2], *J. Montrenes*[3], *J. Vezzoli*[4], *C. Peura*[5], *B. J. Taylor*[6], *M. Siegel*[7], *C. A. Mazefsky*[8] *and M. S. Goodwin*[1],

(1)Northeastern University, Boston, MA, (2)University of Pittsburgh, Pittsburgh, PA, (3)University of Pittsburgh School of Medicine, Pittsburgh, PA, (4)University of Pittsburgh Medical Center, Pittsburgh, PA, (5)Spring Harbor Hospital, Westbrook, ME, (6)Psychiatry, Maine Medical Center Research Institute, Portland, ME, (7)Maine Medical Center - Tufts School of Medicine, Westbrook, ME, (8)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA

Background:
Previous literature demonstrates that individuals with Autism Spectrum Disorder (ASD) can present with arousal dysregulation and difficulties with arousal modulation; however, objective physiological measures of arousal are seldom used in these studies, especially in youth with ASD who are severely affected (i.e., minimally-verbal and/or co-morbid intellectual impairments).

Objectives:

Assess the feasibility of exposing more severely affected youth with ASD from an inpatient psychiatric unit to experimental tasks designed to elicit frustration while wearing a wireless biosensor. We hypothesized that there would be significantly more physiological reactivity during demand tasks than at rest.

Methods:

Forty-five participants drawn from a larger sample (mean age = 12.8, range 6-20yrs; 74.1% male; 20.2% racial or ethnic minority; non-verbal IQ mean = 76.5, sd = 23.7; ADOS Module distribution: 28.9% Module 1 non-verbal, single words; 10.7% Module 2 phrase speech; 44.6% Module 3 fluent speech, child; 17.9% Module 4 fluent speech, adolescent/adult) of the Autism Inpatient Collection (AIC) were administered a subset of tasks designed to elicit negative affect (an inhibitory control task: Tower and two frustration/anger tasks: Locked Box, End of the Line) from the Laboratory Temperament Assessment Battery (Lab-TAB) that began with and interspersed baseline rest conditions. A wrist-worn wireless biosensor (Q Sensor, Affectiva, Inc.) was used to record electrodermal activity (EDA) and resulting data was parameterized within each segment (i.e. task) as normalized mean skin conductance level (SCL), linear trend change, and skin conductance response (SCR) as measured by coefficient of variation (CV).

Results:

An exploratory repeated-measures ANOVA with 7 factors (4 baselines and 3 tasks) revealed a main effect of task on CV ($F(6)=17.5$, $p < 0.0001$) and all Bonferroni-adjusted t-tests showed statistically significant differences between sequential resting baselines and demand tasks (Table 1, Figure 1). Log-adjusting the data to achieve assumptions of sphericity did not change results. The normalized SCL (mean) and trend were not significantly different across demand tasks, seemingly due to similarly escalating arousal during each frustration-inducing condition.

Conclusions:

The current study is the first we are aware of to measure physiological reactivity during standardized tasks in more severely affected youth with ASD in a psychiatric inpatient setting. SCR increases during demand tasks vs. antecedent baselines and an overall increase in SCL and trend throughout the Lab-TAB suggest that the tasks effectively increase physiological arousal associated with distress/frustration/negative affect. We conclude that ambulatory EDA is a feasible and useful objective measure of arousal for those with severe ASD who are unable to provide reliable self-reports, potentially enhancing future studies of temperament, emotion regulation, and emotion expression in this understudied segment of the autism population. Future work is underway to code these sessions for affect/emotion expression and explore relations between arousal, frustration, and emotional response.

179 **239.179** Gender Differences in Emotion Dysregulation in an Autism Inpatient Psychiatric Sample

A. T. Wieckowski[1], *S. Luallin*[2], *Z. Pan*[3], *G. Righi*[4], *R. L. Gabriels*[5] *and C. A. Mazefsky*[6], *(1)Western Psychiatric Institute and Clinic, University of Pittsburgh Medical Center, Pittsburgh, PA, (2)University of Northern Colorado, Greeley, CO, (3)University of Colorado Denver, Aurora, CO, (4)Department of Psychiatry and Human Behavior, The Warren Alpert Medical School of Brown University, Providence, RI, (5)Psychiartry & Pediatrics, University of Colorado School of Medicine, Aurora, CO, (6)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA*

Background: Research on gender differences in Autism Spectrum Disorder (ASD) has shown that females are more likely to present with emotional problems such as anxiety and depression. These emotional difficulties may be related to underlying deficits with emotion regulation (ER), defined as modifications of one's emotional state to promote adaptive behavior. In general, it has been found that poor ER in ASD exacerbates social impairment and increases risk for psychiatric and behavioral problems. Although there is growing appreciation for ER impairments in ASD, understanding factors that increase risk for poor ER is limited. Given the higher rates of internalizing problems in females vs. males with ASD, it is possible that females are particularly vulnerable to ER deficits. It is also possible that other characteristics that vary widely in ASD impact the association between gender and ER.
Objectives: This study aimed to: 1) Explore gender differences in ER in a psychiatric sample of children, adolescents, and young adults with ASD and a wide range of functioning; 2) Investigate whether other characteristics, such as age, nonverbal IQ, or verbal ability moderate the association between ER and gender.

Methods: Data from psychiatrically hospitalized youth diagnosed with ASD (n = 698; 144 females) aged 4-20 years were collected as part of the Autism Inpatient Collection (AIC). This is an ideal dataset for this question, given the full range of ER impairments and wide variability in functioning level, with approximately half of the sample being nonverbal. ER was assessed with the Emotion Dysregulation Inventory (EDI; Mazefsky et al., 2016, 2018), a caregiver-report which produces theta scores (M= 0, SD= 1) for Reactivity (EDI-R; poor ER and high emotional intensity) and Dysphoria (EDI-D). Nonverbal IQ was assessed with the Leiter International Performance Scale (Leiter-3; Roid et al., 2013). Verbal ability was estimated based on the Autism Diagnostic Observation Schedule (ADOS-2; Lord et al., 2012) modules.

Results: Significant gender difference was found for the EDI-R [0.80 (0.84) vs. 0.97 (0.78), $p = 0.026$] and EDI-D [0.51 (0.84) vs. 0.71 (0.78), $p = 0.013$], with females showing significantly higher emotion dysregulation compared to males. Age did not significantly moderate the association between ER and gender (Reactivity: $F(1, 694) = 0.19$, $p = 0.66$; Dysphoria: $F(1, 683) = 3.00$, $p = .08$). Similarly, verbal ability (Reactivity: $F(1, 694) = 0.08$, $p = 0.77$; Dysphoria: $F(1, 683) = 0.62$, $p = .43$) and non-verbal IQ (Reactivity: $F(1, 578) = 0.14$, $p = 0.71$; Dysphoria: $F(1, 566) = 1.79$, $p = .18$) did not significantly moderate the association between ER and gender.

Conclusions: Results indicate that female psychiatric inpatients with ASD have more severe dysregulation than inpatient males with ASD. None of the analyzed factors (i.e., age, nonverbal IQ, verbal ability) moderated the association between gender and ER, indicating that gender alone

contributed to the differences in ER. Improved understanding of ER presentation in females with ASD is critical, as these symptoms may differentially impact females and/or warrant a different treatment emphasis.

180 **239.180** Investigating Electrodermal Response and Anxiety in Preschool Children with ASD

D. P. Carroll[1] *and S. Faja*[2]*, (1)Autism Spectrum Center, Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital, Boston, MA*

Background: Estimates suggest that up to 80% of children with autism spectrum disorder (ASD) experience clinically significant levels of anxiety suggesting the need for earlier screening and intervention. However, assessment of anxiety in this population is challenging and, particularly, in younger children. Electrodermal response (EDR), a noninvasive physiological measure of autonomic activity, has been shown to quantify levels of anxiety in typically developing children but evidence shows significant variability in autonomic function in children with ASD. Additionally, the utility of EDR as a measurement for anxiety in preschool-aged children with ASD is relatively unexplored.
Objectives: To investigate EDR among young children with ASD compared to typically developing children during a face-to-face cognitive task and to explore the relationship between EDR and anxiety symptoms.

Methods: Twelve children ages 6-7 years with ASD and no intellectual disability and fifteen age-matched typically developing children participated to date. Groups did not differ in verbal, spatial, or nonverbal intelligence measured with the DAS-2. EDR was measured as participants performed a digit span task, which assesses verbal and working memory. The maximum fluctuation in EDR was recorded for each trial unless the fluctuation did not exceed 0.05 microsiemens. Scores were averaged into 30 second epochs across the first two minutes of the task. Parents responded to the BASC-2 about emotional and behavioral challenges, including anxiety symptoms.

Results: Children with ASD had higher parent reported anxiety, $t(25) = -2.73$, $p=.02$. Repeated measures ANOVA was used to examine the EDR between groups and their pattern of response over the first four 30s epochs of the task. A main effect of time, $F(3, 72)=3.9$, $p=.01$, indicated that EDR increased throughout the task (i.e., as it became more difficult). EDR also differed by diagnosis, $F(1, 24)=3.1$, $p=.04$, due to larger responses for children with ASD. Across diagnostic groups, children with more reported anxiety exhibited greater EDR during the first, $r(28)=.48$, $p=.01$, and second, $r(28)=.48$, $p=.009$, 30s epochs of the task. When the RM-ANOVA was conducted with anxiety covaried, the main effect of time remained significant, $F(3, 69)=3.2$, $p=.03$, and there was a trend for time x anxiety, $F(3, 69)=2.6$, $p=.06$, but diagnostic group did not significantly differ, $p=0.13$.

Conclusions: Children with ASD had significantly higher anxiety levels and EDR during the digit span task compared to typically developing controls. Overall, both groups exhibited increasing EDR as the task became more difficult. However, greater EDR during the first minute of the task was related to higher anxiety levels and, when anxiety was co-varied, the relation between anxiety and EDR over time approached significance. This preliminary data suggests that parents observe significantly more anxiety among children with ASD by early elementary school and that EDR may be a potentially useful index of anxiety. In particular, higher initial reactivity during a task with both social and cognitive demands and differences in EDR patterns over time may capture anxiety among young children. In the coming months, we plan to increase our sample size and further examine the relation between ASD, anxiety, and EDR.

181 **239.181** Living with Intolerance of Uncertainty: Experiences from Families of Autistic Children

J. Goodwin[1]*, A. Plant*[2]*, A. Henry*[3]*, M. Freeston*[4] *and J. Rodgers*[3]*, (1)Institution of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom, (2)Child and Adolescent Mental Health Service, Northumbria Healthcare NHS Foundation Trust, Newcastle Upon Tyne, United Kingdom, (3)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom, (4)Newcastle University, Newcastle upon Tyne, United Kingdom*

Background:
Anxiety is common in autistic children. One key mechanism underlying anxiety is intolerance of uncertainty (IU), which is a tendency to react negatively on an emotional, cognitive, and behavioural level to uncertain situations. Previous research has indicated that autistic people may be particularly vulnerable to experiencing IU and that there may be important interactions between IU and autism related characteristics. Understanding the contexts, responses to, and impact of IU is critical to the development of appropriate anxiety interventions.

Objectives:

We aimed to explore the types of uncertain situations that cause difficulties for autistic children and how IU impacts on the daily lives of autistic children and their families.

Methods:

60 families were recruited to the study through clinical services or a research database in the North East of England. The children were aged 6 – 16 years, had a diagnosis of ASD, and were experiencing anxiety related to difficulties tolerating uncertain situations in their daily lives. Parents completed Intolerance of Uncertainty Scale - Parent (IUS-P), which reported on their child's IU. Where possible, children completed the child self-report Intolerance of Uncertainty Scale (IUS-C). Parents completed the Anxiety Scale for Children–ASD to assess their child's anxiety and, where possible, children completed the corresponding child version of the scale. Parents completed a semi-structured interview during which they identified two everyday uncertain situations that were challenging for their autistic child: the first was a situation that their child would like to participate in that was difficult for them due to uncertainty (e.g., after school activities), and the second was a situation that was a necessary part of everyday life that their child struggled to engage with due to uncertainty (e.g., completing homework). Parents were asked to report on their child's reactions to these situations, the intensity and duration of their responses and the impact on the child and the wider family unit. The data from the semi-structured interviews were then analysed thematically.

Results:

The levels of child IU reported by parents and children are comparable with other published studies and above indicative clinical cut offs. Parents identified a range of contexts in which their child experienced IU, including situations where there is potential for exposure to aversive sensory stimuli, challenging social communication contexts, changes to routines, and performance related uncertainty.

Conclusions:

Our data indicate that in this sample of 60 families with an autistic child who is experiencing anxiety, rates of both child and parent reported child IU are high, supporting previous research. Parents were able to identify a range of everyday situations which are characterised by

uncertainty that interfere significantly with child and family functioning. Both autism-related characteristics and experiences (e.g., sensory hypersensitivity, social communication difficulties, rigidity) and IU were identified as important in these everyday situations, and were found to interact to increase anxiety. . These data provide further support for the importance of considering the interplay between IU and autism-related characteristics in the development of interventions to tackle anxiety for autistic people.

182 **239.182** Multimodal Emotion Recognition in Children with Autism Spectrum Disorder: Vocalizations Are More Informative Than Faces or Music

***S. Sivathasan**, J. Burack and E. M. Quintin, Educational & Counselling Psychology, McGill University, Montreal, QC, Canada*

Background: The social and communication difficulties cited among children with autism spectrum disorder (ASD) appear to be associated with problems in emotion recognition skills, as typically depicted with facial expressions or non-verbal vocalizations (e.g., laughter, crying). The extent to which these disparities reflect a general concern may be studied with an alternative modality of specific interest to children with ASD, such as music. Systematic comparisons of emotion recognition in faces, vocalizations, and music are lacking.
Objectives: The objective was to provide an initial comparison of emotion recognition skills in children with ASD across the modalities of face, vocalization, or music.

Methods: Twenty-two children with ASD between the ages of 8-14 (*M*=10.7, *SD*=1.49) years participated in this study. They completed tasks associated with identifying emotions in faces, vocalizations, and music, presented in counterbalanced order. Each modality included 8 happy, 8 sad, and 8 fearful emotional expressions from validated stimuli sets for a total of 72 stimuli. After each stimulus was presented on a computer screen for 1.5-2 seconds, the participants selected the verbal label that described the stimuli best from the three possible options of happy, sad, fearful.

Results: Friedman nonparametric repeated measures t-tests revealed mean accuracy scores that were significantly above chance (ranging from 64-93%). A difference in emotion recognition accuracy was found across modalities, $p = .0001$. Post hoc analysis with Wilcoxon signed rank tests (Bonferroni $p < .017$) revealed that the participants more accurately identified emotions from vocalizations than faces ($p < .001$) and music ($p < .0001$), but did not differ in accuracy for faces versus music ($p = .072$). A difference in accuracy was found across emotions $p = .031$, as the participants more accurately identified happy emotions versus fear ($p = .005$). No differences in accurate identification were found between happy versus sad ($p = .039$) and sad versus fear ($p = .65$). A significant modality by emotion interaction was found, $p < .0001$. Post hoc analyses with a Bonferroni correction of $p < .005$ revealed that sadness was more easily identified in vocalizations than music ($p = .001$), and fear was more easily identified in vocalizations than faces ($p = .001$) and music ($p < .001$). No significant differences were found in the accurate identification of happy emotions across modalities ($p > .009$), or between sad faces and vocalizations ($p = .16$), sad faces and music ($p = .045$), or fearful faces and music ($p = .235$).

Conclusions: Significant differences in identifying emotions across modalities were found as the participants identified sadness and fear more accurately in vocalizations than in faces and music, but identified happy emotions equally accurately across all modalities. Contrary to expectations, these findings suggest that the identification of negative emotions when conveyed through non-verbal vocalizations, rather than faces or music, may be easier or more informative for children with ASD.

183 **239.183** Uncovering Empathizing and Systemizing Skills in Autism Spectrum Disorder through Perception of Emotional and Structural Aspects of Music

***H. Dahary**[1], S. Thierry[1], T. Fernandes[2], C. Rimmer[1] and E. M. Quintin[2], (1)McGill University, Montreal, QC, Canada, (2)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada*

Background: The empathizing-systemizing (E-S) theory posits that autism spectrum disorder (ASD) symptomology is related to biases towards empathizing and systemizing traits (Baron-Cohen, 2002). More severe ASD symptomatology is associated with greater deficits in empathizing, a drive to recognize and respond to others' emotions, and superior skills in systemizing, a drive to analyze or construct systems. Music is a unique medium for measuring empathizing and systemizing skills of people with ASD given their common affinity and skill in this area (Heaton, 2009). The examination of musical empathizing and systemizing skills is a relatively novel line of inquiry and thus has only been explored using questionnaires with typically developing (TD) people (e.g., Kreutz et al., 2008; Dahary et al., 2018).
Objectives: The purpose of this research is to assess the ability of an ASD group in completing musical empathizing and systemizing tasks and to compare their task performance to that of a TD group.

Methods: Seventeen adolescents with ASD (aged 12-16 years) and 50 TD adults (aged 18-32 years) completed a musical empathizing task and a musical systemizing task using stimuli adapted from Vieillard et al., 2008. On the musical empathizing task, participants identified the emotion (happy, sad, or scary) of musical excepts and on the musical systemizing task, participants identified if pairs of musical excerpts were the same or different, with one repeated pitch altered on different trials. Both tasks were composed of 24 trials which varied in stimuli complexity (12 easy and 12 difficult trials). It took about 30 minutes to complete both tasks.

Results: The ASD group performed above chance level on the musical empathizing (≥33%) and systemizing (≥50%) tasks, demonstrating successful completion of both tasks ($p < .001$). A mixed design ANOVA model revealed a main effect of task such that, both ASD and TD groups were more accurate on the musical empathizing task than on the musical systemizing task ($p < .001$). A 3-way interaction between task, stimuli complexity, and group showed that ASD and TD groups were equally accurate on the musical empathizing task across easy and difficult trials, but not on the musical systemizing task ($p < .05$). While the ASD group performed less accurately on the easy trials of the musical systemizing task, both groups were equally accurate on the difficult trials.

Conclusions: This study is the first to assess musical empathizing and systemizing skills in ASD through task performance. We demonstrate that adolescents with ASD can understand both emotional and structural elements of musical excerpts; partially supporting but also running counter to the E-S theory. Results may instead support the enhanced perceptual functioning theory of ASD (Mottron et al., 2006), which posits that, when processing complex auditory information, enhanced perception of people with ASD creates a disadvantage (i.e., easy trials of the systemizing task) or can confer an advantage or lead to typical perception (i.e., difficult trials of the systemizing task). However, processing of emotions in music is typical. Results thus lend credence to using music interventions to teach emotion processing skills in ASD.

184 **239.184** Observed Emotion Dysregulation in Children with Autism during a Frustrating Task

***A. S. Mills**, P. Tablon Modica, A. Vorobeichik and J. A. Weiss, Psychology, York University, Toronto, ON, Canada*

Background: Emotion dysregulation (ED) is a common reason for higher rates of anxiety, depression, and anger in individuals with autism. This population has been shown to display greater ED during frustrating tasks than peers without autism (Jahromi et al., 2012). Parent report measures of ED in children with autism predict poorer adaptive skills (Uljarević et al., 2018) and more internalizing and externalizing (maladaptive) behaviours (Berkovitz et al., 2017). However, few studies look at how observed behavioural ED relates to adaptive and maladaptive behaviours in this population. To address this gap, we adapted the Emotion Dysregulation Inventory (EDI; Mazefsky et al., 2018) as an observational measure of children's ED during a frustrating task.
Objectives: 1) Evaluate the reliability of an observational measure of ED. 2) Investigate associations between children's behavioural ED and success during a frustrating task. 3) Examine associations between parent report of child adaptive and maladaptive behaviours, and children's observed ED.

Methods: Preliminary findings are based on 32 children with autism aged 8-13 years (M_{age} = 9.6 years, Males = 31). Children completed a computerized mirror tracing persistence task (MTPT-C, Strong et al., 2003), where they attempted to trace a star with an irritating sound occurring with each tracing error. The task consisted of 3 practice phases and a test phase where children had the option to quit. Observed ED was measured via standardized observer coding of expressed reactivity and dysphoria using a coding scheme adapted from the EDI. Children's observed reactivity and dysphoria scores were correlated with success on the MTPT-C during practice phases and persistence on the test phase. The adaptive skills, internalizing and externalizing composites of the Behaviour Assessment System for Children parent report (BASC-3) were correlated with observed ED.

Results: Coding ED observationally using the EDI demonstrates excellent inter-rater reliability (ICC= 0.94 for reactivity and ICC = 0.93 for dysphoria). Observed reactivity and dysphoria across practice phases were positively correlated with the number of times the child made errors due to being too slow (reactivity: r_s = **.**54, p = .002; dysphoria: r_s = .65, $p < .000$). Mean reactivity and dysphoria negatively correlated with persistence (reactivity: r_s = -.33, p = .07; dysphoria: r_s = - .40, p = .03) and percentage of the star traced (reactivity: r_s = - .43, p = .02; dysphoria: r_s = - .47, p = .01). Both reactivity and dysphoria negatively correlated with the adaptive skills composite (reactivity: r_s = - .36, p = .05; dysphoria: r_s = - .45, p = .01), but not indicators of maladaptive behaviour.

Conclusions: The EDI is a reliable observational measure of ED for children with autism and observed ED during a frustrating task is associated with task behaviours. Findings also highlight that higher levels of reactivity and dysphoria during a frustrating task are associated with lower levels of adaptive skills, but not maladaptive behaviours. This may reflect differences between state-level experiences of negative affect due to a frustrating task, and broader trait-level behaviours observed in naturally occurring situations.

185 **239.185** Parent Discussions of Emotion Regulation Strategies with Their Child with ASD Is Associated with Parent Ratings of Child's Emotion Regulation

***M. Gurm**[1] and G. Iarocci[2], (1)Psychology, Simon Fraser University, Burnaby, BC, Canada, (2)Simon Fraser University, Burnaby, BC, Canada*

Background: Parents play a key role in their child's emotion regulation (ER; e.g., Eisenberg et al, 1998). For example parent scaffolding of children with ASD's emotion regulation during a discussion task was associated with child externalizing behaviour but not internalizing behaviour (Ting & Weiss, 2017). The current study extended this work by including a typically developing (TD) comparison group of children without ASD and examining whether parent emotion-regulation strategies (scaffolding and elaboration) during discussion of an emotion vignette was associated with parent ratings of emotion regulation in school-aged children with ASD compared to those without ASD.

Objectives: The focus was: 1) Are child characteristics associated with how parents speak with their children about emotions and emotion regulation, and 2) Do these associations differ between groups of parents of children with and without ASD?

Methods: Forty-one parent-child dyads participated in the study (21 children with ASD, 20 TD, M_{age} = 10, M_{IQ} = 108). Parents completed the Multidimensional Social Competence Scale (MSCS; Yager & Iarocci, 2013). Through parent-report, the MSCS examines several domains of social competence, including the Emotion Regulation (ER) subscale that is used in the current study (e.g. "his/her emotional responses tend to be extreme"). Each parent-child dyad participated in a two-vignette discussion task where the main character was either anxious or angry. The dyads discussed the main character's emotions and what emotion regulation strategies they thought would help the character. Conversations were coded for parent elaborations of emotions (e.g., helping the child better understand emotions) and scaffolding of emotion regulation strategies (e.g., helping the child to understand and generate emotion regulation strategies).

Results: Poisson family regression was used to examine the research questions. Predictor variables included diagnosis, age, IQ, child ER, and the interaction between diagnosis and child ER. The data from each discussion was examined separately (anxiety vs. anger) and there were two outcome variables for each discussion: elaboration and scaffolding.

When discussing anxiety, the omnibus test predicting parent *elaboration* was not significant (p = .84). When predicting parent *scaffolding*, however, the omnibus test was significant (p = .01) and there was a trending effect of diagnosis (p = .08) where parents of children with ASD used more scaffolding than parents of children without ASD.

Within the anger discussion task, the omnibus test predicting *elaboration* was significant (p < .01), as were all predictor variables (p <.05). Parents of children with ASD were likely to use more elaboration when their child was rated to have better ER compared to when their child had lower rated ER. Parents of children without ASD, however, were likely to use less elaboration when their child had better ER, compared to when their child had lower rated ER (Figure 1). The omnibus test when predicting *scaffolding* was not significant (p = .13).

Conclusions: The findings suggest that parent behaviour when discussing emotion is complex and may be associated with child characteristics such as child emotion regulation, specific emotions being discussed, and child diagnosis.

186 **239.186** Parent-Reported Rates and Stability of Suicidal Ideation and Intent in School-Aged Children with Autism Spectrum Disorders

M. C. Hunsche[1], *S. Saqui*[1], *P. Mirenda*[1], *T. Bennett*[2], *M. Elsabbagh*[3], *S. Georgiades*[4], *I. M. Smith*[5], *P. Szatmari*[6], *W. J. Ungar*[7], *T. Vaillancourt*[8], *J. Volden*[9], *C. Waddell*[10], *A. Zaidman-Zait*[11], *L. Zwaigenbaum*[9] *and C. M. Kerns*[1], *(1)University of British Columbia, Vancouver, BC, Canada, (2)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (3)McGill University, Montreal, PQ, Canada, (4)McMaster University, Hamilton, ON, Canada, (5)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (6)The Hospital for Sick Children, Toronto, ON, Canada, (7)University of Toronto / The Hospital for Sick Children, Toronto, ON, Canada, (8)University of Ottawa, Ottawa, ON, Canada, (9)University of Alberta, Edmonton, AB, Canada, (10)Simon Fraser University, Vancouver, BC, Canada, (11)Tel-Aviv University, Tel-Aviv, Israel*

Background: Suicide is the second leading cause of death in youth aged 10-24 years (Statistics Canada, 2012). Research suggests that youth with autism spectrum disorder (ASD) are at an elevated risk for suicide compared to neurotypical peers (Mayes et al., 2013). However, there is little research on suicidality in youth with ASD (Horowitz et al., 2017). An understanding of the emergence of suicidal thoughts and behaviours in this population is vital for informing prevention services.
Objectives: This study (a) examined the frequency of parent-reported suicidality (ideation, intent) and self-harm behaviours in children with ASD across four time points (ages 7 to 11); and (b) endeavoured to document the age of emergence of suicidal ideation and behaviours to inform optimal service provision.

Methods: Data collected from 99 families across four time points from the Canadian *Pathways in ASD* study were included in the current analyses. Data were included if the CBCL was completed at all four time points. Participating parents completed the *Child Behaviour Checklist 6-18* (CBCL) at four time points between ages 7.3 – 11.9 years. CBCL items included Item 18: *Deliberately harms self or attempts suicide*, and Item 91: *Talks about killing self*, were used to assess suicidality risk, with rating of 1 "somewhat /sometimes true" or 2 "very true/often true" considered endorsement. Descriptive statistics were compared across time points and a repeated-measures ANOVA was conducted to compare the mean frequency of parental item endorsement across time points.

Results: Repeated-measures ANOVA suggest no significant difference in endorsement of Items 18 or 91 over the four time points. Of the 99 participating parents, 15.2% reported self-harm at least once across the four time points, and 12% reported suicidal ideation. Regarding self-harm, 12% of parents reported this at one time point; 0% at two time points; 2% at three time points; and 1% at all four time points. Regarding suicidal ideation, 8.1% of parents reported this at one time point; 3% at two time points; 1% at three time points; and 0% at all four time points. Self-harm was endorsed most frequently at T1 and T4 (both *n* = 7), and ideation was endorsed most frequently at T3 (*n* = 6).

Conclusions: Parents of school-aged children with ASD reported relatively high rates of suicidal ideation and self-harm behaviour across all four time points in comparison to rates of parent-reported self-harm and suicidal ideation in neurotypical children (3% and 0.5%, respectively, compared to 15% and 12% in our sample) (Aitken et al., 2016). Scores did not change significantly across time points; however, suicidal ideation and self-harm were observed to persist in some children over time. Prior work has suggested similar rates of self-harm and suicidal ideation in adolescents with ASD (12% and 15.7%, respectively) (Culpin et al., 2017). This suggests that in children with ASD, suicidality (ideation and self-harm behaviour) may emerge during the early school years and may persist into adolescence. Further research is needed regarding supports and interventions to address emergent suicidality in children with ASD.

187 **239.187** Patterns of Emotion Recognition in Speech and Song Among Children with ASD: Investigating the Effects of Emotion and Intensity

T. Fernandes, *J. Burack and E. M. Quintin, Educational & Counselling Psychology, McGill University, Montreal, QC, Canada*

Background: The social communication profile characteristic of persons with ASD may be related to difficulties in inferring the emotional state of others from several components of social interaction including speech. Yet, researchers have not reliably found deficits in emotion recognition from speech, depending on the specific emotions and the intensity to which they are conveyed. In one example of a strength, people with ASD appear to be particularly able to recognize emotions from instrumental music. The extent to which this strength is generalizable can be seen if it

is extended to song (vocal music).
Objectives: We compared emotion recognition from speech and song among children with ASD by examining the effects of specific emotions and emotional intensity.

Methods: Thirty children with ASD (age M= 11.67, SD = 2.28) completed a computerized task in which they identified emotions of varying intensity from spoken or sung sentences with neutral semantic content. The task comprised of 64 trials (2 stimuli conditions [speech and song] X 4 emotions (happy, angry, sad, scared) X 2 actors (1 male) X 2 statements X 2 intensity [normal vs. high]). The participants also completed the Verbal Comprehension Index (VCI) of the WISC-V and were divided into groups (N=15) based on a median split of a VCI score of 75.

Results: A repeated-measures ANOVA with emotion recognition accuracy as a dependent variable, stimuli condition (speech vs. song), emotion, and intensity as within subject repeated factors, and VCI group as a between subject factor revealed significant main effects of stimuli condition ($p < .001$), emotion ($p < .001$), and intensity ($p < .001$). The main effects were that accuracy was significantly better for speech compared to song and for emotions conveyed intensely compared to normally. Accuracy was highest for angry trials and lowest for scared trials across speech and song . A significant emotion X condition interaction ($p < .001$) was found as recognition of anger and fear was more accurate in speech than in song, while happiness and sadness were recognized as accurately in both conditions. A significant emotion X intensity interaction ($p < .001$) was found as recognition of happiness, anger and fear was more accurate for trials with high intensity, while recognition of sadness was more accurate for trials with normal intensity. The VCI group effect was not significant.

Conclusions: The results from this study demonstrate that children with ASD more easily recognize intensely conveyed emotions (except in the case of sadness) from speech compared to song. This suggests that their observed strength in recognizing emotions from instrumental music may not extend to song. The finding that fear was less accurately identified as compared to other emotions supports the amygdala theory of ASD, that they may show atypical connectivity of the amygdala, an area implicated in fear perception and response. These findings also have implications for interventions that extend beyond recognition of facial expressions and considers emotion intensity by first teaching emotions that are intensely conveyed followed by those that are more subtle.

188 **239.188** Psychometric Properties of the Danva-2 in High-Functioning Children with ASD

***A. J. Booth**, C. J. Rajnisz, J. D. Rodgers, S. L. Andrews, M. Thomeer and C. Lopata, Institute for Autism Research, Canisius College, Buffalo, NY*

Background:
Impairment in facial emotion recognition (FER) has been documented in high-functioning individuals with autism spectrum disorder (HFASD) across a variety of emotions, research methodologies, and assessment tools (Harms, Martin, & Wallace, 2010). Some have proposed that these deficits contribute to the social difficulties that define ASD (Schultz et al., 2003). One of the most frequently used FER measures in HFASD studies (McMahon, Lerner, & Britton, 2013) is the Diagnostic Analysis of Nonverbal Accuracy – Second Edition (DANVA-2; Nowicki & Carton, 1993). However, despite its use in this population, no studies examining the psychometric characteristics within a homogenous HFASD sample have been conducted. Examination of the validity and reliability of the DANVA-2 within samples of children with HFASD would add to the interpretability of previous research utilizing the measure and support future use.

Objectives:

This study assessed the (1) internal consistency, (2) test-retest reliability, and (3) near and broad concurrent validity (comparisons with other established FER and social functioning measures) of the DANVA-2 faces subtests. In addition, this study also explored the relationships between performance on the DANVA-2 and child age, intelligence, and language abilities.

Methods:

Participants. One-hundred twenty-one children, ages 6-13 years, with HFASD were included in this study. Analysis subgroups were formed from the total sample ($N = 121$) for concurrent validity ($n = 36$) and test-retest reliability analyses ($n = 21$ for 5-week and $n = 21$ for 12-week stability). Each child had a prior clinical diagnosis of ASD, a WISC-IV abbreviated IQ >70 (VCI or PRI >80), and a CASL expressive or receptive language score >75. All diagnoses were confirmed using the ADI-R.

Measures. DANVA-2; Cambridge Mindreading Face-Voice Battery for Children (CAM-C); Social Emotional Evaluation (SEE); Behavior Assessment System for Children, Second Edition-Parent Rating Scales (BASC-2-PRS); Social Responsiveness Scale (SRS); Wechsler Intelligence Scale for Children – Fourth Edition (WISC-IV); Comprehensive Assessment of Spoken Language (CASL).

Procedures. All data were collected as a part of the screening and baseline assessments for psychosocial treatment trials. Test-retest reliability samples for the 5-week and 12-week intervals were obtained by using participants from no-treatment (wait-list) conditions.

Results:

Internal consistency estimates were .70 for the DANVA-2-AF and .75 for the DANVA-2-CF subtests. For the DANVA-2-AF, reliability coefficients for immediate, 5-week, and 12-week retest intervals were .84, .75, and .68, respectively. For the DANVA-2-CF, reliability coefficients for the immediate, 5-week, and 12-week retest intervals were .78, .90, and .43, respectively. DANVA-2 scores were strongly associated with the CAM-C and SEE but unrelated to parent BASC-2 and SRS ratings. Significant correlations (small to moderate) were found between DANVA-2 scores and child age, IQ, and language ability.

Conclusions:

Internal consistency and test-retest reliability of the DANVA-2 in an HFASD sample were found to be adequate for research purposes. Likewise, the measure strongly converged with other tests of emotion recognition. However, further research is needed to determine whether the DANVA-2 adequately predicts social competence and ASD symptomology and to what extent participant demographic characteristics may impact DANVA-2 performance.

189 **239.189** Stability, Concurrent Validity, and Relationship to ASD Symptoms of the Cambridge-Mindreading Face-Voice Battery for Children in a Large Sample of High-Functioning Children with ASD

***J. D. Rodgers**, A. J. Booth, C. J. Rajnisz, J. Lodi-Smith, M. Thomeer and C. Lopata, Institute for Autism Research, Canisius College, Buffalo, NY*

Background:
Significant heterogeneity of results has been found in studies of emotion recognition (facial and vocal) in high-functioning individuals with autism spectrum disorder (HFASD). Some studies identify a broader deficit across emotions, while others do not support a deficit. This may be related to inconsistent measurement tools (Harms et al., 2010; Lozier et al., 2014). Despite this inconsistency, emotion recognition has often been used as an outcome measure in trials of psychosocial interventions for children with HFASD (e.g. McMahon et al., 2013; Lopata et al., 2018).

Objectives:

The current study examined the properties of a carefully constructed measure of emotion recognition that uses dynamic facial stimuli (CAM-C Faces) and vocal stimuli (CAM-C Voices) with a range of emotional content, including both simple and complex emotions (Golan et al., 2015) in a large sample of children with HFASD. We predict the total correct, simple emotion items, and complex emotion items of the CAM-C Faces and CAM-C Voices will show: (1) high test-retest stability, (2) robust correlations with other measures of emotion recognition, and (3) a small but significant relationship with ASD symptoms (SRS-2).

Methods:

Participants were drawn from multiple psychosocial intervention trials for children with HFASD. The total sample was 267 individuals (ages 6-12) with a diagnosis of ASD (91% Male; 93% Caucasian). Inclusion criteria also included WISC-IV short-form IQ >70 (VCI or PRI ≥80), and a CASL expressive or receptive language score >75. A majority of participants (96%) also had ADI-R scores confirming the diagnosis of ASD.

The following measures were assessed at screening and baseline of their respective intervention trials: Cambridge Mindreading Face-Voice Battery for Children (CAM-C); Diagnostic Analysis of Nonverbal Accuracy – Second Edition (DANVA-2); Social Emotional Evaluation (SEE); Social Responsiveness Scale-Second Edition (SRS-2)

Results:

Stability. Test-retest stability was assessed over 3-months and 9-months. For the 3-month interval (n = 21), the stability ranged from r = .404 to .760. For the 9-month interval (n = 50), the stability ranged from r = .531 to .756.

Relationship to other measures of emotion recognition. The CAM-C was substantially related to the two other measures of emotion recognition. For the DANVA-2 (n = 168), correlations ranged from r = .424 to .608 between the CAM-C variables and a sum of adult and child faces subtests. For the SEE (n = 36), correlations ranged from r = .532 to .656 between the CAM-C variables and a total score of receptive emotion recognition.

Relationship to a measure of ASD symptoms. We did not find a meaningful relationship between any of the CAM-C variables and ASD symptoms. For the SRS-2 (n = 267), all correlations were non-significant and less than r = .08.

Conclusions:

We found the CAM-C was both a stable and valid measure of emotion recognition, relative to other measures of the same construct. The lack of a relationship between this measure and a measure of ASD symptoms challenges the assumption that emotion recognition independently contributes to the broader deficits in ASD.

190 **239.190** The Experience of Embarrassment in Adults with and without Autism Traits

D. Davidson[1], *S. Vanegas*[2], *E. Hilvert*[3], *I. Misiunaite*[4] *and M. Giordano*[1], *(1)Psychology, Loyola University Chicago, Chicago, IL, (2)School of Social Work, Texas State University, San Marcos, TX, (3)Loyola University, Chicago, IL, (4)Loyola University Chicago, Chicago, IL*

Background:
Embarrassment may have evolved in order to maintain social order, given that embarrassed people typically recognize and regret their social transgression or misbehavior (Miller, 2007). Thus, people who display signs of embarrassment are often better liked and more readily forgiven than those who do not (Keltner & Anderson, 2000). However, despite its importance for social interactions, little is known about the experience of embarrassment in Autism Spectrum Disorder (ASD; Adler et al., 2015; Hillier & Allinson, 2002; Thiébaut et al. 2016).

Objectives:

The present study explored how adults with ASD traits (ASD-T) may experience or respond to embarrassing scenarios compared to adults without ASD-T. Additionally, gender differences in the experience of embarrassment were considered. Relations between proneness to embarrassment and theory of mind (ToM) and fear of negative evaluation were also assessed.

Methods:

A total of 72 adults, those with ASD-T (n = 36) and those without, or neurotypical adults (NT; n = 36), participated. The Social Responsiveness Scale (SRS-2-Adult; Constantino, 2012) was used to identify individuals who showed evidence of ASD-T from those who did not. Research has shown that the SRS-2 can be used to distinguish between individuals with ASD traits from those without (Ingersoll et al., 2011). See Table 1 for additional demographic information.

Participants' proneness to embarrassment was measured using the embarrassment subscale from Sabini et al. (2001). Participants were asked to place themselves within 10 embarrassing scenarios and rate how likely it is that they would experience embarrassment for that event using a 7-point Likert scale (7 = extremely likely). Participants also provided ratings of anger, fear, guilt, regret, and shame in response to each embarrassing scenario. This allowed us to determine (1) how much embarrassment participants felt they would experience in a given scenario, and (2) how much the embarrassing scenarios elicited other emotions.

Participants also completed the Faux Pas Test-Adult (Stone et al.,1998) as a measure of ToM, and the Brief Fear of Negative Evaluation Scale (BFNE; Leary, 1983). Following informed consent, all measures were completed online using a secure survey platform.

Results:

A mixed-model ANOVA and appropriate follow-up tests showed that adults with ASD-T rated embarrassing scenarios similar to NT adults in terms of how much embarrassment they thought each would elicit (see Table 2). However, adults with ASD-T reported higher levels of fear, guilt, and shame in response to embarrassing situations than NT adults. Faux-pas detection and detection of false-beliefs were positively related to higher embarrassment ratings in adults with ASD-T, but not in NT adults (see Table 2). Additional results (see Table 2) will be discussed as they relate to BFNE and gender comparisons.

Conclusions:

Although adults with and without ASD-T were similar in their ratings of embarrassment, the embarrassing scenarios were more likely to elicit other, particularly negative emotions, in adults with ASD-T. The current results also suggest that ToM may play a greater role in feelings of embarrassment in ASD-T than in NT adults. Understanding how embarrassment is perceived may inform social-emotional programs for adults with ASD.

191 **239.191** The Relationship between Emotion Recognition Ability, Subjective Emotional Intensity, and Traits Associated with ASD

F. Shafai[1], *E. Gateman*[2], *A. Abraham*[2], *M. K. Stow*[3], *S. E. Schulz*[4], *E. Altoum*[2], *S. Handy*[2], *A. Hawkins*[2], *C. Sakellis*[2], *T. W. W. Ho*[2], *N. E. Scheerer*[5], *G. Iarocci*[5] *and R. A. Stevenson*[4], *(1)The University of Western Ontario, London, ON, Canada, (2)University of Western Ontario, London, ON, Canada, (3)Psychology, University of Western Ontario, London, ON, Canada, (4)Western University, London, ON, Canada, (5)Simon Fraser University, Burnaby, BC, Canada*

Background: Individuals with Autism Spectrum Disorder (ASD) have been shown to have difficulty with emotion recognition in various studies. It has been suggested that these results are associated with symptom severity, where those who struggle the most with recognizing emotions are those with the highest rates of traits common in ASD. It is still unknown as to which ASD-related traits are most strongly correlated with atypical emotion recognition.
Objectives:

1) Assess whether emotion recognition accuracy is higher for individuals with less ASD-related traits.

2) Determine if subjective ratings of emotional intensity are associated with measures of ASD-related symptoms.

Methods: We assessed emotion recognition accuracy and subjective ratings of emotional intensity using videos of actors saying the same phrase while expressing different emotions, both facial expressions and auditory prosody, at varying intensities. Following each video, individuals reported which emotion the actor just expressed and rated the intensity of the emotion on a scale of 1-9. Each actor expressed anger, disgust, fear, happiness, sadness, and surprise at low and high intensity, as well as a non-emotive control condition. Trials were gaze-controlled to ensure that individuals were looking at the screen prior to each video being presented. Autistic traits were measured using the Broad Autism Phenotype Questionnaire (BAPQ), and social competency was measured using the Multidimensional Social Competence Scale (MSCS). Mean accuracy and intensity ratings were calculated and correlated with levels of autistic traits. This study is ongoing and has collected data from typically-developing (TD) young adults (n=29).

Results: The initial results of this ongoing study indicate that subjective emotional intensity ratings are positively correlated with the *Rigidity* subscale of the BAPQ (r-values 0.324> 0.385) and are negatively correlated with the *Pragmatic Language* subscale (r-values -0.257>-0.296). Emotional intensity ratings were also positively correlated with the *Social Inferencing* and *Emotion Regulation* (r-values 0.257>0.410) subscales of the MSCS, but were negatively associated with the Empathic Concern subscale (r-values -0.279>-0.308) (Figure 1).

Conclusions: Results from this on-going study suggest that subjective intensity ratings of emotions are related to autistic traits. Interestingly, these associations were in the expected direction for some, but not all, of the subscales of interest. As social inferencing and emotion regulation are necessary for comprehending cues in social contexts, it was unsurprising that these related to subjective ratings of emotion intensity. One would predict that empathic concern, however, would also be positively correlated with intensity ratings. It is possible that the negative association may be mediated by other factors, for instance, anxiety, where a disassociation between the concern for another's emotional state can be overshadowed by the internal perception of the emotions being displayed. Similarly, the negative correlation between subjective emotion intensity ratings and pragmatic language may be influenced by factors related to anxiety or influenced more by visual features of the face rather than the auditory prosody of the stimuli. As these findings are found in TD individuals with varying levels of ASD-related traits, further investigation is needed to determine if these results are also found for individuals clinically diagnosed with ASD.

192 **239.192** The Role of Somatic Symptoms on Emotion Recognition in Young Children with ASD

T. M. Rutter, *A. J. Lee, M. Feller, C. Quinnett, L. Molina and B. J. Wilson, Seattle Pacific University, Seattle, WA*

Background: Children with autism spectrum disorder (ASD) often display challenges in facial emotion recognition (FER; Lozier, Vanmeter, & Marsh, 2014). While previous literature suggests individuals with ASD demonstrate challenges in detecting negative emotions compared to typically developing (TD) peers (Ashwin, Chapman, Colle, & Baron-Cohen, 2006), recent literature suggests this extends to detection of happiness (Sato et al., 2018). Internalizing symptoms have been shown to be related to FER challenges (Székely, Tiemeier, Jaddoe, Hofman, Verhulst, & Herba, 2014), however, anxiety and depressive symptoms constitute much of the FER literature across youth samples (i.e., Demenescu, Kortekaas, den Boer, & Aleman, 2010). Given that somatic symptoms in childhood predict later anxiety and depressive disorders (Shanahan, Zucker, Copeland, Bondy, Egger, & Costello, 2015), somatic symptoms are a subset of internalizing symptoms that warrant further investigation. We are unaware of any studies that investigate the unique role of somatic symptoms on FER in young children with ASD.
Objectives: Our objective was to develop a greater understanding of factors associated with accurate recognition of happiness among children with ASD. We hypothesized that somatic symptoms would moderate the relation between developmental status and accuracy response time.

Methods: Participants were 152 children (ages 3:0 to 6:11) and their parents. Eighty-four TD children (42% female) and 68 children with ASD (19% female) were examined. Parent ratings from the Behavioral Assessment System for Children - Second Edition (BASC-2; Reynolds & Kamphaus, 2004) were used to measure somatic symptoms. Children completed a dynamic emotion recognition task via laptops in a laboratory setting. Two trials of twenty slides were presented; scores reflect the mean slide number of first accurate recognition. Higher scores indicate slower recognition.

Results: A moderation analysis was conducted using the SPSS 25 macro PROCESS (Hayes, 2013) to evaluate whether the association between developmental status and recognition of happiness was moderated by parent-reported child somatic symptoms. Children's age was controlled for in the analysis. Results indicated significant main effect of status on emotion recognition (B = 8.490, CI_{95} [3.035, 13.945], p = .002). The main effect of somatic symptoms on emotion recognition was not significant (B = .038, CI_{95} [-0.048, 0.120], p = .386). The contribution of the interaction between status and somatic symptoms was significant (B = -0.121, CI_{95} [-0.233, -0.008], $\Delta R2$ = .02, $F(1,147)$ = 4.512, p = .035. At low-to-moderate levels of somatic symptoms, children with ASD were slower to recognize happiness, while at high levels of somatic symptoms, children with ASD recognized happiness quickly and performed as well as their TD peers.

Conclusions: The current study found children with ASD were slower to recognize happiness compared to their TD peers at low-to-moderate levels of somatic symptoms. However, high levels of somatic symptoms appeared to sensitize children with ASD in their recognition of happiness, with performance similar to TD peers. While studies have shown this sensitizing effect on FER for broadband internalizing symptoms (Rosen & Lerner, 2016), our study provides evidence that somatic symptoms may be a unique contributor to emotion recognition in children with ASD.

193 **239.193** Negative Affectivity As a Mediator of the Association between Caregiver Psychological Distress and Psychopathology in Infants with Early Signs of Autism Spectrum Disorder (ASD)

L. Chetcuti[1,2], *M. Uljarevic*[3], *K. J. Varcin*[2,4], *M. Boutrus*[2,5], *A. J. Whitehouse*[2,4] *and K. Hudry*[1,2,6], *(1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA, (4)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (5)Telethon Kids Institute, University of Western Australia, Perth, Australia, (6)Victorian Autism Specific Early Learning and Care Centre, La Trobe University, Melbourne, Australia*

Background: Individuals with an Autism Spectrum Disorder (ASD) diagnosis experience higher rates of internalizing and externalizing symptoms/disorders than the general population. However, little is known about the pathways towards the development of co-morbid psychopathology in this population. Children's negative affectivity (i.e., propensity towards negative emotions) and caregiver psychological distress are established risk factors for psychopathology in non-autistic children. Further, there is evidence linking early caregiver psychological distress to subsequent variation in child temperament. Bringing together these lines of evidence, a recent study (Allen, Oshri, Rogosch, Toth, & Cicchetti, 2018) found that negative affectivity mediates the association between caregiver psychological distress and psychopathology among non-autistic children. It remains unclear whether this pathway extends to individuals with ASD symptoms; yet, two separate strands of research provide evidence for heightened caregiver psychological distress and negative affectivity in the ASD population.
Objectives: To explore whether the pathway identified in non-autistic children – from caregiver psychological distress to child negative affectivity to child psychopathology – is also observed among a cohort of infants presenting with varying levels of ASD features.

Methods: Participants were a community-referred sample of 103 infants (68% male) aged 9-16 months (*M* = 12.39, *SD* = 1.97) showing early signs of ASD, and a primary caregiver (96% biological mothers). Caregivers completed a series of questionnaires. Psychological distress was measured using the Depression Anxiety Stress Scale (DASS-21), infant negative affectivity was measured using the Infant Behavior Questionnaire-Revised (IBQ-R), and infant internalizing and externalizing symptoms were assessed via the Infant-Toddler Social and Emotional Assessment (ITSEA). Infant ASD features were assessed using the Autism Observation Schedule for Infants (AOSI), a semi-structured observational measure. An SPSS macro was used to estimate the total and indirect effects of caregiver psychological distress on infant internalizing and externalizing (modelled separately) via infant negative affectivity (mediator) at varying levels of ASD features (moderator).

Results: Caregiver psychological distress, infant negative affectivity, and infant internalizing and externalizing symptoms were positively interrelated. Infant ASD features were positively associated with internalizing symptoms (only). The model explained a large proportion of the variance in infant internalizing and externalizing symptoms (44% and 24%, respectively). Infant negative affectivity fully mediated the association between caregiver psychological distress and infant psychopathology in both models. No interaction terms involving the AOSI were significant, indicating that the significance of direct and indirect effects did not vary as a function of infant ASD features.

Conclusions: These results – showing temperamental negative affectivity to mediate the link between caregiver psychological distress and infant psychopathology – are consistent with findings in non-autistic children, with effects in this community-referred cohort of infants not moderated by level of ASD features. While these results require replication and longitudinal validation, they suggest that interventions designed to mitigate internalizing and externalizing psychopathology should apply irrespective of infant ASD symptom presentation.

194 **239.194** Utility of Temperament for Predicting Psychopathology in Infants with Early Signs of Autism Spectrum Disorder (ASD)

L. Chetcuti[1,2], *M. Uljarevic*[3], *K. J. Varcin*[2,4], *M. Boutrus*[2,5], *A. J. Whitehouse*[2,4] *and K. Hudry*[1,2,6], *(1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)Stanford Autism Center, Department of Psychiatry and Behavioral Sciences, Stanford University, CA, (4)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (5)Telethon Kids Institute, University of Western Australia, Perth, Australia, (6)Victorian Autism Specific Early Learning and Care Centre, La Trobe University, Melbourne, Australia*

Background: High rates of internalizing and externalizing psychopathology are reported among individuals with a diagnosis of Autism Spectrum Disorder (ASD). However, the mechanism/s underlying this pattern of co-morbidity remain poorly understood. Abundant research on normative development suggests that individual differences in early temperament characteristics can promote either risk or resilience to the development of psychopathology. Surprisingly, only a handful of studies have explored the relation of temperament to psychopathology in the context of ASD. These existing studies explored associations between psychopathology and *individual* temperament traits, as opposed to multiple-trait *configurations* which more aptly describe each person as a whole. Further, existing studies restricted their focus to individuals with established ASD diagnosis, limiting generalizability to early development when behavioural features of ASD and psychopathology first emerge.
Objectives: To (a) identify distinctive temperament subgroups within a cohort of infants presenting with early signs of ASD and (b) explore the utility of these temperament subgroups for predicting variability in internalizing and externalizing symptoms.

Methods: Participants were a community-referred sample of 96 infants (67.7% male) aged 9-16 months (*M* = 12.38, *SD* = 1.94) showing early signs of ASD. Parents/carers completed the Infant Behavior Questionnaire-Revised (IBQ-R), a 191-item measure of infant temperament, and the Infant-Toddler Social and Emotional Assessment (ITSEA), a 161-item measure of social-emotional and behavioural problems. Latent profile analysis was used to identify temperament subgroups from IBQ-R subscale scores, and one-way ANOVA were used to explore between-subgroup differences across ITSEA domains/scales.

Results: Three temperament subgroups were identified: (1) *well-regulated* (*n* = 51), characterized by high cuddliness, falling reactivity, and soothability, (2) *active/negative reactive* (*n* = 23), characterized by high activity level, distress to limitations, sadness, fear, and low falling reactivity, and (3) *inhibited/low positive* (*n* = 22), characterized by low smiling and laughter, high intensity pleasure, vocal reactivity, approach, and perceptual sensitivity. *Active/negative reactive* infants had the highest levels of separation distress and broad externalizing symptoms, while

inhibited/low positive infants had the highest levels of depression/withdrawal. Both *active/negative reactive* and *inhibited/low positive* subgroups had higher levels of broad internalizing symptoms than *well-regulated* infants, who had the lowest reported levels of co-morbid psychopathology. There were no differences between temperament subgroups with respect to age, sex, or developmental/cognitive ability. *Inhibited/low positive* infants presented with more ASD features than the other subgroups.

Conclusions: Temperament characteristics may contribute to variability in internalizing and externalizing symptoms in young children with early signs of ASD. This study provides an empirical foundation for the development of individualized interventions for the prevention and treatment of co-morbid psychopathology in ASD. The person-centered approach utilized in this study afforded a more nuanced understanding of temperament-psychopathology relations, and the broad inclusion criteria for participant infants extends the generalizability of results across the full continuum of ASD feature presentation.

Poster Session
240 - Epidemiology/population studies
11:30 AM - 1:30 PM - Room: 710

195 **240.195** Neonatal Polyunsaturated Fatty Acid Levels in Association with Autism Spectrum Disorders: Results from a California Population-Based Case-Control Study

K. Lyall[1], *G. C. Windham*[2], *C. Whitman*[1], *R. Kuskovsky*[1], *N. Snyder*[1], *L. F. Robinson*[3] *and C. J. Newschaffer*[1], *(1)A.J. Drexel Autism Institute, Philadelphia, PA, (2)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (3)Epidemiology and Biostatistics, Drexel University, Philadelphia, PA*

Background: Polyunsaturated fatty acids (PUFAs) play key roles in neurodevelopment. Only a few studies have examined prenatal PUFAs in association with autism spectrum disorder (ASD), and results have not been consistent. No prior study has examined the association between measured neonatal levels of PUFAs and ASD, yet PUFAs measured in the newborn period may better capture the more biologically-relevant window of PUFA uptake in the developing brain during late pregnancy than measurements earlier in pregnancy.
Objectives: To determine whether levels of PUFAs, measured in neonatal bloodspots, differ in in children with ASD as compared to those without ASD.

Methods: We conducted a population-based case-control study of 500 cases and 500 general population (GP) controls in order to examine maternal and newborn PUFA levels in association with ASD. Cases, identified from the California Department of Developmental Services (DDS), were matched on sex and month and year of birth (2011-2013) to GP controls, who were randomly selected within strata of matching factors from birth certificate files after excluding DDS clients. For neonatal analyses, 200 cases and 200 controls from the larger study were randomly selected. Newborn bloodspots were obtained from the California Biobank Program, and PUFA levels were measured using liquid chromatography-mass spectrometry/high resolution mass spectrometry (LC-MS/HRMS).To adjust for hematocrit, potassium levels were used to normalize PUFA levels.Logistic regression analyses, accounting for matching factors and other potential confounders, were used to calculate odds ratios (ORs) between PUFA levels (as individual fatty acids and as summed classes of n-3 and n-6 PUFAs) and ASD.

Results: PUFAs were quantifiable above background levels in newborn bloodspots and demonstrated sufficient stability and precision in this matrix. With the exception of docosahexaenoic acid (r=0.42, p<.0001), neonatal PUFA levels were not correlated with maternal PUFA levels in mid-pregnancy serum. Geometric mean levels of individual neonatal PUFAs did not significantly differ between cases and controls. In adjusted analyses we did not observe significant associations between quartiles of PUFA levels and ASD, though a non-significant reduction in risk with the highest quartile of n-3 PUFAs was suggested (OR for Q4 v Q1=0.72, 95%CI 0.40, 1.29). When examining extremes of the distribution, we observed a significant reduction in odds of ASD according to the highest 5thpercentile of n-3 PUFAs (relative to the interquartile range (IQR), OR=0.18, 95%CI 0.04, 0.88). A similar association was found for the highest levels of total PUFAs overall (OR=0.25, 95% CI 0.06, 1.01), along with a suggested increase in risk of ASD for those with the very lowest levels of total PUFAs (lowest 5thpercentile relative to IQR, OR=2.20, 95% CI 0.92, 5.25).

Conclusions: Findings from this population-based case control study suggest that individuals with the highest levels of neonatal n-3 and total PUFAs may have reduced odds of ASD; however, these associations were estimated with low precision and require replication in other studies. Given the role of PUFAs in fetal brain development, and the fact that neonatal PUFAs represent a critical window for PUFA exposure and neurodevelopment, further examination of these associations is needed.

196 **240.196** Neonatal Thyroid Stimulating Hormone and Subsequent Diagnosis of Autism Spectrum Disorders and Intellectual Disability

J. Ames[1], *G. C. Windham*[2], *K. Lyall*[3], *M. Pearl*[2], *C. K. Yoshida*[1], *J. Van de Water*[4,5], *P. Ashwood*[4,6] *and L. A. Croen*[1], *(1)Division of Research, Kaiser Permanente, Oakland, CA, (2)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (3)A.J. Drexel Autism Institute, Philadelphia, PA, (4)MIND Institute, University of California, Davis, Davis, CA, (5)Department of Public Health Sciences, Division of Rheumatology, Allergy and Clinical Immunology, University of California, Davis, Davis, CA, (6)Department of Medical Microbiology and Immunology, University of California, Davis, Davis, CA*

Background: Thyroid abnormalities in early life, if left untreated, are associated with adverse neurodevelopmental outcomes, including intellectual disability (ID). However, evidence addressing the role of neonatal thyroid hormones in the altered neurobiology underlying autism spectrum disorders (ASD), particularly among its subphenotypes, is limited.
Objectives: To determine the association between neonatal thyroid hormone levels and subsequent diagnosis of ASD, ID, and subphenotypes of ASD.

Methods: Utilizing data from the Early Markers for Autism (EMA) Study, we conducted a population-based, case-control study among a sample of 4.5-9-year-old children born during 2000-2003 in Southern California. We examined neonatal thyroid-stimulating hormone (TSH) levels measured during routine newborn screening among children later diagnosed with ASD (n=524), ID (n=124), and general population (GP) controls (n=402). GP controls were randomly sampled from birth certificate files and frequency matched to cases by sex, birth month, and birth year. TSH was further

analyzed in relation to ASD subgroups defined by intellectual ability and onset type (early onset ASD vs. ASD with regression) ascertained by expert review of records from the California Department of Developmental Services. ASD cases with composite scores on standardized cognitive tests less than or equal to 70 were classified as ASD with intellectual disability (ASD+ID) and those with scores greater than 70 were classified as ASD without intellectual disability (ASD-noID). We modeled differences in TSH levels between ASD or ID status vs. GP controls using odds ratios (ORs) obtained from multivariate unconditional logistic regression. We examined neonatal TSH both as a continuous (ln-transformed) and as a categorical variable based on percentiles. In sensitivity analyses, we examined relationships excluding preterm (gestational age <37 weeks) and multiple births.

Results: In models adjusting for matching factors (sex, birth month and year), birthweight, gestational age, and age at newborn bloodspot collection, we found no association between continuous neonatal TSH levels and ASD (adj-OR: 0.96, 95%CI: 0.76-1.21) nor ID (adj-OR: 0.95, 95%CI: 0.69-1.30). Results were similarly null for models examining percentiles of TSH. Among ASD subphenotypes, we observed an inverse trend between neonatal TSH and odds of ASD with regression; ASD with regression was marginally associated with continuous TSH (adj-OR: 0.76, 95%CI: 0.55-1.06) and significantly associated with the highest quartile of TSH (adj-OR: 0.48, 95%CI: 0.26-0.92). The odds of ASD-noID were also lower with increasing TSH but this relationship was more modest and not significant in models of continuous TSH (adj-OR: 0.83 95%CI: 0.63-1.11) and models comparing the highest to lowest TSH quartiles (adj-OR: 0.68, 95%CI: 0.40-1.14). Neonatal TSH was not associated with early onset ASD nor ASD+ID. Sensitivity models excluding preterm and multiple births yielded similar findings.

Conclusions: While there was little evidence that neonatal TSH is related to overall risk of ASD, our findings suggest that neonatal TSH levels may be associated with particular subtypes of ASD defined by onset type and co-occurrence of intellectual disability. Given that thyroid hormone deficiencies at birth are amenable to therapy, further scrutiny of the intersection of thyroid hormones and ASD is warranted, with attention to ASD subphenotypes.

197 **240.197** Neurodevelopmental Outcomes of a High-Risk Autism Spectrum Disorders Cohort of Full and Half Siblings

M. Oliver[1], *E. Angel*[2], *S. Averill*[3] *and R. J. Schmidt*[2], *(1)UC Davis MIND Institute, Sacramento, CA, (2)Public Health Sciences, University of California Davis, Davis, CA, (3)Public Health Sciences, University of California, Sacramento, CA*

Background: The Markers of Autism Risk in Babies – Learning Early Signs (MARBLES) Study is an autism high-risk cohort that started enrolling families in 2006. Eligible families include an older biological sibling with a confirmed Autism Spectrum Disorders (ASD) diagnosis and a new younger sibling followed prenatally until 36 months. The new younger sibling is referred to as the child of interest (COI). The COIs are followed for early signs of ASD and other developmental delays. Research assessing the risk factors of younger siblings for developing ASD or other non-typical development (non-TD) is limited.

Objectives: To assess the risk of developing ASD or non-TD for younger full and half siblings. To compare Autism Diagnostic Observational Schedule (ADOS) comparison (severity) scores among the COIs with a confirmed ASD or non-TD diagnosis and their sibling relationship (full vs half).

Methods: Logistic regression was used to compare the diagnostic outcomes (ASD, non-TD, or TD) and linear regression on ADOS severity scores to sibling relationship (full versus half siblings). All analyses were adjusted for child gender, race, ethnicity, and birth year; and maternal age and education.

Results: We reviewed 275 COIs (116 females and 160 males) who completed a 36 month developmental assessment including Mullen Scales of Early Learning and ADOS with a final diagnosis of ASD (64), non-TD (70), and typically developing (TD, 141) COIs. Of the 275 COIs, 239 had an older full sibling with ASD (97 females 142 males) and 36 had an older half sibling with ASD (18 females and 18 males). When comparing the sibling relationship and its association with an ASD diagnosis, there was no significant risk associated with being diagnosed with ASD versus TD (p=0.49; OR= 0.722; 95% CI: 0.283,1.843). However, a full younger sibling was associated with a borderline significantly higher risk of being diagnosed with non-TD (p=0.08; OR=.414; 95%; CI: 0.151 1.133) . Younger siblings diagnosed with ASD were compared using their autism severity scores obtained from the ADOS. Being a full siblings was associated with higher autism severity scores (p=0.04). Among children with non-TD, no significant difference severity score was found between full and half siblings (p=0.14).

Conclusions: We found no significant difference in estimated risks of developing ASD or non-TD for younger full and half siblings based on the sibling relationship. Full younger siblings diagnosed with ASD have a higher ADOS severity score, when compared to the half siblings with the same diagnosis. Though our study suggests some differences in outcomes between younger full and half siblings, our sample size is small and larger studies are needed to confirm these findings.

198 **240.198** Patterns of Developmental Milestone Delay Identified Using Latent Class Analysis in a Finnish Population Based Sample of Autism Cases and Controls

K. Cheslack-Postava[1], *S. Hinkka-Yli-Salomäki*[2], *I. W. W. McKeague*[3], *A. Sourander*[2] *and A. S. Brown*[4], *(1)Columbia University Medical Center, New York, NY, (2)University of Turku, Turku, Finland, (3)Biostatistics, 455 Central Park West, Apt 8D, New York, NY, (4)Columbia College of Physicians and Surgeons, New York, NY*

Background: Autism spectrum disorders (ASD) are characterized by atypical developmental trajectories in language and social domains. However, delays in non-verbal cognitive and in fine and gross motor domains are also common. Latent class analysis (LCA) may be useful to empirically identify potentially complex patterns of delayed development across domains.

Objectives: To empirically identify developmental classes characterized by shared patterns of delayed milestone achievement, using population-based data from subjects with autism and with typical development.

Methods: Data on the age at achievement for 21 developmental milestones with expected age at attainment between birth and 24 months were abstracted in Finland from well-child clinics for 846 cases with childhood autism identified in the Finnish Hospital Discharge Register and 925 controls matched on sex, date of birth, and place of birth. For each milestone, a dichotomous indicator of delay was coded as positive if the age at achievement was greater than the 90th percentile of control values. Latent class models with 2-10 latent classes were fit based on the dichotomous variables for each milestone and the optimum number of classes was selected based on the Bayesian Information Criterion (BIC). An LCA model with the optimum number of classes was then used to estimate the class membership probabilities for each individual and the item-

response probabilities for each type of delay. Subjects were classified based on their maximum probability of class membership, and the distribution of developmental class membership was compared between autism cases and controls using multinomial logistic regression.

Results: A 5-class model best fit the data based on the minimum BIC. 72.5% of subjects (61.5% of cases and 82.6% of controls) belonged to a "non-delayed" class with low probabilities of delay for all milestones. A class containing 10% of subjects had high probabilities of gross motor delays (crawling and standing). An "early delay/smile" class (6.7%) exhibited delays in early motor (i.e. lifting head) milestones and in smiling responsively, but not in later skills. A "late delay/interactive" class (4.5%) showed delays in social and receptive language milestones (i.e. pointing, collecting objects upon request, playing peek-a-boo). The remaining class was characterized by overall delays. All classes other than "non-delayed" were significantly associated with increased risk of autism. The highest odds ratios (ORs) for autism were associated with the "late delay/interactive" class (OR (95% CI)=7.13 (3.86, 13.2); p<0.0001) and the overall delays class (OR (95% CI)=6.38 (3.73, 10.9); p<0.0001), after adjustment for pre-term birth and low birth weight.

Conclusions: While the majority of cases with autism did not show apparent patterns of delay based on developmental milestones before age 24 months, specific patterns of delay were associated with highly increased autism risk relevant to a subset of cases. Characterizing the heterogeneity of autism based on shared patterns of early development may assist etiological and clinical research by identifying more homogenous groups of cases, for targeted early intervention and identification of correlations with other developmental events and neurobiological processes.

199 **240.199** Pediatric Autism Research Cohort (PARC): Towards a Learning Autism System

A. Kata[1], *C. Roncadin*[2], *I. Drmic*[2], *S. J. Gentles*[1], *M. Spoelstra*[3], *P. Rosenbaum*[4], *W. Mahoney*[1], *O. Kraus De Camargo*[1], *B. Di Rezze*[1], *K. Georgiades*[1], *L. Hoult*[2], *E. Duku*[1], *P. Szatmari*[5], *C. Kasari*[6], *S. Bishop*[7], *C. Lord*[8] *and S. Georgiades*[1], *(1)McMaster University, Hamilton, ON, Canada, (2)Autism Spectrum Disorder Service, McMaster Children's Hospital - Hamilton Health Sciences, Hamilton, ON, Canada, (3)Autism Ontario, Toronto, ON, Canada, (4)CanChild Centre, McMaster University, Hamilton, ON, Canada, (5)The Hospital for Sick Children, Toronto, ON, Canada, (6)University of California, Los Angeles, Los Angeles, CA, (7)University of California San Francisco, San Francisco, CA, (8)University of California Los Angeles, Los Angeles, CA*

Background: In 2017 the Government of Ontario, Canada launched the new Ontario Autism Program (OAP). The OAP aims to provide publically-funded, individualized, flexible, and family-centred services to children with Autism Spectrum Disorder (ASD). The Hamilton-Niagara Regional Autism Program (H-NRAP) is one of the largest regional programs delivering the OAP, serving 3,000+ children with ASD and their families. A major challenge in the successful implementation of the OAP is the use of empirical evidence to guide clinical practice to meet each child's unique needs. To address this challenge the program is working towards the implementation of a Learning Autism System (LAS) in which science, informatics, incentives, and culture are aligned for continuous improvement and innovation.

Objectives: The Pediatric Autism Research Cohort (PARC) Project is a pilot study testing the implementation of a Learning Autism System. The specific objectives are to: a) embed a standardized longitudinal research protocol within the regional program (clinic) and recruit 100 consecutive preschool children with ASD as they enter the OAP; b) describe the developmental trajectories (clinical pathways) in preschool children with ASD – at the individual, subgroup, and group levels – and identify individual and contextual factors contributing to variability in outcomes; and c) through a digital platform, create a 'feedback loop' with the clinic to help disseminate research findings to families and clinicians, allowing for enhanced communication and decision-making processes leading to more tailored and adaptive service plans.

Methods: The pilot phase of PARC includes recruiting and assessing newly-diagnosed preschool children with ASD. Data are collected in two stages: 1) accessing information collected as part of 'standard' clinical practice, and 2) administering a set of additional assessments on child, family, services, and community level variables of interest. Stage 1 includes measures of symptom severity, cognitive functioning, and adaptive behavior; Stage 2 includes measures of social communication abilities, community participation, quality of life, service use, and sociodemographic characteristics. Assessments are repeated at 6-month intervals over a 2-year period and data are synthesized and 'fed back' to the clinic on an ongoing basis.

Results: This pilot study is active and data collection is ongoing. To date 94 children with ASD and their families have been enrolled (mean age 3.81 years, SD 0.846, 79% male) in 8 months, with a 95% recruitment rate. The results of three-way clustering methods consisting of variables and observations over time will be presented, identifying homogeneous groups of children to inform service planning and adaptation. The developmental trajectories of social communication abilities and adaptive functioning will be mapped using longitudinal mixed membership models.

Conclusions: PARC represents a new type of longitudinal investigation in ASD, illustrating the feasibility of consecutive sampling with implications for representativeness. Within a Learning Autism System framework, research and clinical data are systematically collected and synthesized to inform clinical care as children move through the OAP. Findings will be discussed within the context of pragmatic, sustainable research that guides clinical practice and lays the foundation for the evidence base needed to inform programs and policies at a systems level.

200 **240.200** The Independent, Moderating, and Interaction Effects of Prenatal Exposure to Maternal Smoking and Ambient Fine Particulate Matter on Risk of Autism Spectrum Disorder

A. V. Bakian[1], *D. Mendoza*[2], *J. VanDerslice*[3], *D. Chen*[4], *H. Coon*[1], *C. Kingsbury*[5], *N. Taxin*[5], *W. M. McMahon*[1], *A. Fraser*[6], *Y. Zhang*[7] *and D. A. Bilder*[1], *(1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Pulmonary Medicine, University of Utah, Salt Lake City, UT, (3)Family and Preventive Medicine, University of Utah, Salt Lake City, UT, (4)Study Design and Biostatistics Center, University of Utah, Salt Lake City, UT, (5)Bureau of Children with Special Health Care Needs, Utah Department of Health, Salt Lake City, UT, (6)Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, (7)Internal Medicine, University of Utah, Salt Lake City, UT*

Background: Recent estimates of autism spectrum disorder's (ASD) heritability range from 38%-87% indicating an important role for the environment in ASD's etiology. Among the many environmental factors that have been investigated, exposure to prenatal ambient fine particulate matter ($PM_{2.5}$) and maternal smoking have been independently, albeit inconsistently, linked to ASD. Although ambient $PM_{2.5}$ and maternal smoking exposure during pregnancy may engage similar biological mechanisms to incur ASD risk (e.g. inflammation), the moderating and interaction effects of these exposures on ASD risk have yet to be examined.

Objectives: Investigate the independent, moderating and interacting effects of prenatal ambient $PM_{2.5}$ and maternal smoking exposures on ASD

risk.

Methods: Children with ASD born from 2008-2010 in Salt Lake County, Utah (N=247) were identified by the Utah Registry of Autism and Developmental Disabilities and each matched to five population controls (N=1008) based on birth year and sex from the Utah Population Database. Exposure to maximum daily (split at ≤ vs >median concentration in each exposure window) and average daily (split at ≤ vs >12 µm) concentrations of ambient fine particulate matter was estimated separately for five exposure windows including the three months prior to conception, the first, second, and third trimesters, and throughout pregnancy. Prenatal maternal smoking (yes vs. no) and additional pregnancy-related covariates for ASD were acquired from birth certificates. A series of multivariable conditional logistic regression models were fit to determine the relationship between 1) prenatal maximum and average daily $PM_{2.5}$ exposures and ASD risk, and 2) prenatal maternal smoking and ASD risk. The $PM_{2.5}$ models were updated to include a prenatal $PM_{2.5}$ by maternal smoking interaction term.

Results: Average daily ambient $PM_{2.5}$ exposure was not associated with ASD risk during any of the pregnancy exposure windows. Maximum daily ambient $PM_{2.5}$ exposure during the first trimester was associated with decreased ASD risk (Odds ratio (OR): 0.743, 95% CI: 0.56-0.99). Prenatal maternal smoking exposure was associated with increased ASD risk (OR: 1.73, 95% CI: 1.05-2.84). The interaction between average daily $PM_{2.5}$ concentration throughout pregnancy and prenatal maternal smoking was associated with increased ASD risk with an OR of 4.38 (95% CI: 1.52-12.61) among children exposed to maternal smoking vs. an OR of 0.89 (95% CI: 0.635-1.24) for children not exposed to maternal smoking. (p=0.004). The relationship between maximum daily $PM_{2.5}$ exposure and ASD during the third trimester was moderated by prenatal maternal smoking exposure (OR: 2.66, 95% CI: 1.002-7.03 vs. OR: 1.21, 95% CI: 0.88-1.65 in children exposed vs. not exposed to maternal smoking), although the interaction was not significant (p=0.13).

Conclusions: Our results indicate that prenatal maternal smoking is independently associated with ASD, and suggest that the combination of prenatal maternal smoking and fine particulate matter exposure may yield interacting and moderating effects on ASD risk. Effect estimate precision is low, however, indicating that further investigation with a larger sample is warranted. Replication of study findings would suggest that interventions aimed at reducing prenatal maternal smoking might have a corresponding impact on the risk of ASD incurred through prenatal $PM_{2.5}$ exposure.

201 **240.201** Perspectives of Specialized Driving Instructors: Teaching Autistic Adolescents and Young Adults to Drive

A. E. Curry[1], *R. K. Myers*[1], *J. M. Bonsu*[2], *M. E. Carey*[1], *B. E. Yerys*[3] *and C. J. Mollen*[4], *(1)Center for Injury Research and Prevention, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Ohio State University, Columbus, OH, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA*

Background:

Limited access to transportation may curtail the transition to independent adulthood for autistic adolescents, potentially curtailing their ability to attend school, participate in employment, and engage in social activities. Despite documented challenges in the demands of working memory, multitasking, and executive functioning among autistic adolescents—which have been linked to poor driving performance observed in driving simulators—nearly one-third of autistic adolescents and young adults obtain a driver's license by age 21 (Curry et al., 2018). Given both the importance of safely encouraging independence and the potential for increased risk for adverse driving outcomes, research on driving among autistic adolescents and young adults is critical.

Objectives:

Our objective was to document driving instructors' unique experiences and perspectives regarding the autistic adolescents' training needs and recommendations for best practices to inform the development of tailored supports to optimize the safety of autistic adolescents as independent drivers.

Methods:

We conducted interviews with 17 driving instructors who possessed specialized training to teach autistic adolescents and young adults to drive. Participants were recruited through snowball sampling. The semi-structured interview guide investigated: family engagement; instructors' observations; educators' instructional strategies; and recommendations for improving the learning-to-drive process. A directed content analysis approach informed the development of a coding scheme. Coded transcripts were reviewed to identify emergent themes.

Results:

Participating driving instructors primarily identified as occupational therapists. Key themes included: (1) importance of parent engagement; (2) fostering independence; (3) the need for individualization of instructional strategies; and (4) recommendations for best practices to enhance the learning–to-drive process. Instructors emphasized that parent engagement is critical in preparing autistic students to undertake on-road instruction and supporting skill development throughout the learning-to-drive process. While some families paradoxically limit adolescents' independence in tasks of daily living despite wanting them to expand their independence by pursuing driving training, instructors believed that demonstrating independence through other activities (e.g., bike riding, directing a driver to school or work) was necessary for safely undertaking on-road instruction. Further, instructors shared how they extensively individualized their assessments and instruction, tailoring lessons over a prolonged period of time to promote safe driving and skill acquisition. Specific recommendations for enhancing the learning-to-drive process included standardizing educational approaches and refining clinical assessment tools to better support both specialized and non-specialized instructors in meeting the needs of autistic adolescents.

Conclusions:

These first-hand accounts may help to better prepare parents, non-specialized driving instructors, and adolescents for independent licensure. The experience of driving instructors in this study highlights the need for ongoing parental engagement to support the learning-to-drive process and to foster the independence necessary to undertake highly individualized driving instruction. Efforts to support families by increasing utilization of tools and resources to strengthen adolescent independence may help to better prepare youth for on-road instruction. These results also document the need to establish best practices and refine assessment tools and instructional strategies employed by educators. Future research to gather experiences with the learning-to-drive process among parents and autistic adolescents themselves is critical to improving our understanding of these families' needs.

202 **240.202** Population Disparities in Autism Diagnosis in South Israel.

O. Kerub[1], *E. J. Haas*[2], *G. Meiri*[3], *H. Flusser*[4], *A. Michaelovski*[3], *I. Dinstein*[5], *N. Davidovitch*[6], *M. Gdalevich*[7] *and I. Menashe*[8], *(1)Ben-Gurion University, Ministry of Health, Be'er Sheva,, Israel, (2)Ministry of Health, Beer Sheva, Israel, (3)Soroka Medical Center, Beer Sheba, Israel, (4)Child Development / Pediatric, Ben Gurion University in the Negev, Be'er Sheva,, Israel, (5)Negev Autism Center, Ben Gurion University of the Negev, Beer Sheba, Israel, (6)Ben Gurion University in the Negev, Beer Sheva, Israel, (7)Ben-Gurion University in the Negev, Ministry of health, Be'er Sheva,, Israel, (8)Public Health Department, Ben-Gurion University, Beer Sheva, Israel*

Background:
The rising incidence of autism spectrum disorder (ASD) has become a major public health concern. In Israel, ASD rates vary remarkably across geographic regions and ethnic populations, with one of the largest gaps observed between Jewish and Bedouin populations living in southern Israel.

Objectives:

To identify the reasons for the population disparities in ASD rates in southern Israel.

Methods: This study was conducted between March 2015 and January 2017 at 35 maternal child health centers (MCHCs) in southern Israel. A total of 3343 toddlers (996 Jewish and 2347 Bedouin at age 16-36 months were screened for ASD using the M-CHAT/F questionnaire. Toddlers who failed the M-CHAT/F were referred for further evaluation at the Soroka University Medical Center (SUMC). The diagnostic process at SUMC included several meetings with social workers, developmental psychologists, and expert physicians (a child psychiatrist or a child neurologist) who eventually provided a diagnosis according to DSM-5 criteria. Cox regression analysis was used to assess population differences in the diagnosis processes.

Results:

Overall, 39 Jewish (3.9%) and 70 Bedouin (3.0%) toddlers failed the M-CHAT/F (p=0.165 for population difference in failure rates). Jewish toddlers who failed the M-CHAT/F were significantly younger than Bedouin toddlers (20.15±3.38 vs. 23.77±5.01 respectively; p<0.001), and in both populations the male-to-female failure ratio was 2:1. Of the toddlers who failed the M-CHAT/F, 32 Jewish (82.1%) and 56 Bedouin (80.0%) started the diagnosis process at SUMC (p=0.795 for population difference). Notably, only 32 (57.1%) of the Bedouins that attended SUMC completed the diagnosis process compared to 27 (84%) of the Jewish toddlers (p<0.001). In addition, the time from referral until the first diagnosis meeting at SUMC was, on average, two months longer for Bedouins compared to Jewish toddlers (7.86 vs. 5.53; p=0.040). Consequently, the adjusted "risk" of Jewish toddlers who failed the M-CHAT/F to get a diagnosis of ASD was 2.8 higher compared to Bedouin toddlers (HR=2.8, 95%CI=1.01-7.75; p = 0.049), which explains the current ethnic differences in ASD prevalence in southern Israel (1.2% vs. 0.4% for Jewish and Bedouin toddlers respectively).

Conclusions:

The observed population disparities in ASD prevalence between Jewish and Bedouin toddlers in southern Israel are likely stemming from delayed diagnosis and higher loss to follow-up rates among the Bedouin population. Raising awareness and Better case management for toddlers with suspected ASD from the Bedouin population would help in reducing the gap in ASD prevalence between Jewish and Bedouin toddlers in southern Israel.

203 **240.203** Postnatal Acetaminophen: Contribution to Risk of Autism Spectrum Disorder Among Males

S. S. Bittker[1] *and K. R. Bell*[2], *(1)Autism Research Connections, Darien, CT, (2)Independent Researcher, Waterloo, ON, Canada*

Background: In rodents, large doses of acetaminophen early in life have been found to degrade neurotransmission, motor function, spatial memory, and social behavior in later life. Two retrospective case-control studies in humans suggest that postnatal acetaminophen exposure is associated with increased risk of autism spectrum disorder (ASD). Yet, acetaminophen is widely used as an antipyretic and analgesic in infancy and early childhood.

Objectives: Determine the contribution of postnatal acetaminophen exposure to risk of ASD among male children in the USA.

Methods: Using a retrospectively collected data set from a previous study that was derived from an Internet-based survey among parents of children ages 3 through 12 years old (n=1,515), calculate an adjusted odds ratio (aOR) and gender specific aORs for postnatal acetaminophen measured in doses consumed before age two relative to the outcome of ASD using logistic regression. For comparison, calculate an analogous set of aORs for postnatal ibuprofen measured in doses consumed before age two relative to the outcome of ASD. Also, calculate aORs in joint analyses that include both analgesic variables against the outcome of ASD. Akaike information criterion was used to select a consistent sets of covariates for these analyses.

A contribution to risk of ASD from postnatal acetaminophen among males was calculated using the aOR for postnatal acetaminophen among males, the distribution of the number of doses of acetaminophen consumed up to age two by male children later diagnosed with ASD, and data from the literature.

Results: In this data set, postnatal acetaminophen exposure, measured in number of doses consumed before age two, is associated with increased risk of ASD among males (aOR 1.023, CI 1.005 - 1.043, p=0.020*). While there is also a weak association between postnatal ibuprofen and ASD among males, it is not statistically significant and is completely dominated by the association between acetaminophen and ASD in the joint analysis. Thus, it is conceivable that the weak association observed between ibuprofen and ASD could merely be a result of ibuprofen use being correlated with acetaminophen use.

Covariates in the above analyses include age of the child, ethnicity, Midwest, South, maternal education, age of the mother at birth of the child, and relationship to the child. Gender was also included as a covariate in the regressions that were not gender specific.

Postnatal acetaminophen is associated with approximately 20.6% of the total risk of ASD among males in the USA. Alternatively, the incidence of ASD associated with postnatal acetaminophen consumption is approximately 5.5 per 1,000 males annually, which is equivalent to an estimated annualized incidence of 11,600 cases of ASD among male children in the USA. This data set also provides hints of gender specific effects of postnatal acetaminophen on risk of ASD, although the p-value for interaction of 0.253 is not statistically significant.

Conclusions: While there may be some measurement error, as this data set was collected retrospectively, this study suggests that postnatal acetaminophen is associated with a significant proportion of the risk of ASD among male children in the USA.

204 **240.204** Pregnancy Planning and Its Association with Autism Spectrum Disorder and Other Developmental Disabilities: Findings from the Study to Explore Early Development

S. Harris[1], *L. Schieve*[1], *C. Drews-Botsch*[2], *C. J. Newschaffer*[3], *J. Daniels*[4], *C. DiGuiseppi*[5], *L. A. Croen*[6], *G. N. Soke*[1], *C. Bradley*[7] *and G. C. Windham*[8], *(1)Centers for Disease Control and Prevention, Atlanta, GA, (2)Rollins School of Public Health, Emory University, Atlanta, GA, (3)AJ Drexel Autism Institute, Philadelphia, PA, (4)University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (6)Division of Research, Kaiser Permanente, Oakland, CA, (7)Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, (8)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA*

Background: Nearly half of all U.S. pregnancies are unintended at the time of conception. Previous studies demonstrate that women who have unintended pregnancies are more likely to delay prenatal care, smoke and drink during pregnancy, lack daily supplemental folic acid intake prior to pregnancy, and experience certain adverse perinatal outcomes such as preterm birth. Whether pregnancy planning is associated with risks for longer-term developmental disability (DD) outcomes such as autism spectrum disorder (ASD) is not well studied.
Objectives: To examine associations between pregnancy planning and the risk of ASD and other DDs.

Methods: Data for this analysis were obtained from the Study to Explore Early Development (SEED), a multi-site case-control study of ASD risk factors in children ages 30-68 months in 2007-2016. Study groups were children with ASD, children with other DDs, and population-based control children (POP). At enrollment, all children were screened for ASD symptoms with the Social Communication Questionnaire (SCQ); children with a positive screen and/or previous ASD diagnosis underwent further in-person assessments to determine final case status. Children with a DD who had a positive SCQ screen but did not meet ASD case criteria were classified as DD with ASD symptoms. Risk factor data were obtained via maternal telephone interview that included a pregnancy planning question ("At the time of your pregnancy were you trying to get pregnant?"). Mothers who responded yes were scored as having planned their pregnancy. We examined associations between pregnancy planning and 1) ASD (n=1275), 2) ASD or other DD with ASD symptoms combined (n=1743), and 3) DD without ASD symptoms (n=1212) (each vs. POP group [n=1716]). We computed odds ratios adjusted for maternal age, education, parity, and child sex (aORs) and 95% confidence intervals via logistic regression. We repeated analyses in a restricted sample that excluded participants who had certain health outcomes/behaviors possibly in the causal pathway: preterm delivery, multiple birth, pregnancy complications (hypertension, diabetes), smoking just before or during pregnancy, and no folic acid intake just before or during pregnancy.

Results: Initial analyses indicated differential associations by race-ethnicity; we thus conducted subsequent analyses within race-ethnicity strata. Among non-Hispanic white (NHW) mothers, 61.7%, 62.1%, 73.5%, and 80.1% in the ASD, ASD/DD with ASD symptoms, DD without ASD symptoms, and POP groups, respectively, reported they planned their pregnancy. Additionally, after adjustment, pregnancy planning was inversely associated with both ASD (aOR=0.67 [0.54-0.84]) and ASD/DD with ASD symptoms (aOR=0.71 [0.56-0.91]) but not DD without ASD symptoms (aOR=0.94 [0.76-1.17]). Restricting the sample to pregnancies without various health risks or adverse outcomes did not attenuate the findings. In other race-ethnicity groups (non-Hispanic black, Hispanic, and Asian mother-child pairs), pregnancy planning was less common than for NHW mother-child pairs and was not significantly associated with any ASD or DD outcomes.

Conclusions: Our findings suggest an inverse association between pregnancy planning and ASD in NHW children that is not explained by selected demographic, health behaviors, or pregnancy outcomes. Further research is needed on the health and/or behavioral characteristics underlying the observed association and the reasons findings varied by race-ethnicity.

205 **240.205** Prenatal Anemia and Neurodevelopmental Disorders in the Stockholm Youth Cohort: A Population-Based Cohort Study

R. Gardner[1], *A. M. Wiegersma*[2], *B. K. Lee*[3], *H. Karlsson*[4] *and C. Dalman*[5], *(1)Karolinska Institutet, Stockholm, Sweden, (2)Department of Public Health Sciences, Karolinska Institutet, STOCKHOLM, Sweden, (3)Epidemiology and Biostatistics, Drexel University, Philadelphia, PA, (4)Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden, (5)Department of Public Health Sciences, Karolinska Institutet, Stockholm, Sweden*

Background:
Autism spectrum disorders (ASD) often co-occur with attention deficit hyperactivity disorder (ADHD) and intellectual disability (ID), potentially as a result of shared etiologies. Given the critical role iron plays in development, a causal association between prenatal iron deficiency and later risk for neurodevelopmental disorders like ASD, ADHD, and ID is plausible.

Objectives:

The objective of this study was to assess the relationship between anemia diagnosed in mothers during pregnancy and risk of ASD, ADHD, and ID in offspring.

Methods:

Swedish health and population registry data from the Stockholm Youth Cohort (SYC) were used. 532 232 children born 1987 – 2010 were included. To assess potential critical windows of development, timing of anemia diagnosis was considered, categorized as occurring £30 or >30 weeks of gestation. We considered three potentially over-lapping outcomes (any ASD, any ADHD, and any ID) and five mutually-exclusive outcomes: ASD only (no ADHD or ID); ADHD only (no ASD or ID); ID without ASD (no ASD; not excluding ADHD); ASD with ID (not excluding ADHD); and ASD with ADHD (no ID). To model the associations between maternal anemia and offspring risk of these outcomes, we used generalized estimating equation (GEE) models with logit link clustered on maternal identification number to account for the clustering of siblings born to the same mother in our dataset. Since associations between maternal anemia and offspring risk of neurodevelopmental disorders may be confounded by unobserved factors such as shared genetic liability, we conducted a matched sibling analysis for risk of any ASD, any ADHD and any ID diagnoses using a conditional logistic regression model.

Results:

Anemia diagnosed £30 weeks of pregnancy was associated with increased risk for diagnosis of any ASD (OR 1.44, 95% CI 1.13-1.84), any ADHD (1.37, 1.14-1.64) and any ID (2.20, 1.61-3.01) in offspring, in models including socioeconomic, maternal and pregnancy-related factors. Early anemia diagnosis was similarly associated with risk for both ASD (2.25, 1.24-4.11) and ID (2.59, 1.08-6.22) in a matched sibling comparison. Considering mutually exclusive diagnostic groups, we observed the strongest association between anemia and ID without co-occurring ASD (2.72, 1.84-4.01). Risk for ASD with ID was also associated with anemia diagnosed early in pregnancy (1.74, 1.06-2.86), while the associations for ASD with ADHD (1.38, 0.94-2.03) and ASD only (1.35, 0.92-2.00) were weaker and confidence intervals included one. Associations of these disorders with anemia

diagnosed later in pregnancy were greatly diminished compared to the associations with anemia diagnosed earlier in pregnancy.

Conclusions: In contrast to maternal anemia diagnosed towards the end of pregnancy, anemia diagnosed earlier in pregnancy increased the risk for the development of ASD, ADHD, and particularly ID in offspring. Our findings regarding the timing of exposure to anemia indicate that exposure to anemia earlier in gestation may be more detrimental with regard to neurodevelopment of the child, emphasizing the clinical importance of early screening for iron status in antenatal care.

206 **240.206** Prenatal Metabolic Syndrome and Autism Spectrum Disorder: The Moderating Influence of Familial History

C. A. Palmer[1], *A. V. Bakian*[1], *M. S. Esplin*[2], *E. Clark*[3], *A. Fraser*[4], *H. Coon*[1], *S. R. Dager*[5] *and D. A. Bilder*[1], *(1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Department of Obstetrics and Gynecology, University of Utah, Salt Lake City, UT, (3)University of Utah, Salt Lake City, UT, (4)Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, (5)University of Washington, Seattle, WA*

Background: Established prenatal risk factors for autism spectrum disorder (ASD) include maternal conditions characterized by inflammation and/or steroid dysregulation, such as gestational/pre-existing hypertension, preeclampsia, and gestational/pre-existing diabetes. In combination, these risk factors are referred to as prenatal metabolic syndrome (PNMS). Both ASD and PNMS are known to have familial predispositions that are attributable, in part, to heritability.
Objectives: 1) To confirm increased ASD risk associated with PNMS exposure, and 2) investigate the interaction and moderating effects of ASD and PNMS familial predispositions on the association between PNMS exposure and ASD.

Methods: Index offspring of First and Second Trimester Evaluation of Risk (FASTER) study participants (N=6441) were linked to their birth certificate and genealogical records in the Utah Population Database. ASD case status was determined through linkage with research and population-ascertained ASD cohorts, including the Utah Registry of Autism and Developmental Disabilities. PNMS status was determined from birth certificates. Familial predisposition of PNMS and ASD was treated as a dichotomous variable based on the presence of at least one first through third degree relative with PNMS or ASD. A log-linear model assuming a Poisson distribution with robust error variances was fit to calculate ASD relative risk associated with PNMS exposure. The model was adjusted using inverse probability of treatment weights (IPTW). Two additional IPTW models were fit that included 1) PNMS familial predisposition and a PNMS exposure*PNMS familial predisposition interaction to test for effect moderation and interaction and 2) ASD familial predisposition and a PNMS exposure*ASD familial predisposition interaction.

Results: 168 offspring were identified with ASD resulting in a prevalence of 2.6% within the FASTER cohort. PNMS exposure (Overall 11%, n=684) was more frequent in offspring with versus without ASD (19%, n=32 vs. 10%, n=652, respectively; p=0.003). ASD relative risk (RR) associated with PNMS exposure was 1.72 (95% CI: 1.1-2.7, p=0.02). Familial predisposition of PNMS moderated ASD risk associated with PNMS exposure (RR=2.07, 95% CI: 1.22-3.51, p=0.007 in children having a familial PNMS predisposition vs RR=1.49, 95% CI: 0.66-3.33, p=0.33 in children without familial PNMS predisposition); however, no interaction existed between familial PNMS predisposition and PNMS exposure (p = 0.5). In contrast, a similar increased risk of ASD from PNMS exposure was identified in both children having familial risk for ASD (RR=2.20, 95% CI: 1.00-4.82; p=0.05) and those without familial ASD risk (RR=1.72, 95% CI: 1.04-2.84; p=0.03) suggesting no effect modification or interaction (p=0.6).

Conclusions: ASD risk increased by 72% in children exposed to PNMS and over 100% in children exposed to PNMS who shared a familial risk of PNMS. In contrast, while ASD risk was heightened in all children exposed to PNMS, a family history of ASD had an independent but not moderating or interactive effect on ASD risk. Whether PNMS impacts ASD's causal pathway or shares common etiologic factors with ASD, this association appears moderated by familial risk of PNMS, yet independent of familial risk of ASD. Study findings justify further investigation into the nature of this relationship as identifying shared preclinical precursors could establish prevention strategies for ASD.

207 **240.207** Prevalence and Clinical Characteristics of Social (Pragmatic) Communication Disorder in a Clinic-Referred Sample

M. Menezes[1], *M. O. Mazurek*[1], *F. Lu*[2], *E. Macklin*[2] *and B. Handen*[3], *(1)University of Virginia, Charlottesville, VA, (2)Massachusetts General Hospital, Boston, MA, (3)University of Pittsburgh School of Medicine, Pittsburgh, PA*

Background: Social (pragmatic) communication disorder (SCD) was only recently added to psychiatric nosology with the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5). Since it is a relatively new diagnosis, little is known about the clinical characteristics of those that receive it or how its symptomatology compares to that of autism spectrum disorder (ASD). SCD has been conceptualized as a milder form of ASD; an impairment in social communication in the absence of restricted and repetitive behaviors. Although there is evidence to support this characterization, the only studies to investigate the prevalence and characteristics of SCD have mapped data retrospectively on to the DSM-5 criteria. This is problematic because symptom definitions were expanded from the fourth (DSM-IV-TR) to the fifth edition of the DSM; therefore, clinicians using the DSM-IV-TR may not have fully assessed for symptoms in the DSM-5.

Objectives: The study objectives were to: (1) prospectively examine the prevalence of SCD in a sample of children referred for ASD evaluation, (2) describe the clinical characteristics of children with SCD, and (3) compare the characteristics of children with SCD to those of children with ASD and children with other diagnoses (clinic-referred comparison, CC).

Methods: Participants included 438 children and adolescents (2-17 years) referred for clinical evaluation for ASD who received diagnostic evaluations at one of six Autism Treatment Network sites. Assessments included review of records, diagnostic interview, Autism Diagnostic Observation Schedule-2ndEdition (ADOS-2), cognitive assessment, assessment of behavioral functioning (including Child Behavior Checklist, CBCL), and final determination of all relevant DSM-5 diagnoses.

Results: The prevalence of SCD was 1.4% (n = 6). Five males and 1 female received SCD diagnoses with a large range in both age (3-17) and IQ (86-115). For SCD cases, ADOS-2 Calibrated Severity Score (CSS) ranged from 1-7 (mean = 3.7), ADOS-2 Social Affect (SA) ranged from 1-9 (mean = 4.5), and ADOS-2 Repetitive Behavior (RRB) ranged from 1-7 (mean = 4.5). Mean ADOS-2 CSS, SA, and RRB scores were lower for the SCD than the ASD group (CSS = 7.3±1.9, SA = 7.3±1.9, RRB = 7.3±2.1), but higher for the SCD than the CC group (CSS = 2.9±1.9, SA = 3.5±2, RRB = 4±2.7). Mean CBCL Total, Internalizing, and Externalizing scores were lower for SCD cases than ASD and CC groups; however, range in the SCD group was large (e.g., 31-74 for Total score). Four SCD cases (66.7%) also met criteria for DSM-5 attention-deficit/hyperactivity disorder; three SCD cases (50%) also met criteria for DSM-5 generalized anxiety disorder.

Conclusions: This was the first large-scale prospective study to examine the prevalence and characteristics of SCD diagnoses in a clinically-

referred population. The results indicate that SCD diagnoses were rarely made across multiple sites and clinicians. Due to the small number of cases in this sample, it is difficult to make conclusions about clinical characteristics as a whole; however, it is notable that children and adolescents receiving SCD diagnoses demonstrated significant heterogeneity in terms of ASD symptomatology, cognitive functioning, and psychiatric comorbidity.

208 **240.208** Prevalence and Correlates of Medication Use in Youth with Autism and ADHD

J. Rast[1], *A. Roux*[2], *K. Anderson*[3] *and P. Shattuck*[1], *(1)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (2)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)Life Course Outcomes Research Program, Drexel University A.J. Drexel Autism Institute, Philadelphia, PA*

Background: Youth with autism spectrum disorder (ASD) may benefit from medication to treat symptoms of ASD and co-occurring conditions such as attention-deficit/hyperactivity disorder (ADHD) or anxiety. There are only two medications approved by the FDA for use in ASD - risperidone and aripiprazole (prescribed for irritability); there are no medications approved for the core symptoms of ASD (e.g. social communication and interaction deficits). Because prescribing guidelines based on impairment profile are lacking, clinical practice often takes a trial-and-error approach to prescription use. Research providing national estimates of medication use in youth on the autism spectrum is scant.
Objectives: Report nationally representative findings of the prevalence and correlates of ASD-specific medication use and behavioral medication use. First, we describe medication use in youth ages 6-17 with ASD-only, ASD and ADHD, and ADHD-only. Second, we examine correlates of medication use for youth in each group.

Methods: We used data from the National Survey of Children's Health (NSCH), combining data from study years 2016-2017. The NSCH is a cross-sectional, nationally representative survey designed to provide national estimates on the health and well-being of children from parent or caregiver report.

We estimated the prevalence of medication use for ASD symptoms based on parent report that their child was "currently taking medication for autism, ASD, Asperger's disorder, or PDD." We estimated the prevalence of behavioral medication use in the past 12 months for "difficulties with his or her emotions, concentration, or behavior." We then used logistic regressions to assess correlates of medication use.

Results: Youth with ASD-only were more likely to be male, Hispanic, and living in two-parent households than children with ASD and ADHD or children with ADHD-only. Youth with ASD and ADHD were the most likely to be taking medication for ASD symptoms (47% compared to 14% of youth with ASD -only), and behavioral needs (74% compared to 63% of youth with ADHD-only and 20% of youth with ASD-only).

For children and youth with ASD-only, older age and having a diagnosis of a mental, behavioral, or developmental disorder (MBDD) other than ASD or ADHD were both associated with significantly higher odds of medication use for both medication types. For children and youth with ASD and ADHD, use of both medication types was significantly higher among males and those with serious difficulty concentrating. For children and youth with ADHD-only, behavior medication use was more likely in those diagnosed with a MBDD or had difficulty concentrating.

Conclusions: Three quarters of youth with ASD and ADHD use medication for behavioral needs, more than youth with ADHD-only and ASD-only. About half of youth with ASD and ADHD used medication to treat ASD symptoms. There were only differences in medication use by age group for youth with ASD-only. This study highlights medication use for youth with ASD, providing a recent estimate of medication use in this population.

209 **240.209** Timing of Autism Spectrum Disorder Identification in the U.S. from the Autism and Developmental Disabilities Monitoring Network 2006-2012

L. Stewart[1], *J. Baio*[2], *S. Rosenberg*[3], *C. Robinson Rosenberg*[4], *M. S. Durkin*[5], *R. S. S. Kirby*[6], *J. A. Hall-Lande*[7], *B. Harris*[8], *L. Nikolaou*[9], *D. Christensen*[2] *and L. C. Lee*[10], *(1)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Centers for Disease Control and Prevention, Atlanta, GA, (3)University of Colorado Anschutz Medical Campus, Aurora, CO, (4)University of Colorado / JFK Partners, Aurora, CO, (5)Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI, (6)Community and Family Health, University of South Florida, Tampa, FL, (7)UCEDD, University of MN, Minneapolis, MN, (8)Department of Pediatrics, University of Colorado, Denver, CO, (9)Oak Ridge Institute for Science and Education, Oak Ridge, TN, (10)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD*

Background: Timely identification of autism spectrum disorder (ASD) is one of the critical factors determining whether children have access to early intervention services. The most recent estimate of median age at ASD diagnosis among those with a diagnosis by the age of 8 years from the 2016 Autism and Developmental Disabilities Monitoring Network (ADDM) cohort in the U.S is 4.3 years. Prior work in the ADDM network, as well as in smaller community-based studies suggests that age at ASD identification varies across subgroups by factors such as sex, race, ethnicity, geographic location, and socioeconomic status.
Objectives: Examine influence of socio-demographic characteristics on timing of ASD identification during 2006-2012 within the ADDM network.

Methods: The ADDM Network is an active surveillance system that provides ASD prevalence estimates among children age 8 years in parts of the U.S. Data for this analysis come from ADDM surveillance years (SY) 2006, 2008, 2010, and 2012 from communities in Alabama, Arkansas, Arizona, Colorado, Georgia, Maryland, Missouri, North Carolina, New Jersey, and Utah. Children were included in this analysis if they had an ADDM determined ASD case status, information from birth certificates and neighborhood level census data. Median age at ASD identification (AAI) was assessed for the full sample with ASD status as well as across socio-demographic, developmental, site, and surveillance subgroups. Nested, multivariate survival analyses examined how AAI associated with covariates of interest. A series of increasingly complex mixed-effects models were fit nesting child, family, surveillance characteristics clustered on census-tract level poverty and study site.

Results: 13,731 children with ASD case status were analyzed, 30% of whom were not identified as having ASD prior to ADDM abstraction and review at age 8. Compared to those with a documented AAI, children without a documented AAI were more likely to belong to a non-white racial/ethnic group and live in areas with >= 20% of the households below the federal poverty line, or "poverty areas". Incorporating the traditionally censored not-yet-identified children back into the sample with an ADDM-identification age of 8 years yielded a median AAI of 5.8. From SYs 2006 to 2012, median AAI decreased from 6.3 to 5.3 and there was a statistically significant trend towards earlier AAI across SYs. This trend towards earlier AAI was more pronounced in non-white racial/ethnic groups, as the gap in AAI was reduced from 2006-2012. The percentage of children not-yet-identified decreased across SYs from 35% to 25% between 2006 and 2012. The nested multivariate survival models showed that a later AAI was significantly associated with African-American or Hispanic race/ethnicity, lower maternal education, earlier cohort year, and single-surveillance

record source. Earlier AAI was significantly associated with having below average or missing data on IQ, higher maternal education, or being a member of a later birth cohort. Non-substantial variation was found across poverty level and study site variables.

Conclusions: Further examination of the role socio-demographic factors play in the ASD identification timing will help to inform and strengthen current identification infrastructure.

210 **240.210** Prevalence and Prediction of ASD in Non-Hispanic White and Non-Hispanic Black Children: Results from the 2017 National Survey of Children's Health

M. G. Pecukonis *and H. Tager-Flusberg, Psychological and Brain Sciences, Boston University, Boston, MA*

Background: Despite the increasing rates of ASD prevalence in the United States, data from 2014-2016 reports that black children are less likely to be identified with ASD than white children (Baio et al., 2018; Xu et al., 2018). This difference in ASD prevalence may be because over 50% of black children with ASD are initially misidentified with another developmental condition (Mandell et al., 2007). Race may also influence when children are identified with ASD, although findings on this topic are mixed (Daniels & Mandell, 2014), suggesting that other demographic variables play a role in age of ASD identification.

Objectives: This study utilized data from the 2017 National Survey of Children's Health (NSCH) to calculate prevalence rates of ASD and related developmental conditions in Non-Hispanic White (NHW) and Non-Hispanic Black (NHB) children, and to determine which commonly-studied demographic variables independently predict age of ASD identification.

Methods: Primary caregivers living within the United States were randomly selected to complete demographic items about their families. The total sample included 14,593 NHW children (7,529M; 7,064F) and 1,290 NHB children (652M; 638F), ages 0–17 years. Caregivers reported whether a doctor, health care provider, or educator had ever told them that their child has ASD, and how old their child was at time of ASD identification. Based on this item, 422 NHW children (334M; 88F) and 35 NHB children (28M; 7F) were identified with ASD. Caregivers also reported whether their child had ever been identified with another developmental condition.

Results: Calculated rates of ASD prevalence showed that NHW children were more likely to be identified with ASD (3,028/100,000) than NHB children (2,713/100,000). However, NHB children were more likely to be identified with another related developmental condition, such as ADHD/ADD, speech disorder, conduct/behavioral problems, developmental delay, or intellectual disability, than NHW children (Figure 1). A linear hierarchical regression model demonstrated that when controlling for current age, having mild ASD symptoms, being female, and not having health insurance significantly predicted later age of ASD identification. Race, socioeconomic status, and geographical location did not significantly predict age of ASD identification (Table 1). Overall, the model accounted for 22.7% of variance in age of ASD identification.

Conclusions: Differences in ASD prevalence by race may reflect racial biases in identification, as NHB children are more likely to be identified with a related developmental condition instead of ASD. However, results of the regression model imply that race does not independently predict age of ASD identification. Other demographic variables (sex, ASD symptom severity, health insurance status) may have greater influence on age of ASD identification. Because this model only accounted for a portion of variance in age of ASD identification, future studies should continue to investigate which variables predict delayed ASD identification so that they can be targeted in public health program design. Additionally, these results should be interpreted with caution due to the low sample size of NHB children. Further efforts should be made to recruit more NHB children in the 2018 NSCH so that results better reflect the United States population.

211 **240.211** Prevalence of Autism Spectrum Disorders in Qatar: A National Epidemiological Survey

F. Alshaban[1]*, E. Fombonne*[2] *and I. M. Ghazal*[3]*, (1)Qatar Biomedical Research Institute, Doha, Qatar, (2)Psychiatry, Pediatrics & Behavioral Neurosciences, Oregon Health & Science University, Portland, OR, (3)Neurological Diseases Research Center, Qatar Biomedical Research Institute, Doha, Qatar*

Background: Few epidemiological data on autism spectrum disorders (ASD) exist for Arabic countries. In response to heightened public awareness and concerns about ASD, we conducted the first survey of autism in Qatar, a population with high level of consanguinity.

Objectives: To generate a first estimate of the prevalence of ASD among school age children in Qatar, using a whole population-based approach; and to evaluate correlates of ASD in a large representative sample of cases.

Methods: We surveyed the population of children age 5 to 12 (N=176,960) residing in Qatar in 2015. Children of Qatari and resident families were included. Case ascertainment relied on two complementary approaches. First, eligible children attending medical/special needs centers and schools providing diagnostic and treatment services for children with ASD were screened. Records of eligible children were abstracted and supplemented by parental interviews. Second, we performed a two-stage survey for regular primary school children. Following a screening with the locally validated version of the Social Communication Questionnaire (SCQ), random samples of screen positive and negative children were further evaluated to determine ASD case status. Prevalence among children age 6 to 11 was estimated after taking into account different sampling fractions and participation rates at each survey phase. Medical, developmental, educational and behavioral data were collected on all ASD cases and analyzed to describe trajectories of ASD children.

Results: 1,393 children already diagnosed with ASD were identified through the medical and educational centers. Among 9,074 participants in the school survey, 773 (8.5%) were screened positive. In the diagnostic confirmation phase, 163 screen positive and 760 screen negative children were evaluated; 17 were confirmed to have ASD, including 5 children newly diagnosed. Combining data from the two samples, prevalence was estimated to be: 1.14% (95% CI: 0.89-1.46) among 6 to 11 year olds, 1.81% (95% CI: 1.41-2.31) among boys, 0.44% (95% CI: 0.35-0.57) among girls, and 1.52% (95% CI: 1.19-1.94) among 8 year olds. Analysis of detailed information on 844 ASD cases (mean age: 7.2 years; 81% male) showed ASD recurrence in 5.9% full siblings and 9.65% relatives. Most children had experienced language delay (75.1% for words; 91.4% for phrase speech), and 19.4% reported developmental regression. At the time of the survey, a substantial minority of subjects had persisting deficits in expressive language (19.4%), peer interactions (14.0%), behavioral problems (ADHD: 30.2%; anxiety: 11.0%) and 20.5% required behavioral support at school. About 25% of the sample scored high on a composite indicator of severity. In multivariate logistic regression, ASD severity was associated with parental consanguinity, gestational diabetes, delay in walking, and developmental regression.

Conclusions: This study provides the first estimate of ASD prevalence in Qatar which is consistent with recent international studies. The instruments and methods employed should help in designing comparable surveys in the region. We estimated that 50,500 children under age 5

and 187,000 youths under age 20 have ASD in the Gulf countries. This estimate should guide planification of health and educational services in the Gulf countries for a population that is young and growing fast.

212 **240.212** Prevalence of Co-Occurring Mental Health Diagnoses in the Autism Population: A Systematic Review and Meta-Analysis

C. Kassee[1], *M. C. Lai*[2], *R. Besney*[1], *S. Bonato*[1], *L. Hull*[3], *W. Mandy*[3], *P. Szatmari*[2] *and S. Ameis*[4], *(1)Centre for Addiction and Mental Health, Toronto, ON, Canada, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)University College London, London, United Kingdom of Great Britain and Northern Ireland, (4)Department of Psychiatry, University of Toronto, Toronto, ON, Canada*

Background: Autism spectrum disorder (hereafter 'autism') is a neurodevelopmental condition characterized by social-communication difficulties and repetitive/stereotyped behaviours. Autism has a prevalence of around 1% worldwide, and co-occurring mental health/psychiatric conditions (CMHCs) are common, where it is estimated that as many as 70% of individuals with autism have at least one CMHC, and almost 50% are diagnosed with multiple CMHCs. For autistic people, having CMHCs impedes quality of life and leads to poorer long-term outcomes. Accurate pooled prevalence estimates for CMHCs in autistic individuals are needed to enhance recognition and care. However, prevalence estimates in the current literature vary greatly across studies.

Objectives: (1) To determine the best estimates of CMHC in autism and; (2) to identify moderators that account for heterogeneity across studies.

Methods: We conducted a systematic review and meta-analysis according to MOOSE and PRISMA standards. Published studies from 1993 to September 2018 were screened, and articles were included if they were (1) published in English or French, (2) reported on the prevalence rates of CMHCs in individuals with autism and (3) reported confirmed clinical diagnoses of CMHC and autism using DSM, or ICD-based criteria. Abstracts and full-text articles were reviewed, and risk of biases was assessed. The overall pooled estimate of prevalence for different CMHCs in autism was determined using a random-effects model, and reported as a percentage with 95% confidence intervals. Estimates were then stratified by study design (population/registry vs. clinical sample based). Heterogeneity was investigated using random-effects meta-regression models.

Results: Out of 9,515 unique studies, 420 were selected for full text review. CMHCs with sufficient data for meta-analysis (83 studies) showed overall pooled estimates of: ADHD 33% (95%CI 29-37%), anxiety disorders consistent with DSM-IV, DSM-5 or ICD-10 classification 23% (19-27%), anxiety disorders consistent with DSM-5 classification only 22% (17-27%), sleep-wake disorders 13% (7-20%), depressive disorders 12% (9-14%), obsessive-compulsive disorder 10% (8-13%), disruptive, impulse control and conduct disorders 10% (8-13%), schizophrenia spectrum disorders 5% (4-7%), and bipolar disorders 5% (3-7%). Estimates in clinical studies were higher than population/registry-based studies for most CMHCs. Age, gender, intellectual disability and country of origin were associated with heterogeneity across studies.

Conclusions: Given that evidence-based interventions are available, careful assessment of mental health concerns is an essential component of care for all autistic people.

213 **240.213** Regional Variations in the Prevalence and Median Age of Diagnosis of Autism Spectrum Disorder in Arkansas

S. B. Smith[1], *M. Lopez*[2], *T. M. Baroud*[3], *A. E. Hudson*[4] *and Y. D. Schwenk*[4], *(1)Developmental Behavioral Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR, (2)Section of Developmental-Behavioral Pediatrics and Rehabilitation Medicine, UAMS, Little Rock, AR, (3)UAMS, Little Rock, AR, (4)Pediatrics, UAMS, Little Rock, AR*

Background:
The Autism and Developmental Disabilities Monitoring (ADDM) Network gathers data on Autism Spectrum Disorder (ASD) and other developmental disabilities in multiple sites, including Arkansas (AR), in the United States. The AR ADDM data shows a higher median age of diagnosis (SY 2002, 2010 and 2014) and a lower identified prevalence of ASD compared to the ADDM Network average 2014.

Objectives: Given that AR is a largely rural (non-urban) state, we suspect that children living in non-urban areas have more difficulty accessing healthcare resources compared to urban areas. We hypothesize that the identified prevalence of ASD is lower for children in non-urban areas and the median age of diagnosis is higher for children in non-urban areas.

Methods: AR ADDM data was collected statewide for study years (SY) 2002, 2010 and 2014. The methodology is modeled on a standardized retrospective record review created by the CDC's Metropolitan Atlanta Developmental Disabilities Surveillance Program (MADDSP). Counties were then categorized into urban versus rural (non-urban) areas for comparison based on U.S. Census Data. Data analyzed included prevalence (subdivided by race and ethnicity) per 1000 of 8-year-old children diagnosed with ASD and the median age (in months) at earliest evaluation confirming an ASD diagnosis.

Results: The identified prevalence of ASD was significantly higher in urban areas compared to non-urban areas for the total population in SY 2010 and 2014. When looking at the different racial/ethnic groups, this trend is also true for Non-Hispanic Whites in SY 2010 and 2014 but not for other racial/ethnic groups. There was no significant difference in identified prevalence between Black Non-Hispanics and Hispanics (of any race) living in urban and in non-urban areas for any study year. There was no significant difference in median age of diagnosis in non-urban versus urban areas for 2002, 2010 and 2014 for the total population.

Conclusions: The data supports the hypothesis that there is a lower identified prevalence for children in non-urban areas compared to urban areas overall in 2014 (but not in 2010). This is likely due to differences in identified ASD prevalence in non-urban versus urban areas in the White population. The majority of children in Arkansas (as well as this study) are White. This would explain why differences in non-urban versus urban areas in this group greatly impact the total population. Furthermore, there was a much smaller number of Non-Hispanic Black and Hispanic children in the study which may affect why a significant difference was not observed. The data does not show a difference in median age of diagnosis for children in non-urban areas versus non-urban areas for the total population. This study is limited by incomplete race/ethnicity data for SY 2014 (Approx. 15% in Other, Missing, Unknown) and incomplete access to educational data in non-urban counties (but not urban areas) for SY 2014. Further studies are needed to determine contributors to the regional differences, such as migration patterns and limited access to healthcare providers, noted in this study.

214 **240.214** Suicidality in Autism Spectrum Disorder Comorbid with ADHD Symptoms in a Non-Clinical School-Aged Population

M. Adachi[1], *M. Takahashi*[1], *T. Hirota*[2], *N. Takayanagi*[3], *S. Yasuda*[4], *Y. Sakamoto*[5], *M. Saito*[5] *and K. Nakamura*[5], *(1)Research Center for Child Mental Development, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (2)University of California, San Francisco (UCSF), San Francisco, CA,*

(3)Aichi Toho University, Nagoya, Japan, (4)Research Center for Child Mental Development Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (5)Graduate School of Medicine, Hirosaki University, Hirosaki, Japan

Background: Recent studies have indicated an association between autistic traits and suicidality in clinical and non-clinical cohorts (Cassidy et al., 2014; Pelton & Cassidy, 2017). Attention deficits and hyperactivity disorder (ADHD), which are highly comorbid with autism spectrum disorder (ASD), were also reportedly associated with suicide (Impey & Heun, 2012).
Objectives: However, to our knowledge, no studies have yet examined the relationship between ASD and suicidality considering the comorbidity of ADHD symptoms.Therefore, this study examined how ASD and ADHD symptoms interact with suicidal ideation in non-clinical school-aged population.

Methods: A 1-year, prospective school survey including 8,669 children aged 6–14 years at baseline and their parents was conducted in 2016 (time 1) and 2017 (time 2). At time 1, we administered parent-reported ASD and ADHD traits scale (ASD: Autism Spectrum Screening Questionnaire, ADHD: ADHD-Rating Scale)- and self-reported depression scale (Depression Self-Rating Scale for Children: DSRS-C)-based questionnaires, which included items of suicidal ideation. At time 2, DSRS-C was re-administered. For group comparison, participants were divided into eight groups according to the combination of ASD and ADHD traits: (1) non-risk, (2) ASD at risk, (3) inattention (IA) at risk, (4) hyperactivity (HA) at risk, (5) ADHD at risk, (6) ASD + IA at risk, (7) ASD + HA at risk, and (8) ASD + ADHD at risk. Kruskal–Wallis tests were performed with groups as an independent variable and suicidal ideation scores at time 2 as a dependent variable. Subsequently, a series of pass models was computed to examine whether ASD and ADHD traits predict suicidal ideation. Cross-sectional associations at time 1 and longitudinal associations at time 2 were examined.

Results: Kruskal–Wallis tests revealed that ASD and ADHD traits were risk factors for suicidal ideation. Pair-wise comparison revealed that suicidal ideation was significantly higher in the ASD + IA group than in the other groups (ASD + IA > ASD at risk, IA at risk, HA at risk, ADHD at risk, $p < .01$). Results of the path analysis revealed that higher ASD and IA traits were associated with higher levels of suicidal ideation at time 1 (ASD: $b = .076$ BCa, CI [.048, .103], $p < .001$; IA: $b = .120$ BCa, CI [.085, .155], $p < .001$). There was a significant indirect effect of ASD and IA traits on suicidal ideation at time 1 through suicidal ideation at time 2 (ASD: $b = .040$ BCa, CI [.025, .054], $p < .001$; IA: $b = .062$ BCa, CI [.044, .081], $p < .001$). These results indicate that higher ASD and IA traits predict a higher risk for suicidal ideation at time 2 by mediating suicidal ideation at time 1. HA traits consistently showed no significant association with depression and suicidal ideation.

Conclusions: The results of this study suggested that autistic and inattentive symptoms were risk factors for suicidality. Individuals with inattentive symptoms of ASD have a higher risk for suicide.

215 **240.215** The ABA in PA Initiative's Analysis of ABA Providers in the Commonwealth of Pennsylvania

*G. Vece, A. Kwegyir-Aggrey and **C. Tierney-Aves**, Penn State Hershey Medical Center, Hershey, PA*

Background: Pennsylvania's Department of Human Services was not ensuring appropriate availability or quality of Applied Behavior Analysis (ABA) for children with Autism Spectrum Disorder (ASD). This left individuals throughout the state unable to access this medically necessary intervention. ABA therapy is an evidence-based intervention proven to significantly help children with ASD in many developmental domains. The ABA in PA Initiative, a 501(c)(3) advocacy organization, supported the Disability Rights Network of Pennsylvania in a class action lawsuit (Sonny O. v. Dallas) filed in 2014 to hold the Pennsylvania Department of Human Services accountable. While the lawsuit was decided favorably, the terms of the settlement are now being implemented. As a result of the lawsuit, ABA must meet evidence based standards that are published by the Behavior Analyst Certification Board. This settlement opened the door for a large number of behavior analysts to move into the state. However, there is very little information currently known about the availability and quality of care delivered by provider agencies.
Objectives: We seek to evaluate changes in the landscape of ABA provider agencies over the years following the Sonny O v Dallas lawsuit settlement by measuring key agency and provider metrics.

Methods: The ABA in PA Initiative has maintained a directory of ABA providers for Pennsylvania since 2014. This directory is voluntary and agencies are added based on our own web-search for provider agencies and by an agency reaching out to us to be added. We use social media platforms (e.g., Facebook, Twitter, LinkedIn) for outreach purposes. Agencies qualify if they provide ABA services to children in PA. To learn about provider qualifications and availability, agencies will be queried via survey on a variety of agency characteristics.

Results: To date we have collected simple demographics (e.g., contact information, counties served) for 105 agencies. Cursory analysis indicates that 48% currently take Medicaid and 52% do not. All agencies indicate that they employ at least 1 BCBA/BCBA-D (Board Certified Behavior Analyst), 17% indicate they employ BCaBA's (Board Certified Assistant Behavior Analyst) and 49% indicate they employ RBTs (Registered Behavior Technicians). An 11-item survey was developed to capture key additional information including 1) agency size, 2) number of providers that hold the BCBA, BCaBA or BCBA-D certification as well as those who hold the RBT credential, 3) The percentage of cases staffed with certified and credentialed providers, 4) payer mix to include Medicaid, and 5) hiring and staffing strengths and barriers. Survey questions have been created and a link embedded in an email will be used to request agency input. Participation is voluntary but each agency that responds will be entered to win a gift card. Surveys will be emailed every 6 months for 18 months and all responses will be kept confidential in REDCap.

Conclusions: While the Sonny O. v. Dallas class action lawsuit opened the door for behavior analysis in Pennsylvania, characterizing changes to ABA provider agencies using key provider metrics will be important to understanding the needs of children with developmental disabilities in the years ahead.

216 **240.216** The Association of Eating Behavior in Infancy and Later Autistic Traits: Results from a Population-Based Study

M. van 't Hof[1,2,3,4], *W. A. Ester*[4,5,6], *I. A. van Berckelaer-Onnes*[7,8], *M. Hillegers*[9], *H. W. Hoek*[10,11,12] *and P. W. Jansen*[13,14], *(1)Sarr Expert Centre for Autism, Lucertis Child- & Adolecent Psychiatry, Rotterdam, Netherlands, (2)Erasmus MC-University Medical Center, Department of Child and Adolescent Psychiatry / Psychology, Rotterdam, Netherlands, (3)The Generation R Study Group, Erasmus University Medical Center, Rotterdam, Netherlands, (4)Parnassia Psychiatric Institute, The Hague, Netherlands, (5)Sarr Expert Centre for Autism, Lucertis Child- & Adolecent Psychiatry, Rotterdam, Netherlands, Rotterdam, Netherlands, (6)Department of Child and Adolescent Psychiatry, Curium-LUMC, Leiden University Medical Center, Oegstgeest, Netherlands, (7)Faculty of Social Sciences, Clinical Child and Adolescent Studies, Leiden University, Leiden, Netherlands, (8)Sarr Expert Centre for Autism, Lucertis Child and Adolescence Psychiatry, Rotterdam, Netherlands, (9)Department of Child and Adolescent Psychiatry / Psychology, rasmus MC-University Medical Center, Rotterdam, Netherlands, (10)Department of Epidemiology, Columbia University - Mailman School of Public Health, New York, NY, (11)Department of Psychiatry, University of Groningen - University Medical Center Groningen, Groningen,*

Netherlands, (12)Parnassia Academy, Parnassia Psychiatric Institute, Den Haag, Netherlands, (13)Department of Psychology, Education and Child Studies, Erasmus University Rotterdam, Rotterdam, Netherlands, (14)Department of Child and Adolescent Psychiatry / Psychology, Erasmus MC-University Medical Center, Rotterdam, Netherlands

Background: A recent review indicates that breastfeeding may protect against later autism but also emphasized the lack of prospective studies evaluating this association.It remains unknown whether, besides feeding mode, eating behavior of infants is associated with autistic traits, while recent evidence points at a link between eating behavior and autistic traits across childhood. Knowledge about whether early-life feeding and eating behavior predict later autistic traits can be useful to enhance the detection of autism at an early stage.

Objectives: To investigate the association of breastfeeding and eating behavior in infancy with later autistic traits, and the sex-specificity of this association, in the general population sample Generation R.

Methods: We included 3546 mother-child dyads with maternal reports on feeding and eating at two months and autistic traits at six years. We assessed eating behavior with seven specific eating habits. The Social Responsiveness Scale was used to assess autistic traits. Covariates included child gender, maternal psychopathology and maternal autistic traits.

Results: Breastfeeding at two months was associated with a lower autistic trait score at six years (adjusted B=-0.07; 95% CI, -0.14 to -0.00). Children who were drinking only small quantities (adjusted B=0.17, 95%CI, 0.04 to .030) and being hungry/not satisfied (adjusted B=0.23, 95%CI, 0.08 to 0.39) at two months had more autistic traits at six years. No interactions with gender or breastfeeding were found. Drinking slowly or very greedily, spitting up a lot, regurgitating, or refusing breastfeeding in infancy and was not significant related to later autistic traits.

Conclusions: Breastfeeding and eating behavior during infancy are related with autistic traits later in childhood. Although associations were fairly small, these findings suggest that autism screening instruments mighty benefit from an assessment of early-life eating problems.

217 **240.217** Perinatal Factors Associated with Autism Spectrum Disorder in Jamaican Children

S. Saroukhani[1,2], *M. E. Samms-Vaughan*[3], *M. Lee*[2,4], *M. A. Bach*[1,2], *J. Bressler*[1,5], *M. Hessabi*[2], *M. L. Grove*[1,5], *S. Shakespeare-Pellington*[3], *K. A. Loveland*[6] *and M. H. Rahbar*[1,2,4], *(1)Department of Epidemiology, Human Genetics, and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (2)Biostatistics/Epidemiology/Research Design (BERD) core, Center for Clinical and Translational Sciences (CCTS), The University of Texas Health Science Center at Houston, Houston, TX, (3)Department of Child & Adolescent Health, The University of the West Indies, Mona Campus, Kingston, Jamaica, (4)Division of Clinical and Translational Sciences, Department of Internal Medicine, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX, (5)Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (6)Department of Psychiatry and Behavioral Sciences, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX*

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder with no well-defined etiology, mostly believed to stem from complex genetic-environmental interactions. Many environmental exposures during the crucial stages of neurodevelopment, which begins in the first few weeks of gestation and continues into early childhood, have the potential to contribute to ASD. Perinatal exposures such as mode of delivery and suboptimal characteristics at birth, including preterm birth and low birth weight as indicators of intra-uterine development, are thought to be associated with neurodevelopmental disorders such as ASD.

Objectives: To investigate the possible association of three perinatal factors, mode of delivery (cesarean vs. vaginal), low birth weight (<2500 gram), and preterm birth (before 37 weeks of gestational age) with ASD in Jamaican children.

Methods: We used data from the Epidemiological Research on Autism in Jamaica (ERAJ) and ERAJ-2 studies, which enrolled 343 pairs of age-(± 6 months) and sex-matched ASD cases and typically developing controls, collected during 2009-2018. We performed conditional logistic regression analyses to assess the possible association of each perinatal factor with ASD while controlling for potential confounders. Additionally, we explored potential interactions between the perinatal exposures and other covariates in relation to ASD in the multivariable conditional logistic regression models. Matched odds ratios (MORs) and their 95% confidence intervals (95% CIs) were calculated.

Results: Our findings suggest a significant unadjusted association between cesarean delivery and ASD [MOR (95% CI): 1.79 (1.23-2.60), *P* = 0.002]. In the multivariable analysis, we found that the parish of residence may be an effect modifier for the association between cesarean delivery and ASD in Jamaican children. Specifically, for children who lived in Kingston parish which has mainly urban residents, cesarean delivery was significantly associated with ASD after adjusting for the age of the parents at the child's birth [adjusted MOR (95% CI): 2.34 (1.19-4.61), *P*=0.013], whereas this association was not significant for children from other parishes with a higher percentage of rural residents [adjusted MOR (95% CI): 0.94 (0.52-1.69), *P* = 0.824]. Additionally, although not statistically significant, the association between low birth weight and ASD appeared to be modified by car ownership of the parents as a measure of the household socioeconomic status (SES) in Jamaica, after adjusting for the age of the mother at the child's birth [adjusted MOR (95% CI): 1.79 (0.89-3.64), *P* = 0.10 for low SES (i.e., families who did not own a car), and 0.64 (0.30-1.36), *P* = 0.248 for high SES (i.e., families who owned a car)]. Our findings do not support a significant association between preterm birth and ASD after adjusting for the age of the parents at the child's birth and SES [adjusted MOR (95% CI): 1.21 (0.66-2.20), *P* = 0.539].

Conclusions: Our findings suggest that the parish of residence may be an effect modifier of the association between cesarean delivery and ASD in Jamaican children. Also, SES may be an effect modifier of the association between low birth weight and ASD in Jamaica. These findings require replication in future studies.

218 **240.218** The Possible Modifying Effect of Maternal Age on the Association between Breastfeeding and Autism Spectrum Disorder in Jamaican Children

S. Saroukhani[1,2], *M. E. Samms-Vaughan*[3], *M. Lee*[2,4], *M. A. Bach*[1,2], *J. Bressler*[1,5], *M. Hessabi*[2], *M. L. Grove*[1,5], *S. Shakespeare-Pellington*[3], *K. A. Loveland*[6] *and M. H. Rahbar*[1,2,4], *(1)Department of Epidemiology, Human Genetics, and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (2)Biostatistics/Epidemiology/Research Design (BERD) core, Center for Clinical and Translational Sciences (CCTS), The University of Texas Health Science Center at Houston, Houston, TX, (3)Department of Child & Adolescent Health, The University of the West Indies, Mona Campus, Kingston, Jamaica, (4)Division of Clinical and Translational Sciences, Department of Internal Medicine, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX, (5)Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, (6)Department of Psychiatry and Behavioral Sciences, McGovern Medical School, The University of Texas Health Science Center at Houston, Houston, TX*

Background: Breastfeeding, especially for longer than 6 months after birth, has been shown to have medical, developmental and cognitive benefits in children. Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that occurs in early childhood and has long-term consequences throughout life. Several studies have investigated the possible role of breastfeeding in susceptibility to ASD but some of the findings are conflicting. This could be due to lack of attention to the possible synergic effect of breastfeeding and maternal age in ASD. Since neurodevelopment begins in the first few weeks of gestation and continues into early childhood, and breastfeeding practices may depend on maternal age, it is important to investigate the possible role of maternal age as an effect modifier of the possible association of breastfeeding or its duration and ASD.

Objectives: To investigate the possible role of maternal age as a modifier of the effect of breastfeeding, and its duration in ASD in Jamaican children.

Methods: We used data from the Epidemiological Research on Autism in Jamaica (ERAJ) and ERAJ-2 study, which enrolled 343 pairs of age-(± 6 months) and sex-matched ASD cases and typically developing controls. Conditional logistic regression analyses were performed to assess the possible association of breastfeeding, and its duration with ASD while controlling for potential confounders. Additionally, interactions between maternal age and breastfeeding were explored in relation to ASD. Matched odds ratios (MORs) and 95% confidence intervals (95% CIs) are reported for each of the two levels of the maternal age (i.e., <35 and ≥35 years).

Results: In univariable analysis, we did not find any significant association of being ever breastfed with ASD [MOR = 1.22, 95%CI (0.66-2.28), *P* =0.528]. Similarly, no significant univariable association was observed between the duration of breastfeeding and ASD when breastfeeding for >3-6, >6-12, and >12 months were compared to ≤3 month of breastfeeding [Overall Wald test *P* = 0.712, MORs (95% CI): 1.05 (0.68-1.63), 1.17 (0.74-1.86), 0.90 (0.59-1.38), respectively]. However, in the multivariable model, maternal age appeared to be a possible effect modifier for the association between breastfeeding duration and ASD. Specifically, among mothers who were ≥ 35 years of age, the association between breastfeeding duration and ASD was marginally significant when breastfeeding for >3-6, >6-12, and >12 months were compared to ≤3 months of breastfeeding [MOR (95%CI): 0.30 (0.09-1.09), *P* = 0.067; 0.44 (0.14-1.38), *P* = 0.159; and 0.35 (0.11-1.12), *P* = 0.076, respectively]. Whereas, among mothers who were <35 years of age, no statistically significant associations were observed when breastfeeding for >3-6, >6-12, and >12 months were compared to ≤3 months of breastfeeding [MOR (95% CI): 1.19 (0.73-1.94), *P* = 0.475; 1.23 (0.72-2.09), *P* = 0.449; and 0.94 (0.59-1.50), *P* = 0.805, respectively].

Conclusions: Findings from this study imply that Jamaican children whose mothers are 35 years or older may potentially benefit more from breastfeeding for a duration of more than 3 months to protect against ASD compared to those whose mothers are younger than 35 years. These findings require replication in future studies.

219 **240.219** Prevalence and Expression of ASD Among Preschool Age Children in New Jersey: 2010-2014

W. Zahorodny[1], *K. Nebedum*[2], *B. Martins*[3] *and J. Shenouda*[3], *(1)Rutgers New Jersey Medical School, Newark, NJ, (2)Pediatrics, Rutgers NJ Medical School, newark, NJ, (3)Pediatrics, Rutgers NJ Medical School, Newark, NJ*

Background:

Autism Spectrum Disorder (ASD) surveillance of 4-year old children by a population-based method may offer an opportunity to observe shifts in ASD prevalence early and provide timely information on progress toward early identification goals.

Objectives:

The objectives were to estimate ASD prevalence and describe the expression of ASD in three complete birth cohorts (birth years: 2006, 2008, 2010) at age four, residing in a well-defined metro region and to describe changes in the distribution or expression of ASD, during the period.

Methods:

Case-specific information was from three cycles of active ASD surveillance, according to the Centers for Disease Control and Prevention (CDC) multiple source ascertainment method, reflecting retrospective review and independent analysis of information contained in health and education records. Surveillance confirmed and described individuals with ASD (age 4 years) from the 2010, 2012 and 2014 cycles of ASD monitoring in Essex and Union counties New Jersey and provided demographic data as well as information on the distribution by sex and race/ethnicity and case characteristics, including level of impairment due to ASD, age at first (professional) evaluation, age of ASD diagnosis, cognitive functioning level as indicated by intelligence quotient (IQ) scores. Confidence intervals were based on Poisson sampling distribution. Group differences were compared by Pearson Chi-Square and Fisher's Exact Tests.

Results:

One thousand, two hundred and seventy four year-old children with ASD were identified in the two county New Jersey surveillance region. ASD prevalence was 19.7 per 1000 (95% CI 17.7, 21.9) in 2010, 22.0 per 1000 (95%CI 19.9, 24.2) in 2012, and 28.3 per 1000 (95%CI 25.9,30.9) in 2014, reflecting a 44% increase. Males with ASD outnumbered females 4:1 but ASD prevalence estimates for white, black and Hispanic children were similar. Intellectual Disability (ID) was identified in a significant but consistent portion of ASD preschoolers (37-41%). Thirty-five to forty percent of surveillance determined ASD cases had an ASD diagnosis by a community provider. Over the four-year period, an increasing proportion of children received an autism test (2010 = 28%, 2012 = 39%, 2014=38%; p<.01). The proportion of ASD children with severe impairment increased (2010 = 19%, 2012 = 20%, 2014 = 23%; p<.001). The proportions of ASD children receiving their first professional evaluation by 24 months and 36 months decreased significantly between 2010 and 2014 (p<0.001).

Conclusions:

Our findings show a 43% increase in ASD prevalence in a young cohort (4 year-olds) from 2010-2014. During this period and in the same region, ASD prevalence increased by 26% in an older cohort (8 year-olds) of individuals, suggesting that ASD prevalence has not peaked and that future peak ASD estimates will be higher. Unexpectedly, our findings disclose that the age of first evaluation is increasing and that fewer ASD children are receiving evaluations by 24 and 36 months.

220 **240.220** Title: Sex-Based Differences in the Diagnosis and Expression of Autism Spectrum Disorder (ASD) Among Preschool-Age Children: Findings from Population-Based Surveillance in New Jersey

W. Zahorodny[1], *J. Shenouda*[2], *B. Martins*[2] *and K. Nebedum*[3], *(1)Rutgers New Jersey Medical School, Newark, NJ, (2)Pediatrics, Rutgers NJ Medical School, Newark, NJ, (3)Pediatrics, Rutgers NJ Medical School, newark, NJ*

Background:
There are few studies of ASD in the preschool period based on detailed information derived from active surveillance of large, population-based, cohorts. While Autism Spectrum Disorder (ASD) prevalence estimates have increased from 6.5 per 1,000 in 2000 to 1.7 per 1,000 in 2014, one finding has remained consistent overtime, the male to female ratio. Males are four times more likely than females to be diagnosed with ASD.

Objectives:

The purpose of this study is to identify sex-based differences in the diagnosis and expression of autism among preschool age children in a large, multi-cohort, population-based sample.

Methods:

Children with ASD born in 2006, 2008 and 2010 and residing in Essex and Union counties New Jersey in 2010, 2012 and 2014, respectively, were identified from successive cycles of active (multiple source) surveillance, using a Centers for Disease Control and Prevention (CDC), ascertainment method, based on retrospective review and analysis of information contained in health and education records. Information on the expression of ASD according to DSM criteria, associated features, level of cognitive functioning, previous ASD diagnosis and ASD tests provided, as well as demographic information was systematically abstracted and analyzed. Group differences were compared using Pearson Chi-Square and Fisher's Exact Tests.

Results:

A total of 1,270 four-year-old children with ASD were confirmed across three cycles of surveillance. Boys with ASD outnumbered girls with ASD 4 to 1 (boys = 1,012, 80%; girls = 258, 20%). Boys and girls with ASD had similar proportions of cognitive impairment (boys = 39%; girls = 34%). Overall, 57% had a previous ASD diagnosis from a community-based provider and the proportion of ASD-diagnosed children did not differ by sex. Boys were more likely to be administered an Autism test than girls (37% vs 31%, $p<0.05$). Boys and girls with ASD manifested differently. With regard to DSM criteria, boys were more likely to exhibit deficits in nonverbal communication, such as eye contact, than girls (90% vs 85%, $p<0.01$). In addition, boys were also more likely to exhibit restricted patterns of interest (48% vs 34%, $p<0.001$) and inflexible adherence to nonfunctional routines (78% vs 70%, $p<0.1$). Boys demonstrated sensory processing deficits more frequently (47% vs 37%, $p<.01$) than girls and boys were more likely to exhibit the associated features: aggression, opposition and hyperactivity than girls ($p<0.05$).

Conclusions:

The expression of ASD in preschool age boys with ASD is more likely to include deficits in non-verbal communication, as well as to show restricted patterns of interest and non-functional routines than girls with ASD. In addition, young boys with ASD are more likely to express a number of additional, salient, associated features such as hyperactive, oppositional and/or aggressive behavior. Satisfying DSM-5 ASD criteria requires key social communication deficits including deficits in nonverbal communication, presence of restricted and/or repetitive behaviors and/or sensory processing deficits that are manifest in young boys more frequently than girls with ASD, thereby raising the possibility that preschool age girls with ASD will be diagnosed later than boys in the DSM-5 era.

221 **240.221** Trends in Birth Prevalence of Autism Spectrum Disorders (ASD) in California from 1990 to 2010, By Race-Ethnicity and Income

M. Pearl[1], *S. Matias*[2], *V. Poon*[2] *and G. C. Windham*[1], *(1)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA, (2)Sequoia Foundation, La Jolla, CA*

Background: An increase in the prevalence of autism spectrum disorders (ASD) has been noted worldwide over the past 50 years, leading to efforts to identify the reasons. At least some of the increase has been attributed to increased awareness and changes in diagnostic practices or tools. However, access to diagnosis may differ depending on familial sociodemographic factors.
Objectives: To characterize trends in ASD birth prevalence in California over two decades by race-ethnicity and income.

Methods: Data on ASD diagnoses were obtained using statewide Department of Developmental Services (DDS) data of clients receiving services for autism as of February 2018. DDS data were linked to birth certificate data for live births to California resident mothers from 1990 to 2010, excluding infant deaths. The linked data therefore represent children who were at least 7 years old at the time of entry into the DDS system. Annual ASD birth prevalence (cases per 1,000 births) was calculated overall and for non-Hispanic white, non-Hispanic black, and Hispanic mothers, and further stratified by insurance type during pregnancy or delivery, with public insurance used as a marker of low income. Average annual percent change (AAPC) in birth prevalence and change in AAPC were assessed using Poisson regression.

Results: A total of 89,107 cases were identified from 13,014,703 births. ASD birth prevalence increased from 1.9 to 11.7 between 1990 and 2010, or 7.5% annually. The AAPC was highest for children of Hispanic mothers (9.2%, vs. 8.0% for blacks and 6.3% for whites; $p<.001$) and for low-income (publicly insured) families regardless of race-ethnicity (10%, vs. 6.1% for privately insured; $p<.001$). Trends in ASD birth prevalence differed by time period. For children born from 1990 to 2000, ASD prevalence was similar for children of white and black mothers, and lower for Hispanics, with annual increases of 11.2%, 9.5% and 14.2%, respectively. Over the next decade, the AAPC in ASD prevalence decreased to 3.5%, 7.1% and 7.0% among children of white, black and Hispanic mothers, respectively. The largest decrease in the AAPC between decades was for white mothers who were privately insured (AAPC from 10.1% to 1.8% after birth year 2000; $P<.001$). By 2010, ASD prevalence among children of black mothers was significantly higher than among children of white mothers (14.9 vs. 10.7), and Hispanic prevalence (11.4) was similar to white prevalence.

Conclusions: In this large, population-based analysis over 21 years, ASD prevalence increased for white, black and Hispanic children in California, but at different rates so that Hispanic prevalence matched that of whites, and black prevalence exceeded that of whites. Increases were particularly noteable among low-income families. These increases may reflect improved access to screening, diagnosis and/or services.

222 **240.222** Use of Psychotropic Drugs Among Children and Adolescents with Autism Spectrum Disorders in Denmark: A Nationwide Drug Utilization Study

N. Bilenberg[1], *L. Rasmussen*[2], *M. T. Ernst*[3], *S. A. Boysen*[4] *and A. Pottegard*[4], *(1)University of Southern Denmark, Odense C, Denmark, (2)Department of Public Health, Clinical Pharmacology and Pharmacy, University of Southern Denmark, Odense C, Denmark, (3)Department of Public Health,, Clinical Pharmacology and metn, Odense C, Denmark, (4)Clinical Pharmacology and Pharmacy, University of Southern Denmark, Odense C, Denmark*

Background: Children with autism spectrum disorder (ASD) have a considerable use of psychotropics, although no pharmacological agent has proven to be effective against the core symptoms of ASD.
Objectives: We aimed to describe the use of ADHD medication, antidepressants, antipsychotics and melatonin in children and adolescents with ASD in Denmark. More specifically, we wanted to explore changes in prevalence of medication use over time and the duration of drug use. Based on the most recent data, we further explored how medication use is affected by age, sex and psychiatric comorbidities.

Methods: Using the Danish nationwide health registries, we identified all children and adolescents born between 1992 and 2011 with a diagnosis of ASD after the age of three and before the age of 18. We extracted data on all their psychotropic prescriptions and psychiatric hospital diagnoses from birth and until the end of 2017.

Results: The study population comprised 23,935 Danish children and adolescents born in 1992–2011 with an ASD diagnosis. Use of melatonin and attention-deficit/hyperactivity disorder (ADHD) medication increased from 2010 to 2017, while there were limited changes in use of antidepressants and antipsychotics. Thirty percent of the identified children used psychotropics in 2017 most commonly ADHD medication (17%) and melatonin (13%). Methylphenidate, sertraline and risperidone were most often prescribed. Most children filled more than one prescription and, across drug classes, at least 38% received treatment two years after treatment initiation. Use of psychotropics followed psychiatric comorbidities. Comorbidities did not affect age at treatment initiation. Use of psychotropics varied according to age and sex with limited use in the youngest children.

Conclusions: In summary, psychotropic drug use has increased in children with ASD mainly due to an increase in the use of ADHD medication and melatonin. In accordance with previous studies, use seems to follow comorbidities. The long treatment duration underlines the need to investigate long-term effects of psychotropic drug use in children with ASD.

223 **240.223** Wandering Among Preschool Children with and without Autism Spectrum Disorder: Occurrence and Association with Injuries

L. Wiggins[1], *C. DiGuiseppi*[2], *L. Schieve*[1], *E. Moody*[3], *G. N. Soke*[1], *E. Giarelli*[4] *and S. E. Levy*[5], *(1)Centers for Disease Control and Prevention, Atlanta, GA, (2)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (3)University of Colorado, Denver, Aurora, CO, (4)University of Pennsylvania, Philadelphia, PA, (5)Division of Developmental and Behavioral Pediatrics, Center for Autism Research, Children's Hospital of Philadelphia; Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA*

Background: Research suggests that children with autism spectrum disorder (ASD) may wander from safe environments, which places them at increased risk of sustaining injuries. Wandering is moving about from place to place with or without a fixed plan. Wandering is most often studied in samples of children 48 months and older since it is common among toddlers learning to explore their environment and assert independence.
Objectives: The objectives of this study were to:

1. Compare the occurrence of wandering among children 48 months and older in three study groups: ASD, other (non-ASD) developmental delay (DD), and population comparison (POP); and
2. Assess the association between wandering and injuries in each of the three study groups.

Methods: Participants were children 48 months and older enrolled in the Study to Explore Early Development Phase-1 (SEED1). SEED1 is a multisite, community-based study of preschool children designed to investigate the development and risk factors of ASD. The Social Communication Questionnaire (SCQ) assessed symptoms of ASD for all children upon study enrollment. Those with an SCQ score of 11 or higher or a previous diagnosis of ASD received a comprehensive evaluation that consisted of the Mullen Scales of Early Learning (MSEL) and Autism Diagnostic Observation Schedule (ADOS). Parents were interviewed with the Autism Diagnostic Interview – Revised (ADI-R). Results of the ADOS and ADI-R determined ASD status. All other children received a limited developmental evaluation that consisted of only the MSEL.

We examined two injury outcomes. For all children, parents responded during a telephone interview whether their child ever had an injury that required medical attention (yes/no). Parents also completed the Child Behavior Checklist (CBCL), which included items on the frequency of their child getting hurt or being accident-prone (never or sometimes/often) and the frequency of wandering (never/sometimes or often). Attention deficit/hyperactivity (ADHD) problems (yes/no) also was determined from the CBCL; intellectual disability (ID, yes/no) was determined from the MSEL. Associations were assessed for each study group between wandering and being hurt/accident-prone and sustaining an injury that required medical attention. Regression models included ADHD risk, child sex, ID, and maternal education as potential confounders.

Results: The analytic sample included 2,215 children: 610 ASD, 842 DD, and 763 POP. There were significant differences in parental report of wandering based on study classification (χ^2=354.82, p<.001): 57.9% of children with ASD wandered compared to 25.1% of children with other DDs and 12.1% of POP group children. Children reported to wander were more likely than those reported not to wander to get hurt or be accident-prone (ASD odds ratio (OR)=1.55 (1.01,2.25); DD OR=2.51 (1.71,3.68); POP OR=2.52 (1.51,4.22). However, wandering was not associated with injuries that required medical attention in any study group.

Conclusions: Children with ASD wander significantly more than other children do in the SEED1 sample. Parent-reported wandering was associated with getting hurt or being accident-prone but not with sustaining an injury that required medical attention. Future research could explore the antecedents and consequences of wandering in children with ASD and influence on family functioning and child health outcomes.

224 **241.224** Examining the Engagement of Community Partners in Autism Research within the Autism CRC

E. Pellicano and ***J. den Houting****, Macquarie University, Sydney, Australia*

Background: Participatory approaches to research are gaining increased popularity as efficacious methods for conducting health research and research with minority populations. Recently, there has been growing recognition within the research community of the need to engage with the autistic community and other stakeholders not only as research participants, but as active and equal partners in the research process. In Australia, the Cooperative Research Centre for Living with Autism (Autism CRC) has been at the forefront of this movement with their commitment to investing in inclusive and participatory autism research, and have implemented strategies to encourage research co-production. However, to date it has been unclear whether the Autism CRC's goal of inclusive research practice has translated into genuine engagement with community partners throughout the process of Autism CRC funded research projects.

Objectives: This study aimed to examine the nature and extent of community partner engagement within research projects funded by the Autism CRC, by gathering perspectives from both academic and community partners involved in Autism CRC research. We investigated questions such as: are Autism CRC researchers engaging with community partners? If so, how often, and with which community stakeholders? How effective do they perceive this engagement to be? In addition, we aimed to examine whether community and academic partners hold similar or differing perspectives of the nature and extent of community engagement within Autism CRC research.

Methods: Autism CRC Project Leaders (n = 31) were asked to nominate all academic partners (research professionals and research students) and community partners (autistic people, family members, service providers etc.) involved in their Autism CRC-invested research projects. All nominated partners were then invited, via email, to participate in an anonymous online survey. The online survey was designed to measure key elements of participatory research, and was adapted from a measure designed by Oetzel et al. (2018).

Results: Nineteen Autism CRC Project Leaders nominated a total of 163 potential participants, including an estimated 35 community partners and 128 academic partners. Data collection is ongoing, with a total of 21 survey responses (17 academic partners and 4 community partners) gathered to date. Preliminary data indicate that Autism CRC research partners are generally supportive of community engagement in autism research (M = 4.05, SD = 0.67, where 1 = preference for no community engagement and 5 = preference for extensive community engagement). Community engagement was perceived by participants as generating outputs that were more relevant to the autistic community, however efforts to engage with community partners were felt to be hampered by short timeframes, limited resources, and lack of cohesion within the autism community.

Conclusions: Based on preliminary findings, it appears that Autism CRC community and academic partners endorse the organisation's commitment to produce inclusive autism research. Despite the Autism CRC's efforts to implement participatory research approaches, however, there may well be substantial barriers limiting genuine and meaningful community engagement.

225 **241.225** Family Response to Autism Recurrence Risk: Implications for Early MRI Prediction

K. E. MacDuffie[1], *L. Turner-Brown*[2], *J. Pandey*[3], *A. Estes*[4], *S. R. Dager*[4], *J. Pruett*[5], *J. Piven*[6], *H. Peay*[7] *and .. The IBIS Network*[8], *(1)Speech and Hearing Sciences, University of Washington, Seattle, WA, (2)UNC TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)University of Washington, Seattle, WA, (5)Washington University School of Medicine, St. Louis, MO, (6)*Co-Senior Authors, IBIS Network, University of North Carolina, Chapel Hill, NC, (7)Research Triangle Institute International, Durham, NC, (8)University of North Carolina, Chapel Hill, NC*

Background: Emerging MRI-based predictive testing approaches have been developed to predict the diagnosis of Autism Spectrum Disorder (ASD) at 24 months from classification of 6-month structural and functional MRI data in high-risk infants (Emerson et al., 2017; Hazlett et al., 2017). Although this type of predictive testing is not yet available outside of the research context, it is critical to understand parent motivations for such testing prior to disclosing predictive risk information to families.

Objectives: We investigated perceptions of risk for ASD in a cohort of parents involved in an MRI study of infants at high familial risk. The goal was to explore parent reactions to perceived autism recurrence risk as a first step towards understanding motivations to seek early predictive testing.

Methods: 37 interviews were conducted with parents enrolled in the Infant Brain Imaging Study (IBIS), a longitudinal, multi-site study of early brain and behavioral development in infants at high and low familial risk for ASD. High-risk families had at least one older child with ASD, and an infant aged 3-15 months enrolled in IBIS. A codebook was developed, tested, revised by consensus, and applied to the interview data. Coding reports were reviewed and used to develop a set of emerging themes, informed by the Common Sense Model (Fig. 1; Diefenbach & Leventhal, 1996).

Results: Parents were aware that their infants were at increased risk of ASD, and most who provided quantitative estimates overestimated the risk. Parent perceptions of their infant's vulnerability to ASD were heterogenous, and informed by comparisons made to their affected child. Noted similarities to the older sibling were associated with increased worry, while differences tended to relieve worry. Parents reported a variety of emotional responses to perceived vulnerability, including worry, fear, and sadness. Behaviorally, many parents reported being watchful or vigilant for early signs of ASD. Some parents reported that their knowledge of recurrence risk affected their reproductive decisions (though an approximately equal number reported no impact on family planning), and a few parents reported effects on other healthcare decisions (e.g., choosing to not vaccinate). Parents also described cognitive efforts to cope with uncertainty, such as perceiving ASD risk as out of their control, or reflecting on how prior experience has prepared them to accept and/or manage another ASD diagnosis.

Conclusions: As the field of autism research moves towards earlier identification via brain-based biomarkers, this study provides novel insights into the perspectives and motivations of families who might seek predictive MRI testing. Among this group of parents—"early adopters" of infant MRI in the research setting—enrolling in research and obtaining regular developmental testing appears to be an active coping effort in response to perceived vulnerability. Parents are looking for ways to manage the uncertainty associated with their infant's increased risk, and MRI testing could provide a more precise estimate of that risk. Future studies will build upon these results and investigate potential strategies for supporting parents before and after the receipt of predictive risk information.

Poster Session
242 - Family Issues and Stakeholder Experiences
11:30 AM - 1:30 PM - Room: 710

226 **242.226** Relation between Child's Age of Autism Diagnosis and Parents' Stress, Perceived Quality of Life, and Empowerment Status

A. Milgramm *and K. V. Christodulu, Center for Autism and Related Disabilities, Albany, NY*

Background: It is well understood that a diagnosis of autism spectrum disorder (ASD) impacts not only the child, but the entire family unit. In fact, prior research has indicated that parents of children with ASD experience more parenting stress, compromised quality of life, and increased need for support compared to parents of children who have another disability or are typically developing (Hayes & Watson, 2013). Given the persistent gap between the age at which ASD can be reliably diagnosed and the median age of diagnosis, an important next step in this line of research is to consider the role of child's age of diagnosis on parenting experience. Considering that children diagnosed after the age of three miss the window of opportunity for early intervention services, we hypothesized that parents of these children would demonstrate higher stress levels and reduced quality of life and empowerment.

Objectives: To compare parenting stress, perceived quality of life, and empowerment status in parents of children who received an early and delayed diagnosis.

Methods: Participants included 71 parents (mothers, *n*=44; fathers, *n*=27) who enrolled in a parent education program designed to teach families about ASD. The children of enrolled parents ranged in age from 2-16 years and were classified as receiving either an early (i.e., first 3 years; *n*=35) or delayed (i.e., 4 years or older; *n*=36) diagnosis. Parents completed the Family Empowerment Scale (FES; Koren et al., 1992), Parenting Stress Index–Short Form (PSI-4-SF; Abidin, 2012), and Family Quality of Life Scale (FQOL; Beach Center on Disabilities, 2006). The FES measures empowerment in three domains: Family, Service System, and Community. The PSI is comprised of three subscales: Parental Distress, Parent-Child Dysfunctional Interaction, and Difficult Child. The FQOL measures five domains: Family Interaction, Parenting, Emotional Well-Being, Physical Well-Being, and Disability-Related Support. Mann-Whitney U tests were used to examine differences between parents of children who received an early and delayed diagnosis.

Results: With regard to empowerment, results revealed that delayed diagnosis parents felt less empowered with respect to the family (*U*=459, *p*<.05), service system (*U*=401, *p*<.01), and larger community (*U*=395, *p*<.01). With regard to parenting stress, delayed diagnosis parents perceived their child as more difficult (*U*=394, p<.01) than early diagnosis parents, but no differences emerged on the Parental Distress (*p*=.80) or Parent-Child Dysfunctional Interaction subscales (*p*=.13). With regard to quality of life, delayed diagnosis parents perceived their child as having fewer disability related supports (*U*=423, *p*<.05), but no differences emerged on the Family Interaction, Parenting, Emotional Well-Being, or Physical Well-Being domains (*p*'s=.27-.70)

Conclusions: Parents of children who received a diagnosis after the age of three felt less empowered and perceived their child as more difficult and with fewer disability-related supports. The implications of these findings are two-fold. First, the results provide additional evidence supporting the importance of early detection of ASD from a family perspective. Second, the results suggest that children diagnosed after the age of three and their families may require extra support. Incorporating forward planning into the diagnostic process may be one avenue to consider.

227 **242.227** Relationships Matter: The Association between Parent-Teacher Alliance, Parent Stress, and Student Outcomes

M. Adams[1]*, Y. Yu*[2]*, K. Pinkman*[3]*, J. H. McGrew*[4] *and L. A. Ruble*[1]*, (1)University of Kentucky, Lexington, KY, (2)Indiana University - Purdue University Indianapolis, Indianapolis, IN, (3)Department of Educational School and Counseling Psychology, University of Kentucky, Lexington, KY, (4)Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN*

Background:

Positive parent-teacher relationships are critical for student success generally (Garbacz, McIntyre, & Santiago, 2016) and are paramount for students with autism spectrum disorders (ASD) who require coordinated plans that promote generalization of skills across home and school (National Research Council, 2001). Parents and teachers agree that collaboration and communication are critical for the education of students with ASD (Syriopoulou-Delli, Cassimos, & Polychronopoulou, 2016). Furthermore, stronger parent-teacher alliance has also been associated with lower stress for parents of younger children with ASD (Krakovich, et al., 2016). For transition age youth (TAY) with ASD, collaboration and coordination may be especially important given their poor outcomes (e.g., employment, friendships, community engagement) compared to peers with other disabilities (Anderson, et al., 2014) and the increased parental demands when navigating new systems. Thus, successful interventions for TAY may work in part through establishing and leveraging a stronger parent-teacher alliance. Accordingly, as part of a randomized controlled trial of an adaption of Collaborative Model for Promoting Competence and Success (COMPASS) for transition age youth with ASD we examined intervention impacts on alliance and the association between alliance and student and parent outcomes. COMPASS is a student-centered, teacher coaching intervention that results in improved IEP outcomes (Ruble et al., 2018) and encourages collaboration by bringing together the student's parent and teacher.

Objectives:

The goals were to examine the relationships between parent-teacher alliance and IEP goal achievement and parenting stress respectively and to examine whether COMPASS results in measurable improvements in parent-teacher alliance.

Methods:

Participants included 20 students with ASD (n_{female} = 18, n_{male} = 2), their parent/caregiver (n_{female} = 18, n_{male} = 2), and their primary special education teacher. The mean age of students was 18.2 years (*SD* = 1.1; range: 17-20 years). Seventy percent of students were White. Participants completed baseline assessments before random assignment to one of two groups: COMPASS intervention (*N* = 11) or placebo control (*N* = 9). The Parent Teacher Alliance Questionnaire (PTAQ) and the Parenting Stress Index – Fourth Edition Short Form (PSI-4 SF) were completed by the parents/caregivers to measure parent-teacher alliance and parenting stress, respectively. Parents also completed a brief questionnaire about student's progress on IEP goals.

Results:

Based on parental reports, stronger parent-teacher alliance was related to higher IEP goal achievement (r = -.62, p < .01) and decreased parenting stress (r = .50, p < .05). A one-way analysis of covariance (controlling for baseline alliance scores) indicated a trend toward significance between the two groups on post-intervention alliance [$F(1,14) = 2.87$, p = .11], with a medium effect size (η^2 = .17). Also at a trending level, the level of alliance improved from Time 1 (*M* = 41.44, *SD* = 13.36) to Time 2 (*M* = 35.56, *SD* = 9.32) for the intervention group, $t(8) = 1.94$, p = .088.

Conclusions:

Stronger parent-teacher alliance is associated with greater student improvements and lower stress as perceived by parents. The findings also

suggest that COMPASS may improve parent-teacher alliance. Further research with larger samples is necessary.

228 **242.228** Relationships between Child Factors and Parental Mental Health Symptoms

R. L. Gruen[1], *E. A. DeLucia*[1], *A. Pomales*[1], *L. L. Booth*[1] *and P. E. Ventola*[2], *(1)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Parents of children with developmental disabilities present with higher rates of anxiety, depression and stress than parents of typically developing children. Furthermore, there is a higher prevalence of these mental health symptoms in parents of children with autism spectrum disorder (ASD) than in parents of children with other developmental disabilities (Dumas, Wolf, Fisman & Culligan, 1991; Sanders & Morgan, 1997; Taylor & Warren, 2012). We aimed to explore relationships between parental symptoms and behavioral characteristics of children with ASD.

Objectives: In a sample of children with ASD and their mothers, we examined possible relationships between child and parent symptoms and behaviors.

Methods: Participants included thirty-three 5- to 8-year old children with ASD (*M* = 72.1 months, *SD* = 15.6 months) and their mothers. All children had an ASD diagnosis as confirmed by the Autism Diagnostic Observation Schedule (ADOS). Parents reported on their children's behavioral and emotional symptoms using the Child Behavior Checklist—Preschool and School Age (CBCL/1.5-5 and CBCL/6-18). Parents also completed the Repetitive Behavior Scale—Revised (RBS-R) to assess children's repetitive behaviors. Additionally, mothers reported their own depression, anxiety, and stress symptoms using the Beck Depression Inventory-II (BDI-II), Beck Anxiety Inventory (BAI), and the Parenting Stress Index—Fourth Edition (PSI-4), respectively.

Results: Scores for maternal anxiety on the BAI were positively correlated with child ritualistic behaviors on the RBS-R Ritualistic Behavior subscale (r = .376, p = .034, n = 32). For children ages 6 and above (n = 15), somatic complaints on the CBCL also correlated with maternal anxiety (somatic complaints: r = .597, p = .019). Additionally, higher BDI-II scores and higher scores on the Parental Distress subscale of the PSI-4 correlated with lower rates of child participation in extracurricular activities as reported on the CBCL/6-18 (depression: r = -.575, p = .025; parental distress: r = -.587, p = .021).

Conclusions: Maternal mental health symptoms correlated with a number of child factors. Children of mothers with higher levels of anxiety showed higher rates of somatic symptoms compared with children of mothers with lower levels of anxiety. Additionally, maternal anxiety was correlated with child ritualistic behavior. Given that anxiety symptoms have a genetic component, it is possible that children of anxious mothers also have greater symptoms of anxiety, which in these young children may manifest as somatic complaints and/or heightened ritualistic behaviors. Children's involvement in extracurricular activities was negatively correlated with maternal depression and parenting distress, meaning that children whose mothers showed higher levels of depression or distress were less likely to be involved in activities. Further work is needed to determine the directionality of these relationships and consider the possibility of bidirectional interactions. Further understanding can help inform future interventions to best support both children with ASD and their parents.

229 **242.229** Respite Care Among Parents of Children, Adolescents and Adults with ASD

A. C. Woodman*, B. Hennigar, C. Wilson and K. Loring, University of Massachusetts Amherst, Amherst, MA*

Background: Parents of children with autism spectrum disorder (ASD) face a considerable amount of caregiving stress. While many families rely on informal supports such as friends and family, others use formalized supports such as respite care. Respite care is similar to other forms of child care, however the intention is explicitly to provide parents with a temporary relief of caregiving responsibilities. Although there was a great deal of research on the impacts of respite care when it was first introduced after deinstitutionalization, few recent studies have examined respite care use among parents of children with ASD.

Objectives: The purpose of this study is to examine use of respite care among parents of children with ASD. This study aims to identify barriers to accessing respite care among those who have not yet used this service. This study also aims to better understand the experiences of parents who have used respite care.

Methods: Parents of children, adolescents and adults with developmental disabilities were invited to complete an online survey on respite care through community newsletters and events. The present study focuses on 38 parents of children with ASD. Most caregivers were biological mothers (84%). On average, parents were 31.08 years old (*SD* = 9.55). Most (84.2%) identified as white, non-Hispanic and approximately half (55%) were married. The median annual family income was $60,000-69,999. Ten parents had two children with ASD. For these parents, analyses focused on their older child with ASD. The target children with ASD ranged in age from 7 to 27 years old (*M* = 16.73, *SD* = 5.82). The majority were male (78%) and most (84%) lived with the participating parent full time.

Results: Over half (58%) of parents had used respite care. Among those who had never used respite care, half had inquired or applied for respite care. The most common reason for not using respite care was difficulty finding a provider (85%), followed by an inability to pay for a provider (68%). Few participants felt they did not need respite care (42%) Among those who used respite care services, most (63%) received services in the home. Few (12%) never paid out of pocket for services. When receiving respite care, parents were most likely to engage to activities related to managing the house, such as running errands (78%), cleaning (78%), and cooking (72%). Much more infrequent was engaging in leisure activities (47%) or socializing with friends (44%). Related to their child with ASD, parents were most likely to complete school paperwork (76%), make appointments (67%), and contact their child's providers (67%). Of all members of the family, participants perceived the greatest benefit of respite care to be for themselves, with most (67%) caregivers reporting that it benefited them a lot or a great deal.

Conclusions: Parents of children with ASD find respite care to be beneficial, but not all parents are accessing this service. Additional work is needed to reduce barriers related to finding providers and paying for services.

230 **242.230** Retrospective Case Study on Advocate Latina Mothers and Their Educational Journey with a Child with Autism Spectrum Disorder

J. Padilla[1], *P. Luelmo*[2] *and C. Kasari*[3], *(1)Autism Learning Partners, Downey, CA, (2)Special Education, San Diego State University, San Diego, CA,*

(3)University of California, Los Angeles, Los Angeles, CA

Background: Latinx children are more likely to receive a late diagnosis of autism, delaying critical early intervention services. Any delay jeopardizes long term outcomes in children with ASD. Capturing and understanding the experiences of underserved Latinx communities is needed in order to address this diagnosis gap. Parents play a critical role in the early diagnosis of treatment of children. Hence, exploring Latinx parents experiences as community advocates sheds light into potential solutions to the ASD diagnosis gap for Latinx families.
Objectives: The study's aim is to explore the experiences of Latina mothers as they become active advocates for their children and other families in a community-based setting in Southern California. Specifically, the study research questions were RQ1: What are the experiences of Latinx mothers of a child with autism as they advocate for services for they child within the U.S. school system? RQ2: What previous experiences have helped Latina mothers of a child with autism become active parent mentors to other parents?

Methods: This retrospective case study analysis employed a qualitative approach that specifically targeted three Latina mothers of a child with ASD through convenience sampling and who were recruited within a community-based organization focused on parent advocacy. Participants were interviewed one-on-one in a semi-structured format. Interviews lasted between 1 hour to 2 hours and 25 minutes. All three interviews were audio recorded and destroyed after transcribed. The interview included 14 questions that were based on four areas (i.e., Background, child Information, school experience, and advocacy). The settings of the interviews were a public library, community organization center, and a participant's home. In order to conduct data analysis, researchers used open-coding techniques and application of labels to find similar themes across all of the three interviews.

Results: Findings were organized into five broad themes that came across the three interviews in relation to the mother and her community-based advocacy experience. These themes included parent personality qualities, actions, unresolved concerns or events, understanding of the special education process, and obstacles in acquiring services.

Conclusions: Within an underserved community, the lack of direct resources may encourage Latinx mothers to seek information and resources available in the community needed in order to navigate the special education system. Likewise, while in their parent advocacy educational journey, Latinx parents are able to get informed and at the same time help other parents with education and advocacy. The results from this study suggest that previous life experiences that parent advocates go through make them ideal candidates to educate other parents.

231 **242.231** Returning Home after Hospitalization - Insights from Parents of Adolescents with Autism Spectrum Disorder and Intellectual Disability

L. Cuillerier[1] *and C. Genest*[2]*, (1)Hopital Riviere-des-Prairies, Montreal, QC, Canada, (2)Faculty of nursing, University of Montreal, Montreal, QC, Canada*

Background: Adolescence is a difficult period in one's life, particularly for adolescents with Autism Spectrum Disorder (ASD) and their family. It is in this period of their lives that youth with ASD are the most likely to be hospitalized in a mental health unit, especially if they have intellectual disability (ID). Disruptive and aggressive behaviors, which include self-injury, are the leading reason for hospital admission and emergency department visits. Moreover, studies show that the inaccessibility or lack of specialized services cause these adolescents to consult emergency services on more occasions than youth without disabilities. Along the same line, repeated hospital admission can occur due to the lack of appropriate services, even with well-planned discharges.
In Canada, several services are currently offered to children with ASD and their family. More specifically in the province of Quebec, those services are divided as primary (first-line), specific (second-line) and specialized (third-line) services. However, literature on the effectiveness of these services after hospitalization is sparse, and no study has yet explored the experience of parents using those services for their children in Quebec. Therefore, to adjust services and reduce re-hospitalization rates, it is important to assess the experience of parents of adolescents with ASD and ID after hospitalization throughout first-, second- and third-line services.

Objectives: To explore the experience of parents of adolescents with ASD and ID after hospitalization in a child psychiatric unit across the first-, second- and third-line services.

Methods: In this qualitative research, a descriptive and exploratory form was used. A total of six face-to-face semi-structured interviews were conducted with nine parents (six mothers and three fathers) of six adolescents (five boys and one girl) with ASD and ID. To be eligible, each participant had to live in the greater region of Montreal, speak French and have a child with ASD and ID who was hospitalized in a child psychiatric unit between the age of 12 and 17 years old.

Results: Results show that the experience of these parents consists of a succession of disappointments as the offered services were unable to address their needs and expectations. Indeed, their biggest desire —keeping their children at home— could not be met as five out of six adolescents were separated from their families and put in a residential or institutional placement. Their struggles can be summarized in four main themes: 1) the expectations expressed, 2) the encountered difficulties, 3) the solutions put in place, and finally 4) the feeling of failure, which is related with the out-of-home placement.

Conclusions: In light of these findings, changes need to be made in the follow-up services offered to these families after the discharge of their adolescent. Among other things, the return home must be better prepared by appointing a health care professional as a reference person to each family and by offering uninterrupted services across the lifespan based on the true needs of these families and their adolescent.

232 **242.232** Having a Second Child, When Your First Has Autism: A Qualitative Study of Parental Experiences

ABSTRACT WITHDRAWN

Background: Around 20% of infants who have an older sibling with Autism Spectrum Disorder (ASD) develop ASD themselves (Ozonoff et al., 2011), and a further 20–30% develop broader developmental difficulties (Messinger et al., 2013). It is known that the diagnosis of a child with ASD has short- and long-term impacts on family functioning, including on family planning (Navot et.al, 2016). However, research has yet to explore the lived experience of parents having a second child when they already have a child diagnosed with ASD, and how this situation impacts parents' decision to have another child as well as their perinatal experiences.
Objectives: This study sought to better understand the impact of this familial risk on parents, and the experiences of parents of a child diagnosed

with ASD around the conception, pregnancy and early developmental period of a subsequent child.

Methods: The current ongoing study involves in depth interviews with (1) parents of a child diagnosed with ASD, who have a subsequent child (with or without ASD); and (2) parents of two typically developing children. Current recruitment of 8 parents in each group are approaching thematic saturation, however, the analysis and potential data collection are ongoing, with expected completion in the next two months. Interviews with parents involved a set of open-ended questions developed to explore parental experiences around the pregnancy and early developmental periods of the subsequent child. A minimal number of broad, data-generating questions were asked as recommended in phenomenology (Brod, Tesler, & Christensen, 2009; van Manen, 2016), allowing participants to speak about the experiences that were most salient to them, with prompts from the interviewer given to facilitate their storytelling. Interviews lasted between 1-1.5 hours and were transcribed verbatim. Data analysis has been concurrent with data collection, and involves a thematic analysis of the data conducted using NVivo (QSR International Pty Ltd. Version 11, 2016).

Results: Preliminary analyses have found three main themes. The first of these focuses on parents' experiences of 'uncertainty'; exploring parents guilt and stress over the potential of subsequent children being diagnosed with ASD, alongside positivity for any future children, regardless of their potential diagnostic status. The second of these focuses on 'balancing roles'; exploring the impact of a diagnosis on the management of a family during pregnancy and with a newborn. The third theme 'getting through' explores parents' methods of supporting their children and finding support for themselves.

Conclusions: Identifying the unique experiences of parents around the pregnancy and early development of a subsequent child when the first has ASD include the identification of psychoeducational focuses and resources that would be important for future parents. The results of this study will be used to inform a parent-mediated intervention for siblings at risk of developing ASD, but have broader implications for clinicians and researchers working with the parents of children with ASD.

233 **242.233** Service Needs and Barriers for Children and Adults with ASD

***N. Bardikoff**, K. Buchan, M. Spoelstra, T. McEvenue and C. Sawyer, Autism Ontario, Toronto, ON, Canada*

Background: Research on children with ASD has shown that appropriate interventions, delivered at appropriate developmental periods, can lead to marked increases in functioning across a range of domains (for review, Warren et al., 2011). The ability to access appropriate services and supports also leads to a number of benefits for families, including alleviating financial burdens and reducing family distress (Bradford, 2010). Given the far-reaching effects of receiving services, it is important to ensure care is as accessible as possible. However a survey of caregivers of children and adults with ASD in Ontario found that a majority of individuals continue to face a number of barriers to accessing services. Given the importance of timely and effective supports, it is important to determine the specific needs and experiences of service delivery across the lifespan in order to tailor appropriate systems of care.

Objectives: To explore the experiences of service delivery for individuals with ASD across the lifespan by examining identified service needs and subsequent barriers to service for individuals aged 2 to 29.

Methods: Autism Ontario conducted an online survey for caregivers in May, 2018. It was distributed across our network, via partner organizations and Ontario's regional autism providers. It was available in English and French, and focused on various aspects of service and support.

Results: There was a total of 1,475 respondents. The majority of respondents cared for male children (79.7%) and 16.7% indicated that they cared for more than one child with ASD. Children ranged in age from 2.0 years to 29.10 (M = 11.8, SD = 5.9). Respondents rated potential barriers to service on a 5-point likert scale. The largest barrier to service for all age groups was long waitlists, the second largest barrier to service differed by age group as did individuals' top service need. See table 1 for details on service needs by age.

After controlling for child's gender and region, affordability was rated as a significantly larger barrier to service for caregivers of children aged 12 and below compared to children 13 to 29 (F (4, 1,320) = 3.70, p = 0.005), while a lack of professionals who understand ASD and a lack of needed services were rated as significantly larger barriers to service for caregivers of children aged 9 to 29 compared to children below 9 years of age (Fs > 4.59, ps < 0.001). Factors including, difficulty getting to appointments, long waitlists, not knowing where to go to access services and services in non-preferred language were not significantly different across age groups (Fs < 1.21, ps > 0.05).

Conclusions: Individuals with ASD require different services and experience different barriers to accessing said service at different time points in their life. We will discuss the implications of these findings in regards to the tailoring of services and supports for individuals across the lifespan.

234 **242.234** Sharing Their Child's Autism Spectrum Disorder Diagnosis in Community Programs: Influencing Factors and Parents' Perceived Outcomes on Experiences and Participation

*S. Thompson-Hodgetts[1], **A. McKillop**[1], C. Dubland[2] and D. Visscher[2], (1)University of Alberta, Edmonton, AB, Canada, (2)The King's University, Edmonton, AB, Canada*

Background: Children with autism spectrum disorder (ASD) participate in significantly fewer mainstream (inclusive) community-based programs than their peers. This matters because social participation, including in one's community, is vital to health, development, and quality of life. Our previous research found that many parents grapple with whether sharing their child's ASD diagnosis will increase understanding, acceptance and inclusion, or increase exclusion, in community-based programs.

Objectives: This study aims to (1) identify factors associated with whether a parent shares a child's ASD diagnosis in community-based programs, and (2) explore parents' perceptions of how sharing this information influenced their child's experiences and participation in community programs.

Methods: Parents of children with ASD from Canada and the United States completed an online survey hosted through REDCap. The survey included child and family demographics (e.g., child age, communication ability, presence of disruptive behaviours, size of community, identified culture, etc.), the number and types of mainstream community programs in which the child with ASD participated (past and present), what information was provided about a child's ASD diagnosis and by whom, and open-ended questions, including, "How did sharing this information influence your child's experience in this program?". Multiple logistic regression analysis will be conducted to identify child, family, and/or program factors associated with whether diagnosis was shared. Qualitative responses to the open-ended question will be thematically analyzed.

Results: To date, n=82 parents, with n=92 children with ASD (mean = 8.97 years, range 2-20 years) have completed the survey (closes December 31, 2018). Most parents chose to share their child's ASD diagnosis within community-recreation programs; however, 17 (22%) participants did not disclose their child's ASD diagnosis.

Conclusions: Findings will increase understanding of factors associated with, and parents' perceived outcomes of, sharing (or not sharing) their child's ASD diagnosis, including outcomes related to social participation and inclusion. This knowledge may inform future research and community practices on how to improve inclusion and participation in community-based programs for children with ASD.

235 **242.235** Sibling Contact and Young Adults' Well-Being: The Moderating Role of the Broader Autism Phenotype

M. Lieber[1], *A. Jensen*[1] *and G. I. Orsmond*[2], *(1)Brigham Young University, Provo, UT, (2)Department of Occupational Therapy, Boston University, Boston, MA*

Background:

Siblings who have more contact with each other during young adulthood report greater well-being (Sherman et al., 2006). Contact may be particularly important for those with developmental disabilities. Past work, however, highlights that in some cases the positive benefits of social relationships are lessened for those who are higher in Broader Autism Phenotype (BAP) characteristics (Jobe & White, 2007).

Objectives:

The aim of this study was to examine how contact between siblings through traditional (e.g., in person) and technological (e.g., social media, texting) means was associated with young adults' well-being (depressive symptoms and general health). Further, we examined if links between contact and well-being varied by young adults' and their siblings' BAP characteristics.

Methods:

The data came from a study on sibling influence and young adulthood collected through self-reports from Amazon Mechanical Turk. The data collected resulted in 866 responses to the survey. Participants ranged between 18 and 29 years old (*M age* = 25.43, *SD* = 2.54) and lived in the United States. The sample was mostly female (58%) and Caucasian (73%). The 866 participants reported on their own BAP characteristics and those of their closest aged sibling using the Autism Spectrum Quotient questionnaire (Baron-Cohen et al., 2001). Depressive symptoms were assessed with the DASS (Lovibond & Lovibond, 1995) and general health with one item.

Results:

Analysis was conducted in a hierarchical ordinary least squares regression. Models were tested separately for each dependent variable: depressive symptoms and general health. In the first step, each model included family demographics, sibling relationship quality, the participant's and their sibling's BAP characteristics, traditional contact, and technological contact. In the second step, four two-way interactions were included: traditional contact X participant BAP, traditional contact X sibling BAP, technological contact X participant BAP, technological contact X sibling BAP.

Results revealed that when participants and/or their sibling were higher in BAP characteristics, the participant reported more depressive symptoms. In the second step, the analysis revealed a significant interaction of technological contact X sibling BAP. Testing of the simple slopes (Figure 1) revealed that for high sibling BAP there was no association between technological communication and depressive symptoms, but for low sibling BAP the association was negative (b = -.05, se = .02, p < .01, β = -.17).

Results for general health revealed that participant's with higher levels of BAP reported significantly lower health. In the second step, the analysis revealed a significant interaction of technological contact X participant BAP. Testing of the simple slopes (Figure 2) showed that for low participant BAP there was no association between technological communication and general health. For high participant BAP, however, there was a positive association (b = .08, se = .03, p < .05, β = .15).

Conclusions:

Overall, these results suggest a nuanced role of BAP for the link between sibling contact and well-being. In particular, technological communication may be more important than traditional communication. In some cases, higher levels of BAP characteristics may minimize the role of communication and in others, it may heighten it.

236 **242.236** Sleep Problems in Children with ASD: Effects on Parental Employment

B. A. Malow[1], *A. R. Marvin*[2], *D. Coury*[3], *A. Bennett*[4], *P. H. Lipkin*[2] *and J. K. Law*[2], *(1)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (3)Nationwide Children's Hospital, Columbus, OH, (4)Children's Hospital of Philadelphia, Philadelphia, PA*

Background:

Sleep problems are a frequent co-occurring medical condition in individuals with autism spectrum disorder (ASD), with reported prevalence up to 80%. Co-occurring sleep problems affect family quality of life. However, the mechanisms by which co-occurring sleep problems have this impact are not clear.

Objectives:

To examine the relationship between sleep problems in children and adolescents with ASD as measured by the Composite Sleep Disturbance Index (CSDI) and parental decision to work outside the home.

Methods:

U.S.-based parents of children with ASD were recruited from a validated and verified national autism registry. Parents completed an online survey on co-occurring conditions that incorporated family and child demographic information including the CSDI, a validated tool that scores the frequency and duration of six sleep habits (scored 0-2) over the previous month; total score range= 0-12; score ≥ 4 indicates a severe sleep problem. Parents also answered questions regarding family employment and parental health and well-being. Descriptive statistics, independent t-tests, and Pearson chi-square (χ^2) tests were performed.

Results:

610 parent/child dyads were analyzed. Responding parents were the primary caregiver, primarily women (94%), white (89%), and non-Hispanic

(92%); mean age of 43.3 (SD 7.2; range 25-65) years. Children were primarily male (81%), white (84%), and non-Hispanic (88%); mean age of 12.1 (SD 3.6; range 3-17) years. On the CSDI, 377 (62%) subjects were classified as severe and 233 (38%) as not severe. Parental age, race (white/non-white), and ethnicity (Hispanic/Non-Hispanic) did not differ between those with severe and not severe sleep problems. For parents who are employed outside the home, there was no difference in percentage who work full-time vs. part-time. However, there was a significant difference in employment status associated with sleep problems, with fewer parents of children with severe sleep problems being able to work outside the home compared to those with non-severe sleep concerns. Parents of children with severe sleep problems reported needing to stay home to care for their child with ASD much more frequently than those without severe sleep problems (43% vs 26%, χ^2 (1) = 10.80, p = 0.001). The proportion of working parents missing 5 or more days of work annually due to their child's ASD was higher for those with severe compared to non-severe sleep problems (37% vs. 16%; χ^2 (2) = 19.64, p = 0.000).

Conclusions:

We found a strong association between the presence of severe sleep problems in the child with ASD and parental employment as well as work attendance. Parents of children with ASD and severe sleep problems tend to stay at home more frequently than parents of children with ASD without severe sleep problems, and miss more days of work. Co-occurring sleep problems may affect employment status in parents of children with ASD. Since identification and treatment of sleep problems in children with ASD may have benefits not only for the child, but also for family economic status and overall quality of life, children with ASD should be regularly screened for sleep problems.

This study was supported by Neurim Pharmaceuticals.

237 **242.237** Social Networks and Autism Spectrum Disorder: A Review of Findings for People with Autism, Their Families, and Communities

E. McGhee Hassrick[1], *C. Sosnowy*[1], *J. L. Walton*[2], *Z. Shamsi*[3] *and P. Shattuck*[1], *(1)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (2)AJDAI, Drexel University, Philadelphia, PA, (3)Drexel University, Phialdelphia, PA*

Background: While decades of sociological research confirms that social networks provide critical social capital, including information, knowledge, advice and social-emotional support that create better life-course outcomes (Burt, 1992; Coleman, 1988, 1990; Granovetter, 1973; Lin, Ensel, & Vaughn, 1981), there is little research in the field of autism investigating the social capital ecosystem of people with ASD. (Hassrick, Shattuck, & Carley, 2018) We know almost nothing about what these networks look like and how to make them better. Social capital is defined as the resources embedded in and accessible through one's social connections. Social capital deficits can be framed as a life course health development challenge, where weak social capital during childhood and young adulthood shape later adult outcomes, such as job attainment.
Objectives: To describe the social networks of individuals with autism, and to identify current challenges and strategies relating to social capital attainment and maintenance for individuals with ASD for the purpose of improving adult outcomes for individuals with ASD.

Methods: The review included 15 studies. Ten studies included children age 7-17; one study included young adults age 19-37; and three studies focused on parents of children with ASD ranging in age from 2-50. Authors assessed eligibility for inclusion based on inclusion of social network protocols and analysis. Each article was double-coded and then consensus coded in pairs. The 15 articles incorporated data from 515 students with ASD and 623 parents across 2 continents (North America and Europe). The articles differed by methods: 8 quantitative and 7 mixed-method. Coding of data was conducted in two stages: 1) findings were extracted and pasted exactly as written into an SPSS data file. A codebook was developed, based on themes and subthemes of social capital findings and strategies, constructed through consensus. All data was then doubled coded and inter-rater reliability between coders was > .80.

Results: Findings suggested that individuals with autism face challenges building and maintaining relationships in part due to social difficulties typically associated with autism. Overall, individuals with ASD had smaller social networks. Children and youth age 11-16 had smaller peer, acquaintance, and same-gender acquaintance networks. Young adults age 19-37 had smaller informal, professional, and family networks. Adults had particularly small social networks when staff members from residences were excluded. People with ASD also experienced challenges maintaining personal networks due to lack of reciprocity in relationships and difficulty with maintaining friendships. Strategies for building networks include creating contexts that facilitate interactions, such as providing access, direct teaching and modeling, and the utilization of self-management. Overall, very few types of social capital were measured, with most studies focused on friendship and social and emotional supports.

Conclusions: Few studies have been conducted about social capital for people with ASD. There is a pressing need for more knowledge about how people with ASD acquire social capital, what kinds of social capital they need and how they can build networks that are embedded with the social capital they require to be successful.

238 **242.238** Stakeholder Engagement and Participant Satisfaction in SPARK Research Match Studies

J. Toroney[1], *B. Vernoia*[2], *J. K. Law*[1], *C. W. Lehman*[2], *P. Feliciano*[2] *and W. K. Chung*[3], *(1)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (2)Simons Foundation, New York, NY, (3)Pediatrics, Columbia University, New York, NY*

Background: Online surveys are a fast-growing method for conducting research as digital technologies improve and access to such platforms expand. However, little is known about participants' experience with and attitudes towards online research. To capture this information, it is important to acquire participant feedback after completing an online research study. Such information will lay the groundwork for successful recruitment and retention in online research studies now and in the future. The Simons Foundation Powering Autism Research for Knowledge (SPARK) provides an ideal platform to examine factors related to participant engagement and experience. SPARK is a collaborative, online study that enrolls individuals with a professional diagnosis of autism and their family members into an autism research cohort. With over 50,000 participants with ASD, SPARK offers the opportunity to facilitate autism research broadly by assisting researchers with study recruitment, called "research match."
Objectives: Utilize data from participant feedback surveys to identify common themes across family experiences and evaluate satisfaction participating in online research.

Methods: SPARK facilitates recruitment via research match by building online studies to which eligible participants are invited. After participants complete an online study, the following screen provides a feedback survey consisting of three questions. The first two questions ask for a

quantitative rating 1 to 5 (5 being the highest) on how important the study's research topic is to them and their experience participating in the study. The third question is an open-ended text box for comments. For each research match study, ratings for the first two questions were averaged to yield a final rating. The open-ended comments were qualitatively analyzed to capture common themes within and across studies.

Results: All online studies were rated highly for importance of the research topic and participation experience (see table 1).

In the open text comments, four common themes were found across the online studies (see table 2). The first theme was an expression of gratitude for the research SPARK does and a sense of pride in participating in autism research.

The second theme includes suggestions to modify and improve the study. Participant suggestions include changing or adding questions, shortening the length of a survey, and adding "don't know/not sure" or "not applicable" as an answer option. Participants also suggested adding more open text fields so they could provide richer, more meaningful answers.

A third common theme is the desire for families to obtain survey results from their participation in a study. Lastly, families used the feedback survey to share additional information with researchers to further clarify their survey responses.

Conclusions: Participant feedback allows researchers to understand the perspectives and concerns of parents, children, and young adults with autism when completing an online survey, which is critical to improving user experience as well as overall data quality. By addressing participant comments and suggestions, the research match team can improve future surveys and facilitate participant engagement and retention in SPARK. With research focusing on more patient-centered approaches, stakeholders and researchers can work together to improve autism research and the participant experience.

239 **242.239** Stakeholder Insights on Supporting Neurodiversity at Work and School

J. H. Fede[1] *and A. C. Laurent*[2]*, (1)College of Pharmacy, University of Rhode Island, Kingston, RI, (2)Psychology, University of Rhode Island, Kingston, RI*

Background:

The number of individuals diagnosed with Autism Spectrum Disorders has increased (CDC, 2013) with worldwide prevalence estimated from 1% (Elsabbagh, Divan & Koh, 2012) to 2.6% (Kim, Leventhal & Koh, 2011). Research tends to focus on children, and while there remains much to be done for autistic children, one certain outcome is that autistic children become autistic adults. Limited research exists on educational and employment activities of autistic adults (Taylor & Seltzer, 2012). Research suggests autistic adults can and want to work or continue education (Hendricks, 2009), but in the UK, 16% of autistic adults are employed full-time (National Autistic Society, 2016). Rates are likely similar in the US where 16.8% of disabled persons work full-time (Autism Society, 2015). Many factors contribute, however research in Germany found 94% of autistic adults had worked and 53% had pursued higher education (Frank et al., 2018). Thus, understanding the challenges faced by autistic adults at school and work may be crucial to improved outcomes.

Objectives:

To gather stakeholder insights about the best supports for autistic workers and students.

To create an instrument assessing importance and feasibility of implementation of stakeholder-authored approaches to supporting neurodiversity.

Methods:

An open-ended prompt presented via social media platforms and tagged to reach autistic populations asked, *"what are some of the best tools, supports and strategies you have used or been provided in work or at school?"* Twenty-seven people responded to this prompt generating 48 ideas. These 48 items were analyzed for themes and used to create a survey tool asking autistic workers and students to rate the importance of each item from and how feasible they perceived implementation to be. The survey also asks about educational/employment statuses, qualitative experiences in work and school, and basic demographics (e.g., country, gender, age).

Results:

In line with Autism Spectrum Conditions, most of the 48 ideas generated by stakeholders were aimed towards social communication (31.25%) and sensory processing (25%) differences However, many items spoke to independence (20.83%), respect and understanding of autism (10.42%), and ability to be open about being autistic (6.25%). Two respondents detailed how hiring practices often require face-to-face interactions that can be exclusive for autistics. Table 1 provides example ideas by topic.

All 48 ideas were included in the survey which has been shared with stakeholders, organizations, and prominent researchers for further dissemination. The survey has been shared widely across six countries.

Conclusions:

Results suggest that autistic adults have important insights into their own communication, sensory and needs and routines that work for them at work and school. These results are also promising in that most of the ideas generated appear to be feasible for many employers and educators (e.g., walking breaks, direct feedback). The next stages of this study include collecting survey responses, surveying employers and educational institutions about their current practices to support neurodiversity and comparing the fit between these two stakeholder groups. It is well documented that diversity can be a positive force if and when institutions provide an environment where diversity can thrive (Dos Reis et al., 2007).

240 **242.240** Student Voices: The Perspectives of Autistic Youth on High School Experiences

K. Bottema-Beutel[1]*, J. Cuda*[2]*, S. Y. Kim*[1] *and S. Crowley*[1]*, (1)Lynch School of Education, Boston College, Chestnut Hill, MA, (2)Boston College, Chestnut Hill, MA*

Background: Students in US schools are increasingly identified with autism as a primary disability category. Autistic high school students have reported dissatisfaction with their school experiences, and often feel inadequately supported by school professionals (Bottema-Beutel, Mullins, Harvey, Gustafson, & Carter, 2016). Currently, there is little research that solicits the perspectives of autistic individuals that could be used to improve provision of school-based supports. Gathering and understanding the perspectives of these students on school-based services is critical

to ensuring their usability and effectiveness.

Objectives: The purpose of this project is to examine perspectives of US autistic high school students and recent graduates on their experiences in high schools, gathered via an online survey.

Methods: Participants were recruited via email solicitations to groups serving autistic populations (e.g. Federation for Children with Special Needs, Special Needs Advocacy Network), a Facebook advertisement, recruitment flyers posted on several Boston/Cambridge area campuses, and word of mouth. Two-hundred and thirty-six participants that reported receiving special education services in high school under the autism category completed an online survey. The survey included demographic questions, and questions pertaining to school experiences in four domains: (a) teachers and other service providers, (b) friends and peers, (c) family, and (d) factors that made high school positive and negative. Responses were coded using content analysis (Neuendorf, 2016). After developing a code book inductively from the data, three graduate students coded all survey responses, and overlapped on 20% of the data. All categories were coded to kappa levels > .60, indicating sufficient inter-coder agreement. Frequencies were derived for each category; we report the five most prevalent categories within each open-ended question, as well as statistics indicating the valence (i.e., whether positive or negative) of several questions.

Results: Respondents were 50% female, 18% LGBTQ, and 31% non-white. Ages ranged from 16- 24. Sixty-six percent of respondents indicated that their disability (ASD) negatively impacted their time in high school, while only 3.7% of respondents indicated positive impacts. Thirty percent provided responses that were neutral, ambiguous, or un-codable as negative or positive. Ninety-one percent of respondents were able to identify at least one positive aspect of their experience in high school, and 85% were able to identify at least one negative aspect (another 10% indicated that they preferred not to think about/report negative aspects). Specific contributions of teachers, family, and peers to school experiences are reported in Table 2.

Conclusions: Our results have several implications for school professionals who support autistic students. First, school professionals should take proactive steps to encourage autistic students to consider the positive aspects of their diagnosis. Second, autistic students should be supported in developing peer friendships that are emotionally supportive, and relationships with teachers or caregivers that provide help, attention, and care. Finally, as nearly a third of respondents reported having been bullied in high school, school professionals should work with the general population of students to prevent bullying and other forms of peer aggression toward autistic students.

241 **242.241** Taking Care of Their Child or Themselves? Adujsting Parent-Mediated Interventions to Answer the Various Needs of Parents Having a Toddler Suspected of ASD

A. J. Beaudoin[1]*, G. Sebire*[2] *and M. Couture*[3]*, (1)Rehabilitation, Université de Sherbrooke, Sherbrooke, QC, Canada, (2)Pediatrics, McGill University, Montreal, QC, Canada, (3)Rehabilitation, Universite de Sherbrooke, Sherbrooke, QC, Canada*

Background: Parent-mediated interventions may be an interesting alternative to increase timely access to interventions, especially during the period surrounding the diagnosis assessment for ASD. Although parents are the main actors in parent-mediated interventions, few studies have examined the impact of parent-mediated interventions on parental well-being.

Objectives: This sequential explanatory mixed methods study aimed to: 1) describe the impact of a 12-week parent-mediated intervention on parental outcomes (satisfaction, sense of competence, stress), and 2) identify potential factors associated with these outcomes based on parents' experience with the program.

Methods: Thirteen families with a toddler (12-30 month old) suspected of ASD were randomized either in the Intervention group (n=7) or the Waitlist group (n=6). Quantitative analyses of the direct impact of the intervention were conducted using the change in parental outcomes between assessment times T1 (baseline) and T2 (post-intervention for the Intervention group; second baseline for the Waitlist group) separately for the two groups. Then, a combined analysis looked at the effect of time comparing scores at baseline, post-intervention and follow-up for the combined group (Intervention and Waitlist groups merged). Qualitative interviews were conducted with a subsample of 6 families after receiving the intervention and analyzed independently by two evaluators. Finally, quantitative and qualitative data were compared for convergence and divergence, and then integrated, resulting in a more in-depth understanding of the impact of the parent-mediated intervention based on parental perspectives.

Results: Parents reported a high level of satisfaction with the intervention. Quantitative data revealed a stabilizing effect on parenting sense of competence compared to a decrease in the control group (PSOC Efficacy scale; p=.048; ES=.46). There was a trend toward reduced parental distress (PSI-SF; p=.141; ES=.48) during the intervention. Qualitative data pointed up the importance of providing: 1) early parental training about ways to stimulate their child, and 2) social support for parents in the stressful period surrounding the diagnosis. More precisely, parents were positive about being involved in stimulating their child and liked being able to take action, which gave them a sense of competence. However, they also highlighted their need for social support, especially during the stressful period surrounding the diagnosis assessment of their child. Parents felt torn between improving their skills and confidence in stimulating their child and reaching out for social support.

Conclusions: This study highlights the importance of considering the delicate balance between providing educational support to enhance parents' sense of competence and offering targeted social support for parents of children suspected of ASD.

242 **242.242** The 2016-2017 Iacc Strategic Plan's New Objectives and Trends in ASD Research Funding

J. Rava[1]*, O. Celestin*[2] *and S. Daniels*[3]*, (1)National Institute of Mental Health, Office of Autism Research Coordination (OARC), Rockville, MD, (2)OARC, NIH/NIMH, Bethesda, MD, (3)National Institute of Mental Health (NIMH), Rockville, MD*

Background: The Interagency Autism Coordinating Committee (IACC) is a federal advisory committee composed of federal officials and public stakeholders; it was established by Congress to coordinate activities concerning autism spectrum disorder (ASD) within the U.S. Department of Health and Human Services (HHS) and among member federal agencies. The IACC produces an annual *Strategic Plan*, providing a framework to guide the efforts of federal and private funders of autism research. For the *2016-2017 IACC Strategic Plan*, the Committee formulated new objectives for each of the seven research question areas. The 23 new objectives address critical gaps and opportunities they perceived in the current research landscape.

Objectives: The Office of Autism Research Coordination (OARC), which coordinates and manages the Interagency Autism Coordinating Committee (IACC), will present the new *2016-2017 IACC Strategic Plan for Autism Spectrum Disorder* objectives along with analysis on funding trends towards

these objectives and the new recommended budget for U.S. investment in ASD research.

Methods: Each question in the *Strategic Plan* includes an Aspirational Goal, or long-term vision for the question, as well as a description of the state of the field; the needs and opportunities in research, services, and policy; and three to four broad objectives for each question topic. There is also one cross-cutting objective on the topic of ASD in females. Data on individual research-related projects is aligned with objectives in the *IACC Strategic Plan*, providing an accounting of how much funding has supported projects related to *Strategic Plan* objectives and highlighting trends.

Results: OARC has collected U.S. ASD research funding data for 2016 and 2017 and aligned research projects with the 23 objectives in the *2016-2017 Strategic Plan*. The overall ASD funding amounts for 2016 and 2017 are compared to the Committee's recommended annual budget (2015-2020). Funding data will provide information on if the Committee's objectives are being met as well as the Committee's budget recommendations.

Conclusions: The *2016-2017 IACC Strategic Plan* for ASD along with the recent analysis on ASD research funding will provide an insightful overview of the state of autism research.

243 **242.243** The 2016-2017 Iacc Strategic Plan's New Objectives and Trends in ASD Research Funding

*J. Rava[1] and **O. Celestin**[2], (1)National Institute of Mental Health, Office of Autism Research Coordination (OARC), Rockville, MD, (2)OARC, NIH/NIMH, Bethesda, MD*

Background: The Interagency Autism Coordinating Committee (IACC) is a federal advisory committee composed of federal officials and public stakeholders; it was established by Congress to coordinate activities concerning autism spectrum disorder (ASD) within the U.S. Department of Health and Human Services (HHS) and among member federal agencies. The IACC produces an annual *Strategic Plan*, providing a framework to guide the efforts of federal and private funders of autism research. For the *2016-2017 IACC Strategic Plan*, the Committee formulated new objectives for each of the seven research question areas. The 23 new objectives address critical gaps and opportunities they perceived in the current research landscape.

Objectives: The Office of Autism Research Coordination (OARC), which coordinates and manages the Interagency Autism Coordinating Committee (IACC), will present the new *2016-2017 IACC Strategic Plan for Autism Spectrum Disorder* objectives along with analysis on funding trends towards these objectives and the new recommended budget for U.S. investment in ASD research.

Methods: Each question in the *Strategic Plan* includes an Aspirational Goal, or long-term vision for the question, as well as a description of the state of the field; the needs and opportunities in research, services, and policy; and three to four broad objectives for each question topic. There is also one cross-cutting objective on the topic of ASD in females. Data on individual research-related projects is aligned with objectives in the *IACC Strategic Plan*, providing an accounting of how much funding has supported projects related to *Strategic Plan* objectives and highlighting trends.

Results: OARC has collected U.S. ASD research funding data for 2016 and 2017 and aligned research projects with the 23 objectives in the *2016-2017 Strategic Plan*. The overall ASD funding amounts for 2016 and 2017 are compared to the Committee's recommended annual budget (2015-2020). Funding data will provide information on if the Committee's objectives are being met as well as the Committee's budget recommendations.

Conclusions: The *2016-2017 IACC Strategic Plan* for ASD along with the recent analysis on ASD research funding will provide an insightful overview of the state of autism research.

244 **242.244** Family Capacity Building through Parent-Mediated Intervention for Children with Autism

***X. Liu**[1] and H. Schertz[2], (1)Indiana University - Bloomington, Bloomington, IN, (2)Indiana University, Bloomington, IN*

Background: Research and current policy has highlighted the importance of supporting families and building family capacity to support the learning of children with autism spectrum disorder (ASD; Carter et al., 2009; IDEA, 2004). Parents who deliver intervention reported reduced stress and increased confidence in parenting a child with ASD (Woods and Brown, 2011). However, few studies have assessed parent learning and these effects on child outcomes. The aim of this study was to examine parent outcomes from the Joint Attention Mediated Learning (JAML) intervention. JAML was designed to improve preverbal social communication for toddlers with ASD through parent-mediated play-based interaction (Schertz, Odom, Baggett, & Sideris, 2018).

Objectives: To determine differences between intervention and control groups in parents' use of mediated learning principles and in parent-child social engagement

Methods: Intervention Coordinators (ICs) conducted weekly 1-hour home-based sessions with parents for 32 weeks. The ICs facilitated parents' learning of five mediated learning principles: focusing on social interaction (FO), organizing/planning for engagement (OP), encouraging self-reliance (EN), giving meaning and promoting motivation for engagement (GM), and expanding engagement across environments. Each week parents received conceptual guidance on the use of principles to promote child learning based on the child's current targeted outcome. This guidance included "Ideas Other Parents Have Used" in verbal and written forms and with video examples of other parents applying the principles. Further, ICs guided parent reflection on their use of the principles by reviewing videos of parent-child interaction. Control group participants were not exposed to the intervention until after post-intervention data were collected.

A total of 58 parent-child dyads from the larger three-site JAML study (the first 20 participants from each site minus two with missing data) were included in this study. Toddlers aged 30 months or younger who met ASD criteria were randomly assigned in pairs within sites to experimental or control groups. The Mediation of Social and Transactional Engagement Measure (MOSTE; Schertz & Horn, 2018, unpublished) was used to assess FO, OP, GM, and EN, parent and child demeanor/affect (PD & CD), and transactional social orienting (SO). Using 10-minute parent-child interaction videos that had been recorded pre- and post-intervention for intervention and control group participants, three independent observers coded 40 15-second intervals for occurrences of targeted outcomes. Inter-rater reliability was established and maintained between coders (kappa=.85). A one-way MANOVA was used to examine the group differences.

Results: No pre-intervention differences were found between groups in FO, OP, EN, GM(d=.11, p=.29). Significant advantages were found for the experimental group in FO, OP, EN, GM and PD (d=.24, p=.01) at post intervention assessments, indicating that parents in the experimental group increased their learning of mediated learning principles. Significant differences also favored the experimental group for SO (d=.14, p=.02) at post

intervention assessment.

Conclusions: The results support the usefulness of targeted professional guidance in parent-mediated intervention to help parents build their capacity to mediate child learning. Replication is needed to further validate the effects of JAML or other interventions on parent mediation of child learning and its relation to child outcomes.

245 **242.245** The Comparative Effectiveness of Study Recruitment and Task Completion between Social Media and Clinical Sites in SPARK, an Online Research Initiative

V. J. Myers[1], *A. Daniels*[1], *B. E. Robertson*[1], *B. Han*[1], *N. Volfovsky*[1], *P. Feliciano*[1] *and W. K. Chung*[2], *(1)Simons Foundation, New York, NY, (2)Pediatrics, Columbia University, New York, NY*

Background:

Research has shown that social media is an effective tool for recruiting individuals for health research. One systematic review found benefits such as reduced costs, shorter recruitment periods, and better representation including improved participant selection in young and hard to reach populations. While social media may be effective at recruiting individuals to participate in research, less is understood about whether individuals recruited via social media are more engaged or if completion rates of study tasks are higher compared to research participants recruited through traditional approaches (e.g. direct contact from a clinical site).

Objectives:

The aim of this study was to compare recruitment and task completion between individuals and families who joined SPARK from January 31 to November 15, 2018 via social media outreach and those who joined through contact with a clinical site.

Methods:

Data from all individuals who enrolled in the SPARK study from January 31 to November 15, 2018 were included in this study. The referral source was defined by the web URL from which an individual joined, specifically a social media platform URL (e.g., Facebook) or through a clinical site-specific URL (e.g., https://sparkforautism.org/UNC). For both individuals and families (biological mother, father and proband), enrollment was defined as consent to the genetic component of the SPARK study (Y/N), and tasks were defined as completion of initial surveys (Y/N) and saliva kit return (Y/N).

Results:

During the study period, a total of 20,312 individuals and 2,243 families initiated the enrollment process in SPARK via social media, compared to 8,772 individuals and 1,815 families from clinical sites. However, for both individuals and families, those recruited through a clinical site were significantly more likely to complete online enrollment in SPARK as compared to those recruited through social media (p<.05 for both individuals and families). Forty nine percent (n=9,957) of individuals and 42% (n=947) of families recruited via social media completed their first round of online surveys compared to 51% (n=4,501) of individuals and 34% (n=611) of families recruited via clinical sites (p<.05 for both individuals and families). Among those recruited via social media, 31% (n=6,352) of individuals and 43% (n=975) of families returned their saliva kit(s), compared to 60% (n=5,260) of individuals and 70% (n=1,275) of families recruited via clinical sites (p<.05 for both individuals and families).

Conclusions:

This study suggests that social media advertising may lead to enhanced study recruitment compared to traditional methods such clinical site recruitment. However, individuals and families that were recruited through a clinical site were more likely to complete online enrollment and return their saliva kits. We also found that families recruited via social media are more likely to complete online surveys. A multi-modal recruitment approach that combines social media advertising with clinical site staff to assist with task completion may improve recruitment and study participation.

246 **242.246** The Cost of Caring: The Impact of Autism on Parental/Caregiver Workforce Participation

J. Ashburner, *Autism Queensland, The University of Queensland, Sunnybank, Australia*

Background:

Previous research has indicated that parents (or other caregivers) often reduce their workforce participation in order to care for their child on the spectrum. Limited information is available, however, on the characteristics of children that are associated with reduced parental employment, or parents' reasons for reducing their employment. Additionally, previous studies have focused on children, with little attention given to the workforce-participation restrictions of parents of adults on the spectrum.

Objectives:

This study explored (a) the percentage of parents who reduced their workforce participation in order to care for their son or daughter on the spectrum, (b) characteristics of the child or adult on the spectrum that can impact their parents' workforce participation, and (c) parents' reasons for reducing their employment.

Methods:

In response to an online survey, responses were received from 732 parents including parents of 85 children yet to start school, 403 primary school-aged children, 175 secondary school-aged children, and 69 young people who had left school. Descriptive and inferential statistics were used to analyse data on parental workforce participation rates and the characteristics of young people that impact their parents' workforce participation. Content analysis was used to analyse the open-ended responses on the parents' reasons for their need to reduce their workforce participation.

Results:

Sixty-eight per cent of parents of children yet to start school, 67% of parents of primary school-aged children and 60% of parents of secondary school-aged children said that they work less hours or did not work, because of the need to care for their child on the spectrum. A significant minority (47%) of parents of adolescents and adults on the spectrum who had left school, had reduced their workforce participation to care for their son or daughter. Co-occurring anxiety disorders in the primary and secondary school-aged children and the young adults were significantly

associated with the parents' reduced workforce participation. Specific learning disorders in the primary school-aged children and attention deficit disorders in the young adults were also significantly associated with their parents' reduced workforce participation. The reasons that parents gave for reducing their employment included (a) frequently reduced school attendance due to school refusal and/or parents being asked to collect the child early, (b) a lack of autism-friendly after-school and vacation care, (c) the need to take the child to appointments, (d) the need to home-school the child, and (e) the child's mental health issues. Parents of adults who had left school also described the need to provide support for mental health issues, the need to transport the young person to work or tertiary education, as well as the need to support the young person in basic activities of daily living. The financial impact of reduced parental employment was highly concerning for many families.

Conclusions:

These parental perspectives are enlightening in terms of the support needs of families. Additional supports such as autism-friendly schools, after-school and vacation care services, mental health services, and a range of programs for young adults would reduce the burden on families and enhance their workforce participation.

247 **242.247** The Decision to Participate in EHR Research: Factors Important to Adults with ASD

A. Edwards[1], *L. Turner-Brown*[2], *S. Andrews*[1], *M. Raspa*[1], *A. Wheeler*[1], *L. Wagner*[1], *R. Moultrie*[1] *and M. Frisch*[2], *(1)RTI International, Research Triangle Park, NC, (2)UNC TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: Electronic health records (EHR) can potentially provide large amounts of clinical data to researchers investigating autism spectrum disorders (ASD). Inclusive research design can lead to increased participant engagement and better outcomes. However, little research has investigated the perspectives of adults with ASD on sharing their EHR for research. These individuals may have much to gain from research participation, but they have many legitimate concerns. Understanding their preferences may help researchers enact more effective informed consent procedures, effect higher levels of participant engagement and ultimately, produce greater benefits.
Objectives:

- To investigate the preferences of young adults with an autism spectrum disorder (ASD) regarding research use of EHR data.
- To compare the preferences of adults with ASD with the preferences of young adults who are neurotypical (NT)

Methods: Adults with ASD and NT adults, aged 18-40, were invited to participate in an online survey about preferences for research using EHR. 207 NT adults completed the survey. As of submission, 129 adults with ASD have completed the ongoing survey with a recruitment goal of 200.

The survey uses a discrete choice experiment (DCE) to assess preferences for studies using EHR. A DCE uses random utility theory to explain choices individuals make. The DCE presents a series of questions asking participants to compare research studies and choose the one they prefer. Each study is depicted with different combinations of attributes that may influence the decision to share EHR. Combinations are generated using an experimental design algorithm that statistically varies combinations to estimate the probability that an individual will choose a specific option. Analyses reveal which attributes are most and least important to participants. Additional survey questions ask about demographics, adaptive skills, and healthcare experiences.

Results: DCE analysis results will be presented by plotting average preference weights by attribute and study population. Preferences of the two groups will be compared. Associations between preferences and demographic factors or health and behavioral variables will be explored.

Results for the NT group show significant preferences for research that uses deidentified data, is conducted by university researchers, investigates topics important to the individual, and returns study results. Preliminary data for the ASD group is inconclusive, possibly due to insufficient power. Current data shows less pronounced preferences which trend similarly to those of the NT group except for a preference for research using identifiable data.

Conclusions: Preliminary results indicate that individuals with ASD may be more likely to participate in research using identifiable data which is conducted by university researchers. Study topics important to participants and the return of study results may also influence their decision to participate in a study. Understanding the preferences of potential study participants with ASD may inform research design leading to increased participation rates and more impactful outcomes.

248 **242.248** The Impact of Social Stories on Neuroscience Research in ASD: A Qualitative Study of Parents' Perspectives

L. A. Alba*, A. Losh, J. Blacher and K. K. Stavropoulos, Graduate School of Education, University of California Riverside, Riverside, CA*

Background: Neuroscience research has provided helpful information about mechanisms underlying the development of ASD. Although neuroscience research provides pivotal findings, recruiting ethnically diverse participants presents a challenge. Research on participant perspectives suggests that minority individuals report high levels of distrust and limited knowledge about the risks and benefits of research[3]. Studies have shown that using social stories that describe steps about new situations may decrease stress in children with ASD[1,2]. However, the impact of social stories in parents of children with ASD is unknown. This study explored the effect of a social story on parents' willingness to bring their child with ASD to participate in neuroscience research.
Objectives:

1. What were the reasons parents reported for being willing/unwilling to bring their child to participate in neuroscience research?
    - Did these reasons, given at pre-test, differ between English and Spanish-speaking parents?
2. What were the reasons that parents reported for change from pre to post-test?
    - Did reasons given differ based on condition (presentation of the information)?
    - Did participation willingness at post-test differ between English and Spanish-speaking parents?

Methods: Eighty parents (43 Spanish-speaking, 37 English-speaking) of children with ASD participated in an online survey. Parents were randomly assigned to one of two conditions: the social story condition (N=39), illustrating a child participating in an EEG study, or the read condition (N=41), where they read a description of the EEG process. Before presenting conditions, parents provided reasons for willingness/unwillingness to

participate. After seeing the social story or reading the description (post-test), parents reported whether their willingness/unwillingness had changed and if so, were asked to elaborate on the reasons.

Results: At pre-test, a one-way ANOVA on willingness was conducted between Spanish and English-speaking parents. No significant differences were observed (p=.66). At post-test, the same ANOVA was run. No significant differences were observed (p = .18). Qualitative themes of willingness/unwillingness were analyzed at pre-test (Table 1). Of the 80 participants, 13 parents reported reasons for change (Table 2). Fifty-seven participants reported no change. Thirty-five parents remained willing to participate at post-test (social story N=20, read N=15), while 22 remained unwilling (social story N=11, read N=11).

Major themes differed across conditions. In the social story condition, change in willingness was in response to the type of study, whereas unwillingness was in response to child's behaviors and child previously completing an EEG. In the read condition, change in willingness was in response to the procedure being noninvasive and for advancing ASD research, whereas unwillingness was in response to: child's behaviors, needing more information, safety concerns, child's willingness, time commitment, or other.

Conclusions: Social stories may be a useful recruitment strategy to help parents better understand procedures associated with neuroscience research. In the social story condition, parents did not report needing more information or safety concerns about participating when compared to the read condition. Moreover, no differences in willingness to participate were found between English and Spanish-speaking families for pre or post-test. Thus, social stories may be an effective way to provide more information about neuroscience research to ethnically diverse populations.

249 **242.249** The Journey through Healthcare and Educational Services: Perspectives of Parents of Teens on the Autism Spectrum

E. Badone[1], *B. Di Rezze*[2], *I. O'Connor*[3], *G. B. Hall*[4], *R. Brennan*[5], *S. Georgiades*[2], *A. DiFazio*[6], *K. Fish*[2] *and T. Bennett*[7], *(1)Anthropology, McMaster University, Hamilton, ON, Canada, (2)McMaster University, Hamilton, ON, Canada, (3)McMaster Universtiy-Offord Centre, Dundas, ON, Canada, (4)Psychology, Neuroscience & Behaviour, McMaster University, Hamilton, ON, Canada, (5)Woodview Mental Health and Autism Services, Burlington, ON, Canada, (6)Hamilton-Wentworth District School Board, Hamilton, ON, Canada, (7)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA*

Background:

In summer 2018, a community-university partnership between MacART, the McMaster Autism Research Team, and McMaster University developed the Job-Train Program (JTP), a 13 week program providing vocational skills training and a job placement at McMaster with job coaches for 12 autistic students in Hamilton, Ontario, Canada. From varying socioeconomic backgrounds, all participants were credit bearing students in secondary school. To provide background information for the JTP about prevocational training and other supports students had accessed in their communities, interviews were conducted with their parents to document their experiences seeking and using services in the healthcare and educational systems.

Objectives:

To ascertain the extent to which existing publicly-funded healthcare and educational services had met the needs of this group of autistic adolescents.

Methods:

Interviews were based on open-ended questions from an interview guide generated by the research team. Interviews were conducted in family homes or public places that parents selected. Responses were recorded through note-taking during the interviews. Reports were prepared on each family's experience, using a phenomenological perspective, and common themes were identified among families.

Results:

Ten parents were interviewed. Nine themes emerged from the interviews.

Useful Services Available. Most parents reported having received some helpful services from local healthcare and educational systems.

Difficult Elementary School Years. Most parents reported that their child's situation had been precarious in elementary school. Difficulties with school services involved accessing educational assistants and assistive technology, communication problems with school personnel, and bullying.

Importance of Confirmed Diagnosis. Parents reported that their child's situation improved once a diagnosis of autism had been confirmed, facilitating access to services.

Specialized Highschool Classes. At the highschool level, Social Communication Classes offered by the public school board were perceived by parents as highly effective in meeting student needs, although there were a limited number of places available.

Reliance on Private Health Insurance. Many parents, especially those with private health insurance coverage through their employers, reported paying privately for psychoeducational and/or psychological assessments which facilitated their child's diagnosis and access to services.

Importance of Parent Advocacy and Knowledge. Effective parent advocacy and a high degree of parent knowledge about available resources is crucial to obtaining good outcomes for autistic children and adolescents.

Socioeconomic Status. Higher socio-economic status appears to influence outcomes, since families can afford to pay privately for some services.

Invisible Disability. There is a perception among parents that services are particularly difficult to obtain for "high-functioning" autistic individuals because they have an "invisible disability."

Importance of Interpersonal Relationships. The quality of inter-personal relationships among parents, teachers and/or healthcare professionals, and the children and adolescents receiving services is also an important factor contributing to the success of these services.

Conclusions:

Preliminary conclusions suggest that programs like the JTP are a positive addition to existing services for adolescents on the autism spectrum. By preparing participants for the transition from highschool to the workplace, the JTP provided a unique form of support for students that would otherwise have not been available through the local healthcare and educational systems.

250 **242.250** The Leisure Participation Profiles of Australian Adolescents with ASD: The Interest-Participation Gap

B. Afsharnejad[1], *M. Falkmer*[2], *B. T. Milbourn*[3], *S. Bolte*[4], *M. H. Black*[3], *T. Lima Zarzuri*[5] *and* ***S. J. Girdler***[3], *(1)Autism Research Team, Telethon Kids*

Institute, Perth, Australia, (2)Curtin University, Bentley, Australia, (3)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia, (4)Center for Neurodevelopmental Disorders (KIND), Center for Psychiatry Research, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (5)Curtin University, Perth, Western Australia, Australia

Background: Adolescence is characterized as a time of social development during which peers become increasingly important. Adolescents typically spend a large proportion of their time engaging in various leisure pursuits important to their development, health and well-being. While previous research has examined differences in the participation of adolescents with Autism spectrum disorder (ASD) and their peers in leisure activities, little in known in regard their levels of interest in various leisure pursuits, nor if there is an interest participation 'gap'.
Objectives: To describe the interest and participation profiles of Australian adolescents with ASD in leisure activities and compare these profiles with those of their neurotypical peers.

Methods: A modified version of the Pediatric Interest Profiles (PIP) (Henry, 2000) captured the interest and participation profiles of adolescents with and without ASD, in the leisure domain including areas of clubs/community, socializing, creative, intellectual, relaxation, outdoor, exercise and sporting activities. PIP provides a measure of interest, level of engagement, and with whom activities are undertaken across 85 activities. A total of 143 Australian adolescents (118 with ASD, 25 typically developing (TD)) between the ages of 12-17 years (62% male) participated. For ASD participants diagnosis was confirmed via the ADOS with the PIP completed during a face-to-face interview. TD adolescents completed the PIP online. Activity participation rates between groups were compared using Chi-square test for independence.

Results: Both Adolescents with ASD and their neurotypical peers reported high levels of interest in the activity areas of socializing and relaxation activities, with listening to music and taking vacations of most interest across both groups. While adolescents with ASD had high levels of interest in various activities there emerged a significant interest/participation gap. TD adolescents participated in all activities ($p<0.05$) more than adolescents with ASD, with the exception of sporting activities ($p>0.05$). In relation to 'who they do the activities with', adolescents with ASD more frequently participated on 'their own' or with 'their families' than 'with friends' compared to their TD counterparts in intellectual activities (playing with computer ($\rho=0.005$); math ($\rho=0.009$); politics ($\rho=0.006$); History ($\rho=0.005$); debates ($\rho=0.028$); literature ($\rho=0.034$); reading ($\rho=0.009$)). This pattern was repeated in socializing activities where TD peers participating more frequently with friends (going to: arcades ($\rho=0.003$); cinema ($\rho<0.001$); parties ($\rho=0.035$); shopping mall ($\rho=0.002$) and sporting events ($\rho<0.001$)).

Conclusions:

While adolescents with ASD show high levels of interest in a range of activities, particularly those social in nature, their participation rate falls significantly below that of their TD peers, with the exception of sporting activities which were most frequently engaged in at school. Clearly, despite high levels of interest in leisure activities adolescents with ASD experience significant participation restrictions. It is likely that challenges in social communication and interaction experienced by adolescents with ASD act as barriers to participation, particularly with friends. These findings highlight the importance of developing interventions which bridge the interest participation gap for adolescents with ASD.

251 **242.251** The Process of Autism Diagnosis and Access to Services: Zeibabwean and Ethiopian Parents 'view

W. A. Zeleke[1] *and M. Chitiyo*[2]*, (1)Counseling, Psychology and Special Education, Duquesne University, Pittsburgh, PA, (2)Counseling Psychology and Special Education, Duquesne University, Pittsburgh, PA*

Background: The number of children diagnosed with autism around the world is increasing. Unlike a few years ago, more about the disorder is known today, which facilitate the improvement of outcomes of the many children diagnosed with the disorder. However most of what is documented about autism today is based on researcher from the Western world. Limited research has been conducted about children with autism and their families in other part of the world, particularly Africa
Objectives: This presentation aims to address parents view and experience on their journey in getting diagnosis and accessing service for their children with autism in Ethiopia and Zimbabwe , the two African countries.

Methods: Using purposive sampling ,10 parents (five from each country) of children with autism were interviewed. A semi-structured in-depth interview is used to collect data. Data were analyzed using systematic content analysis.

Results: The result indicated that parents viewed the process of diagnosis as difficult and at times in accurate. They also identified several challenges including social stigma, strained family relationship, and lac of access to appropriate services.

Conclusions: Based on the results of this study it is recommended that parents and service provider of children with autism should be educated about child development and autism promote efficient diagnosis. It is also recommended that service provider working with children with autism should collaborate with the parents in order to improve the treatment outcomes of children.

252 **242.252** The Types and Rates of Stigma Experienced By Parents and Carers of Children with Autism Spectrum Disorder (ASD) or 22q11.2 Deletion Syndrome (22q11DS) and Aggression: A Systematic Review.

L. Swaab[1]*, J. Wroe*[2]*, A. J. Woolard*[3]*, J. Goodwin*[4]*, L. McCormack*[5] *and L. E. Campbell*[5]*, (1)School of Psychology, The University of Newcastle, Newcastle, Australia, (2)University of Newcastle, Newcastle, NSW, Australia, (3)University of Newcastle, Australia, Callaghan, Australia, (4)Institution of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom, (5)School of Psychology, University of Newcastle, Newcastle, Australia*

Background: Young people with a neurodevelopmental disorder are three to four times more likely to experience psychological disorders (particularly anxiety and mood disorders) than those in the general population. Challenging behaviours often co-occur in children with neurodevelopmental disorders. The most common behavioural challenge for young people with neurodevelopmental disorders, their families and their service providers, is aggression. Research has shown that up to 68% of young people with a neurodevelopmental disorder display aggressive behaviours. Aggression can cause social isolation and low quality of life for the individual and can have significant ramifications for family members and carers.
Objectives: This systematic review was interested in gaining an insight into how much is currently understood about the impact a child with a neurodevelopmental disorder, who behaves aggressively, has on parents and carers. In particular, the purpose was to identify what the available literature shows about the types and rates of stigma experienced by parents and carers of children with autism spectrum disorder (ASD) or 22q11 Deletion Syndrome (22q11DS), with aggression.

Methods: In accordance with the PRISMA guidelines, six databases were searched and studies were systematically screened against scheduled inclusion criteria. 23 articles met the inclusion criteria. Of these, 15 were included in an analysis of the rates and types of stigma experienced by parents and carers of children with ASD or 22q11DS, with aggression. A grey literature search was also conducted resulting in two additional articles.

Results: The analysis showed that stigma was identified within the ASD cohort; however, it was rarely specified in the title or abstract. Further scrutiny of the results and conclusion sections in the full texts was required to identify stigma. We found that stigma was often discussed in terms of judgement or isolation. Most commonly, public stigma and self-stigma were experienced. There were no results for the 22q11DS cohort.

Conclusions: Findings demonstrate that parents and carers raising a child with ASD, who is aggressive, experience stigma on a regular basis and would benefit from more understanding from professionals such as teachers, clinicians, medical staff, politicians and policy makers, as well as from the public. The structure of the options currently offered by the education system also presented significant challenges for these families. Further research is needed to gain a greater understanding of the experience of stigma within ASD cohorts as well as the unexplored phenomenon of stigma associated with 22q11DS and aggression. A theoretical framework has been developed to assist in the underpinning of future research.

253 **242.253** Titre : An Analysis of the Support Needs of Fathers Living with a Child with Autism Spectrum Disorder

C. Bédard[1,2]*, É. Milot*[1,2] *and S. Tétreault*[3,4]*, (1)School of social work and criminology, Laval University, Québec, QC, Canada, (2)Réadaptation, Centre interdisciplinaire de recherche en réadaptation et en intégration sociale (CIRRIS), Québec, QC, Canada, (3)Occupational therapy, University of Applied Sciences and Arts, Lausanne, Switzerland, (4)Réadaption, Centre interdisciplinaire de recherche en réadaptation et en intégration sociale (CIRRIS), Québec, QC, Canada*

Background: The support needs of fathers living with a child with autism spectrum disorder (ASD) are rarely documented in the scientific literature. In fact, most research present mothers perception. That explain why support services offered to families seem to be more adapt to women, without integrating the needs of both parents. This findings supports the relevance of documenting father's experience and needs. It is also important to note that a high number of families living with a child with ASD experience a separation or a family restructuring. Step-parents are called on more and more to play a significant role in the life of the child and very little research has been done on their experience.
Objectives: The goal of this presentation is to present a portion of the results collected as part of a master's level research project in social work. This research project focussed on the comparisons between the needs of parental figures of children with ASD between 5-12 years of age. The participants were encouraged to express their needs for support as a parent and as a partner in a couple. This presentation will focus mainly on the support needs of fathers and stepfathers.

Methods: A review of the publications on the parental need for support allowed for particularities related to the father's experience to come out. Next, four fathers and one step father were invited to share their perspectives during focus group (n=3) or individual interview (n=2). Qualitative data were treated following Paillé et Mucchielli (2016) directives for thematic content analysis.

Results: All fathers indicate their limited knowledge about services offered to families. They claimed that it was the spouse who usually sought the services available. Fathers tend to be very preoccupied about schooling and socialisation of the child. They would like to have more strategies to support the development of the autonomy of their child. They wish to participate in more social activities and hobbies as well as to rest. Finally, the fathers mentioned a desire to attend practical training sessions on ASD. They prefer training that is more practical than theoretical.

Conclusions: A better understanding of the needs of fathers and stepfathers involved in families of a child with ASD is essential for optimising the practices of professionals who are also involved in daily life. Future research should look to developing how services can be adapted to support the reality of fathers and stepfathers.

254 **242.254** Toward Increased Self-Determination of Autistic Individuals: Perspectives of Autistic Adults

J. Ryan*, Rehabilitation Medicine, University of Alberta, Edmonton, AB, Canada*

Note about language: Consistent with the preference of autistic individuals, this abstract is written with identity-first language.
Background: Self-determination enhances quality of life. It is a fundamental human right, regardless of disability, as confirmed in the 2006 United Nations' *Convention on the Rights of Persons with Disabilities,* ratified by Canada in 2011. However, autistic individuals have lower levels of self-determination than their non-autistic peers, including peers with other developmental disabilities.

Objectives: What can be learned from independent autistic adults that would enhance autism service provider practices to support self-determination of autistic individuals?

Methods: A research advisory team was formed that included the Executive Team of a large community autism service provider and an autistic individual. Six interviews with independent autistic adults were conducted using an interview guide co-created by the autistic member of the advisory team and the researcher. Interviews took place in person (n=5) or over Skype (n=1). Interview questions addressed participants' interpretations of and experiences with self-determination, as well as potential strategies to improve self-determination. Interviews were audio-recorded and transcribed verbatim. The researcher generated initial codes and potential themes, guided by Braun and Clarke's six stage approach to thematic analysis. These themes were then reviewed and refined with the assistance of the Executive Team members of the research advisory team. A neurodiversity lens was employed throughout the process. This lens positions autistic individuals as equal citizens while recognizing that some individuals will require supports to enact their citizenship. As such, all data was considered equally valid and important, even if it did not align with the researcher's interpretation of self-determination.

Results: Participants included four men and two women. One participant lived on her own, one participant lived with his mother, three participants lived with their spouses and/or children, and one, a university student, lived with roommates. All participants used verbal language to communicate. Two overarching themes emerged: (1) individual factors related to self-determination, and (2) systemic factors related to self-determination. Within each theme, data were organized related to enablers of, barriers to, and strategies to improve self-determination. Strategies to support individuals primarily related to teaching skills (e.g., communication, stress management, social skills) and working from an individual's interests and strengths. Strategies to support systemic change primarily focused on self-advocacy and broad autism education.

Conclusions: Self-determination is complex and achieved via multiple means and strategies. Independent autistic adults all reinforced the

importance of including autistic voices in all that affects them. Strategies to directly engage autistic individuals in service decisions and planning at autism service providers could enhance their self-determination and ensure targeted outcomes are relevant. The creation of Advisory Committees of Self-Advocates within autism service providers could help ensure their programs and services support self-determination.

255 **242.255** Traits, Traumas and Treatments: The Many Associations between ACEs and Autism

R. L. Dodds, *Special Education and Counseling, California State University Los Angeles, Los Angeles, CA; Special Education & Counseling, California State University Los Angeles, Los Angeles, CA*

Background: In recent years, trauma and adverse childhood experiences (ACEs) have been discovered to be elevated in children with ASD, but little is known about how ACEs and ASD are associated, and the magnitude of the impact of trauma on children with ASD.
Objectives: The purpose of the current scoping review is to (a) summarize the current understanding of the relationships between adverse childhood experiences and Autism Spectrum Disorder, (b) synthesize key findings, and (c) make therapy recommendations based on the identified literature.

Methods: To meet the purposes proposed in the previous section, the first author performed a scoping review of the literature. The search for studies included two reference databases; *PsycINFO* and *PubMed* and limited search results to peer-reviewed English-language articles published between January 1st, 2008 and May 31st, 2018. Search terms included; ACEs, adversity, trauma, social determinants, and filtered the results for "autism". A pool of 214 articles met all search criteria. The author then read the titles and abstracts of those articles meeting the search criteria and excluded those that were not within the scope of the research questions stated above, reducing the number of articles included to 53. The articles were then read and summarized in a table and subsequently grouped by thematic category. 12 articles were determined to be thematically unrelated and were removed from the review, leaving 41 articles in the final analysis.

Results: 41 articles were included in the final analysis and grouped under six thematic categories; *ACES and ASD*, *Trauma and ASD*, *Trauma and ASD-like traits*, *Pre and Post-Natal Risk*, *Caretaker Burden and Resilience*, and *Therapy Recommendations.* These subjects are discussed at multiple ecological levels with a primary focus on the impact on the individual with ASD.

Conclusions: This scoping review explored the literature of the past decade to illuminate multidirectional, multigenerational relationships amongst adversity and ASD traits. These findings highlight the need for pediatric screening for ACEs and therapeutic accommodations for children with ASD who have experienced complex trauma.

256 **242.256** Using Parent-Identified Strengths of Adolescents with Autism to Inform Transition Interventions

N. Warren[1], *B. Eatchel*[1], *A. V. Kirby*[2], *C. Wright*[3], *V. D'Astous*[4] *and M. Diener*[3], *(1)FCS, University of Utah, SLC, UT, (2)University of Utah College of Health, Salt Lake City, UT, (3)University of Utah, Salt Lake City, UT, (4)King's College London, London, UNITED KINGDOM*

Background: Adolescence is a critical time in which families of adolescents with autism spectrum disorder (ASD) plan and prepare for the future. Recent evidence suggests that parents' expectations during adolescence act as significant mediators of outcomes in adulthood (Kirby, 2016). However, few research studies use parents identified strengths to inform transition interventions. Our research uses a qualitative approach that allowed for in-depth exploration of parent visions of the future, which also revealed their perceptions of the strengths of their adolescents. Research in this area is needed to provide professionals with information to better meet youth's transition needs and inform strength-based transition interventions.
Objectives: To examine parental perceptions of the strengths of their adolescents with ASD.

Methods: We analyzed qualitative interviews from parents of youth with ASD. Using similar interviews conducted as part of three related research studies, we collected qualitative interviews with 41 parents of youth with ASD (4 females, 37 males). All the youth were verbally-competent and most had average or above-average IQ scores. In the interviews, parents were asked about their visions for the future related to their adolescent with ASD transitioning to adulthood. Interviews were semi-structured in nature, audio-recorded, transcribed verbatim, and were analyzed using multiple coders. Although questions did not specifically address strengths, all participants discussed the strengths of their children. Interviews were thematically coded and categorized to identify parent perceptions of youth strengths.

Results: The qualitative analysis suggests a wide variety of strengths among adolescents with ASD. These strengths grouped into 5 key domains: Creative Thinking (creative, innovative thinking), Cognitive Strengths, (science, math, language arts), Strength in Structure (routines, following rules), Hands-on Learning Style and Technology. The large majority of the parents identified their children as smart, with reported strengths in a range of areas. Additionally, parents viewed youth preferences for structure and consistency as a strength.

Conclusions: The results of this qualitative analysis suggest that parents are important informants of the strengths of youth with ASD. Related to the transition to adulthood, we encourage parents and professionals to consider these strengths when planning for adulthood. Many transition plans focus on social-communication challenges that might overshadow strengths. The most commonly recognized skill domains were Creative Thinking, Cognitive Strengths, and Structure, suggesting that a focus on these strengths may be particularly important when discussing future outcomes for youth with ASD. For example, priority areas of career exploration could include those fields that might target the youth's strengths. Although individual youth present with unique strengths and challenges, this study suggests that parents can play an important role during transition to harness strengths for more successful transition plans. Future research should focus on the incorporation of strengths that are balanced with an awareness of challenges when supporting the transition process for youth with ASD in adulthood.

257 **242.257** Vaccine Hesitancy and Attributions for Autism in the SPARK Cohort

R. P. Goin-Kochel[1], *C. G. Minard*[2], *L. C. Sahni*[3], *R. Cunningham*[3], *S. S. Mire*[4], *L. Berry*[1] *and J. A. Boom*[1], *(1)Baylor College of Medicine, Houston, TX, (2)ICTR, Baylor College of Medicine, Houston, TX, (3)Texas Children's Hospital, Houston, TX, (4)Psychological, Health, & Learning Sciences, University of Houston, Houston, TX*

Background: Although some data indicate that children diagnosed with autism spectrum disorder (ASD) are well-vaccinated until 2 years of age, new evidence suggests that vaccine receipt may decline later in childhood. Moreover, younger siblings of children with ASD often have lower rates

of vaccine receipt compared to both their older siblings and younger siblings of children without ASD. This suggests that parents of children with ASD may be at risk for becoming vaccine hesitant, resulting in concerns about vaccine safety and possible vaccine delay and/or refusal.
Objectives: To (a) estimate the prevalence of vaccine-hesitant parents (VHP) within the SPARK (Simons Foundation Powering Autism Research for Knowledge) cohort—a national sample of families with at least one member experiencing ASD—using the *Parent Attitudes About Childhood Vaccines* questionnaire (PACV; scores ≥ 50 indicate vaccine hesitancy); (b) describe attributions for ASD in this sample using the *Revised Illness Perception Questionnaire* for parents of children with ASD (IPQ-R-ASD); and (c) identify factors associated with vaccine hesitancy.

Methods: Invitations to participate in an online survey were emailed to 1,000 SPARK parents of minor children with simplex ASD; 225 parents (23%) responded. The majority were white (75%, *n*=168) and mothers (92%, *n*=207). Descriptive statistics were used to determine the prevalence of VHP, distribution of PACV scores, and average scores for IPQ-R-ASD subscales (Timeline-Acute/Chronic, Timeline-Cyclical, Consequences, Personal Control, Treatment Control, Illness Coherence, Emotional Representations). Multivariable logistic regression was used to estimate the odds ratio for vaccine hesitancy.

Results: Overall, 29% (65/225; 95% CI: 23%, 35%) of parents were vaccine hesitant. VHP had lower incomes (p=0.007), were less likely to be white (p=0.002), and were more likely to endorse accident/injury (13% vs. 4%; p=0.027), deterioration of the child's immunity (29% vs. 4.5%; p<0.001), diet (40% vs. 16%; p<0.001), environmental pollution (50% vs. 30%; p=0.007), general stress (47% vs. 26%; p=0.006), negative views (13% vs. 5%; p=0.038), own decisions (21% vs. 6%; p=0.002), own emotional state (27% vs. 13%; p=0.016), and toxins in vaccines (65% vs. 3%; p<0.001) as causes for their child's ASD. Compared to non-hesitant parents, VHP scored higher on the Personal Control (M=18.9 vs. 18.0, p=.011), Treatment Control (M=13.5 vs. 12.3, p<.003), Illness Coherence (M=15.5 vs. 14.3, p=.019), and Emotional Representations (M=18.2 vs. 16.0, p<.002) subscales of the IPQ-R. The final multiple logistic regression included two causes for ASD: general stress and vaccines. The odds of being vaccine hesitant were 3.3 (95%CI: 1.4, 7.6) times higher among parents endorsing general stress as a cause for their child's ASD and 61.5 (95%CI: 21, 180) times higher among parents endorsing toxins in vaccines as a cause.

Conclusions: Endorsement of general stress and vaccines as causes of ASD were associated with current vaccine hesitancy among SPARK parents. Based on IPQ-R subscales, VHP felt they had more control over their child's ASD, a clearer understanding of ASD, yet reported more negative feelings about their child's ASD compared to non-hesitant parents. This information could inform the development of preemptive vaccine-safety information targeted to parents of children with ASD.

258 **242.258** What's Next?!: Engaging Patients, Caregivers, and Stakeholders to Address Transitioning to Adulthood

S. N. Brasher[1], *J. Elder*[2], *S. Close*[1], *J. L. Stapel-Wax*[3] *and K. Martyn*[1], *(1)Nursing, Emory University, Atlanta, GA, (2)FCH, College of Nursing University of Florida, Gainesville, FL, (3)Emory University School of Medicine, Atl, GA*

Background: Recent estimates indicate 1 in 59 children are diagnosed with autism spectrum disorder (ASD). Each year in the United States, approximately 50,000 of these youth transition to adulthood.Given that ASD emerges in early childhood, research and interventions have largely focused on children with ASD and not older youth. Another concern is that youth with ASD often have complex medical and psychiatric comorbidities (e.g., seizures, anxiety, depression, sleep disturbances, gastrointestinal disorders) in addition to the core symptoms of ASD (e.g., impairments in social interaction, communication deficits, repetitive behaviors). Thus, it is not surprising to find that research suggests young adults with ASD have poorer transition outcomes compared to peers with other disabilities. Clearly, there is a knowledge gap regarding the complex transition needs of young adults with ASD.
Objectives: This study had two primary objectives. First, to form partnerships between patients, caregivers, and stakeholders to gain insight into the challenges encountered during the transition phase of ASD. Second, to develop comparative effectiveness research questions alongside patients, caregivers, and stakeholders to address these challenges.

Methods: A patient-centered outcomes research (PCOR) approach was used to form partnerships among adolescents and young adults with varying degrees of ASD severity ages 14-36, caregivers, clinicians, independent living facility directors, educators, directors of medical and adult ASD services, patient care coordinators, advocates, special needs lawyers, legislative experts, and researchers. Patients and stakeholders were divided into six groups and met within their respective communities over a 12-month timeframe. Groups were facilitated by patients, caregivers, and stakeholders. An Autism Advisory Board (AAB) consisting of patients, caregivers, and stakeholders met monthly to provide overarching guidance to the project. Field notes were collected from all meetings. Qualitative content analysis was used to evaluate recurrent themes.

Results: This study identified seven key areas of transition in ASD (e.g., healthcare, self-advocacy, independent living skills, safety, career/job, social/relationships, and education) that have not been adequately addressed in research from the patient and stakeholder viewpoint. Additionally, this study identified the presence of racial and gender differences in the transition phase that presented unique challenges and needs. Lastly, patients and stakeholders identified four comparative effectiveness research (CER) questions to address the seven key areas of transition. CER questions focused on delivery methods of interventions, mentor models, peer navigators, and transition readiness assessment tools.

Conclusions: The transition from childhood to adulthood represents a tumultuous time for most, but especially for young adults with ASD and their families. This project demonstrated that a PCOR approach provides a unique opportunity for patients and stakeholders to identify their needs and to shape future research that is responsive to their needs. The use of this approach was critical in creating a deeper understanding of the complex needs of transition-age young adults with ASD and informing meaningful ways to address these needs. Patients, caregivers, and stakeholders identified several gaps in research, care, and services for individuals with ASD transitioning to adulthood. New research is currently being conducted by the partnerships formed in this PCOR study to advance this critical foundation.

259 **242.259** "I Am Different Because I Have ASD Sibling": A Qualitative Study on Siblings of ASD Child in Lithuania

R. Buivydaite[1], *C. Newton*[2] *and A. Prasauskiene*[3], *(1)University of Oxford, Oxford, United Kingdom of Great Britain and Northern Ireland, (2)Kenya Medical Research Institute, Kilifi, KENYA, (3)Psychiatry, Lithuanian Health University, Kaunas, Lithuania*

Background:
The relationship among the siblings is the longest lasting relationship among humans (Beyer, 2009). Sibling studies are extensively researched area (Beyer, 2009). However, there is still less known about the relationship among siblings when one of them has ASD and the existing findings

are mixed (Benderix & Sivberg, 2007; Mascha & Boucher, 2006; Orsmond & Seltzer, 2007).

Objectives:

This was a novel study that aimed to look at the siblings' experiences in growing up with ASD sibling in Lithuania. Especially, to capture the different types of experiences: risk and prevention factors through the eyes to the sibling. We also considered age, gender and ASD severity which are usually not considered in previous studies.

Methods:

We have used qualitative methods to access more in-depth experiences of the participant's. We used semi-structured interviews. Total of 15 siblings agreed to participate, age range from 11-24 years, from 13 families. The data was than transcribed and analysed using NVIVO 12 software. We applied grounded theory analytic framework to understand the findings.

Results:

Lithuanian siblings reported stress due to responsibilities given to them. Participants were obliged to take care of their ASD sibling despite the birth order (being younger sibling) or age difference (being 10 years apart). They have shared about challenges of having ASD sibling such as behavioural problems of ASD, feeling "secondary child", experiences of stigma and embarrassment of their ASD sibling. This was reported by siblings who had brother/sister with severe symptoms of ASD. Despite of all the difficulties siblings reflected on positive aspects like being more understanding and able to cope better in challenging situations compared to their friends.

Conclusions:

The current study highlighted the impact of ASD on sibling's relationships. In addition, it informed about existing family dynamics from the sibling's point of view. While it is not possible to mediate sibling's age, gender or severity of ASD, there are strategies that can be employed to facilitate more positive relationships between sibling participants and ASD sibling and family as a whole.

260 **242.260** "It's Not a User-Friendly System": Mothers Realities of Raising Children with ASD

N. J. Reinders[1], *B. K. Redquest*[2], *L. Thompson*[3], *P. J. Bryden*[1] *and P. C. Fletcher*[1], *(1)Kinesiology and Physical Education, Wilfrid Laurier University, Waterloo, ON, Canada, (2)Centre for Addiction and Mental Health, Toronto, ON, Canada, (3)Ministry of Education, London, ON, Canada*

Background: Mothers raising children with Autism Spectrum Disorder (ASD) experience vast challenges when navigating the diagnostic process, medical system, funding programs, all while managing their own self-care needs.
Objectives: Through the theoretical orientation of phenomenology, this study sought to understand the lived experiences of mothers raising children with ASD, including diagnosis, symptoms, struggles, lessons learned, and advice for others.

Methods: Eleven biological mothers from the Region of Waterloo were interviewed for this research and many themes emerged, ranging from the diagnostic process, school experiences, therapies, and coping mechanisms.

Results: For the purpose of this presentation, the theme called "We fall in a gap" will be discussed, which includes the following subthemes: funding, programming, and mental health. Mothers discussed the availability of resources for families raising children with ASD, but many were not suitable for their children due to the spectrum nature of the disorder. For instance, programs may be tailored for boys, so mothers of girls do not feel welcome; or funding is available for those who require assistive devices, but not for all forms of therapy. In this way, mothers felt their needs were not being met adequately within the Region of Waterloo.

Conclusions: Several suggestions will be discussed for parents, program coordinators, health professionals, and policy makers in order to better meet family's needs.

261 **242.261** "Lo Ví En Facebook [I Saw It on Facebook]": The Role of Social Media in Informing Underserved Latino Parents about Autism

T. De los Santos[1], *I. Arriaga*[1], *A. Gulsrud*[1] *and D. Hayes-Bautista*[2], *(1)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (2)David Geffen School of Medicine at UCLA, Los Angeles, CA*

Background: Social media platforms, such as Facebook, have become popular reference sites for gathering health information, including information related to autism spectrum disorder (Saha and Agarwal, 2015). The utility of social media sites has been explored and are found to have some success in providing social support and as a means to disseminate health related information among Latinos (Anguiano, 2017). Low-income Latinos, in particular, use social media at higher rates compared to other race/ethnic groups including non-Latino Whites (NLW) (Lopez et al., 2013).
Objectives: This study aims to understand the role of social media platforms in providing emotional and informational support to underserved/low-income Latino parents after they receive an autism-diagnosis for their children.

Methods: As part of this study, 22 self-identified Latino parents of children with ASD and 4 key informants (community leaders) were interviewed. Participants were recruited using snowball sampling and targeted Facebook advertisements. Criteria for study participation included residence in Los Angeles County, being of Latin American descent, and a parent of a child between the ages of 2 and 10 years with a professional diagnosis of ASD. Enrollment was limited to participants with low socio-economic status (SES) as defined by the U.S. Federal Poverty Guidelines used to determine financial eligibility for federal programs. In addition, key informants were eligible if they worked with low-income, Latino parents of children with autism. Focus groups and interviews were audio-recorded, transcribed verbatim, and independently coded for major conceptual models. Exploratory, qualitative analyses was conducted using a modified grounded theory approach. Six raters coded each transcript to ensure reliability. Data triangulation and methodology triangulation were employed to ensure validity and reliability of data interpretation.

Results: Parents reported heavily relying on social media platforms, such as Facebook and YouTube, for autism-related information after receiving a diagnosis for their child. They also reported that Facebook was one of the best ways to connect with other parents because it eliminated barriers to traditional methods of engagement, such as attending support groups. Participants reported using Facebook as a means to gather information, but also as a source of emotional support, endorsing feeling a sense of community through their online interactions with other parents. However, parents also endorsed concerns about unreliable resources being distributed across social media platforms. Community

partners reported relying on Facebook as a means to keep parents engaged and informed, particularly when the parents are unable to attend in-person support groups or when bilingual professionals were limited.

Conclusions: These findings confirm that low-income Latino parents are using social media for emotional and informational support, especially when they first receive their child's diagnosis. Understanding how Latino parents navigate and reference social media may facilitate initiatives to ensure that reliable and dependable information is accessible across social media platforms.

262 **242.262** Decision Makers Perceptions on the Current State of the Family Navigator Project in Quebec

A. Ibrahim[1], *I. Winkelmann*[2], *K. Shikako-Thomas*[3] *and M. Elsabbagh*[4], *(1)McGill University, Montreal, QC, Canada, (2)Douglas Mental Health University Institute, Montreal, QC, Canada, (3)School of Physical and Occupational Therapy, McGill University, Montreal, QC, Canada, (4)McGill University, Montreal, PQ, Canada*

Background: Families with an autistic child often experience stress as a result of the prolonged waiting period in accessing services in many communities. Our previous research in the Canadian context has shown that families experience significant barriers to access and coordinate care for their child, which can increase the burden on caregivers and prevent the delivery of necessary intervention services for their child. Navigation is defined as a professional-led model aiming to facilitate continuity of care and promote patient empowerment. Access to a Family Navigator is one of the policy priorities articulated as a strategy to address challenges in care coordination. However, there are currently no validated models for autism nor information on the potential active ingredients for effective delivery.

Objectives: To describe the perceptions of decision-makers on the Family Navigator model and the current and potential role of the Family Navigator strategy within public sector services.

Methods: Key informant open-ended interviews with decision makers within a large health care network in the province of Quebec (serving 37,4400 people). Of 22 decision makers, 8 were identified from the organizational chart of the health and social services network. They were included because their areas of involvement covered physical, intellectual deficiency, autism, mental health or youth protection. Interviews were audio-recorded and transcribed verbatim. Thematic analysis of interview transcripts was conducted by two independent reviewers using NVivo11.

Results: Emerging themes suggest diverging perspectives and experiences of Family Navigator functions across different levels of services (primary vs secondary vs specialist).This includes (a) the professional background of a Navigator, e.g., social worker vs educator, (b) whether their involvement is episodic (i.e. during transition periods and crisis), or continuous (addressing the various needs as they emerge), and (c) their initial point of contact (i.e., around time of diagnosis vs. in primary care around the time of initial concerns). In terms of current implementation of navigation functions in health and social services, decision makers identified duplication in the functions in first and second line services which can be addressed by increasing communication and collaboration between care teams. Finally, beyond public sector health and social services, the role of the community organizations was highlighted as a potential facilitator of navigation functions.

Conclusions: Decision-makers need a more concrete definition of the role and functions of Family Navigators in health and social services. Navigation is perceived as an essential strategy in supporting families of autistic children however the importance of having a Navigator assigned to one person early on across different levels of services is crucial for its beneficial outcomes. Future directions may include adaptation of evidence-based models from other areas of research into the autism system of care.

263 **242.263** Is There a Relationship between Cyber-Dependent Crime, Autism and Autistic-like Traits?

K. L. Payne[1], *A. Russell*[2], *K. L. Maras*[3], *D. Rai*[4], *R. J. Mills*[5] *and* ***M. Brosnan***[6], *(1)Psychology, University of Bath, Bath, United Kingdom, (2)Psychology/Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (3)Psychology, Centre for Applied Autism Research, University of Bath, Bath, United Kingdom, (4)Population Health Sciences, Bristol Medical School, Centre for Academic Mental Health, Bristol, United Kingdom, (5)Psychology, Research Autism, Bath, UNITED KINGDOM, (6)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland*

Background:

A significant proportion of cybercrimes are termed 'cyber-dependent', that is, crimes that require digital technology, such as hacking, phishing and Distributed Denial Of Service. Several high profile extradition cases for cyber-dependent crime, where the USA has attempted to extradite hackers from the UK, have involved autistic hackers. The number of such cases is very small and evidence for a link between autism and cyber-dependent crime has not been established. International law-enforcement agencies, however, report that autism appears to be more prevalent amongst cyber-dependent criminals than the general population - although no empirical evidence exists to confirm or refute this common perception.

Objectives:

To identify any potential relationships between cyber-dependent crime, autism and autistic-like traits.

Methods:

174 individuals aged 14 or older from the general population without a known record of offending anonymously completed an online questionnaire assessing demographic information, non-verbal IQ (Ravens Matrices-short), Autistic-like traits (AQ), explicit Theory of Mind (Social Know How), perceived support (ISEL), basic digital skills, advanced digital skills and number of illegal digital activities. 72 (41.3%) reported engaging in illegal cyber-dependent crime and 10 (5.7%) individuals reported a diagnosis of autism. The characteristics of the sample by the absence or presence of illegal digital activity are described in Table 1 below.

Results:

Those who had carried out one or more illegal digital activities were likely to be older, have a higher total AQ score, have greater advanced digital skills and were less likely to have had received a diagnosis of autism.

Table 1: Descriptive statistics of the sample by the absence or presence of any illegal digital activity (n=174)

	No Illegal Digital activity (n=102) Mean (SD)	One or more Illegal digital activity (n=72) Mean (SD)	p

Age mean	22.9 (11.1)	26.6 (8.5)	0.020
Male sex (n, %)	72 (70.6%)	42 (58.3%)	0.094
Total Ravens	9.9 (2.8)	10.4 (1.8)	0.168
Total AQ Score	20.6 (8.3)	24.4 (8.9)	0.004
Social Know How	8.4 (4.5)	9.4 (4.8)	0.140
ISEL 12	23.5 (7.1)	23.6 (8.3)	0.892
Basic Digital Skills	48.9 (2.7)	49.6 (2.2)	0.074
Advanced Digital Skills	29.4 (12.6)	43.8 (8.4)	0.000
Autism diagnosis (n, %)	9 (8.8%)	1 (1.4%)	0.038

Conclusions:

Cyber-dependent crime was significantly related to autism and autistic-like traits, in opposite directions. Higher autistic-like traits related to increased likelihood of computer-dependent crime, whereas a diagnosis of autism related to decreased likelihood of cyber-dependent crime. This is particularly interesting given that typically the autistic population has been found to be higher in autistic-like traits than the non-autistic population. Previous research has found that autism can also be associated with being honest and trustworthy, and cyber-dependent crime may be an area that distinguishes those with high autistic-like traits and those with a diagnosis of autism. Obviously, the numbers of autistic respondents in this initial study was small, limiting such potential implications. Age and experience were also important, whereas non-verbal IQ, theory of mind and perceived support were not.

264 **242.264** The Attractiveness, Trustworthiness and Desirability of Autistic Males' Online Dating Profiles

*J. Gavin[1] and **M. Brosnan**[2], (1)University of Bath, Bath, United Kingdom, (2)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland*

Background:

A lack of success through traditional, face-to-face dating has led some autistic adults to pursue relationships through online dating. Creating an online dating profile, however, is a process that requires a range of complex social skills, the ability to balance a number of social demands, and self- and other-awareness - all of which can be challenging for autistic people.

Objectives:

The study explored the relative desirability of online dating profiles that include autistic attributes and interests presented in a positive way compared to the same attributes and interests presented negatively. It also measured the relative desirability of online dating profiles with and without an explicit autism diagnosis being stated.

Methods:

Participants were 127 self-identified heterosexual females who were 'seeking a man' through online dating, with an average age of 20.4 years (range 18-25; sd=1.56). These respondents were recruited through an advertisement on social media.

Participants viewed one of six profiles, all of which featured the same profile photo and basic details, for instance height and ethnicity. However, the profiles differed in regards to what was written in the 'About Me' section. Two variables were manipulated, the first being whether a diagnosis of autism was explicitly stated ('I am autistic') or not, and the second being the wording used to describe the male's autistic-like attributes (positive, negative or neutral). The neutrally worded profile was taken from the world's most popular online dating site. The authors inserted five autism-relevant statements that were either negatively or positively worded (e.g. I do not find social situations easy vs I am happy in my own company) for autistic-like attributes.

The dependent variables were interpersonal attraction (physical, social and task attraction), trustworthiness, desire to date, and familiarity with autism was controlled for.

Results:

There was a significant main effect for autism label on physical attractiveness ($F(1,120)=6.87$, $p=.01$) and trustworthiness ($F(1,120)=5.00$, $p<.05$). Post-hoc independent t-tests identified that an explicit statement of a diagnosis of autism related to the image being perceived to be more physically attractive ($t(125)=2.44$, $p<.05$) and more trustworthy ($t(125)=2.33$, $p<.05$). There was a significant main effect of wording on social attractiveness ($F(2,120)=3.75$, $p<.05$) and task attractiveness ($F(2,120)=4.21$, $p<.05$). Post hoc independent t-tests identified that positive wording was associated with a significantly higher social attractiveness rating than negative wording ($t(81)=3.04$, $p<.01$) and approached significance for neutral wording ($t(81)=1.83$, $p=.07$). In addition, negative wording was associated with a significantly higher task attractiveness rating than positive and neutral wording ($t(81)=2.05$, $p<.05$; $t(81)=3.29$, $p<.001$; respectively). There were no significant two-way interactions between label and wording (all $p>.05$).

Conclusions:

Explicitly stating a diagnosis of autism and positively-worded attributes associated with autism related to enhanced perceived attractiveness in online dating profiles. It is interesting that an explicit statement of a diagnosis of autism related to enhanced perceived physical attractiveness (as the same photo was used in all conditions) and may be related to enhanced perceived trustworthiness. Positivity would seem to be related to enhanced perceived social attractiveness.

Poster Session
243 - Interventions - Non-pharmacologic - School-Age, Adolescent, Adult
11:30 AM - 1:30 PM - Room: 710

265 **243.265** Launch: Development and Implementation of a Transition Planning Program for Youth with Autism

V. R. Smith[1] *and K. C. Lowe*[2]*, (1)Educational Psychology, University of Alberta, Edmonton, AB, CANADA, (2)Sinneave Family Foundation, Calgary, AB, Canada*

Background:
It is uncommon for youth with autism spectrum disorder (ASD) to receive services to help them transition ***from*** childhood health, education and social service support systems of childhood services ***to*** adult services, activities, and systems of support. In fact, according to a recent report, only one fifth of youth with ASD receive any transition planning services (Kulhthau, et al., 2015) and the majority of these services focus only on employment and education (Gorter et al., 2011), not the full complement of domains that contribute to adult well-being.

The *Launch Program* was developed in response to family and community needs to have transition support and planning for youth with ASD. Development of the program was guided from consultation with family and community stakeholders and aims to support families and youth with ASD to identify their unique transition priorities across five life domains (i.e., 1) health and well-being, 2) education and employment, 3) communication and social relationships, 4) independent living skills and self-advocacy, and 5) legal and financial issues), help them to develop an Individual Transition Plan (ITP), and source resources in the community to meet their transition goals.

Objectives:

- To evaluate the *Launch* program impact, and
- To provide recommendations as Launch prepares to move forward from Phase One (development and pilot) to Phase Two (refinement and export to other community settings)

Methods:

A mixed method sequential explanatory design was used to address the research objectives. Questionnaires were completed by youth and their parents to better understand the program impact and implementation model. Questions addressed readiness for change, aspects that influence engagement (i.e., trust, cooperation, and diligence), key benefits of the program including skills, knowledge, and resources obtained, and barriers to implementing transition plans. Interviews were conducted with youth and their parents to help enrich understanding of the questionnaire results.

Results:

Fifty-eight families participated in the study. Youth presented with priorities from each of the five life transition domains. Social skills, communication, and relationships with peers were the most prevalent presenting concerns, with employment and employment supports higher for the clients who were older. Both parents and clients reported that they began Launch with a readiness to change and were engaged in the program, indicating that they trusted the clinicians and co-operated with them. Survey respondents indicated that they obtained knowledge, skills, and resources by participating in the program and there was a strong sentiment that the program served a vital guidance to help negotiate transitions to adulthood. Barriers to implementing the transition plans included personal, logistic, and resources difficulties. In addition, while the overwhelming response to Launch was positive, some barriers included issues related to the program including follow-up, adequacy of resources, and documentation.

Conclusions:

The Launch program components, delivery, and outcomes have the potential to contribute to the paucity of effective transition programming for youth with ASD. Proposed next steps include a Canada-wide scale out of Launch through the development of province-specific versions of the program, and training of local community facilitators to deliver transition planning workshops.

266 **243.266** Learning without Teaching: Social Performance-Based Intervention Promotes Gains in Social Knowledge in the Absence of Explicit Training for Youth with Autism Spectrum Disorder

B. Marro[1]*, E. Kang*[1]*, K. M. Hauschild*[2]*, K. M. Normansell*[2]*, T. M. Abu-Ramadan*[1] *and M. D. Lerner*[2]*, (1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY*

Background:
Children with autism spectrum disorder (ASD) display deficits in social knowledge, including formal social knowledge, facial emotion recognition (FER) and theory of mind (ToM; Mendelson, Gates, & Lerner, 2016). Traditionally, it was presumed that individuals with ASD *could not* acquire such knowledge without explicit teaching. Subsequently, most social skills interventions (SSIs) have employed a didactic approach (White et al., 2007). Recent literature shows improvements in overall social functioning using so-called "performance-based SSIs" (e.g., Lerner & White, 2015), where skills are taught implicitly via activities designed to potentiate prosocial engagement. However, it is unknown whether youth with ASD learn explicit social knowledge through these non-didactic, performance-based approaches.

Objectives:

To determine if performance-based SSIs can impact social knowledge in youth with ASD without explicit instructions.

Methods:

Youth with ASD participated in a randomized controlled trial of two performance-based social skills interventions (see Table 1). Both interventions aimed to provide enriched environments for reinforcing peer interaction and targeted specific social skills goals with minimal didactic instruction or instrumental reinforcement of skills (Lerner & Levine, 2007). The modified Children's Assertiveness Behavior Scale (CABS; Michelson & Wood, 1982; Wojnilower & Gross, 1988), and Test of Adolescent Social Skills Knowledge (TASSK; Laugeson & Frankel, 2006) assessed formal social knowledge. The Theory of Mind Inventory (ToMI; Hutchins, Prelock, & Bonazinga, 2012) assessed ToM and the Diagnostic Analysis of Nonverbal Accuracy (DANVA-2; Nowicki, 2004) assessed FER. All areas were assessed at baseline, endpoint, and 10-week follow up.

Results:

Generalized estimating equations (GEE; Hanley et al., 2003) were used to estimate effects of timepoints on change in dependent variables while accounting for nesting within groups (Table 1). There was a significant main effect of timepoint in CABS scores (Wald's χ^2= 6.56,p =.038) indicating that at endpoint youth had lower CABS scores than at baseline (Figure 1). There was a significant main effect of timepoint on TASSK scores (Wald's χ^2=10.31, p =.006) from endpoint to follow up. There was a significant main effect of timepoint on ToMI scores (Wald's χ^2=12.15, p<.001), evincing a

linear increase over time. There was no effect of timepoint on DANVA-2 Faces (Wald's χ^2=1.69, p=.43).

Conclusions: This is the first study to examine the effects of performance-based SSIs on social knowledge in youth with ASD. Findings indicate that such SSIs may improve aspects of social knowledge (formal social knowledge and ToM) without explicit, didactic teaching of social knowledge content. This was seen in both conditions, despite the absence of explicit teaching, contrary to extant theory suggesting that this should not occur. In contrast to previous reports on intensive performance-based community-administered SSIs (Lerner et al., 2011), we did not see results for FER. Factors such as dosage or the specific approaches used may be essential for acquiring a less explicit, formal aspect of social knowledge such as FER. Overall, these findings support the principle that youth with ASD are able to acquire aspects of social knowledge *without* direct teaching, provided there is sufficient scaffolding of the social context and activities are properly matched to outcomes.

267 **243.267** Malleability of Comorbid Anxiety and ADHD Symptoms and Moderating Effects across the PEERS® Intervention for Autistic Adolescents

A. J. McVey[1], *H. K. Schiltz*[1], *A. D. Haendel*[2], *B. Dolan*[3], *K. Willar*[4] *and A. V. Van Hecke*[5], *(1)Marquette University, Milwaukee, WI, (2)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (3)Medical College of Wisconsin, Milwaukee, WI, (4)Stanford University, Stanford, CA, (5)Psychology, Marquette University, Milwaukee, WI*

Background: Comorbid anxiety and ADHD symptoms are common among autistic adolescents, with rates of roughly 40% (van Steensel, Bögels, & Perrin, 2011) and 30-80% (Mattila et al., 2010), respectively. Additionally, each of these comorbid symptoms have been found to exacerbate social difficulties (Ames & White, 2011; Bellini, 2004). Social skills interventions may have secondary effects on anxiety (Corbett, Blain, Ioannou, & Balser, 2017; Lei, Sukhodolsky, Abdullahi, Braconnier, & Ventola, 2017; McVey et al., 2016; Schohl et al., 2014); secondary effects on ADHD are unknown. In one study of moderating effects, anxiety did not influence intervention response, but ADHD was associated with nonresponse (Antshel, Polacek, Dygert, Miller, & Faisal, 2011). More work is needed to better understand secondary effects on anxiety and ADHD symptoms and the potential moderating role of anxiety and ADHD symptoms on improvements *via* social skills intervention.
Objectives: The present study examined the malleability and moderating effects of anxiety and ADHD across the Program for the Education and Enrichment of Relational Skills (PEERS®).

Methods: One-hundred and thirteen adolescents aged 11-16 with IQ ≥ 70 were included in this *post hoc* study. Autistic adolescents were randomly assigned to an experimental or a waitlist control group as part of a larger randomized controlled trial. Parents reported upon social behavior *via* the Social Responsiveness Scale (SRS; Constantino & Gruber, 2002). Anxiety and ADHD symptoms were measured *via* parent-report on the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001).

Results: Gender and IQ were included as covariates in the following analyses, given that groups differed on IQ (Table 1) and gender was related to the CBCL ADHD Problems subscale ($r(99)=0.20$, $p<.05$). Four mixed model MANCOVAs were conducted. Results indicated improvements in some SRS subscales for the experimental, but not the waitlist control group (Table 2). For anxiety, results revealed nonsignificant main and interaction effects of Group, Time, and Group*Time. Exploratory paired samples *t* tests revealed that both groups showed declines across time (EXP: $t(41)=1.96$, $p=.056$); WL: $t(48)=2.91$, $p=.005$; Table 2). Results of ADHD also revealed nonsignificant main and interaction effects of Group, Time, and Group*Time. Exploratory paired samples *t* tests similarly revealed that both groups declined across time (EXP: $t(41)=2.29$, $p=.027$); WL: $t(48)=4.97$, $p<.001$; Table 2). Results examining the possible moderating effects of anxiety, ADHD, both, or neither, revealed a nonsignificant Group*Comorbidity*Time interaction ($p>.05$).

Conclusions: Some changes in social behavior were evident for the experimental but not the waitlist control group, consistent with prior literature (Laugeson, Frankel, Gantman, Dillon, & Mogil, 2012; Schohl et al., 2014). Declines in anxiety and ADHD were seen across the intervention for the experimental group, yet this pattern was also observed in the waitlist control group. Contrary to expectations, the presence of clinically-significant anxiety and/or ADHD symptoms did not moderate improvements in social behavior. Importantly, this evidence may suggest that, while it is unclear if PEERS® affects anxiety and ADHD symptoms, the integrity of the intervention is upheld for autistic adolescents with clinical levels of anxiety, ADHD, or both.

268 **243.268** Management and Intervention of the Children with ASD at Home Environment in a Developing Country

ABSTRACT WITHDRAWN

Background:
After assessing the child with ASD (Autism Spectrum Disorder) parents try to intervene the behavioral issue but most of the time parents do not know the proper way of ASD management. The Institute of Paediatric Neurodisorder and Autism (IPNA) in Bangabandhu Sheikh Mujib Medical University (BSMMU), Bangladesh, initiated home visit program for 35 Children with ASD who were admitted at IPNA Autism School in 2016. Home visit conducted by a team (at least two members must visit the child's home). This team consisted by: Paediatric Neurologist, Educational Psychologist, Head Teacher, Autism Instructor/Teacher, Counselor, Autism Teacher, Assistant Autism Teacher

Objectives:

Short term :

For Parents: Observed how parents dealt with child's behavior, Which types of methods and materials were followed by parents at home.**For Children:** Child's relationship with their family members, How they expressed own need at home and which place or task child liked most.

Aims:

For Parents: How they constructed work environment for child, How they built up materials and manage the child in future.**For Children:** How the child improved own self skill (ADL-Activities of Daily Living), How they coped/ shared own experience of emotion with others.

Methods:

Using semi-structured demographic questionnaires for observation/systematic observation (coding system), observer can give some intervention to the parents so that they can improve their management skills or how to deal with their ASD child. Each member of the team fill up Questionnaire developed by specialist team of IPNA Autism School and must deliver an evaluation report with the consultation of the expert team. For this purposes the child's activities of daily living (ADL), play, sharing and intimacy others information were taken. **Duration:** 1st Home

Visit: June 2016, 1st Follow-up Home Visit: June 2017

Results:

Both home (1st and 2nd) visit showed a clear structured improvement and involvement of the parents. Though a few numbers of parents didn't start to use each material utterly but most of the parents commenced the few PECS (Picture Exchange Communication System) item for some task. Comparison between two years improvement graphical representation shows that parents give a lot of effort on outing and self help activities (toileting, eating, and dressing) but structure routine and materials are not used enough. Parents commented that they need more technical structured training on making material and PECS item. IPNA Autism School home visit team also showed some pictured routine which were used in classroom and conduct some 1:1 task in front of the parents. Home visit is one kind of intervention technique that parents and other caregivers can use to help their children when professional services and school are not available.

Conclusions:

The strategies by the home visit team gave parents skills that improved how they interacted with their children and dealt with challenging behaviors. The goal was for the parents to help foster their children's communication and, when possible, their language skills. The emphasis was on skills that the parents and their children could use daily as they participated in activities at home and play.

269 **243.269** Mental Health Benefits of a Robot-Mediated Emotional Ability Training for Children with Autism: An Exploratory Study

A. P. Costa[1], *L. Kirsten*[2], *L. Charpiot*[3] *and G. Steffgen*[4], *(1)University of Luxembourg, Esch sur Alzette, LUXEMBOURG, (2)University of Trier, Trier, Germany, (3)University of Luxembourg, Esch-sur-Alzette, Luxembourg, (4)Institute for Health and Behaviour, University of Luxembourg, Luxembourg, Luxembourg*

Background: Children with Autism Spectrum Disorder (ASD) have a high prevalence of mental health problems that are linked to reduced emotional abilities. Therefore, interventions that teach emotional abilities are fundamental for their development. However, existing interventions are costly, of difficult access, or inefficient for children with ASD. Furthermore, children with ASD have a preference for sameness and routines that makes technology, and especially robots, an ideal medium to convey interventions that are suitable to their needs.
Objectives: The aim of the present exploratory study is to evaluate whether a robot-mediated emotional ability training is effective in enhancing the emotional ability and the mental health of children with ASD.

Methods: Using a pre-post training design, 12 children with ASD (all boys) aged between 8 and 14 years (M = 10.93; SD = 2.46) undertook a 7 week long emotional ability training mediated by a robot. Sessions took place weekly and lasted 1h each. Children were compared before (T1) and after (T2) the training on their emotional ability and their mental health. Emotional ability was measured through the parent-report measures Emotion Regulation Checklist (ERC; Shields & Cicchetti, 1997), Emotion Regulation Rating Scale (ERRS; Carlson & Wang, 2007), Self-Control Rating Scale (SCRS; Kendall & Wilcox, 1979), and the Alexithymia Questionnaire for Children (Rieffe et al., 2006); as well through a direct measure of children's use of emotion regulation strategies using the Reactive and Regulation Situation Tasks (Carthy et al., 2010). Mental health was measured through the parent-report measures Children Behavior Checklist (CBCL; Achenbach & Rescorla, 2001), Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997), and the Social Responsiveness Scale-2 (SRS-2; Constantino, 2002).

Results: It was found that regarding emotional ability, children's use of emotion regulation strategies in the Reactive and Regulation Situation Task, improved significantly after the training ($t(10) = 2.81$, $p < .01$) but no significant improvements were found on the parent-reported measures (ERC: $t(10) = 0.43$, $p = .34$; SCRS: $t(10) = 1.26$, $p = .12$), except for a marginally significant effect on children's emotional control (ERRS: $t(10) = 1.79$, $p = .05$). Regarding mental health, the training significantly reduced internalizing problems (CBCL: $t(11) = 1.91$, $p < .05$; SDQ: $t(11) = 3.19$, $p < .01$) and autism-related symptomatology (SRS-2: $t(11) = 3.24$, $p < .01$), but did not have an effect on externalizing problems (CBCL: $t(11) = 0.41$, $p = 34$; SDQ: $t(11) = 3.13$, $p = 07$).

Conclusions: Overall, the results of the present study are to be interpreted cautiously, they provide restricted evidence of positive effects of the robot-mediated emotional ability training in children's use of adaptive emotional abilities and in mental health issues such as depressive symptomatology and anxiety as well as autism-related social communication difficulties. This exploratory study contributes to the research progress in the domain of robot-mediated interventions for children with ASD.

270 **243.270** Mindfulness-Based Stress Reduction for Adults with Autism Spectrum Disorder: Feasibility and Estimated Effects

K. B. Beck[1], *C. M. Greco*[2], *L. Terhorst*[3], *E. R. Skidmore*[3], *J. Kulzer*[1] *and M. McCue*[1], *(1)Rehabilitation Science & Technology, University of Pittsburgh, Pittsburgh, PA, (2)Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, (3)Occupational Therapy, University of Pittsburgh, Pittsburgh, PA*

Background: Adults with autism spectrum disorder (ASD) consistently report lower quality of life (QOL) and functioning compared to neurotypical peers. Despite the growing population and needs of adults with ASD, many psychosocial interventions target children and adolescents while relying on high level cognitive strategies for symptom reduction. Mindfulness-Based Stress Reduction (MBSR), which cultivates regulation skills through experiential practice instead of cognitive strategies, has been modified for autistic samples across the lifespan. However, it has not been tested if the standard MBSR curriculum for heterogenous adults is appropriate for an autistic population to improve functioning and QOL.
Objectives: This pilot feasibility trial aimed to (1) Establish the feasibility and acceptability of a traditional MBSR group intervention with adults diagnosed with ASD; (2) Evaluate teacher fidelity and integrity to the MBSR curriculum; (3) Calculate effect size estimates of change in QOL, life satisfaction, and mindfulness.

Methods: Participants included twelve adults with ASD (IQ>70; age 22-63). MBSR consisted of a one-hour orientation, 8 weekly 2.5 hour group classes, a full day (7.5 hours) silent meditation retreat after week 6, and 45 minutes of assigned daily meditation homework. The instructor was a certified rehabilitation counselor and recognized as a qualified MBSR teacher through the University of Massachusetts Oasis Institute. Fidelity was evaluated with the Mindfulness-Based Intervention Teacher Assessment Criteria (MBI-TAC) by a senior MBSR teacher trainer. Participants completed a self-report assessment battery at three time points (pre-, mid-, and post-treatment), including: Satisfaction with Life Scale (SWLS), World Health Organization Quality of Life questionnaire (WHOQOL-BREF-ID), the Child and Adolescent Mindfulness Measure (CAMM), and the Positive Outlook scale from the Healing Encounters and Attitudes Lists (HEAL). Participants also completed the client satisfaction questionnaire (CSQ-8) and a qualitative exit interview post-treatment with a research assistant not involved in the intervention.

Results: All participants completed the MBSR intervention and post-assessments (100% retention). Participants reported high satisfaction with the intervention on the CSQ-8 (*M* = 27.92, *SD* = 3.5). Sessions 4 and 5 were randomly selected for fidelity review. Both session 4 (*M*=5.33; *SD*=.5) and 5 (*M*=4.67; *SD*=.5) met fidelity with an overall rating of "proficiency +" on the MBI-TAC. While fidelity to MBSR was met without modification, ASD specific supports within the flexibility of the curriculum were identified. Participants required concrete structuring for small-group discussions and additional consultation between sessions (*M*=28.75, *SD*=22.48 minutes). Effect size estimates suggested large improvements in positive outlook ($F(2,22) = 12.42$, $p<.001$, d=2.12), satisfaction with life ($F(2,22) = 3.22$, p=.059, d =1.08), mindfulness ($F(2,22) = 3.34$, p=.054, d =1.10), and quality of life ($F(2,22) = 3.09$, p=.066, d=1.059). Seven of twelve participants listed emotion regulation as the primary benefit during qualitative exit interviews.

Conclusions: This project established feasibility and acceptability of traditional MBSR for adults with ASD while estimating that MBSR could be a promising QOL intervention. Utilization of a traditional heterogenous MBSR program would expand effective, affordable, and inclusive treatment options for autistic adults. Exit interviews suggest that future research should consider measuring emotion regulation as a mechanism for improved functioning.

271 **243.271** Neuroplasticity-Based Cognitive Training for Adolescents with Autism Spectrum Disorder: Preliminary Findings from a Computerized Intervention Program

*A. Tseng, O. Newman, G. Hooks, N. Lillie and **S. Jacob**, Department of Psychiatry, University of Minnesota, Minneapolis, MN*

Background: Autism Spectrum Disorder (ASD), a complex neurodevelopmental disorder, is characterized by persistent deficits in communication and interaction, and restrictive, repetitive patterns in behavior, interests, and activities. Many difficulties experienced by individuals with ASD have been attributed, in part, to deficits in cognitive functions necessary for goal directed behavior that is adaptive to the environment. Cognitive training methods in auditory and social/communication (SC) domains have emerged as a promising approach to improve functional impairments in multiple pathologies (e.g., Schizophrenia, Attention-Deficit/Hyperactivity Disorder; ADHD). In particular, computerized and adaptive brain-based programs have shown considerable potential as effective and accessible interventions. This approach has been applied effectively to address general cognitive deficits in chronic schizophrenia and in children and adolescents with ADHD. However, despite the likely utility of these methods for the treatment of cognitive deficits in autism, few trials have been implemented in the ASD population.

Objectives: Longitudinal studies of adults with ASD with and without intellectual disability have shown consistent and persistent deficits across cognitive, social, and vocational domains. Moreover, the cognitive and social skill deficits that are core features of ASD have been identified as major challenges to employment success for these adults, highlighting the critical need for evidence-based interventions as adolescents with ASD transition into adulthood. Thus, we aim to assess the efficacy of a novel, computerized, adaptive, brain-based targeted cognitive training (TCT) program designed to leverage neuroplasticity in a pilot sample of adolescents with ASD.

Methods: We enrolled 20 adolescents (6F; Age=14.9±1.4years) with a prior diagnosis of ASD and IQ ≥ 70 from local ASD clinics. We customized two web-based TCT modules (Auditory/SC) and participants were randomized to each group. Study procedures included: 1) Pre-Intervention Assessments; 2) 10-14 weeks of TCT including forty (25-45 minute) training sessions; and 3) Post-Intervention Assessments. The Auditory Module was designed to improve information processing speed and accuracy while engaging working memory and cognitive control under conditions of close attention and reward. The SC Module applied principles of implicit learning to improve processing and use of socially-relevant information. Exercises continuously adjusted difficulty level to user performance to maintain an approximately 80% correct performance rate. Correct trials were rewarded with points and animation.

Results: Data collection and recruitment is ongoing, but to date, five participants (1F; Age=14.6±0.5years) have completed the Auditory Module and four participants (2F; Age=15±1.4years) have completed the SC Module. We anticipate having a total of ten participants in each group by Spring 2019. Preliminary data show mean percentage improvement from baseline to best performance of 24% for the Auditory Group and 21% for the SC Group.

Conclusions: Preliminary results are promising and indicate overall improvement on training tasks across groups. Pre- and Post-Assessment sessions include functional neuroimaging and behavioral measures of social and cognitive functioning. We will compare neural, clinical, and cognitive changes between the baseline and outcome assessments to gauge the efficacy of the TCT programs as well as generalizability across training domains.

272 **243.272** Parent-Child Agreement on Internalizing Symptoms before and after a Cognitive Behavioural Intervention

***J. Baraskewich**[1], M. McConnell[2], K. McFee[2], K. Johnston[2] and C. A. McMorris[1], (1)Werklund School of Education, University of Calgary, Calgary, AB, Canada, (2)BC Children's Hospital, Vancouver, BC, Canada*

Background: Assessment and diagnosis of many mental health disorders relies on multiple informants, one of which is typically child or adolescent self-report (Silverman & Ollendick, 2005). However, many individuals with ASD have difficulties engaging in introspection and demonstrate a lack of awareness and/or difficulties identifying their emotions (Losh & Capps, 2006). Consequently, whether children and youth with ASD provide valid self-reports of their mental health symptoms has been questioned (Mazefsky et al., 2011). Previous research examining parent-child concordance on measures of internalizing symptoms has been mixed (Magiati et al., 2014; Russell & Sofronoff, 2004). Although limited, there is literature to suggest that, in children and adolescents with anxiety but not ASD, parent-child agreement increases following treatment (Los Reyes et al., 2010). In children and adolescents with ASD, despite suggestions that discrepant reporting might relate to a lack of insight into mental health symptoms, no research to date has examined if and how the concordance between parent and child reported internalizing symptoms may be impacted following involvement in an intervention.

Objectives: The present study examined agreement between parent- and child- reported internalizing mental health symptoms after participating in a cognitive-behavioural intervention for children and adolescents with ASD and anxiety.

Methods: Fifty-one children (age 8-13 years, FSIQ ≥ 70) and a parent or caregiver participated in Facing Your Fears (Reaven et al., 2011) – a 14-week cognitive-behavioural intervention to address anxiety in ASD. Before and after participation in the intervention, children and their caregivers independently completed comprehensive (i.e., multi-informant, multi-method) assessments of their child's internalizing mental health symptoms. Preliminary analyses examined parent-child agreement on the Spence Children's Anxiety Scale (Spence, 1998) pre- and post-intervention using

intraclass correlations (ICC).

Results: Parent-child agreement for total anxiety symptoms at pre-intervention was modest (ICC = .47) but decreased post-intervention (ICC = .36). At the subscale level, agreement for generalized anxiety symptoms was poor at pre-intervention (ICC = .29) and increased to modest at post-intervention (ICC = .48). Similarly, agreement on the separation anxiety subscale was modest at pre-intervention (ICC = .45) and increased slightly post-intervention (ICC = .56). This pattern of decreased overall anxiety symptom agreement despite increases on certain subtests may be related to the issues addressed in the intervention. Secondary analyses will compare agreement on anxiety symptoms with agreement on the Children's Depression Inventory (Kovacs, 1992) while controlling for ASD severity and cognitive abilities.

Conclusions: Agreement between parent and child reports of internalizing symptoms may differ following participation in a cognitive-behavioural intervention. The intervention may present an opportunity for children and parents to discuss anxiety symptoms which could result in higher levels of agreement between ratings. Conversely, if children better understand their symptoms, they may report higher levels of symptoms while their parents endorse lower levels following participation. Secondary analyses will explore the pattern of reporting before and after participation. Understanding how participation in an anxiety intervention impacts how children and adolescents with ASD self-report internalizing symptoms can help clinicians better conceptualize discrepant parent-child reports and inform the development of self-report measures for ASD.

273 **243.273** Peer-Reported Social Distance in Response to DSM-5 Symptomatology

***C. McMahon**, M. Linthicum and B. Stoll, Miami University, Hamilton, OH*

Background: In their Reciprocal Effects Peer Interaction Model, Humphrey and Symes (2011) suggest two causal pathways for poor relationships between individuals with Autism Spectrum Disorder (ASD) and their peers: (1) social communication difficulties in individuals with ASD and (2) a limited understanding and acceptance of those difficulties among peers. While clinical interventions have been designed to address both causal pathways (e.g., social skills interventions, peer knowledge interventions), such interventions may be more efficacious if they target those clinical symptoms most disruptive to peer relationships.

Objectives: The aim of this exploratory study was to examine peer reports of social distance in response to autistic symptomatology and symptomatology consistent with other clinical diagnoses in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; American Psychiatric Association, 2013).

Methods: 226 undergraduate students completed a revised version of the Social Distance Scale (Gillespie-Lynch et al., 2015). Across 34 clinical symptoms, participants responded to five Likert-scale questions indicating their willingness to interact with (e.g., "move next door to", "date or marry") a person with that clinical symptom. Sixteen symptoms represented the DSM-5 diagnostic criteria for ASD, with 2-3 symptoms indexing each of the core diagnostic components (social-emotional reciprocity deficits, nonverbal communication deficits, relationship difficulties, stereotyped behaviors, insistence on sameness, restricted interests, sensory sensitivity; American Psychiatric Association, 2013). Eighteen symptoms represented the diagnostic criteria for other clinical diagnoses (oppositional defiant disorder, generalized anxiety disorder, major depressive disorder, attention deficit hyperactivity disorder, anorexia nervosa, specific learning disorder). Two repeated-measures ANOVAs were conducted to determine whether peer-reported social distance varied across (1) clinical diagnoses and (2) core diagnostic components of ASD. The Bonferroni correction was used for all post hoc pairwise comparisons.

Results: Peers significantly differed in their desire for social distance across the clinical diagnoses, $F(6, 1350) = 297.70$, $p < 0.01$, $\eta^2_p = 0.57$. Among the seven diagnoses, peers were most reluctant to interact with others who showed symptoms of oppositional defiant disorder and second most reluctant to interact with others showing symptoms of ASD or generalized anxiety disorder (Figure 1). Peers also significantly differed in their desire for social distance across the core diagnostic components of ASD, $F(6, 1350) = 28.30$, $p < 0.01$, $\eta^2_p = 0.11$. Peers were least willing to interact with others with deficits in social-emotional reciprocity or an insistence on sameness (Figure 2).

Conclusions: Peers modified their willingness to interact with others, depending on the specific autistic or clinical symptoms exhibited. ASD was among the top three clinical diagnoses that yielded the greatest social distance scores from peers. Across the autistic symptoms, peers responded most negatively to others with deficits in social-emotional reciprocity (e.g., initiating social interactions, sharing emotions) and insistence on sameness (e.g., difficulty adapting to change). As these autistic symptoms may be most disruptive to peer relationships, interventions that target these symptoms, both those that strengthen social-emotional reciprocity and cognitive flexibility in individuals with ASD and those that increase awareness and understanding of these symptoms in peers, may be most efficacious.

274 **243.274** Pilot Test of an Intervention for Parents of Youth with ASD Focused on Life Skills and Preparing for Adulthood

***A. V. Kirby**[1], K. J. Feldman[2], M. Himle[2], M. Diener[2] and C. Wright[2], (1)University of Utah College of Health, Salt Lake City, UT, (2)University of Utah, Salt Lake City, UT*

Background: Adolescence is an important time for families of adolescents with autism spectrum disorder (ASD) planning and preparing for adulthood. Parents play an important role in the transition process, with evidence suggesting that parents' expectations during adolescence are significant mediators of key outcomes for adults with ASD and that higher parent expectations and self-efficacy are associated with more positive post-secondary preparation activities (e.g., social activities, volunteer work/employment, parent-youth discussions about the future, working toward goals). There is a need for effective interventions to support the transition to adulthood for parents and youth with ASD. Maximizing Adolescent Post-Secondary Success (MAPSS) is a six-week intervention program developed by our research team to support transition preparation for parents and youth.

Objectives: To pilot test an intervention to provide support for parents of youth with ASD, focused on increasing positive post-secondary preparation activities and life skills by addressing parents' expectations and self-efficacy related to preparing youth for adulthood.

Methods: Parent participants were required to be a caregiver of an adolescent (ages 14-18 years) with ASD in high school and anticipating receipt of a high school diploma. Some parents chose to attend with a spouse/co-parent. Upon completion, we collected participant feedback about the program. The primary outcome measure was the Transition Preparation Activities Measure (T-PAM; Kirby, n.d.), which includes ratings of preparedness for the transition to adulthood, worry about the future, and frequency of various transition preparation activities. Secondary measures included the Competency factor of the Family Empowerment Scale (Koren et al., 1992) and Adulthood Expectations Questionnaire (AEQ; Kirby, n.d.), all of which were administered at baseline and at program completion. Included measures have demonstrated acceptable internal

consistency with this population. We summarized participant feedback and conducted paired t-tests to compare pre- and post-intervention ratings.

Results: At the time of submission, 14 families participated in the pilot study of the MAPSS; two additional groups will be completed prior to May 2019. 100% of participants remained in the program, however, 1 family did not complete post-intervention questionnaires within the necessary time frame. Participant feedback was positive (see Table 1). From pre- to post-intervention, parents' reported levels of preparedness for their youth's transition was significantly greater (t=-5.262, p<0.001) and their levels of worry related to their youth's future was significantly lower (t=2.88, p<.05). Both parent and youth transition preparation activities significantly increased (t=-5.07, p<0.001 and t=-2.51, p<0.05, respectively). A slight, but not significant, increase was noted in parent self-efficacy (i.e., competency). We observed slight, but not significant, increases in parent expectations for adult outcomes; parent sense of control over those outcomes did significantly increase (t=-2.47, p<0.05).

Conclusions: Last year we presented proof-of-concept data on the MAPSS intervention and made improvements to the program based on participant feedback. To date, two new groups (14 families) have participated in the updated program, and we will run two additional groups prior to May 2019. Preliminary results suggest the MAPSS program is well-received by participants and is demonstrating statistically significant improvements on the primary outcome measure related to family transition preparation.

275 **243.275** Preliminary Outcomes of a New Executive Function Treatment for Transition-Age Youth with ASD

C. E. Pugliese[1], *M. F. Skapek*[2], *M. D. Powers*[3], *L. Saldana*[3], *L. Anthony*[4] *and L. Kenworthy*[1], *(1)Children's National Health System, Washington, DC, (2)Psychological Sciences, University of Connecticut, Storrs, CT, (3)Children's National Health System, Rockville, MD, (4)University of Colorado, Denver, Aurora, CO*

Background: Individuals without intellectual disability make up the fastest-growing subgroup of ASD, but as few as 9% reach full functional independence as adults (Farley, McMahon, & Fombonne, 2009). Executive Function (EF) problems are pivotal targets for intervention (Hume, Loftin & Lantz, 2009) because they are common (Hill, 2004), linked to independence (Pugliese et al., 2015), and responsive to treatment (Kenworthy et al., 2015). Flexible Futures (FF) is a new 20 session CBT delivered by trained teachers in the school setting. FF targets self-advocacy, flexible problem solving, planning, time management, and independent goal-setting through scripts and routines that are to be applied to real-world situations. Generalization is maximized with school staff as interventionists, parent training, and home and classroom extension activities.
Objectives: This project tests the effectiveness of FF in improving EF skills, including flexibility and planning, in transition-age youth with ASD compared to students who received the usual care in their school environment.

Methods: The trial compared Flexible Futures (FF) to treatment as usual (TAU) in 8 high schools across the DC Metro Area using a randomized, clustered, parallel clinical trial design. All participants (n=43, 8 female) were aged 14-20 (M=16.4, SD=1.3) had an FSIQ ³80 (M=105.8, SD=14.7) on the WASI-2 and diagnoses were verified using parent report & school classification of ASD supported by the Social Communication Questionnaire (n=35) or ADOS (n=21). Independent samples t-tests and corresponding effect sizes were used to examine between group change on WASI Block Design (problem solving), Tower of London (ToL; planning), parent Behavior Rating Inventory of EF (BRIEF, Plan/Organization & Shift scales), and Adaptive Behavior Assessment System (ABAS; Global and Practical domains).Paired samples t-tests were used to measure change from baseline to endpoint within each group. There were no significant differences between intervention group in age, gender, full-scale IQ, ethnicity, or race (Table 1).

Results: When examining the effect size differences between the groups, students in the FF group improved more than the TAU with small to medium effect sizes on Block Design (d=.5), ToL Total Correct (d=.4)/Total Move (d=.3), ABAS Global (d=.4) and Practical (d=.6), and BRIEF Shift scales (d=.6). However, it is important to note that these differences did not reach statistical significance. Students within the FF group significantly improved from baseline to endpoint on all domains with medium to large effect sizes (.5-1.0), while students within the TAU significantly improved on BRIEF planning (d=.6; Table 1).

Conclusions: This pilot RCT provided evidence that FF implemented at school led to improvement in key EF outcomes. Although between group analyses were not significant, and likely affected by the small sample size, effect size calculations demonstrated that students receiving FF improved on several key outcomes above those receiving TAU, and the pattern of results within the FF group was also in the expected direction. Small to medium improvements in the TAU are not unexpected given that students at these schools also received autism specific supports at school. Next steps include refining the FF curriculum and testing in a larger RCT.

276 **243.276** Regulating Together: Emotion Regulation Treatment for Children and Teens with ASD in an Intensive, Group, Parent-Assisted Program Pilot Trial

R. Shaffer[1], *L. Schmitt*[2], *C. A. Erickson*[3], *L. Wink*[3], *J. Ruberg*[2], *A. Blackburn*[2], *J. Harms*[2] *and N. Klein*[4], *(1)Division of Developmental and Behavioral Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Division of Child and Adolescent Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Cincinnati VA, Cincinnati, OH*

Background: Individuals with Autism Spectrum Disorder (ASD) consistently present to treatment with non-compliance, temper tantrums, and aggression. At age 8, >95% of youth with ASD demonstrate co-occurring behavioral and emotional symptoms that are related to negative outcomes throughout development. Across all cognitive functioning levels, these clinical issues are hypothesized to arise from difficulties in *emotion regulation* (ER). Inadequate ER skills in individuals with ASD have been linked to higher rates of hospitalizations, school disciplinary action, peer rejection, failed transitions to college and employment, and use of psychotropic medications. Unfortunately, there are no empirically-validated interventions to address this impactful issue in ASD. Due to the severity of concerns associated with weak ER skills in ASD, traditional school- and outpatient-based programs are not equipped to deal with this population, and thus children with ASD are often excluded from treatment. Moreover, traditional interventions are typically individual-based and do not actively include caregivers. Thus, a group-based, parent-assisted model may be an effective method of treating many individuals with ASD who have ER deficits. CBT-based approaches have been shown to be effective at improving select aspects of ER in ASD and general child psychology indicate mindfulness and acceptance are needed for long-term ER skills, but their usefulness is untested for individuals with ASD.
Objectives: *Our group developed Regulating Together (RT)*, a unique comprehensive program including both caregivers and children in a group format that uses elements of CBT, ABA, and Mindfulness approaches. Here, we aim to determine the feasibility and efficacy from a pilot study

containing child (8-12 years) and adolescent (13-18 years) groups that met twice weekly for 5 weeks.

Methods: We examined a multi-diagnostic clinical RT group via a chart review of 59 participants (40 8-12, 19 13-18), 31 with ASD (20 8-12, 11 13-18), comparing pre- and post-treatment scores on the Aberrant Behavior Checklist, Pediatric Quality of Life Family Impact Module (PedsQL), and clinician rated CGI-I[7]. Each age group was analyzed separately.

Results: The ASD child group had statistically significant changes on all subscales of the Aberrant Behavior Checklist and the ASD teen group had significant changes on the Irritability, Lethargy, and Stereotypy subscales. Regarding CGI-I, 53% of the children were rated as Much Improved, 24% minimally improved, 21% no change, and one participant minimally worse post-treatment and 28.6% of adolescents were rated as Much Improved and 71.4% minimally improved. Parents provided overwhelmingly positive feedback in regard to learning, enjoying the program, and increased confidence in behavior management. There was a 15% attrition and a 13% absence rate suggesting overall feasibility. No significant changes were found on the PedsQL for either group.

Conclusions: ER is a critically under-studied and under-treated issue in ASD and other developmental disorders leading to high rates of hospitalizations and social and academic difficulties. Thus, we developed a short-term parent-assisted group intervention approach aimed at increasing ER. Our novel Regulating Together treatment program shows promising short-term preliminary findings, and thus indicate further evaluation of efficacy, identification of treatment responder characteristics and active components, and long-term benefits is warranted.

277 **243.277** Stepping It up: Assessing Physical Activity of College Students with Autism Spectrum Disorder

T. Todd[1], *N. Miodrag*[2,3], *M. Caris*[4], *B. Endinjok*[5], *R. Herrera*[6], *E. V. Perez*[7] *and M. Salazar*[5], *(1)Kinesiology, California State University, Northridge, CA, (2)Child and Adolescent Development, California State University Northridge, Northridge, CA, (3)Child and Adolescent Development, California State University, Northridge, Northridge, CA, (4)California State University Northridge, Los Angeles, CA, (5)Kinesiology, California State University Northridge, Northridge, CA, (6)California State University Northridge, Northridge, CA, (7)Psychology, California State University Northridge, Northridge, CA*

Background: College students with Autism Spectrum Disorder (ASD) often face unique challenges in the college environment (Van Hess et al., 2015), experience higher levels of loneliness, depression, and anxiety than peers (Scott et al., 2018), and are more likely to lead sedentary lifestyles (Stanish et al., 2017). Lack of physical activity may be problematic as active lifestyles can lead to physical and mental health benefits. It is critical to assess physical activity, especially among busy college students. Physical activity programs may be one method to increase PA levels, yet empirical evidence is needed to evaluate new programs.
Objectives: The purpose of this study was two-fold: 1) to describe 10 weeks of physical activity for college students with ASD using wearable step trackers, and 2) to compare their mean steps per day (SPD) across 10 weeks of a physical activity program.

Methods: Twenty-one college students with ASD (Male = 19, Female = 2) from a large urban university participated in a 10-week peer-mentored physical activity intervention. Participants and Kinesiology students (i.e., Peer Mentors) were paired and worked out together two hours each week for 10 weeks. Participants wore a Fitbit Charge HR 2© daily for 10 consecutive weeks and SPD data were collected. Data were synced twice a week to Fitabase—a proprietary online database used to track activity levels and SPD for each participant.

Results: Average SPD were divided into step defined activity levels using Tudor-Locke's classifications (Tudor-Locke et al., 2009). Two students (9.5%) were classified as "low active: 5,000-7,499 SPD", 10 students (47.5%) were classified as "somewhat active: 7,500-9,999 SPD", 5 students (24%) were classified as " active: 10,000-12,4999 SPD", and 4 students (19%) were classified as "highly active: ≥ 12,500 SPD". There was a slight increase of mean SPD across the 10 weeks, however the exercise intervention did not have a statistically significant effect on steps per day, $p > .05$.

Conclusions: Although previous researchers have reported sedentary lifestyles in adults with ASD, our data provide evidence to suggest that college students with autism on this large urban campus appeared to lead active lifestyles. The majority of our participants consistently walked more than 7,500 SPD, with 43% of them regularly walking more than 10,000 SPD. These results are striking when compared to the average US adult SPD of 5,100-6,500 (Basset et al., 2010; Tudor-Locke et al., 2009). Participation in a 10-week physical activity program did not significantly affect the number of SPD. This may in part, be due to the university environment, which already promotes walking as students change classes and access services such as cafeterias and libraries across the large campus. Further research exploring the effects of exercise interventions on other health outcomes are warranted. Still, our finding that college students with ASD on this campus are physically active is highly encouraging for both students and the institutions that support them.

278 **243.278** Social Validity of the Working Together Intervention for Young Adults Wtih ASD and Their Families

A. Walsh[1], *R. Hudock*[2], *K. Szidon*[3], *M. Mailick*[4] *and L. E. Smith DaWalt*[4], *(1)University of Wisconsin-Madison, Madison, WI, (2)University of Minnesota, Minneapolis, MN, (3)Waisman Center, University of Wisconsin-Madison, Madison, WI, (4)University of Wisconsin-Madison Waisman Center, Madison, WI*

Background: A growing population of adults with autism spectrum disorder (ASD) has spurred increased interest in developing interventions to support positive outcomes across the life course. We developed a multi-family psychoeducation model, *Working Together*, designed for young adults with ASD and their families. The *Working Together* model adapts an approach commonly used with individuals with varying mental health conditions (McFarlane, 2002) and applies it to families of individuals with ASD, resulting in improvements in behavior and employment.
Objectives: The present study examined the social validity of the *Working Together* program for adults with ASD and their families. Qualitative and quantitative data were collected from young adults with ASD and their parents to examine their satisfaction with and level of engagement throughout the program as well as knowledge gained and personal goals achieved.

Methods: Data were drawn from the *Working Together* study, a multi-site randomized waitlist control trial which tested the *Working Together* intervention. Families were eligible to participate if they had a young adult with a diagnosis of ASD without intellectual disability, who co-resided with their parents, and who was disengaged from educational/employment activities (<10 hours per week). Forty-nine families enrolled in the study. The intervention included 8 weekly group sessions, 2 individual family sessions, 3 monthly group booster sessions, and a method for providing ongoing resources and referrals. Session topics for young adults and parents included goal setting, problem-solving, coping strategies, planning for independence, employment, community/relationships, personal safety, and health and well-being. At each session, interventionists rated participant engagement and participants rated satisfaction. Participants also reported on what they learned from the program at the

completion of the intervention. Measures of goal attainment were assessed at baseline and post-intervention.

Results: Preliminary analysis of data from 36 families indicated that 100% of parents and adults with ASD were satisfied or very satisfied with the program. Observational weekly engagement ratings indicated that 82% of young adults and 93% of parents were mostly/clearly engaged, on average, across sessions (interrater agreement was 87%). Young adults demonstrated more variability in engagement ratings, showing the clearest engagement during sessions involving coping strategies and employment information; there was less engagement during community/relationships and personal safety sessions. Qualitative analysis of exit interview data from the young adults suggested common themes that promoted positive changes including learning how to solve problems and learning how to help themselves. Parent exit interview data revealed common themes around learning to better understand their young adult, gaining skills to help support their adult in their journey to independence, and appreciation for the information provided during the intervention. Almost 80% of adults with ASD achieved at least one of their goals. Analysis of results is ongoing.

Conclusions: Findings highlight the social validity of the intervention for the targeted end users of the program, young adults with ASD and their parents. These findings, in conjunction with achievement of program goals of reduced behavior problems and increased rates of employment, support the potential of this program to enhance functioning of adults with ASD.

279 **243.279** Socialization Education and Learning for the Internet (SELFI): A Pilot Intervention Program for Online Social Skills for Adults with ASD

A. Osuna[1], *D. Tagavi*[2], *T. W. Vernon*[1], *S. Said*[1] *and J. Nguyen*[2], *(1)University of California Santa Barbara, Santa Barbara, CA, (2)University of California, Santa Barbara, Santa Barbara, CA*

Background: Individuals with autism spectrum disorder (ASD) suffer from impairments in social communication skills that may severely limit their quality of life and key outcomes. Previous research has reported that those who are not socially confident, such as individuals with ASD, may feel more comfortable communicating online (Goby, 2006). Furthermore, online social media communication has been shown to increase quality of friendships, decrease loneliness, and benefit individuals with social anxiety (Mazurek, 2013). These data suggest that social media could be a relevant tool and a critical target for social skills intervention. Although in-person social interaction has been frequently studied in individuals with ASD, it is currently unknown how effectively they engage with their peers online. The Socialization and Education Learning For the Internet (SELFI) program was developed to evaluate and improve the online social skills and etiquette of adults with ASD in an increasingly digital world.
Objectives: The objective of this study was to test the feasibility and preliminary efficacy of an eight session intervention targeting online social skills, specifically for adults with ASD.

Methods: In this pilot study, twelve young adults with ASD and average cognitive ability are scheduled to participate. SELFI is an 8-week socialization intervention aimed at systematically improving individual's positive social impression by targeting their interactions, responses, and initiations online. Four participants have completed the program thus far. The package placed a specific focus on modeling, teaching, and reinforcing skill use, common strategies that are often employed in in-person autism social skill interventions. Clients completed a battery of psychosocial measures before and following intervention and at a 3 months follow-up. Screenshots and other data from participants' social media accounts were gathered and coded for quantitative and qualitative indicators of appropriateness.

Results: To assess for treatment feasibility, data regarding the study's recruitment, treatment fidelity, attrition, and participant attendance will be analyzed. Recruitment for the current study is feasible, with ample response to recruitment advertisements and adequate enrollment. A fidelity checklist was completed during each session to monitor adherence to the established intervention protocol, with treatment fidelity falling consistently above 95%. There has been no participant attrition from the study and participants attended 100% of scheduled sessions. Subjective ratings of screenshot and online activity data made by raters masked to study time point and hypotheses are indicative of improvements in both quality and quantity indicators after completion of the program.

Conclusions: Preliminary data analysis suggests that the online social skills treatment intervention is feasible and may lead to positive gains in effective use of online social strategies and guidelines. These results suggest that SELFI may be a feasible approach to teaching online social skills to cognitively able individuals with ASD. This innovative format has the potential to target an area of communication that has not been focused on with individuals with autism previously. Future directions include a randomized controlled trial to systematically test the intervention and its long-term impacts on online communication and friendships.

280 **243.280** Sportsmanship Interventions for Individuals with Autism Spectrum Disorders: A Systematic Review

L. B. Glugatch[1] *and W. A. Machalicek*[2], *(1)Special Education, University of Oregon, Eugene, OR, (2)University of Oregon, Springfield, OR*

Background:
Children with autism often have impairments in social behaviors which can lead to difficulties in developing meaningful friendships with peers (Bauminger, Shulman, & Agam, 2003). Deficits in social interactions including appropriate commenting and turn taking in children with Autism Spectrum Disorder (ASD) can result in problems in understanding abstract games and displaying sportsmanship behaviors. Previously, good sportsmanship has been defined as guiding the behavior of peers in a constructive direction, working together and playing cooperatively, and independently solving peer conflict (Kohlberg, 1963). However, these higher order social-communication skills may be difficult for individuals with autism. Developing sportsmanship behaviors, such as turn-taking, positive comments, and treating other players with respect, are instrumental skills to successful inclusion and engagement in team sports and leisure games. Children with autism may need to be explicitly taught sportsmanship behaviors to promote appropriate and effective participation in team sports and board games. While many researchers have studied social skills interventions for individuals with ASD, fewer studies have examined specifically targeting sportsmanship skills for individuals with autism.

Objectives:

The purpose of current systematic literature review is to: (a)identify interventions used to teach sportsmanship skills , (b) identify the effectiveness of the interventions used, and (c) identify methodological limitations within this body of research.

Methods:

Electronic database searches were conducted using PsycINFO, ERIC, and Academic Premiere with the combined set of keyword search terms: (1) autis*, OR Asperger*; OR PDD-NOS, (3) sports* OR "board game*" OR "social skills" OR "play. Articles were coded for participant demographics, methodology, intervention type, target outcomes, and quality of empirical evidence (Reichow, et al., 2011).

Results:

There was a total of 41 children included in the review from the 12 studies. The researchers targeted multiple domains of social-communication behaviors during game play or during unstructured school recess periods. From the articles reviewed, intervention targets included social skills, play skills, and sportsmanship skills. Various types of interventions and strategies including 1:1 social skills intervention, social narratives, Power Card, and Cool versus Not Cool were implemented to improve sportsmanship behaviors for individuals with autism. Of the studies reviewed, all the researchers reported increases in the targeted behaviors. Using Reichow's method for evaluating empirical evidence, the studies included ranged from weak to strong rigor ratings.

Conclusions:

Overall, results revealed that sportsmanship interventions may be a promising strategy to increase appropriate game play with peers. The specific strategies used to broadly teach sportsmanship behavior were flexible and varied in intensity in the studies reviewed. For studies using 1:1 support, results indicated improvements in turn taking, eye contact, and social interactions with peers in a small group. Social narrative strategies, such as social stories and the Power Card, reported increases in losing graciously and treating players with respect, and decreases in whining after game loss. Although these positive results should be interpreted with caution because of the small number of studies and methodical issues, they suggest that interventions can teach behaviors with autism sportsmanship behaviors.

281 **243.281** Salivary Cortisol in Children with Autism Spectrum Disorder : Longitudinal Variations in the Context of a Service Dog's Presence in the Family.

S. M. Fecteau[1], *M. Trudel*[2,3] *and F. Picard*[4], *(1)psychoeducation and psychology, Université du Québec en Outaouais, Saint-Jérôme, QC, Canada, (2)Université de Sherbrooke, Longueuil, QC, Canada, (3)Psychoeducation, University of Sherbrooke, Mercier, QC, Canada, (4)Université Laval, Québec, QC, Canada*

Background: The primary function of service dogs for children with autism spectrum disorders (ASD) is to ensure the safety of the child. Several parents report that the mere presence of the dog encourages the family to follow a lifestyle typical of an average family in addition to providing a source of support. A preceding study suggested that the presence of a service dog in the family induces a significant and continuous decline of cortisol secretion at awakening for children with ASD over a period of four weeks (Viau et al., 2010). This reduction of stress measured by salivary cortisol would confirm parents' perception that their child is calmer when the dog is present (Harwood, 2018). Following this first study, our research group has established a new research design involving a larger sample of families of children with ASD, including a control group, and repeated daily measurements.

Objectives: The aim of the present study seeks to evaluate services dog's impact on a group of children with ASD, based on their well-being measured by salivary cortisol. The study also estimated if age and the severity of symptoms related to autism affected variations in the children stress system.

Methods: The sample was composed of 95 families of children with ASD, aged between 5 and 11 years old (20.7% of girls). 48 of these families received a service dog (certified and trained by the Mira Foundation). The remaining 47 families were recruited from a waiting list and composed the control group (WLC). Autism severity was estimated by the Childhood Autism Rating Scale (Schopler et al., 1988) filled out by an evaluator during the first three weeks of the study after a home visit. Effects of the service dog were evaluated by repeated measures of children's salivary cortisol. These weekly home-based samples were collected twice daily by a parent (wakening and bedtime). The cortisol analyses were based on aggregation of samples over a period of 15 consecutive weeks, yielding five blocks of data each for wakening and bedtime samples; a first block composing the baseline (T0) and four once the family received the dog (T1, T2, T3, T4).

Results: No significant relationship between diurnal cortisol, autism severity and gender was detected. As expected, temporal stabilities in wakening and bedtime cortisol across the last 4 blocks were higher for the control group compared to children who received a dog. Overall, salivary cortisol across the different periods do not differentiate the two groups. However, with a median split based on age, significant differences between the two groups at T1 and T4 are present only among children aged 7 to 11 who received a service the dog ($t = 2.1$ and 2.3, $p < .05$).

Conclusions: Cortisol regulation showed no association to autism severity nor gender. Cortisol remained stable for children of the WLC. Effects of the service dog on children's stress were present for a subgroup of children, demonstrating long lasting effects of the service dog for older children.

282 **243.282** Supporting Youth with ASD to Better Cope with Stress through Destress for Success: An Exploratory Study

S. M. Fecteau[1], *M. H. Poulin*[2] *and C. Normand*[3], *(1)psychoeducation and psychology, Université du Québec en Outaouais, Saint-Jérôme, QC, Canada, (2)Psychoeducation, UQAT, Rouyn-Noranda, QC, Canada, (3)Psychoéducation et psychologie, Université du Québec en Outaouais, Gatineau, QC, Canada*

Background: Adolescence is marked by the development of important skills and physiological changes, increasing vulnerability to stress and the onset of mental health disorders in some adolescents. Adolescents with ASD might experience more stress than those with a typical development during social interactions, as suggested by high cortisol activity during social interaction and in the evening which is illustrative of stressful experiences during the day. Chronic (i.e. repeated and prolonged) stress induces excessive wear of biological systems and increases the risk of physical and psychological pathologies such as depression and anxiety, co-occurring conditions that undermine quality of life in youths with ASD. It thus becomes relevant to support teens in the prevention of chronic stress. Destress for Success^{c} was developed by the Center for Studies on Human Stress (CSHS). Destress for success^{c} includes 5 workshops of 50 minutes, each addressing a theme: (a) universal components of stress; (b) cognitive assessment; (c) problem solving in a stressful setting; (d) emotional regulation strategies and (e) problem-centered strategies. This program has been validated with a sample of adolescents with typical development. We conducted a first study, in collaboration with the CSHS, with a group of seven male adolescents with ASD (age range 12.11. to 15.6, mean 14.04 y.o.). **Objectives:** The objectives were 1- to evaluate the

relevance and feasibility of the evaluation protocol, and 2- to estimate the potential adaptations to make the program relevant for adolescents with ASD. **Methods**: Estimation of the potential effects of the program are studied according to pre and post-tests study design, combining stress-related physiological measure (salivary cortisol taken at wakening, 30 minutes later, 4pm and bedtime) and psychological measures (adaptive behavior and emotion recognition). Qualitative analyses of satisfaction questionnaires completed individually by the participants and their parents, and a journal completed by the trained clinician added to the comprehension of the program's potential. **Results:** The results show an increase in the adolescents' sense of control ($F = 4.42$; $p<.05$), a decrease in depressive symptoms ($F= 4.51$; $p<.05$), as well as an improvement in the recognition of emotions of joy ($F = 9.75$, $p <.01$) and anger ($F = 4.6$, $p<.05$). The group daily cortisol pattern at pre-test revealed a reverse profile, were cortisol at wakening is higher than at bedtime. One week following completion of the 5 workshops, mean group cortisol pattern showed expected daily profile. However, the difference was not statistically significant. **Conclusions**: This exploratory study supports the relevance to pursue validation of the adapted program based on the potential effects detected. Adaptations were mainly made to the animation of the program to make it more meaningful for adolescents with ASD. For example, we added visual aids, examples taken from the youths' experience and there were fewer participants taking part in the group. Conclusions also emphasize the importance of parental involvement to promote generalization.

283 **243.283** Sustainable Social Gains after Completion of a Group Socialization Program for ASD: Confluence Among Parent Survey, Self-Report Survey, Peer Conversation, Social Impression Rating, and Real-World Social Metric Measures

***T. W. Vernon**, J. A. Ko, S. Said, M. Allison, A. R. Miller, A. Barrett and E. McGarry, University of California Santa Barbara, Santa Barbara, CA*

Background: Social competence is the ability to understand, navigate, and adapt to unfolding social interactions in order to estabilsh and maintain age appropriate relationships. It is a complex, multi-faceted construct that cannot be easily quantified using a single measurement strategy. Therefore, adequately capturing the sometimes nebulous construct of social competence is best accomplished through a combination of complementary evaluative tools, each providing a unique contribution to our understanding of an individual's interpersonal ability. Parent report measures provide endorsements based on repeated family interactions. Self-report tools offer valuable information about internal thought processes and social self-perceptual accuracy. Live conversations with peers provide data on effective skill use in an uncontrolled, dynamic exchange. Social impression ratings provide insight into peers' perception of one's social desirability. Finally, data on the real world social metrics (number of friendships and frequency of peer contact) provide information on the practical impact of learned competencies.

Objectives: The objective of the current investigation is to examine follow-up data collected 20 weeks after participants had completed the Social Tools And Rules for Teens (START) program for evidence of sustained social competence gains.

Methods: Participants consisted of 35 adolescents with ASD (ages 12-17) who enrolled in an RCT of the START program and were randomly assigned to treatment or waitlist groups. The START program is a 20-week experiential socialization intervention consisting of peer facilitators, free socialization periods, interactive topic discussions, structured social activities, and individual check-in and check-out sessions. At pre, post, and 20-week follow-up time points, participants and their parents completed a comprehensive set of social measures, including parent survey measures (Social Skills Improvement System, Social Responsiveness Scale-2, Social Motivation & Competency Scale), adolescent self-report measures (SSIS, SMCS), two video-recorded 5-minute conversations with untrained peers, and reports of real-world social metrics. Trained research assistants systematically coded all peer conversations for a variety of key social behaviors (i.e. questions asked, speaking/listening ratio, eye contact, facial expressions, engagement). Additionally, multiple peers provided a composite social impression rating after reviewing randomized participant videos.

Results: Repeated measure ANOVA procedures were used to compare pre, post, and follow-up data for all described measures. Participation in the START program was associated with significant increases across social competence measures from pre- to post-intervention time points (p-values < 0.01) with medium to large effect sizes. Across most measures, there were no significant differences between post- and follow-up data, which was reflective of sustainable social gains. Cases of significant post- to follow-up differences were actually due to continued improvements in social functioning even though START participation had ended.

Conclusions: In targeted efforts to improve the social competence of individuals with ASD, the sustainability and social validity of post-intervention gains are arguably the most important metrics of a program's efficacy. Significant gains in social competence are irrelevant if they do not generalize to everyday peer interactions or persist after a program has concluded. The results of this START efficacy trial are indicative of sustainable, comprehensive social improvements reflected in a confluence of parent, peer, self-report, and observational social gains.

284 **243.284** The Active Ingredients of Specialist Peer Mentoring for Autistic University Students.

***C. Thompson**[1,2], T. Falkmer[1,2], S. Bolte[1,2,3] and S. J. Girdler[2,4], (1)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)Center for Neurodevelopmental Disorders (KIND), Center for Psychiatry Research, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (4)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia*

Background:

Despite wide recognition of the benefits of post-school education in improving life outcomes for autistic adults the university completion rate for autistic adults remains below that those with and without disabilities. University environments are inherently unpredictable, with high social demands, which may overwhelm autistic students. This unpredictability can exacerbate executive functioning difficulties in planning and prioritising tasks.

Objectives:

The aimed to identify the active ingredients of specialist peer mentoring (SPM) and examine its impact on autistic university students.

Methods:

A total of 30 (8 female and 22 male; mean age=22.3; SD=6.7) autistic university students engaged in the Curtin Specialist Mentoring Program and UWA Specialist Peer Mentor Program participated in this study; with 18 (5 female; mean age=22.5; SD=9.9) completing both aspects of the study. Seven (2 female; mean age=22.3; SD=3.5) only completed the quantitative aspect and 5 (1 female; mean age=21.0; SD=8.9) participated only in the interview.

A convergent mixed-methods approach was utilised, including a pre-test post-test design examined changes in symptomology experienced by autistic university students. In parallel, the experiences of participating in SPM was explored through semi-structured interviews.

Results:

Thematic analysis of the interviews revealed five themes of active ingredients: *Developing Partnership and Understanding*, *Engagement*, *Modelling and Practising Communication, Psychological Support* and *Grading and Planning Skills*.

Significant improvements were noted at post-test on the SRS-2 total score (M1=89.72, SD1=24.00; M2=79.66, SD2=26.66; t(17)=2.52, p=0.02), and the Social Communication (M1=29.94, SD1=7.89; M2=25.50, SD2=11.29; t(17)=2.24, p=0.03) and Social Motivation (M1=18.22, SD1=5.88; M2=16.00, SD2=5.91; t(17)=2.27, p=0.03) sub-scales.

Conclusions:

These results indicated that the active ingredients of SPM included the mentor-mentee partnership. Mentors utilisation of person-centred counselling skills promoted the development of a *partnership and understanding*. This partnership appeared to modify social cognition and motivation for autistic university students through the active ingredient of *modelling and practising communication*. *Psychological support* provided by mentors was a key active ingredient in developing autistic students' autonomy and self-efficacy. While the active ingredient of the mentors using *grading and planning* allowed autistic university students to develop strategies to manage their studies and social communication challenges, maximising their social competence.

285 **243.285** The Effect of Early Intervention on Long-Term Developmental Outcomes of Children with Autism Spectrum Disorders: A Systematic Review and Meta-Analysis

B. Shi[1], *J. Jing*[2], *W. Wu*[3] *and M. Dai*[3], *(1)Faculty of Maternal and Child Health, School of Public Health, Sun Yat-sen University, Guangzhou, China, (2)Faculty of Maternal and Child Health, School of Public Health,Sun Yat-Sen university, Guangzhou, China, (3)Sun Yat-sen University, Guangzhou, China*

Background: Early intervention has been shown to improve short-term developmental outcomes in children with autism spectrum disorders (ASD), but little is known about its effect on long-term outcomes.

Objectives: This meta-analysis aimed to evaluate the long-term effects of early intervention on multiple developmental outcomes of children with ASD.

Methods: We searched PubMed, EMBASE, PsycINFO, Scopus, the Cochrane Library, OVID, ERIC and Web of Science from inception through April 24, 2018 for relevant full-text articles in English. Studies were selected if they investigated the long-term developmental outcomes of early intervention in 6-to-18-year-old children with ASD; they were excluded if they targeted subjects with a medical complications or drug treatment. The quality of included studies was examined by the Cochrane risk of bias tool and the Risk Of Bias In Non-randomized Studies-of Interventions assessment tool. Meta-analyses were performed on studies judged sufficiently similar and appropriate to pool using fixed-effect or random-effect models. The standard mean difference (SMD) was used as the effect measure: up to 0.5=small effect, 0.51 to 0.79=moderate effect, and larger than 0.8= large effect. Additionally, we conducted stratified analysis to explore the potential differences in effects of the various intervention methods on children with ASD.

Results: A total of 8 pre-post studies and 9 between-group studies were selected, with aggregate data on 634 non-overlapping children with ASD. Among these studies, 11 conducted the Application of Behavioral Analysis therapy (ABA), 2 performed the Early Start Denver Model (ESDM), and the others used comprehensive interventions. The quality assessment showed that 6 of included studies were low risk of bias. Meta-analysis demonstrated that early intervention can prominently enhance the IQ level (SMD= 0.94, 95% CI: 0.57-1.32), expressive language (SMD= 1.12, 95% CI: 0.70-1.53), and receptive language (SMD= 1.07, 95% CI: 0.73-1.42) in children with ASD. In addition, early intervention can improve certain domains of adaptive behavior, including socialization (SMD= 0.59, 95% CI: 0.02-1.16), social (SMD= 0.75, 95% CI: 0.35-1.16) and communication (SMD= 0.85, 95% CI: 0.62-1.08). However, the results indicated that early intervention has no significant long-term effect on adaptive behavior composite (SMD= 0.19, 95% CI: -0.32-0.71), as well as on ASD symptoms (SMD= -0.61, 95% CI: -1.22-0.01). Moreover, the stratified analysis indicated that ABA was more effective than other methods in reducing symptoms (pooled SMD= -1.33, 95% CI: -2.28 to -0.39). In contrast, ESDM displayed the largest effects in improving the IQ level of affected children (pooled SMD= 1.37, 95% CI: 0.95-1.80).

Conclusions: Our study demonstrated that early intervention improves the long-term prognosis of children with ASD, especially for the cognitive function, language and communication. Furthermore, ABA and ESDM show different effects in improving certain long-term outcomes. These findings may have implications for developing customized interventions that are targeted at improving specific developmental outcomes in children with ASD.

286 **243.286** The Effectiveness of Pivotal Response Treatment (PRT) in School-Aged Children and Adolescents with Autism Spectrum Disorder: A Randomized Controlled Trial

M. W. P. De Korte[1], *I. Smeekens*[2], *J. K. Buitelaar*[1,2], *W. G. Staal*[1,2,3] *and M. Van Dongen - Boomsma*[1], *(1)Karakter Child and Adolescent Psychiatry University Centre, Nijmegen, Netherlands, (2)Radboud University Medical Center Nijmegen, Donders Institute for Brain, Cognition and Behaviour, Department of Cognitive Neuroscience, Nijmegen, Netherlands, (3)Institute for Brain and Cognition, Leiden University, Leiden, Netherlands*

Background: Pivotal Response Treatment (PRT) is a naturalistic behavioral intervention targeting core deficits in social communication and motivation. The treatment has been shown to enhance social skills, language skills, and adaptive behavior (Koegel et al., 1999; Mohammadzaheri et al., 2015). The majority of studies on the effectiveness of PRT focus on preschool children (e.g., Koegel et al. 2003, 2014). Studies on the effectiveness of PRT for school-aged children and adolescents are lacking or have methodological limitations (i.e. lack of control group, no blinded measurements). Since children with ASD often face challenges in social communication when entering school, examination of PRT as a promising intervention is needed for this population.

Objectives: The current study aims to explore the effectiveness of PRT, compared to treatment-as-usual (TAU), on improving social communication skills and clinical functioning of school-aged children and adolescents with ASD.

Methods: A randomized controlled trial was conducted to evaluate the effectiveness of PRT for children aged 9-15 years with ASD and a

total/verbal IQ above 80. Participants (n=44) were randomly assigned to PRT or TAU (i.e. other treatment or waitlist control). In the PRT group, parents were trained to apply PRT techniques and the teacher of the child was also informed about how to incorporate PRT in the classroom. At baseline, week 12, 20 and 28 (follow-up), social communication skills of the child were assessed with the Social Responsiveness Scale (SRS, Roeyers et al., 2011) completed by parents and teachers. Clinically significant improvement was examined using the Clinical Global Impression-Improvement Scale (CGI-I, Guy, 1976) completed by a blinded child and adolescent psychiatrist. Clinical responders were defined as being much or very much improved on the CGI-I.

Results: There were no baseline differences of participant characteristics between groups (see table 1). Repeated measures analysis performed over the currently finished cases (n=27), indicated a significant main effect of time ($F(3,23) = 5.56$, $p = .005$) and a time x group interaction effect ($F(3,23) = 3.54$, $p = .03$) on the parent-rated SRS score, with a steeper improvement of social communication skills over time in the PRT group. For the teacher-rated SRS score a significant main effect of time was found ($F(3,21) = 4.53$, $p = .013$), but no significant time x group interaction effect ($F(3,21) = .90$, $p = .457$). There were no significant differences in percentage of clinical responders between groups at week 12 (PRT (45,0 %) vs. TAU (36,4%): χ^2 (1) = 0.32, $p = .75$) and week 20 (PRT (57,9 %) vs. TAU (47,6 %): χ^2 (1) = 0.42, $p = .51$). However, at follow-up results showed a significant higher percentage clinical responders in the PRT group compared to the TAU group (PRT (91,7 %) vs. TAU (47,6 %): χ^2 (1) = 6.4, $p = .011$).

Conclusions: The preliminary findings of this study suggest that PRT is effective in improving social communication skills and clinical functioning of school-aged children and adolescents with ASD. Results of the complete dataset (available May 2019), implications of findings, and future research will be discussed.

287 **243.287** The Effects of Dance on Social and Motor Performance of Children with Autism Spectrum Disorder.

I. Peace[1], *E. Manders*[2], *L. Levine*[1], *M. Tavino*[3], *A. Pope*[1], *S. Cipollini*[1], *W. C. Su*[3], *M. Culotta*[3], *L. Overby*[1] *and A. Bhat*[4], *(1)University of Delaware, Newark, DE, (2)Drexel University, Philadelphia, PA, (3)Physical Therapy, University of Delaware, Newark, DE, (4)Department of Physical Therapy, University of Delaware, Newark, DE*

Background:

Children with ASD display significant impairments in social communication as well as sensori-motor abilities. However, the majority of ASD interventions focus on improving social communication and behavioral skills and less focus is placed on sensori-motor impairments. We believe that a multisystem approach involving high engagement, social interactions (non-verbal and verbal), as well as sensori-motor experiences will address the needs of the whole child. In the present study, we used creative movement/dance to promote social communication and motor skills, such as imitation quality, whole body coordination, social attention, and emotional understanding.

Objectives:

We evaluated the effects of an 8-week dance intervention provided by dance experts on the social and motor skills of school-age children with ASD between 6 and 12 years of age.

Methods:

13 children with ASD between 6 and 12 years of age received 8 weeks of training (2-3 sessions per week) involving a variety of dance activities. Each 45-minute training session comprised of various training conditions: hello, warm up, idea dance, partner dance, creating, and chance dance/farewells. We examined the smile rates, percent duration of attention to social partners, as well as verbalization quantity/quality during the first, mid, and last training sessions. We also coded for social and motor improvements before and after training during a standardized praxis/motor assessment.

Results:

Our preliminary analysis of 2/3^{rds} of the sample suggests that children found the intervention to be enjoyable as seen by an increase in smile rates, words per minute, as well as more spontaneous and functional verbalization following training. During the creativity condition during training and generalized testing, children with ASD were more creative in generating new movements and required less prompting following training. Lastly, in terms of standardized testing before and after training children showed a reduction in spatial and temporal praxis errors when acquiring novel postures and while performing rhythmic actions.

Conclusions:

Children with ASD improved their social communication and imitation/praxis skills following dance training as seen by greater smiling, increased spontaneous verbalizations, increased creativity scores, and reduced need for prompting by the trainer. In a standardized testing context, they showed improvements in praxis as seen by fewer spatio-temporal errors in the posttest compared to the pretest. Future studies must extend this work to a randomized controlled trial in a larger sample and a more intense training protocol.

288 **243.288** The Effects of Hippotherapy on Repetitive Behaviors and Verbalization in Children with Autism Spectrum Disorder.

E. Knocke[1], *D. Longo*[2], *M. Tavino*[3], *B. Tripp*[2], *W. C. Su*[3], *B. Gillespie*[4], *L. Janusz*[2] *and A. Bhat*[1], *(1)Department of Physical Therapy, University of Delaware, Newark, DE, (2)University of Delaware, Newark, DE, (3)Physical Therapy, University of Delaware, Newark, DE, (4)Brandywine OT LLC, Wilmington, DE*

Background:

Communication impairments and repetitive/maladaptive behaviors (RMBs) are the hallmarks of Autism Spectrum Disorder (ASD) according to the DSM V (*American Psychiatric Association, 2013)*. However, children with ASD often present with significant sensory processing and motor impairments such as atypical sensory preferences and poor motor coordination and balance. These comorbidities are not addressed in standard ASD interventions that mainly focus on communication and behavior. Hippotherapy, a treatment tool used by trained Occupational Therapists, Physical Therapists, and Speech Language Pathologists, addresses the core impairments of ASD while integrating treatment for the sensory processing and motor impairments as well. There are limited studies on the effects of hippotherapy for children with ASD and the effects it has on communication impairments and repetitive/maladaptive behaviors are largely still unknown.

Objectives:

In the present study, we evaluated the effects of an 8-week hippotherapy intervention on the repetitive/maladaptive behaviors and

communication skills of school-age children with ASD.

Methods:

Nine children with ASDs between 3 and 8 years of age were observed for 8 weeks with pretest and the posttest visits conducted in the first and last weeks of the study respectively. ASD diagnosis was confirmed with medical and/or school records. While majority of the children were low verbal, two children were highly verbal. Treatment, including hippotherapy, was provided 1 time/week for 45 min to 1 hour for 8 weeks. Each therapy session was videotaped and included: a play activity; warm up; pace changes; school figures; transfers; forward, backward and sideways positioning on the horse; a client-centered coordination activity astride the horse; and preparation and feeding of the horse. We coded the videos for the frequency of repetitive/maladaptive behaviors per minute, words per minute, and verbalization quality during an early, mid, and late therapy session. Repetitive/maladaptive behaviors were categorized into arm/leg stereotypies, object-related stereotypes, and negative behaviors.

Results:

The average frequency and duration of RMBs decreased significantly from early to late sessions across all children. In the early sessions, negative and inappropriate behaviors made up approximately 55% of all coded behaviors, but at the late sessions, they only made up approximately 35% of all coded behaviors. In addition to the treatment variables, we also found some decrease in the frequency of RMBs from pre-test to post-test. Lastly, there were some improvements in spontaneous and responsive verbalizations following the 8-week intervention.

Conclusions:

We found a significant decrease in the frequency of RMBs from early to late treatment sessions and from pre-test to post-test. We also found that the percentage of negative and inappropriate behaviors decreased by about 20% from the early to late session and some improvement in verbalizations was also noted. Our findings support the growing body of literature that hippotherapy reduces repetitive/negative behaviors and may improve verbalization in children with ASD.

289 **243.289** The Moderating Effects of Implementation Factors on Improvement in Classroom Behaviors in Unstuck and on Target and Contingency Behavior Management

T. L. Hill[1], *L. Kenworthy*[2], *B. J. Anthony*[3], *M. Troxel*[3], *A. Verbalis*[2] *and L. Anthony*[3], *(1)Pediatric Mental Health Institute, Children's Hospital, Colorado, Aurora, CO, (2)Children's National Health System, Washington, DC, (3)University of Colorado, Denver, Aurora, CO*

Background: *Unstuck and On Target* (UOT; Cannon, Kenworthy, Alexander, Werner, & Anthony, 2018), a manualized executive function intervention for children with autism spectrum disorder (ASD) or attention deficit hyperactivity disorder (ADHD), has demonstrated effectiveness in increasing children's flexibility, organization, and planning skills. In a recent randomized effectiveness study comparing UOT to Parents and Teachers Supporting Students (PATSS), an enhanced contingency behavioral management intervention, neither interventionist profession (for the sample as a whole) nor average overall fidelity (for the sample as a whole and within each intervention group) was significantly related to improvements in students' classroom behaviors pre- to post-intervention.

Objectives: To examine the potential moderating effects of implementation factors (i.e., fidelity and interventionist profession) on improvements in classroom behavior.

Methods: The current study analyzed data from the randomized, comparative effectiveness study of UOT and PATSS in 21 Title 1 elementary schools. Participants included 136 3rd to 5th grade students with ASD (*n*=45) or ADHD (*n* =91). The outcome of interest was pre to post changes in masked observations of students' classroom behavior. The presence or absence of six behaviors were coded by observers and summed, yielding total scores ranging from 0 (i.e., the student exhibited every problem behavior during the observation) to 6 (i.e., the student exhibited no problem behaviors). Fidelity was measured through two observations of each interventionist, with observers rating ten items (e.g., content fidelity) on a 5-point scale (1 = strongly disagree, 5 = strongly agree) and an overall fidelity item on a 10-point scale. The potential moderating effects of the ten fidelity items rated at pre-intervention were explored within each intervention and diagnostic group as well as the sample as a whole, while the effect of interventionist position was explored within each intervention group and for the sample as a whole.

Results: For students in UOT (but not PATSS), interventionist profession had a significant effect on changes in classroom behavior, $F(4,63)=3.338$, $p=.015$. Specifically, the mean change in classroom behavior was significantly lower for students whose interventionist was a school social worker (M=.238) compared to students whose interventionist was a teacher. It did not matter whether the interventionist was a school psychologist, counselor, special education teacher, or school administrator. Significant intervention-specific relationships between fidelity and changes in classroom behavior were observed for students with ASD (but not for ADHD). For students with ASD who participated in UOT, greater use of visuals during sessions was associated with greater improvement in classroom behavior, $r(21)=.435$, $p=.049$. For students with ASD who participated in PATSS, greater adherence to content delivery was associated with greater improvement in classroom behavior, $r(15)=.582$, $p=.023$.

Conclusions: Interventionist profession was related to changes in classroom behavior for students in UOT but not PATSS; however, this finding should be interpreted with caution due to small numbers of certain interventionist positions in the analysis. Furthermore, although specific fidelity ratings were related to changes in classroom behavior for students with ASD, the aspects of fidelity that were related to improvements in behavior differed across treatment groups.

290 **243.290** Humanoid Robot Social Intervention Shows Promise

R. Landa[1], *E. Holliday*[2] *and K. J. Greenslade*[3], *(1)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (2)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltmore, MD, (3)Communication Sciences and Disorders, University of New Hampshire, Durham, NH*

Background: Affect recognition is a core deficit in autism spectrum disorder (ASD); this deficit compromises ability to interpret facial cues to interpreting others' communicative intent. Humanoid robots offer potentially useful supports for interventions targeting social skills of children with ASD.

Objectives: 1) To evaluate responsiveness of children with ASD to a robot-mediated affect recognition intervention (ARI); and 2) To gather preliminary evidence on effect of an ARI curriculum on distal measures of affect recognition.

Methods: An RCT was used to investigate the effects of a social skills ARI for children 4-8 years with ASD on distal affect recognition measures. Participants were randomized to the ARI (Milo) (n=20) or Treatment-As-Usual (TAU) group (n=20) utilizing a matched-pairs design. The Milo group participated in a maximum of 24 sessions with the Milo robot and an instructor. Three treatment subgroups were created based on participants' rate of skill acquisition in Milo's affect curriculum (Slower, Moderate, Average+Rapid Rate). Demographic and outcome variables were examined for each treatment subgroup.

Results: Milo participants advanced through the ARI curriculum with an average total accuracy rate of 84%. Families were highly engaged, reflected by low attrition (5%) during the treatment phase. All parents either agreed (16%) or strongly agreed (84%) on the importance of weekly Milo treatment sessions, and 79% of parents rated the treatment as "very" or "very much" worthwhile. In the Milo group, 70% of children reported enjoying learning about emotions, and 75% reported enjoying how the robot helped them learn emotions. Descriptive analyses of the Milo subgroups revealed that Slower Rate (M age=55.71 months, SD=5.85) and Moderate Rate (M=59.46 months, SD=18.70) groups were significantly younger than the Average+Rapid Rate (M=81.71 months, SD=9.35) group (p=.0004, p=.0065). The Slower Rate group had higher ADOS-2 Total scores (M_{Total}=19.33, SD=1.15) and calibrated severity scores (CSS) (M_{CSS}=9.00, SD=1.00) compared to the Moderate (M_{Total}=9.66, SD=3.05; M_{CSS}=5.00, SD=1.00; p=.0068, p=.0080, respectively) and Average+Rapid Rate groups (M_{Total}=12.92, SD=4.64; M_{CSS}=7.35, SD=1.69; p=.0351,p=.1310, respectively). Repeated measures ANOVAs revealed no significant differences between Milo and TAU groups on the NEPSY-II Affect Recognition subscale [F(1,37)=0.05, p=0.818] or on The Transporters computerized quiz (Autism Research Centre, 2009) (1) matching questions [F(1,37)=0.18, p=0.6749], (2) identification questions [F(1,37)=1.63,p=0.2097], and (3) scenario questions [F(1,37)=0.16,p=0.6928].

Conclusions: Results show promise for humanoid robot-mediated intervention in engaging children with ASD. Indicators of treatment acceptability were high among parents and children, suggesting social validity of the intervention. A comprehensive analysis of the three Milo subgroups revealed important and unique trends that may inform future research with children with ASD and ARI. Older children and those with lower levels of ASD symptoms tended to progress through the curriculum at a faster rate than younger children or those with more severe ASD symptoms. Exploratory findings suggest there may be specific variables that could predict children's responsiveness to social robotic interventions. Although group differences were minimal on distal measures of affect recognition, the Milo robot has several other social skills curricula which warrant evaluation of efficacy.

291 **243.291** Effectiveness of Noise-Attenuating Headphones in Children with Autism Spectrum Disorders

B. Pfeiffer[1] *and L. I. Duker (Stein)*[2]*, (1)Rehabilitation Sciences, Temple University, Philadelphia, PA, (2)Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA*

Background: Children with Autism Spectrum Disorders (ASD) often demonstrate atypical responses to auditory stimuli in the environment (Stiegler & Davis, 2010). This can increase stress and overall arousal levels impacting functional performance (Pfeiffer et al., 2017). There are a number of methods to create more optimal auditory environments including the use of noise-attenuating headphones (NAH). Although this is often a low-cost and easily implemented intervention, there is minimal research documenting its effectiveness.
Objectives: The objective of this study was to examine the effectiveness of two types of NAH in reducing stress in children with ASD while in natural environments.

Methods: Single-case study design with randomization to sequence of intervention (ABAC or ACAB) was used to test the effectiveness of two NAH. Six children between the ages of 8 and 16 diagnosed with ASD completed the study and were randomly assigned into two groups for different phase sequences. Five points of data were collected in the 4 phases of baseline, intervention 1, wash out, and intervention 2. Participants were provided with a set of Bose over-ear and in-ear NAH for the intervention phases. Physiological data of heart rate and electrodermal responses (EDR) were collected using an Empatica wireless wearable device to measure arousal state. Momentary assessment data was collected on type of daily activity and environmental stimuli. Smart phone technologies collected decibel readings two times in each session and a visual scan of the environment. Moeyaert's model parametrization, a multilevel hierarchical linear random effect model was used to evaluate treatment effects (Manolov & Moeyaert, 2017).

Results: Participants had significantly lower NS-SCR scores (G1: = 15.67, $p < .001$; G2: = 33.65, $p < .001$) during the intervention phases as compared with the baseline. The levels of NS-SCR scores did not differ (G1: = 0.35, $p = .557$; G2: = 2.07, $p = .151$) between over-ear and in-ear phases. SCL scores were also significantly lower (G2: = 238.04, $p < .001$) during the intervention phases compared with the baseline for a random subsample. SCL scores were similar (G1: = 0.00, $p = .979$; G2: = 0.04, $p = .845$) between different intervention phases. Participants also had lower heart rates (G1: = 23.87, $p < .001$; G2: =111.23, $p < .001$) during intervention phases as compared with the baseline, in particular during the in-ear intervention (G1: = 23.66, $p < .001$; G2: = 43.29, $p < .001$). Further analyses showed that the interventions may have moderating effects on the relationships between environmental noises and the physiological responses, in particular NS-SCR (= 3.34, $p = 0.067$) and SCL (= 2.83, $p = 0.092$) levels.

Conclusions: Results provide preliminary evidence for the use of NAH to reduce or maintain physiological arousal levels in stimulating environments for children with ASD. Generalization is limited due the single-case approach. Findings provide information to guide treatment planning when integrating environmental-based interventions in natural settings.

292 **243.292** A Systematic Review of the Role of Parent Characteristics in Parent-Mediated Interventions for Children with Autism Spectrum Disorder

R. Shalev[1]*, C. Lavine*[1] *and A. Di Martino*[2]*, (1)Child Study Center at NYU Langone Health, New York, NY, (2)The Child Mind Institute, New York, NY*

Background: Parent-mediated interventions (PMI) are increasingly being employed to improve outcomes for individuals with Autism Spectrum Disorder (ASD). Although the benefits of PMI are well documented (Oono et al., 2013), it is unclear whether parents' characteristics affect their children's outcomes. The lacuna is notable given long-standing literature suggesting that parents' characteristics – including stress, mental health concerns, education, demographics, and certain cognitive profiles – may affect parents' participation in treatment (Burrell & Borrego, 2012; de Veld et al., 2017; Karst & Van Hecke, 2012; Kazdin & Weisz, 2003). Better knowledge of how these characteristics, which are observed in parents of children with ASD, bear on PMI may enhance treatment procedures and outcomes.
Objectives: We reviewed the PMI literature and identified articles that explored the relationship between parent characteristics and children's treatment outcomes.

Methods: We conducted multiple searches across PubMed, PubMed Central, and Web of Science databases, and screened, selected, and included articles in accordance with PRISMA guidelines (Moher, Liberati, Tetzlaff, Altman, & The PRISMA Group, 2009). We included articles that (a) were published in a peer-reviewed journal from 1987 to September 2018; (b) were written in English; (c) included at least one participant with a diagnosis of a Pervasive Developmental Disorder based on the DSM-III-R (American Psychiatric Association, 1987) or ASD in later DSM versions or the ICD classification systems; (d) included an intervention that explicitly employed a parent-mediated approach; (e) reported outcomes that focused on children's behavior; (f) and employed an experimental design. Two authors then extracted and recoded key information about each study that met those criteria and was available in full text.

Results: We identified 511 unique articles that satisfied our selection criteria; of them, 115 met criteria for full-text review and 11 (~10%) examined the relationship between parent characteristics and children's treatment outcomes. Their results indicated that stress, socioeconomic status, and the broad autism phenotype may be related to children's outcomes in PMI, with the direction of the effects varying based on the specific treatment and outcome examined.

Conclusions: Existing literature suggests that treatment response may vary as a result of the individual characteristics of the child and/or parent in PMI. In recent years, researchers have strived to understand how the characteristics of the child affect treatment response. But, as shown by the limited number of studies available to date, we know far less about how the characteristics of the parent bear on children's outcomes. Further research on that front is essential to understanding which families are best suited for particular interventions and how treatment procedures can be modified to improve intervention efficacy.

293 **244.293** Atypical Anatomy of Primary Visual Cortex and Links with Intelligence in Children with Autism Spectrum Disorders

M. A. Reiter[1,2], *J. S. Kohli*[1,2], *R. J. Jao Keehn*[1], *I. A. Martindale*[1], *C. H. Fong*[3], *R. A. Carper*[1,2], *I. Fishman*[2,3] *and R. A. Mueller*[2,3], *(1)Brain Development Imaging Laboratories, Department of Psychology, San Diego State University, San Diego, CA, (2)Joint Doctoral Program in Clinical Psychology, SDSU / UC San Diego, San Diego, CA, (3)Brain Development Imaging Laboratories, San Diego State University, San Diego, CA*

Background: Previous research has indicated that individuals with Autism Spectrum Disorders (ASDs) show widespread abnormalities in cytoarchitecture and MRI derived measures of neuroanatomy, including cortical thickness (CT) and surface area (SA). However, primary visual cortex (V1) has received relatively little attention. Functional MRI findings, on the other hand, have shown atypical recruitment of V1 during performance on language and cognitive tasks in ASDs. In a previous study on a smaller, partially overlapping sample, our group found differences in functional connectivity of V1 in comparisons of ASD subgroups with high (>115) vs. low (<85) IQ.
Objectives: To characterize CT and SA of V1, and relate these measures to intellectual functioning in children with and without ASDs.

Methods: High quality T1 MRI scans from 165 children [83 ASDs, 82 Typically Developing (TD)], ages 7-18 [mean age(standard deviation) =13(3), mean IQ = 108(13), range: 66-141)], from two ABIDE sites (San Diego State University and New York University), were included. Groups were matched on age, sex, handedness, and IQ. After standard preprocessing and rigorous quality control of images, CT and SA of left and right pericalcarine (V1) cortex, and left and right hemisphere were calculated using Freesurfer. Linear regression was used to test group differences in CT and SA, as well as group by IQ interactions; relationships between age and CT and SA, and group by age interactions were also examined. In all analyses, we controlled for scanning-site and average whole-hemisphere CT or total SA.

Results: The ASD group had significantly decreased left V1 SA compared to the TD group (p = .002). In contrast, V1 CT was significantly increased bilaterally (left: p = .03; right p =.02) in the ASD, compared to the TD group. Diagnosis significantly moderated the relationship between IQ and V1 SA, bilaterally (left: p = .01; right p =.02). There was no such moderating effect for CT. ASD symptom severity (ADOS scores) was not significantly related to V1 SA or CT. Finally, independent of diagnosis, age significantly predicted an increase in right V1 SA (p = .004), and decrease in right V1 CT (p < .001); however, after controlling for whole-hemisphere SA/CT these effects were not significant.

Conclusions: In congruence with the literature on atypical function of visual regions in ASD, we found abnormal anatomy of V1 (reduced SA, but increased CT). Our findings add an anatomical basis to the growing evidence of a 'special status' of visual functions in behavioral profiles of intelligence in ASDs. In ASDs, but not in matched TD controls, SA of V1 was positively associated with IQ. Notably, diagnosis did not moderate the relationship between IQ and whole hemisphere SA, indicating that this effect may have some specificity for visual cortex. In contrast, age-effects were not specific to visual cortex, and didn't differ by group. These results suggest that our previous findings, implicating atypical functional connectivity of the pericalcarine cortex in intellectual functioning in autism, extend to the underlying anatomical morphology, including CT and SA, and that these differences may emerge before mid-childhood/adolescence.

294 **244.294** Developmental Trajectory of Pathological Brain Growth in a Mouse Model of Pten Haploinsufficiency: An MRI Study

A. E. Clipperton-Allen[1], *O. S. Cohen*[1], *M. Aceti*[1,2], *J. Levy*[1], *A. Zucca*[1], *J. Ellegood*[3], *J. P. Lerch*[3] *and D. T. Page*[1], *(1)Neuroscience, The Scripps Research Institute, Jupiter, FL, (2)Drug Discovery, Moffitt Cancer Center, Tampa, FL, (3)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada*

Background: Macrocephaly/autism syndrome is caused by mutations in the gene *PTEN* (*Phosphatase and tensin homolog*), which encodes a negative regulator of the PI3K-Akt-mTOR pathway. Some individuals with autism spectrum disorder (ASD) and/or *PTEN* mutations show brain enlargement and white matter abnormalities. Mice haploinsufficient for *Pten* (*Pten*$^{+/-}$) display brain overgrowth and ASD-like behavioral phenotypes.
Objectives: While *Pten*$^{+/-}$ mice show macroscale brain overgrowth, it is unknown whether this is region-specific or consistent across the brain. We used magnetic resonance imaging (MRI) to analyze the volume of the brain and individual structures in *Pten*$^{+/-}$ and wild-type littermate control (WT) mice at postnatal day 7 (P7; equivalent to human birth) and in adulthood (P60).

Methods: MRI was performed on brains of male WT and *Pten*$^{+/-}$ mice collected at P7 (WT: n=10; *Pten*$^{+/-}$: n=10) and P60 (WT: n=10; *Pten*$^{+/-}$: n=9) to measure the volume of different structures. Immunohistochemistry, immunocytochemistry, isotropic fractionator, and flow cytometry were used

to confirm findings and to examine glial overgrowth in the *Pten*$^{+/-}$ mice. All experiments were performed blind to genotype.

Results: *Pten*$^{+/-}$ mice showed similar patterns of regional overgrowth to humans with *PTEN* mutations and ASD. At P7 and P60, virtually all individual regions, collapsed grey matter (GM), collapsed white matter (WM), and total brain volume were increased. Examining relative volume across brain areas, we found that WM was increased, and GM was decreased, in adulthood, similar to human patients. Juvenile *Pten*$^{+/-}$ mice showed no relative differences in WM or GM. This may be due to increased inter-subject variability at P7 relative to P60, which is more pronounced in *Pten*$^{+/-}$ mice. Previously, we found hyperplasia in neuronal but not glial populations at P0. At P7, however, we found increased glia, but not neurons, indicating that the adult pattern of hyperplasia was already established. This increased proliferation of glia likely contributes to increased WM volume.

Conclusions: *Pten*$^{+/-}$ mice recapitulate the increased brain volume, WM overgrowth, and regional relative volume increases found in individuals with macrocephaly/autism syndrome. Increased variability among P7 *Pten*$^{+/-}$ mice in comparison to age-matched controls and *Pten*$^{+/-}$ adults suggests that specific brain region growth may be desynchronized across animals and during early developmental stages before stabilizing by adulthood. These findings indicate that *Pten*$^{+/-}$ mice are a useful model for investigating the mechanistic basis of brain structure abnormalities found in humans with *PTEN* haploinsufficiency. Furthermore, this model may help illuminate the relationship between abnormal scaling across brain areas and the behavioral and cognitive symptoms of ASD and intellectual disability.

295 **244.295** Neuroanatomical Underpinnings of Autism Symptomatology in 22q11.2 Deletion Syndrome and Idiopathic Autism Spectrum Disorder

A. Bletsch[1], *M. Gudbrandsen*[2], *C. Mann*[1], *E. Daly*[2], *C. M. Murphy*[2], *R. H. Wichers*[2], *V. Stoencheva*[2], *E. Perry*[2], *D. S. Andrews*[3], *C. E. Blackmore*[2], *M. Rogdaki*[4], *L. Kushan*[5], *C. Bearden*[5], *D. G. Murphy*[2], *M. Craig*[2,6] *and C. Ecker*[1,2], *(1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe-University Frankfurt am Main, Frankfurt, Germany, (2)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (4)Psychiatric Imaging Group, MRC London Institute of Medical Sciences, Imperial College, London, United Kingdom, (5)University of California, Los Angeles, CA, (6)National Autism Unit, Bethlem Royal Hospital, London, United Kingdom*

Background:

22q11.2 Deletion Syndrome (22q11.2DS) is a genetic condition resulting from a microdeletion at the q11.2 band of chromosome 22 (Scambler et al., 1992). All individuals with 22q11.2DS display a deletion within the same locus of chromosome 22. However, the phenotypic consequences of the deletion are both complex and variable (McDonald-McGinn et al., 2015), making the neurobiology of 22q11.2DS inherently difficult to characterize. One of the neuropsychiatric phenotypes commonly present in 22q11.2DS is co-morbid autism spectrum disorder (ASD)-symptomatology. However, the neuroanatomical underpinnings of these symptoms remain poorly understood.

Objectives:

We aimed to establish (1) whether the neuroanatomical underpinnings of ASD-symptomatology in 22q11.2DS are shared with - or distinct from - the neural systems mediating autistic symptoms in idiopathic ASD, and (2) whether the neuroanatomy of ASD is significantly modulated by the 22q11.2 microdeletion.

Methods:

We examined neuroanatomical differences in 126 individuals (6-25 years; 66 males and 60 females; IQ ≥ 60) assessed at three sites: (1) the Child and Adolescent Psychiatry, Frankfurt, Germany; (2) the King's College London, UK; and (3) the University of California, Los Angeles, US. The total sample included (1) 25 individuals with 22q11.2DS who also met diagnostic criteria for ASD (22q11.ASD), (2) 25 individuals with 22q11.2DS without a diagnosis of ASD (22q11.nonASD), (3) 25 individuals with idiopathic ASD, and (4) 51 neurotypical controls. All groups were matched for age and gender. The 22q11.2 microdeletion was confirmed by *in-situ* hybridization (FISH) or microarray analysis test. ASD-symptomatology was assessed using the Autism Diagnostic Interview-Revised (ADI-R; Lord et al., 1994). We employed a 2-by-2 factorial design, controlling for age, gender, site, IQ, and total brain measures to identify neuroanatomical diversity associated with (1) the 22q11.2 microdeletion (i.e. main effect of 22q11.2DS), (2) ASD-symptomatology (i.e. main effect of ASD), and (3) a 22q11.2DS-by-ASD interaction term.

Results:

We observed a significant main effect of ASD for cortical volume (CV), cortical thickness (CT), and surface area (SA) in several regions across the cortex that have previously been linked to wider autistic symptoms and traits (e.g. superior temporal lobes, entorhinal cortices, and anterior cingulate cortex). Moreover, individuals with 22q11.2DS were neuroanatomically distinct from those without the microdeletion displaying (1) decreased CV, SA, and CT in occipito-temporal and cingulate regions, and (2) increased CV and SA in frontal regions (see **Fig.1**). Notably, we also identified brain regions (i.e. dorsolateral prefrontal cortex, precentral gyrus, and posterior cingulate cortex) where the 22q11.2 microdeletion significantly interacted with ASD-symptomatology to elicit neuroanatomical differences that could not be predicted by either main effect alone (see **Fig.1** and **Fig.2**). Thus, in these brain regions the neuroanatomy of ASD-symptomatology was modulated by individuals having the 22q11.2 microdeletion.

Conclusions:

Our findings indicate that even though behaviourally similar, the neuroanatomical underpinnings of ASD-symptomatology differ between individuals with the 22q11.2 microdeletion and those without. Thus, the co-existence of both conditions does not appear to represent a combination of the neuroanatomical diversity exhibited by each of the two conditions in isolation, but rather constitutes an independent subgroup with a unique neurophenotype.

Background: There is increasing interest in the use of cannabis and its major non-intoxicating component cannabidiol (CBD) as a treatment for mental health and neurodevelopmental disorders, e.g. autism spectrum disorder (ASD). ASD is a common but complex condition, which shortens life. Currently there are no effective pharmacological treatments for its core symptoms. Therefore alternative options, such as CBD, are beginning to be explored. However, before embarking on large-scale clinical trials, it is necessary to better understand how CBD acts on human brain, and in ASD specifically. Among CBD's multiple actions there is preclinical evidence that it may directly or indirectly modulate brain excitatory glutamate (E) and inhibitory γ-aminobutyric acid (GABA) (I) systems, including in brain regions linked to ASD, such as the basal ganglia (BG) and the dorsomedial prefrontal cortex (DMPFC). Also, abnormalities in glutamate and GABA pathways are consistently associated with ASD.
Objectives: Therefore, for the first time, we tested whether CBD 'shifts' glutamate and GABA in the BG and DMPFC in adults with and without ASD *in vivo*.

Methods: We used a placebo-controlled, cross-over, double-blind design and magnetic resonance spectroscopy (MRS) to investigate the impact of CBD on measures of glutamate (Glx = glutamate + glutamine) and GABA in 34 healthy men (neurotypicals n=17, ASD n=17). Data acquisition from the left BG (including the caudate and putamen) and bilateral DMPFC (including the anterior cingulate cortex) was timed to commence (at peak plasma levels) 2 hours after a single oral dose of 600 mg CBD or placebo.

Results: There were no baseline group differences in Glx or GABA concentration. Also, the response of Glx to CBD challenge was similar. In both groups CBD increased Glx in the BG but decreased it in the DMPFC ($F(1,21)=5.235$, $p=.033$). In contrast, there were significant group differences in GABA response. In both regions CBD increased GABA in the neurotypicals, but decreased it in ASD ($F(1,22)=13.506$, $p=.001$).

Conclusions: Our results provide the first direct evidence that CBD can modulate the glutamate and GABA system in neurotypicals and in ASD. However, prefrontal-subcortical GABA systems respond differently in ASD. Our results do not speak to the efficacy of CBD; therefore the next steps will be to examine the effects of more chronic administration on brain and behaviour; and to determine if acute brain changes predict longer-term response.

297 **245.297** Citalopram Modulates the Neural Systems Involved in Processing of Facial Emotion in ASC but NOT in Neurotypical Controls

N. Wong[1,2,3], *R. H. Wichers*[2,4], *J. Findon*[1,2,5], *V. Giampietro*[6], *V. Stoencheva*[1,2,3], *C. M. Murphy*[2,4], *C. Ecker*[7], *D. G. Murphy*[2,3,8,9], *G. M. McAlonan*[1,2,3,9] *and E. Daly*[2,4], *(1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Biomedical Research Centre for Mental Health at the Institute of Psychiatry, Psychology and Neuroscience and South London and Maudsley NHS Foundation Trust, London, United Kingdom, (4)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)Department of Neuroimaging, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom, (7)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe-University Frankfurt am Main, Frankfurt, Germany, (8)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (9)MRC Centre for Neurodevelopmental Disorders, King's College London, London, United Kingdom*

Background: The neurobiology underlying the processing of facial emotion is reported to be altered in autism spectrum conditions (ASC), but its neurochemical basis remains unclear[1]. Abnormalities in serotonin (5HT) systems have been linked to ASC and 5HT is also implicated in emotion control, but to our knowledge no one has examined whether serotonin reuptake inhibition modulates facial emotion processing regions in ASC.
Objectives: Therefore, we examined whether an acute dose of the selective serotonin reuptake inhibitor (SSRI) citalopram would alter the activity of the amygdala and fusiform regions (known to be involved in facial emotion processing) in adults with and without ASC in a task-based fMRI study.

Methods: A sample of 18 right-handed male adults with ASC (mean age=29.22 years, mean IQ=111.39) and 19 age and IQ matched neurotypical right-handed male adults (mean age=26.79 years, mean IQ=114.95) were included in the current randomised double-blind crossover study. Participants with ASC were diagnosed by consultant psychiatrists according to ICD-10 and all participants completed two MRI scanning sessions. They were given either 20 mg citalopram or placebo before scanning, during which an adapted version of an emotional face-matching task[2] was administered. The task consisted of eight experimental blocks and half of them were trials with angry/fearful faces and the other half were with geometric shapes (**Figure 1**). Participants were asked to match the images in each trial. The preprocessed task-based fMRI data were analysed with a general linear model approach and permutation testing using FSL.

Results: The amygdala was less activated in adults with ASC than controls in the *Faces>Shapes* contrast during placebo ($k=56$, $MNI_{xyz}=[27,-7,-25]$) and citalopram eliminated this difference (**Figure 2**). This was due to an increase in amygdala activation in adults with ASC but no change in controls post citalopram.

Conclusions: Serotonin reuptake inhibition 'restores' a typical pattern of amygdala activation during facial emotion processing in adults with ASC.

298 **245.298** Event-Related Functional Spectroscopy Reveals Distinct Glutamate and GABA Abnormalities in ASD and High-Risk Children

O. J. Surgent[1,2], *B. G. Travers*[1,3] *and B. Nacewicz*[1,4], *(1)University of Wisconsin - Madison, Madison, WI, (2)Neuroscience Training Program, Univeristy of Wisconsin-Madison, Madison, WI, (3)Occupational Therapy Program in the Department of Kinesiology, University of Wisconsin - Madison, Madison, WI, (4)Department of Psychiatry, University of Wisconsin - Madison, Madison, WI*

Background: Individuals with Autism Spectrum Disorder (ASD) often have impairments in social domains, such as difficulty decoding facial expressions and motor domains, including weakened grip strength. It is possible that a global imbalance of neural excitation and inhibition drives both of these behavioral atypicalities. In order to explore this potential relationship, we assessed grip response to perception of facial expressions using a motor-specific, event related, high-temporal resolution functional Magnetic Resonance Spectroscopy (ht-fMRS), which has the capacity to quantify second-by-second accumulation of the major excitatory and inhibitory neurotransmitters (i.e. glutamate and GABA) in specific regions of interest. Our ht-fMRS focused on the median pontine nuclei due to its implication in our prior DTI studies of ASD and the importance of these nuclei in integrating top-down emotion modulated startle circuits.

Objectives: 1) To use novel motor-specific ht-fMRS to characterize the neurochemical signature of perception of facial expression and initiation of grip response in the pons, and 2) to examine the motor-specific neurochemical signatures within the pons of children with ASD, at a high risk for ASD (ASD-Related), and with typical development (TD).

Methods: Data pertaining neurochemical accumulation during the perception of neutral and emotional faces and the subsequent grip response to those faces were gathered from 18 children with ASD, 12 children at a genetically higher risk for ASD (ASD-Related), and 13 children with TD, ages 6 -10 years. The ASD-Related group included children who had a genetic risk factor for ASD (i.e., having an ADHD diagnosis or a first-degree relative with ASD, major depressive disorder, bipolar disorder, or schizophrenia). Participants used bilateral MRI-compatible grip strength responders to indicate grip response (hard or light) in response to faces (emotional or neutral). A general linear model was constructed using the raw spectroscopic data to deconvolve the neurochemical signatures unique to grip in response to presentation of emotional and neutral faces.

Results: Baseline grip was associated with diagnostic group (p = 0.02), and latency to grip was significantly correlated with autism symptom severity (p=0.04). Neurochemical signatures of emotion modulation (emotion-neutral) of trial-by-trial grip intensity showed a blunted glutamate response in ASD compared to ASD-R and TD, but absent GABA in both ASD and ASD-R compared to TD (p =0.03).

Conclusions: Using a grip-strength and emotion task in ASD, we show a clearly impaired neurotransmitter response in ASD. Interestingly, we also find an intermediate phenotype in ASD-R: ASD-like GABA blunting but high-normal glutamate during emotion-modulated grip. Taken together these results provide evidence for altered neurochemical responses to sensory stimuli during a motor task in children with ASD as well as those with higher genetic risk for ASD.

299 **245.299** Excitatory-Inhibitory Response to GABA-B Challenge Is Different in Adults with and without an Autism Spectrum Condition

Background: The underlying neurobiology of Autism Spectrum Conditions (ASC) is still poorly understood, but progress is being made. Multiple lines of research converge to suggest that there are alterations in glutamate (excitation, E) and gamma-aminobutyric acid (GABA) (inhibition, I) function, especially in the GABA system(Coghlan et al., 2012). For example, post-mortem abnormalities in $GABA_B$ receptor expression [which regulates the release of both glutamate and GABA(Padgett and Slesinger, 2010)] have been reported in ASC (Fatemi et al., 2009). Our recent studies suggest that brain E-I responsivity differences in ASC can be detected in-vivo using proton magnetic resonance spectroscopy (^{1}H-MRS) (Ajram et al., 2017), however, no one has directly tested whether $GABA_B$ receptors modulate E-I differently in autistic individuals compared to neurotypical individuals.

Objectives: In the current study we used ^{1}H-MRS HERMES (Saleh et al., 2016) to investigate the role of $GABA_B$ receptors in the modulation of E-I after a single high or low oral dose of Arbaclofen, a $GABA_B$ receptor agonist, compared to placebo in adult men with and without ASC.

Methods: Thirty-two adult men, half with ASC, were scanned on 3 different days at least 5 days apart to ensure complete drug washout. On each visit a single-dose of Arbaclofen (15mg or 30mg) or placebo was administered in a double-blinded, randomised order. ^{1}H-MRS data collection from the dorsomedial prefrontal cortex (DMPFC) and medial occipital cortex (mOCC) started 60 min after drug administration, corresponding to expected drug peak plasma levels. We computed the Glx/GABA+ (E-I) ratio (Glx = Glutamate + Glutamine; GABA+ = GABA + macromolecules) and used a repeated measures ANOVA to test group, drug, and group x drug interaction effects within each voxel.

Results: Group differences: There was no main effect of group in E-I measures in the DMPFC. There was a main effect of group (p=0.021) in the mOCC region; E-I was lower in the ASC group. Effect of drug: Arbaclofen shifted E-I in the DMPFC voxel in both groups (main effect of drug p=0.024). However, the direction of change was different in the two groups (interaction *p*=0.026). In controls, E-I was reduced by both the 15mg and 30mg doses compared to placebo; however, this E-I reduction only reached statistical significance at the higher dose (p=0.017). Conversely, in the ASD group, low dose Arbaclofen increased E-I above baseline; high dose Arbaclofen decreased E-I below baseline, thus E-I was significantly higher in

the 15mg Arbaclofen condition compared to the 30mg condition (p=0.026). There was no drug effect or drug x group interaction in the mOCC voxel.

Conclusions: The responsivity of $GABA_B$ receptor systems is atypical in ASC. Arbaclofen is currently being examined in Clinical Trials for ASC. Our finding that the effect of Arbaclofen in ASC is both dose and region dependent may have implications for dose selection and/or understanding how this target engagement relates to a longer-term treatment response.

300 **245.300** Imbalance Glutathione Biosynthesis in Cingulated Cortices: ASD Kinetic Patterns In Vivo.

C. D. Jimenez-Espinoza[1,2], *F. J. Marcano Serrano*[2] *and J. L. González-Mora*[1,2,3], *(1)Physiology, University of La Laguna, Santa Cruz de Tenerife, Spain, (2)Neurochemistry and Neuroimage Lab., University of La Laguna, Santa Cruz de Tenerife, Spain, (3)University Hospital of Canary Islands HUC, La Laguna, Spain*

Background: Toxic effects defenses of reactive oxygen species are an essential task within the brain during a long human life, which indicates the presence of an effective antioxidant system. Markers of oxidative stress are strongly associated with severe mitochondrial dysfunction in autism spectrum disorders (ASD) pathology associated with deficits in the antioxidant defense of glutathione in selective regions of the brain, although the molecular pathway continue being unclear. Glutathione (GSH; γ-L-glutamyl-L-cysteinyl-glycine) is the most abundant endogenous antioxidant present in mammalian cells (0.1 to 15 mM) and plays a protective role for exogenous toxins and endogenous in the central nervous system. It biosynthesis pathway, have two consecutive reactions that consume ATP, including two enzymes; glutamate cysteine ligase (GCL), and glutathione synthetase (GSS), to generate GSH. Previously, we described the kinetic imbalance in tri-cellular metabolism of N-acetyl-aspartyl glutamate (NAAG), in anterior (ACC) and posterior (PCC) cingulated cortices relate to the executive control networks and the attention alert functions linked to pathogenesis of ASD, which lead the next step in our investigation to elucidate the multiple causes of imbalance neurochemistry linked to cingulated cortices.

Objectives: To study Kinetic imbalance of glutathione biosynthesis in the cingulated cortices as target of oxidative stress in individuals with ASD using ^{1}H-MRS.

Methods: Single voxel (^{1}H-MRS) in ACC and PCC, in adults with a clinical diagnosis of ASD (n=21) and controls (TD) typically development (n=46), matched for age, gender and Autism quotients (AQ) score were assessed. The affinity between enzyme and substrate (ES) associated with GSH biosyntethis was measured as Michaelis Menten constant (Km). Statistic one-way ANOVA and Bonferroni correction were applied.

Results: Km for glutathione biosynthesis in ASD group is significantly lower [$1.1e^{-012}$ (mM)]; R^2 = 0.001 in ACC and the dissociation constant (ki) reduced 67.22% compared to the TD group. Conversely, Vmax of the appearance of the product that depends on the slowest process of the reaction is significantly decreased [15.12 µM / min]; R^2 = 0.51 in PCC.

Conclusions: Imbalance enzymatic kinetic in ASD does not mean that the enzyme is not present. Our findings indicate that, at a small amount of substrate, the rate increases rapidly and linearly in ACC, suggesting that the active sites of the enzyme are saturated with the substrate. The enzyme-substrate complex is very tight and rarely dissociates without the substrate reacting to give the product. Imbalance enzymatic kinetic in glutathione biosynthesis in the autism cingulated cortices is a novel finding indicative of a chronic neuroinflamatory state in these regions. We further conclude that a better understanding of the enzymatic activity in the synthesis of glutathione in the cingulated cortices can lead us to a new therapeutic pathway in the treatment of individuals with ASD.

11:30 AM - 1:30 PM - Room: 710

301 **246.301** Longitudinal EEG Markers of Language Development in Infants and Toddlers at Risk for Autism Spectrum Disorder

C. L. Wilkinson[1], *L. Gabard-Durnam*[2], *A. R. Levin*[3], *K. Kapur*[4], *H. Tager-Flusberg*[5] *and C. A. Nelson*[6], *(1)Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Pediatrics, Harvard Medical School, Boston, MA, (3)Neurology, Boston Children's Hospital, Boston, MA, (4)Department of Neurology, Boston Children's Hospital, Boston, MA, (5)Psychological and Brain Sciences, Boston University, Boston, MA, (6)Boston Children's Hospital, Boston, MA*

Background:
Language development in children with autism spectrum disorder (ASD) varies greatly. While many children first present with delayed language skills, roughly one quarter go on to have age-appropriate language skills by school age, and an estimated 30% will be minimal verbal. One of the best predictors of later achievement in children with ASD is language acquisition. Despite this, we know little about the neurobiological correlates of language development in infants at high risk for autism. Here we present the results from baseline EEG data longitudinally collected from infants, as part of the Infant Sibling Project, aimed at comparing infants with familial risk of developing ASD with low risk controls.

Objectives:

This study aims to characterize longitudinal EEG data collected over the first two years of life in children at low (LR) and high risk (HR) for autism, and specifically determine (1) which EEG measures correlate with later language development and (2) whether there are differences between LR and HR infants.

Methods:

Each infant was seen at multiple points between 3 and 36 months for EEG collection, developmental evaluation using the Mullen Scales of Early Learning (MSEL), and eventual ASD evaluation at 18, 24, or 36 months. Data used for this analysis was collected from 112 infants (54LR, 58HR). Ordinary least squares modeling of longitudinal baseline power from 3 to 24 or 3 to 12 months over several frequency bands was used to determine each infant's estimated 6-month intercept and slope. Multivariate linear regression was then used to characterize the relationship between EEG measures and the MSEL verbal quotient at 24 months.

Results:

Model estimated language scores significantly correlated with actual scores (Model Adjusted R^2 = 0.329; Pearson r = 0.70, 95% CI:

0.59-0.78,*P*=1x10^{-18}). Two-way interactions between risk and EEG measures were assessed to characterize differences in brain-language associations between LR and HR infants. Here we found that estimated 6-month intercept in low frequency bands delta and theta significantly contributed to estimated language scores *only*in the HR group, while estimated beta slope significantly contributed to estimated language only in the LR group. A second model, limited to EEG data collected between 3-12 months of age estimated language scores with similar accuracy (Pearson r = 0.66, 95% CI: 0.54-0.76,*P*=2.5x10).

Conclusions:

These data support the potential use of longitudinal EEG data in providing estimates of future language development in HR infants. Furthermore, these data support a growing body of research showing early brain differences between LR and HR infants regardless of ASD diagnosis, and emphasizes the need to characterize EEG biomarkers of language development in ASD within a high-risk population. Future work will further characterize these differences between risk groups, and determine the effect of ASD as a possible mediator of EEG predictors of language within the high-risk group.

302 **246.302** An EEG Biomarker of Delayed Sensitive Period Onset in Autism Spectrum Disorder

L. Gabard-Durnam[1], *C. L. Wilkinson*[2], *T. Hensch*[3], *H. Tager-Flusberg*[4] *and C. A. Nelson*[5], *(1)Pediatrics, Harvard Medical School, Boston, MA, (2)Developmental Medicine, Boston Children's Hospital, Boston, MA, (3)Harvard University, Cambridge, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA, (5)Boston Children's Hospital, Boston, MA*

Background:

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder thought to result from dysregulated sensitive periods in development. Sensitive periods are windows of increased neuroplasticity when experiences get embedded in brain function with lifelong effects on cognition and behavior. Neural measures of sensitive periods in animal models have shown that the timing of sensitive periods is regulated by maturing inhibition, which shifts the balance of spontaneous neural activity and experience-induced neural activity (the S/E ratio). Specifically, the S/E ratio decreases during sensitive period onset relative to pre-sensitive period levels.

Objectives:

The present study sought to translate the S/E ratio measure of sensitive period onset into human ASD neurodevelopment with longitudinal high-density electroencephalography (EEG) from 3 to 12 months of age. Specifically, this study tested how the language phoneme sensitive period manifests in ASD neurodevelopment, as language deficits are frequent ASD symptoms. We hypothesized that reduced neural inhibition in ASD may delay the developmental timing when inhibition is robust enough to reduce the S/E ratio (i.e. delayed sensitive period opening).

Methods:

Data were contributed by 79 typically developing infants (TD), 67 high-risk infants without ASD at 3 years (HR-), and 24 high-risk infants with ASD diagnoses at 3 years of age (ASD+). Spontaneous EEG power was collected with a silent baseline recording, while experience-induced EEG power was generated by a phoneme oddball paradigm. All EEG data were processed through HAPPE software, optimized for developmental EEG data. The ratio of spontaneous EEG power to phoneme induced EEG power was calculated over auditory cortex to generate the S/E ratio.

Results:

The S/E ratio in TD infants decreased between 3 and 6 months of age, consistent with the native phoneme sensitive period onset behaviorally ($p < 0.05$, n = 79). However, the S/E ratio in ASD+ infants remained elevated at 6 months of age, and was significantly higher than both HR- and TD infants ($p = 0.015$, n = 170), consistent with a delayed phoneme sensitive period. HR- infant S/E ratios did not differ from those of TD infants at any timepoint. Post-hoc analyses showed the elevated 6-month S/E ratio in the ASD+ infants was due to elevated spontaneous EEG power, consistent with the model of hyper-excitability in early ASD neurodevelopment. The S/E ratio in ASD+ infants was significantly negatively associated with later receptive language scores at 12 months ($p < 0.05$, n = 24).

Conclusions:

These findings suggest early auditory sensitive periods may be delayed in ASD with ramifications for later language development. This delay appears to be specific to infants who go on to ASD diagnoses, rather than reflecting high-risk for ASD. Moreover, the S/E ratio measure may serve as a translational sensitive period biomarker that can link ASD animal model insights to human brain and behavior development.

303 **246.303** Using the Mcgurk Effect to Investigate the Neural Indices of Audiovisual Speech Processing in Infants at Risk for ASD

K. H. Finch[1], *C. A. Nelson*[2] *and H. Tager-Flusberg*[3], *(1)Boston University, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)Psychological and Brain Sciences, Boston University, Boston, MA*

Background:

The McGurk effect is an audiovisual (AV) illusion such that when the listener hears one syllable, /ba/, while seeing a speaker articulate /ga/, people report hearing /da/ (McGurk & MacDonald, 1976). Individuals with ASD are thought to have impairments in AV integration since they have difficulty perceiving the McGurk effect (Irwin et al., 2011) and show atypical neural processing to AV speech as measured by event-related potentials (ERPs; Magnee et al., 2011). Little is known about how ERPs to AV speech differ earlier in development.

Objectives: Our current study investigated ERPs in response to AV speech in infants at risk for developing ASD. We included infants at familial risk, infants who fail a 12-month screener, and an age-matched group of low-risk infants.

Methods:

*Participants*Seventy 12- to 14-month-olds (M=13.47) were divided into two groups: 1)low-risk typically developing controls (LR; N=41) or 2)high-risk for ASD (HR; N=32) defined as having an older sibling with ASD (N=18) or failing the Communication and Symbolic Behavior Scales Checklist (Wetherby & Prizand, 2002; N=14).

*Procedure*ERPs were recorded while infants watched 4 video types up to 120 times: 1)AV-congruent-ba (Visual-ba, Audio-ba or VbaAba), 2)AV-congruent-ga (VgaAga), 3)AV-incongruent-impossible (VbaAga), and 4)AV-incongruent-McGurk (VgaAba).

*Analysis*Analyses focused on the mean amplitude of the AV mismatch response (AVMMR; 290-390ms post-audio-onset) as it is modulated by

incongruent AV speech in infants (Kushenerenko et al., 2013). We combined the AV-congruent conditions (conditions 1 and 2). Controlling for age, we analyzed AVMMR differences using an ANOVA across 3 conditions (AV-congruent, AV-impossible, AV-McGurk), two regions of interest (central, temporoparietal), and two hemispheres (left, right; see Figure1). Also, given that the AVMMR relates to age specifically in the AV-impossible condition, we conducted Pearson correlations between age and AVMMR.

Results:

We found no condition or group differences at central sites (all *p*'s>0.200). At temporoparietal sites, there was a significant condition by hemisphere response (F(2, 140)=4.36, *p*=.015; see Figure2). Follow-up analyses revealed that AV-impossible showed a more negative response in the left temporoparietal sites compared to AV-Congruent (*p*=.034) and AV-McGurk (*p*=.050). There were no other main or interaction effects, and no effects involving group. We found a significant association between age and the AVMMR response to AV-impossible in the left temporoparietal sites (*r*=0.288, *p*=.013) which was driven by the LR infants (*r*=0.377, *p*=.015). No association was found in the HR infants (*p*=0.355).

Conclusions:

The AVMMR was modulated by incongruent AV stimuli. Infants showed a more negative response to speech that could not be fused together into a single percept (VbaAga) compared to congruent (VbaAba, VgaAga) or fusible (VgaAba) speech percepts. There were no group differences as LR and HR groups showed the same pattern. However, older LR infants showed a more positive response to AV-impossible speech, similar to past findings (Kushnerenko et al., 2013), while HR infants did not show this age difference. Future work will follow these infants longitudinally to investigate potential maturational delays in the AVMMR for HR infants, including HR infants who are later diagnosed with ASD.

304 **246.304** Neural Processing of Observed Actions Is Related to Imitation and Language Abilities in Young Children with Autism Spectrum Disorder

***M. A. Krol**, D. Plesa-Skwerer, J. Leano and H. Tager-Flusberg, Psychological and Brain Sciences, Boston University, Boston, MA*

Background:

The mirror neuron system (MNS), which becomes active when carrying out actions and observing actions in others, is considered to serve as a foundation for children's social-cognitive learning, language and understanding intentionality in others' actions. Given the core deficits in social communication in ASD, it has been proposed that the MNS may be impaired in this population, but there is ongoing debate and controversy about the functioning of the MNS in ASD. However, no studies have explored the MNS in very young children with ASD or how it might be related to individual variability to both language and social cognitive functioning.

Objectives:

The goal of the present study was to explore activation in the MNS, which was approximated by recording the EEG mu rhythm (power in the alpha frequency band over the sensorimotor areas), in preschoolers with ASD and compared to activation in age matched typical children. MNS activity was recorded in communicative (i.e. pointing actions) and non-communicative contexts (i.e. grasping actions) and we examined the relationship between neural activity and the children's language and imitation skills.

Methods:

Participants were between the ages 21 and 59 months (M = 39.2, SD = 10.4). Good quality EEG data was obtained from 23 TD children and 19 children with an ASD diagnosis (confirmed by administering the ADOS). Using an EGI system, EEG recordings were obtained to measure power in the central alpha frequency band (7-12 Hz) during action execution and observation. A minimum of 15 toys were grasped and placed in a container and 30 video clips were presented in which an actor performed grasping and pointing actions (Figure 1). The receptive and expressive language scales of the Mullen Scales of Early Learning (MSEL; Mullen, 1995) were administered to measure language abilities and an elicited imitation battery (based on Rogers et al., 2003) was administered to assess motor imitation skills (with and without objects).

Results:

Lower levels of central alpha power during action observation were found in children with ASD (Figure 2). Specifically, there was a group difference in power recorded from the left hemisphere during the observation of grasping actions, $F(1, 40) = 4.68$, $p = .04$, $\eta_p^2 = .11$. In addition, positive correlations were found between power levels in this area and imitation abilities, $r(30) = .48$, $p = .007$, and receptive, $r(31) = .53$, $p = .002$, and expressive language, $r(31) = .57$, $p = .001$. There were no group differences in power recorded during execution of grasping actions, $F(1, 28) = 1.09$, $p = .31$, $\eta_p^2 = .04$, or the observation of pointing actions, $F(1, 40) = .001$, $p = .95$, $\eta_p^2 < .01$.

Conclusions:

The current findings suggest that the MNS plays a role in language and social development. These findings contribute to our understanding of the mechanisms that support language and social development in the first few years of life and how impairments in these mechanisms might underlie early symptom expression in ASD.

305 **246.305** Abnormal Auditory Mismatch Fields Arising from Superior Temporal Gyrus in Minimally Verbal / Non-Verbal Children

***J. Matsuzaki**[1], T. P. Roberts[1], L. Blaskey[1], L. Bloy[1], J. C. Edgar[1], M. Kim[1], M. Ku[1], E. S. Kuschner[1] and D. Embick[2], (1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)University of Pennsylvania, Philadelphia, PA*

Background: Approximately 30 % of the autism spectrum disorder (ASD) population can be categorized as minimally-verbal/non-verbal (MVNV). Previously, abnormal auditory/language discrimination processes, indexed by abnormal mismatch negativity (MMN) potentials or their magnetic counterparts (MMNm or MMF), have been reported in higher-functioning (verbal) children with ASD along with an association with degree of language impairment; however, little is known about neural correlates of language ability in lower-functioning MVNV children with ASD. Objectives: To understand the neurophysiological mechanisms underlying auditory language discrimination of vowel stimuli in MVNV children with ASD, magnetoencephalography (MEG) measured mismatch fields (MMFs) arising from left and right superior temporal gyrus during an auditory oddball paradigm in three cohorts: 1) MVNV children with ASD, 2) higher-functioning children with ASD (both with and without clinical language impairment) and 3) typically developing (TD) children.

Methods: Eighty-seven participants (aged 8-12yrs) were included in the final analysis (MVNV children with ASD; n=12, 10.13±1.49yrs, higher-

functioning children with ASD; n=48, 10.61±1.20yrs (without language impairment, operationally defined as Clinical Evaluation of Language Fundamentals - fifth edition (CELF 5) core language index > 85): n=27, with language impairment (CELF-5 CLI < 85): n=21), TD children, n=27, 10.14±1.38yrs). MEG data were obtained in a magnetically shielded room using a 275-channel whole-cortex CTF magnetometer (CTF MEG, Coquitlam, Canada). Vowel stimuli /a/ and /u/ of 300ms duration were presented binaurally at 45dB SL with each token as the standard (85%) or deviant (15%) stimulus, respectively; stimulus onset asynchrony was 700ms. MMF was defined from subtraction of the standard response from the corresponding deviant. To assess language ability, The Vineland Adaptive Behavior Scales, second edition communication scores were used. Linear mixed model were used for statistical analysis. The study was approved by the Children's Hospital of Philadelphia IRB and all participants' families gave written informed consent, in accordance with the principles of the Declaration of Helsinki. As indicated by institutional policy, where competent to do so, children over the age of seven additionally gave verbal assent.

Results: There were no group differences of age (p>.05).There were statistically significant main effects of group on MMF latency and MMF amplitude (p's<.01) with no effect of Hemisphere and no interactions. Significantly delayed MMF latencies were found in MVNV children with ASD (247.5 +/- 3.9 ms;p's<.01) compared to higher-functioning children with ASD (with (215.9+/-2.9ms) and without (210.1+/-2.6ms) language impairment) and TD children (189.2+/-2.6ms), and these delayed MMF responses were negatively associated with language ability (r=-.52;p<.01). Furthermore, while TD children showed a leftward lateralization of MMF amplitude (LI=0.14+/- .05;p's<.01), MVNV children showed the abnormal rightward lateralization (LI=-.19 +/- .07) as did higher functioning children with ASD both with (LI=-.14 +/- .05) and without (LI=-.10 +/- .05) language impairment.

Conclusions: Findings suggest that delayed auditory discrimination processes and abnormal rightward laterality could be effective and objective markers associated with language ability both in higher functioning and, importantly, in MVNV children with ASD.

306 **246.306** Abnormal Maturation of Alpha Peak Frequency in Children with Autism Spectrum Disorder May be Explained By Abnormal White Matter Maturation

M. DiPiero, *J. I. Berman, M. Ku, L. Blaskey, E. S. Kuschner, M. Kim, H. L. Green, T. P. Roberts and J. C. Edgar, Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Characterization of abnormal neural oscillatory processes in children with autism spectrum disorder (ASD) is considered a promising route to understanding brain dysfunction in ASD. Our laboratory reported abnormal maturation of resting-state alpha activity in children with ASD, with higher peak alpha frequency (PAF) in young children with ASD than age-matched typically-developing children (TDC). A study by Valdés-Hernández et al. established a relationship between PAF and diffusion magnetic resonance (DMR) fractional anisotropy (FA) in adults. The present study investigated relationships between PAF and DMR measures in TDC and ASD to better understand the structural features that contribute to normal/abnormal alpha rhythms in children

Objectives: To determine if PAF and diffusion associations are observed in TDC and children with ASD.

Methods: Eyes-closed resting-state MEG data were obtained from 73 male TDC (M=11.9±2.97years) and 107 male children with ASD (M=11.7±2.72 years). Groups did not differ on age(p>0.05). A 15 regional source model was used to project MEG surface data into source space. A Fast Fourier Transform was applied to 3.41 second epochs of continuous data at each regional source. PAF was identified (8-12 Hz) from regional sources' average power spectra, with the PAF value obtained from the source showing the largest amplitude alpha activity. DMR with b=1000s/mm2 and 30 gradient directions was collected. Artifacts in the data were corrected using FSL's eddy. FA and radial diffusivity (RD) were measured in white matter subserving PAF regional source (midline parietal regions) to characterize local white matter maturation.

Results: Given known associations between age and both PAF/white matter integrity, a regression model with age, diffusion, and group was used to predict PAF. For both FA and RD, significant group-x-age-x-diffusion interactions(ps<0.01) indicated a different pattern of association for TDC and ASD. Simple effect analyses showed that whereas TDC age and diffusion metrics explained unique variance in PAF, neither age nor diffusion metrics predicted variance in PAF in ASD. In the TDC group, regression analyses with age entered 1st and FA 2nd showed that age explained 24% of variance(p=0.001) and FA explained 4% of variance(p<0.05) in PAF. Reversing the order of entry, FA explained 14% of variance(p=0.001) and age explained 14% of variance(p=0.001) in PAF. In the ASD group, age and FA together explained a non-significant 2% of PAF variance(p>0.05). A similar pattern of findings was observed for PAF and RD.

Conclusions: This is the first study to show associations between white matter structure and PAF in children, indicating white-matter maturation determines, in part, the dynamics of resting-state alpha. DMR measures of white-matter fiber density and myelination were directly proportional to occipital-thalamo-cortical alpha frequency. Myelination and white matter maturation support the rapid conduction velocities necessary to drive faster alpha rhythms. This relationship was not observed in ASD, indicating disruption of a basic developmental mechanism underlying resting-state-processes in ASD. To the extent that resting-state alpha rhythms are supported by thalamo-cortical circuitry, present findings support the hypothesis of a thalamic contribution to abnormal cortical activity in ASD.

307 **246.307** An Event-Related Potentials Study of Response to Name in Preschool-Aged Children with and without Autism Spectrum Disorder

R. P. Thomas[1], *L. A. Wang*[2], *W. Guthrie*[3], *M. Cola*[2], *J. McCleery*[4], *J. Pandey*[2], *R. T. Schultz*[2] *and J. S. Miller*[3], *(1)Department of Psychological Sciences, University of Connecticut, Storrs, CT, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: The ability to respond to one's own name is an important aspect of social and language development, and is disrupted in autism spectrum disorder (ASD). Event-related potentials (ERP) research has demonstrated that typical adult brain responses differentiate own name from other stimuli (e.g., Tateuchi et al., 2012). To date, however, no studies on the neural indices of response to name have been conducted with typically developing preschool children or children with ASD. In addition, it remains unclear whether these responses index familiarity processing or subject's own name (ON) specific processing.

Objectives: To examine the neural response to name in preschoolers with and without ASD using an ERP paradigm that delineates the effects of speaker familiarity (familiar vs. unfamiliar) and stimulus type (own name vs. nonsense name).

Methods: Participants were age-matched 3-5-year-old typically developing (TD) children (*n*=13) and children with ASD (*n*=13). Each ASD participant was matched individually to a TD participant closest in chronological age, yielding a chronological age matched sample. Stimuli consisted of the ON and a pseudoword "nonsense name" spoken by either the child's parent or a stranger. Speakers were instructed to call both names as though they were attempting to solicit the child's attention. Stimuli were presented in random order in a single block of trials. Analyses focused on the frontal ON negativity component, given the previous findings supporting this component as an index of response to name in adults. A 2x2 repeated measures ANOVA was conducted using mean amplitudes with name (ON vs. nonsense name) and voice (familiar vs. unfamiliar) as within-subjects factors, and diagnostic group as a between-subjects factor.

Results: Within the TD+ASD comparison, the ANOVA revealed a marginally significant main effect of name (p=.05), such that ON elicited a more negative mean amplitude than did the nonsense name across both groups ($F(1, 24)=4.10$, p=.05, η_p^2=.15). There was also a marginally significant interaction between voice and group ($F(1, 24)=4.22$, p=.05, η_p^2=.15), such that the TD group exhibited a marginally stronger response to parent's voice than to stranger's (Bonferroni corrected p=.06), while the ASD group demonstrated the opposite pattern (corrected p=.36) (Fig. 1).

Conclusions: The current findings address a gap in the current neural processing literature on auditory processing of self-relevant stimuli in preschool children with and without ASD. Both TD and ASD preschool children had a stronger response to their own name than to a nonsense name. Children with ASD exhibited marginally stronger responses to the stranger's voice than to their own parent's voice, suggesting that that the familiarity of the speaker plays a unique role in how children with and without ASD process their name.

308 **246.308** Assessing Lateral Interactions in Autism Spectrum Disorder Using Visual Evoked Potentials

S. M. Lurie[1], *M. A. Rowe*[2], *J. George-Jones*[3], *V. Zemon*[1], *J. Buxbaum*[4], *A. Kolevzon*[2] *and P. M. Siper*[2], *(1)Ferkauf Graduate School of Psychology, Yeshiva University, Bronx, NY, (2)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Psychology, University of Texas at Austin, Austin, TX, (4)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: Excitatory/inhibitory (E/I) imbalance is one hypothesis of autism spectrum disorder (ASD) which can be tested objectively using electrophysiological methods such as visual evoked potentials (VEPs). VEPs reflect the sum of excitatory and inhibitory postsynaptic potentials, and provide a rapid, noninvasive, and reliable technique to assess the functional integrity of visual pathways in the brain. Previously, our group identified weaker excitatory input and a consequential reduction in an inhibitory component of the transient VEP in children with ASD.
Objectives: The aim of the current study was to use steady-state VEPs (ssVEPs) with two radial stimulus conditions, partial-windmill (PW) and windmill-dartboard (WD), to assess short- and long-range lateral inhibitory interactions in children with ASD.

Methods: ssVEPs were obtained from 47 children with ASD and 33 typically developing (TD) controls between the ages of 2 and 12 years old. PW and WD patterns were contrast-reversed in time at 4.29 Hz (peak contrast = 32%). Fourier analysis extracted amplitude and phase measures of frequency components of the response, and a magnitude-squared coherence (MSC) statistic was used to quantify the relative response power at each frequency. Facilitation (short-range lateral interaction) and suppression (long-range lateral interaction) indices were computed based on 1st and 2nd harmonic amplitude measures.

Results: There were no significant differences between groups for measures of amplitude, MSC, facilitation or suppression indices. Significant differences in combined PW and WD amplitude and phase measures, equivalently expressed as sine and cosine coefficients, were observed for diagnostic group (p < .001), age (p = .034) and Diagnosis x Age (p = .001) interactions. Sine-cosine plots for 1st and 2nd harmonics for both conditions indicate that responses change with age for each diagnostic group.

Conclusions: There were no significant differences in short-range or long-range lateral inhibitory interactions between groups, which is consistent with previous findings from tVEP studies demonstrating intact inhibitory activity, on average, in ASD. However, results indicate that global measures of lateral inhibitory interactions significantly differ between groups when age is included as a developmental factor. Further research is needed with larger samples within specific age cohorts to explore these findings in greater detail.

309 **246.309** Delayed M50 / M100 Latency Arising from Superior Temporal Gyrus in Minimally Verbal / Nonverbal Children

T. P. Roberts[1], *J. Matsuzaki*[1], *L. Blaskey*[1], *L. Bloy*[1], *J. C. Edgar*[1], *M. Kim*[1], *M. Ku*[1], *E. S. Kuschner*[1] *and D. Embick*[2], *(1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)University of Pennsylvania, Philadelphia, PA*

Background: Abnormal auditory M50 and M100 responses, which reflect early auditory processing, have been reported in children with autism spectrum disorder (ASD) along with an association with abnormal language comprehension; however, most prior research has focused on higher functioning individuals and so rather little is known about neural activity during auditory processing in lower-functioning (e.g. minimally verbal / non-verbal (MVNV)) children.
Objectives: To understand the neurophysiological mechanisms underlying early auditory processing in MVNV children, magnetoencephalography (MEG) measured M50 and M100 arising from left and right superior temporal gyri during tone stimuli in four cohorts: 1) MVNV children with ASD, 2) lower Intellegence Quotient (IQ) Intellectual Disability/ Developmental Disability (ID/DD, non-ASD) clinical controls (of mixed genetic etiology), 3) high functioning children with ASD and 4) typically developing (TD) children.

Methods: One hundred and sixteen participants (aged 8-12 yrs) were included in the final analysis (MVNV children with ASD; n=17, 9.83±1.27 yrs, lower IQ ID/DD (non-ASD) clinical controls; n=6, 10.54±0.62 yrs, higher functioning children with ASD; n=59, 10.67±1.30 yrs, TD children, n=34, 10.18±1.36 yrs). MEG data were obtained in a magnetically shielded room using a 275-channel whole-cortex CTF magnetometer (CTF MEG, Coquitlam, Canada). Sinusoidal tones (300 ms duration; 10 ms ramps) with a pseudo-randomized 600-2000ms inter-trial interval were presented binaurally at 45dB SL. Responses were averaged, filtered and source-modeled to allow identification of M50 and M100 components bilaterally. To assess language and cognitive abilities, The Vineland Adaptive Behavior Scale, second edition (VABS-2) communication scores, Differential Ability Scale - II and Leiter International Performance Scale, third Edition Nonverbal IQ were used. The study was approved by the Children's Hospital of Philadelphia IRB and all participants' families gave written informed consent, in accordance with the principles of the Declaration of Helsinki. As indicated by institutional policy, where competent to do so, children over the age of seven additionally gave verbal assent. Analyses used linear mixed models (LMM's) with subject as a random effect.

Results: There were no group differences of age (p> .05). There were statistically significant main effects of group on M50 latency and M100 latency (p's< .001) with no effect of Hemisphere and no interactions (p's> .05). Significantly delayed M100 latencies were found in MVNV children with ASD

(169.28+/-7.47ms) and in the low IQ ID/DD clinical control children (174.38+/-12.40ms) compared to TD (128.79+/-5.47ms; $p < .01$) as well as higher functioning children with ASD (150.50+/-4.06ms; $p < .05$). Delayed M50 latencies were also found in MVNV children with ASD (93.15+/-2.47ms) and the low IQ ID/DD children (93.75+/-4.09ms) compared to TD children (80.05+/-1.76ms;*p's*< .01). These delayed latencies were negatively correlated with language and communication ability (M50: $r = -.45$; M100: $r = -.27$;*p*'s < .01).

Conclusions: Findings suggest that the delays in early auditory cortex neural activity in minimally verbal/non-verbal children with ASD were exacerbated compared to higher functioning children with ASD and could thus be effective objective markers in MVNV children with ASD, associated with language impairment as well as general cognitive ability (as evidenced by the delayed latencies also in the non-ASD, low-IQ clinical control cohort).

310 **246.310** Diminished Gamma Oscillatory Response in Autism Spectrum Disorder

H. Grosman[1], *S. Guillory*[1], *C. McLaughlin*[1], *E. Isenstein*[1,2], *M. Amezcua*[1], *P. M. Siper*[1] *and J. Foss-Feig*[1], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)University of Rochester, Rochester, NY*

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder behaviorally defined by a core set of features, including social interaction deficits and restricted and repetitive behaviors. Sensory abnormalities are present in up to 90% of affected individuals, and impairment in cognitive processing is common. Neural oscillations are a key mechanism by which communication and synchronization occur within the brain, in turn driving coordinated cognition and behavior. Gamma band oscillations reflect GABAergic synaptic function, and alterations in the balance between inhibitory GABAergic and excitatory glutamatergic activity have been identified in ASD. Therefore, measurement of gamma oscillations may offer a valuable biological tool to reveal mechanisms underlying cognitive dysfunction and behavioral symptomatology. Auditory steady-state response (ASSR) is a neurological response that occurs when the brain entrains to rapid auditory stimuli presented at a given frequency. ASSR in the gamma frequency range (30-50 Hz) has been identified as a robust measure of abnormal neural oscillations in other disorders where excitatory/inhibitory balance is disrupted. This study used electroencephalography (EEG) to explore gamma oscillations with the ASSR paradigm in order to probe fundamental disruptions in ASD.
Objectives: Test for alterations in gamma band response during entrainment using an ASSR paradigm. Explore the relationship between gamma band response and sensory abnormalities as indexed by clinical self-report measures.

Methods: Seventeen individuals participated in the study, including 8 participants with ASD (63% male, mean age=20.6), and 9 typically-developing (TD) controls (67% male, mean age=22.6). EEGs were recorded at 128 electrode sites using Hydrocel Geodesic Sensor Net and Philips/EGI NetStation software. The auditory stimulus was a 500ms click train with a stimulation rate of 40Hz presented 150 times (inter-trial interval: 50ms). Data were filtered, re-referenced to the average, and segmented to the event onset. We completed artifact detection, bad channel replacement and baseline corrections before conducting time-frequency analyses and calculating absolute power at 40 Hz.

Results: Deficits in 40Hz gamma-band ASSR were found in the ASD group when compared to typically-developing controls ($t(15) = -3.99$, $p < .001$). Mean 40Hz power was $0.25 \pm 0.09 \mu V^2$ in ASD and $0.43 \pm 0.10 \mu V^2$ in TD. Though not significant, a trend was observed between 40Hz power and the Auditory Processing domain of the Adolescent/Adult Sensory Profile ($r = -.76$, $p = .079$).

Conclusions: These results reinforce prior findings of diminished ASSR response in ASD. Because it is collected through a passive, non-invasive task, ASSR may be a promising objective biomarker to be used as an ASD screening and stratification tool. For example, ASSR may be diminished in individuals with ASD where GABAergic functioning is disrupted, as in some syndromic forms of ASD caused by rare genetic variants affecting synaptic functioning. In addition, ASSR may be useful as a biomarker for assessing change in clinical trials, particularly for drugs targeting the GABAergic system. Further directions for this work include increasing sample size and diversity to include those that are minimally verbal and/or have cognitive impairments. We similarly seek to implement the paradigm in syndromic ASD populations to test its sensitivity to GABAergic dysfunction in populations with known alterations in this system.

311 **246.311** Discriminant Diagnostic Quality of Resting-State EEG for Fragile X Syndrome, Autism Spectrum Disorders, and Typical Development

N. Gorbachevskaya[1,2], *A. Mitrofanov*[1] *and* ***A. Sorokin***[2,3,4], *(1)Lab of Neurophysiology, Mental Health Research Center, Moscow, Russian Federation, (2)FRC, Moscow State University of Psychology and Education, Moscow, Russian Federation, (3)Haskins Laboratories, New Haven, (4)Pediatric Institute, PIMU, Nizhny Novgorod, Russian Federation*

Background: Fragile X chromosome syndrome (FXS) is a neurodevelopmental condition, caused by a mutation of the FMR1 gene. It is the second most common single-gene cause of inherited intellectual disability and the most common genetic cause of autism. While similar in several behavioral manifestations and probably neurobiologically related, FXS is different from idiopathic autism spectrum disorders (ASD) in intervention strategies, prognosis, and relevance of genetic counselling. A reliable and accessible biomarker, such as EEG, could enable timely differential diagnosis. The findings of the resting-state EEG changes in FXS are relatively consistent: most authors report elevated theta power, reduced alpha power as well as increased epileptiform abnormalities. Some EEG changes in ASD follow the same pattern but in general they are more variable, probably reflecting the higher heterogeneity of autism. Most resting-state EEG studies have had limitations associated with the experimental sample size.
Objectives: The spectral resting-state EEG data were used to determine typical changes in FXS and ASD in larger samples and individual spectral features with good discriminant properties were chosen to predict assignment of subject to FXS or ASD groups based on EEG.

Methods: 47 children with FXS (age 4 to 18) and 51 children with ASD (age 3 to 18) participated in the study. All subjects with FXS had a full FMR1 mutation; the subjects with ASD had a clinical diagnosis within the autism spectrum (F84.0, F84.1 or F84.5) according to ICD-10, they also scored 15 or higher on Social Communication Questionnaire. The resting-state EEG (with closed eyes) was collected from 14 standard 10/20% electrode locations with A1+A2 reference and recorded with a Neuro-KM EEG system. Spectral power was calculated for standard and narrow – 1, 1.5 and 2 Hz – frequency bands. The values were compared to 70 EEG records of typically developing (TD) children from the normative database of 700 TD records organized in one-year age groups. Linear discriminators were chosen with forward stepwise analysis among normalized power, relative power, coherency, asymmetry, and power ratio predictors. Linear discriminant functions were identified with leave-one-out cross-validation method.

Results: The FXS showed a particular pattern of EEG changes with higher theta and beta-2 power and lower alpha power (p<0.01 FXS vs.TD). In ASD alpha power was lower and beta power was higher (p<0.01 ASD vs.TD). Models for optimal discrimination of groups were identified. They included four predictors for the FXS-TD comparison, three predictors for the FXS-ASD comparison, and four predictors for ASD-TD comparison. Sensitivity ranged from 90% for FXS vs.ASD to 100% for FXS vs.TD (93% for ASD vs. TD); sensitivity ranged from 90% for FXS vs.ASD and ASD vs.TD to 92% for FXS vs.TD.

Conclusions: We identified the distinct pattern of resting-state EEG changes in FXS, manifesting in higher theta and beta 2 power and lower alpha power, in a larger sample of children. Discriminant analysis assigns subjects to ASD, FXS, and TD groups with excellent specificity and sensitivity.

312 **246.312** Dysregulation of Temporal Dynamics of Neural Activity in Adolescents on Autism Spectrum

E. Malaia[1], *S. Ahn*[2] *and L. Rubchinsky*[3,4], *(1)Communicative Disorders, University of Alabama, Tuscaloosad, AL, (2)Department of Mathematics, East Carolina University, Greenville, NC, (3)Department of Mathematical Sciences, Indiana University Purdue University Indianapolis, Indianapolis, IN, (4)Stark Neurosciences Research Institute, Indiana University School of Medicine, Indianapolis, IN*

Background: Autism spectrum disorder is increasingly understood to be based on atypical signal transfer among multiple interconnected networks in the brain (Sun et al., 2012). Relative temporal patterns of neural activity have been shown to underlie both the altered neurophysiology and the altered behaviors in a variety of neurogenic disorders (Ahn et al., 2018). The present study investigated the temporal aspect of brain network stability and variability in resting state EEG of ASD adolescents and neurotypical controls.
Objectives: The purpose of the study is to assess brain network flexibility in ASD using measures of synchronization (phase-locking) strength (γ), and timing of synchronization and desynchronization of neural activity (desynchronization ratio, DR) in theta (4-7 Hz), alpha (8-12 Hz), beta (15-30 Hz), and low gamma (30-60 Hz) bands of resting state EEG.

Methods: Resting state EEG data was recorded from 14 individuals with the diagnosis of ASD (2 F, age M = 13.7, SD = 2.2, range 10–16) and 15 TD participants (5F, age M = 13.4 years, SD = 1.8, range 10–17). Pairwise γ and pairwise DR were computed between anterior (F3, F4) and parietal (P3, P4) electrode sites.

Results: EEG data of ASD participants manifested altered temporal of coordination in anterior and parietal brain regions in multiple frequency bands on very short temporal scales. Pairwise synchronization strength in fronto-parietal sites was, in general, lower in ASD (alpha P3-P4, p<.001; beta F3-P3, p<.001, F4-P4, p<.001; gamma F3-P3, p<.001, P3-P4, p<.012). Short desynchronizations were also more numerous in EEG data of ASD participants (alpha band: F3-P3 p<0.001, P3-P4 p<0.002; low gamma, F4-F4 p<.001, F4-P4 p<.046, P3-P4 p<.026). Pairwise analysis of right hemisphere electrodes (F4-P4) indicated an contrasting effect: synchronization was significantly lower in TD, as opposed to ASD participants, in the alpha band (alpha F4-P4, p<.005), while desynchronization ratio was higher in EEG data of TD participants over in the theta band (theta F4-P4, p<.04).

Conclusions: In ASD adolescents, stable cross-frequency networks during resting state have been previously shown to endure for a longer period of time, in comparison with the same in neurotypical peers (Malaia et al., 2016). The present analysis extends the findings to the temporal aspect of synchronization: we demonstrate that fronto-parietal synchronization is lowered in ASD, with more short periods of desynchronization. Mathematical modeling (Ahn & Rubchinsky, 2017) suggests that neural networks with high desynchronization ratio have increased sensitivity to inputs; this sensitivity may disrupt production of an adequate neural and behavioral responses to external stimuli. Cognitive processes dependent on integration of activity from multiple networks may be, as a result, particularly vulnerable to disruption. Contrasting findings of increased synchronization and lowered DR in the lower frequency bands over the right hemisphere in ASD participants require further exploration with regard to their relationship to linguistics (left-lateralized) vs. numeric (bilateral) manipulation skills. The study advances the understanding of the biological mechanisms underlying cortical computations in the complex ASD phenotype.

313 **246.313** EEG Repetition Suppression in Children with Neurofibromatosis Type 1: Evidence from Time-Frequency Analysis

E. Lalancette[1,2], *F. Barlaam*[1], *A. R. Charlebois*[1,2], *K. Agbogba*[3], *I. S. Knoth*[1], *P. Major*[4], *S. Perreault*[4] *and S. Lippe*[1], *(1)Neurosciences of Early Development Lab, CHU Sainte-Justine, Montreal, QC, Canada, (2)Psychology Department, Université de Montréal, Montreal, QC, Canada, (3)Electrical Engineering Department, École de Technologie Supérieure (ÉTS), Montreal, QC, Canada, (4)Division of Child Neurology, CHU Sainte-Justine, Montreal, QC, Canada*

Background: Neurofibromatosis type 1 (NF1) is a genetic disorder associated with neurodevelopmental disorders, including autism spectrum disorder (ASD), the prevalence of which in this population is approximately 25% (Garg et al., 2013). Studies on animal models of NF1 have identified deficits in habituation, a simple form of repetition learning that is conserved across species and crucial for the development of higher cognitive functions (Larkin et al., 2010; Wolman et al., 2014). Repetition suppression (RS), the reduction of brain activity in response to repeated presentations of a single stimulus, is considered the neurophysiological equivalent of habituation and can be measured using electroencephalography (EEG). However, RS has not yet been investigated in humans with NF1.
Objectives: The purpose of this study is to explore RS in children with NF1 ranging from 4 to 16 years of age. We investigate RS in the time-frequency domain through the variation of event-related spectral power, hypothesizing that the NF1 group would present habituation deficits reflected by lower RS compared to controls.

Methods: EEG was recorded in 13 participants with NF1 and 13 age-matched neurotypical controls using a 128-channel EEG system (Electrical Geodesics System Inc.) in a soundproof room at the CHU Sainte-Justine hospital. Participants were presented with recordings of thirty pseudowords read by a female native French speaker, which were repeated six times each and allowed us to observe auditory RS in a previous study using a similar design (Knoth et al., 2018). Timeframes of -400 ms (pre-stimulus) to 1400 ms were segmented for each presentation of a pseudoword. Artifact-free segments were averaged according to presentation order (first through sixth presentation of a pseudoword) and analysed in the time-frequency domain using the Morlet decomposition.

Results: A mixed-design ANOVA controlling for IQ revealed a significant interaction between repetition and group ($F(5,115) = 3.770$, $p = 0.03$) in the lower theta band (3-5 Hz), between 800 and 1400 ms. Post-hoc one-way ANOVAs controlling for IQ revealed a significant difference between the two groups at the third repetition of the pseudowords ($F(1,23) = 9.006$, $p = 0.006$), with higher suppression of theta power in the control group (Bonferroni-corrected, $p = 0.036$). A repeated measures ANOVA controlling for IQ revealed a significant RS effect in the control group ($F(5,55) =$

3.929, p = 0.004), but not in the NF1 group (F (5,55) = 0.310, p = 0.905).

Conclusions: Considering the role of theta activity in language processing and memory (Bastiaansen et Hagoort, 2003), the absence of repetition suppression for that frequency range in the NF1 group could reflect an altered habituation process in response to auditory presentations of language stimuli. Thus, RS alterations in NF1 may help us understand language, memory and learning deficits that are common in this population (Batista, Lemos, Rodrigues et de Rezende, 2014). Also, EEG markers of habituation promise to be highly relevant translational markers of basic learning mechanisms for clinical trials aimed at learning disabilities in NF1.

314 **246.314** EEG Time-Frequency and Phase-Locking Alterations during Auditory Processing in SYNGAP1 Mutation Individuals

V. Côté[1], *S. Lippe*[2], *I. S. Knoth*[2], *F. Barlaam*[2], *S. Jacquemont*[3], *P. Major*[4], *K. Agbogba*[5], *J. Michaud*[6] *and L. Côté*[7], *(1)Psychology, University of Montreal, Montreal, QC, Canada, (2)Neurosciences of Early Development Lab, CHU Sainte-Justine, Montreal, QC, Canada, (3)CHU Sainte Justine, University of Montreal, Montreal, QC, Canada, (4)Division of Child Neurology, CHU Sainte-Justine, Montreal, QC, Canada, (5)Electrical Engineering Department, École de Technologie Supérieure (ÉTS), Montreal, QC, Canada, (6)Centre de recherche, CHU Sainte-Justine, Montreal, QC, Canada, (7)Neurology, CHU Sainte-Justine, Montreal, QC, Canada*

Background: Alterations in basic sensory processing have been reported in various genetic syndromes related to neurodevelopmental disorders. SYNGAP1 is a mutation thought to be a common cause of intellectual disability (ID), epilepsy and autism spectrum disorder (ASD). Excitation/ inhibition imbalance at the molecular level has been shown in several genetic neurodevelopmental disorders involving ID and ASD. Haploinsufficiency of the SYNGAP1 gene affects the GABAergic circuit function and oscillatory activity in mice (Berryer et al., 2016). In electroencephalography, these imbalances impair synchronisation in brain rhythms oscillations (Garrido et al., 2009; Larrain-Valenzuela et al., 2017; Lee et al., 2017; Rojas & Wilson, 2014).

Objectives: Here we assessed brain response oscillation and synchronisation in the time-frequency domain of individuals with SYNGAP1 mutation.

Methods: We recorded EEG in 61 participants ranging from 3 to 19 years of age (SYNGAP1 n = 8, neurotypical n = 37 and Down syndrome (DS) n=16) with an auditory stimulus (broadband white noise). We investigated auditory evoked potentials (AEP), time-frequency (TF) and inter-trial coherence (ITC) in SYNGAP1 mutation compared to DS and neurotypicals. Group comparisons were performed using ANOVA and Gabriel or Tamhane post hoc tests.

Results: ANOVA revealed a group effect on P2 latency and amplitude where DS shows a tendency of longer latency. TF analysis demonstrated delayed responses in SYNGAP1 mutation carriers compared to other groups. Specifically, they showed more power in late beta-low gamma band (18-35 Hz/ 150-300 ms) compared to neurotypicals (p=.046) and low gamma (30-40 Hz/ 250-380 ms) in comparison to neurotypicals (p=.004) and DS (p=.022). Importantly, SYNGAP1 mutation carriers showed less phase locking ITC compared to controls in early time windows and lower frequency bands. Specifically, they showed less ITC compared to neurotypicals and DS in theta-alpha (6-10Hz/ 300-450ms; vs. neurotypicals (p=.003); vs. DS (p=.012)) and less ITC compared to neurotypicals in early theta band (3-5 Hz/ 0-300ms; p=.014), (3-6Hz/ 100-350 ms; p=.035). Further, SYNGAP1 individuals expressed less ITC in low beta (16-19 Hz/ 0-100ms; p=.001) and early alpha (7-12Hz/ 50-300 ms; p<.001) compared to neurotypicals, and DS (p=.015). ITC in SYNGAP1 mutation carriers is also significantly reduced in later theta-alpha bands (6-10Hz/ 300-450ms) compared to neurotypicals (p=.003) and DS (p=.012).

Conclusions: SYNGAP1 mutation carriers showed delayed brain responses to auditory sensory stimulations that were also less synchronized in the theta, alpha and beta bands. Beta/low gamma oscillations also occur delayed compared to neurotypicals and DS. Lack of synchronisation in SYNGAP1 individuals could reflect the imbalance of excitation/ inhibition found at the molecular level in several animal models of ID/ASD. Further research is needed to investigate how these auditory processing characteristics in SYNGAP1 relate to cognition and behavior.

315 **246.315** EEG-Indexed Conditional Salience Processing Mediates the Relationship between ASD Symptom Severity and Theory of Mind

E. J. Libsack[1], *C. M. Keifer*[1] *and M. D. Lerner*[2], *(1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY*

Background: Theory of Mind (ToM) reasoning involves making attributions about others' mental states and is critical for competent social functioning. Although impairments in ToM are a common feature of autism spectrum disorder (ASD; Baron-Cohen, 2001), individual differences in ToM ability exist across ASD (White et al., 2014), and do not consistently vary by ASD symptom severity. Such heterogeneity suggests upstream individual differences in the recruitment of neural mechanisms necessary for ToM reasoning. However, no research has examined whether individual differences in the association between ASD symptom severity and behavioral performance on ToM tasks are attributable to specific neurocognitive components. Two distinct event-related potentials (ERPs) have been elicited during ToM tasks in typically developing (TD) youth (Meinhardt, et al. 2011); the Late Positive Complex (LPC), associated with automatic processing of conditional salience, and the Late Slow Wave (LSW), related to making mental state attributions. It is essential to examine these neurocognitive components in conjunction with ASD symptom severity to understand whether they may account for variability in ToM deficits in youth with ASD.

Objectives: Investigate whether LPC and LSW are elicited in youth with and without ASD during a ToM task. Explore whether magnitude of the difference between ERPs elicited to correct vs. incorrect conditions is associated with ToM accuracy and ASD symptom severity.

Methods: Participants were 76 adolescents (47 ASD, 54 male) ages 11-17 (M_{age}=13.0, SD_{age}=1.8) with IQ ≥ 70. ASD symptom severity was measured using the ADOS-2 Calibrated Severity Score (CSS) in all participants. During EEG acquisition, participants viewed illustrated, narrated ToM vignettes and were asked to make mental state inferences about characters' behavior (McKown et al., 2015). ERPs were time-locked to the presentation of correct and incorrect response options, measured at parietal electrode sites, and extracted as mean area amplitudes within post-stimulus time windows (LPC 300-600ms; LSW 600-1200ms). Residualized scores were calculated to index the difference between ERPs elicited to correct vs. incorrect conditions. Pearson correlations were used to assess the relationship between ERP residualized scores, ToM accuracy, and ADOS-2 CSS. Bootstrapped mediation analyses were performed to assess whether these components may explain the relationship between ToM accuracy and ADOS-2 CSS.

Results: LPC and LSW residualized scores correlated with ToM behavioral accuracy and ADOS-2 CSS (Table 1). Mediation analyses revealed LPC (but not LSW) partially mediates the relationship between ADOS CSS and ToM accuracy with a medium effect size (Figure 1).

Conclusions: Results show the LPC and LSW are elicited to a novel ToM EEG task in TD and ASD adolescents. ERPs were associated with ADOS-2 CSS

and ToM in opposite directions. This suggests the ASD group may rely on compensatory neurocognitive mechanisms to engage in ToM, resulting in attenuated discrimination between ToM conditions. Furthermore, although ToM performance is related to ASD symptom severity, mediation analysis revealed that this relationship disappears when LPC magnitude is taken into account. Therefore, automatic processing of conditional salience during active ToM reasoning partially explains the relationship between ASD severity and individual differences in ToM ability in adolescents with and without ASD.

316 **246.316** ERP Responses to Social Stimuli and ASD Symptoms in "Unaffected" Siblings of Children with Autism Spectrum Disorder

A. L. Hogan[1], *C. J. Black*[1], *J. Escorcia*[2], *M. Guy*[3], *J. McPartland*[4], *J. E. Richards*[2] *and J. E. Roberts*[5], *(1)Department of Psychology, University of South Carolina, Columbia, SC, (2)University of South Carolina, Columbia, SC, (3)Loyola University Chicago, Chicago, IL, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Psychology, University of South Carolina, Columbia, SC*

Background: Siblings of children with autism spectrum disorder (ASD), even those who are not later diagnosed with ASD themselves (non-ASD ASIBs), often exhibit elevated ASD-related social-behavioral difficulties, known as the broad autism phenotype (BAP). Few studies have characterized the BAP in young children or investigated underlying neurophysiological mechanisms.
Objectives: The objectives of the present study were to a) characterize ERP responses to social and non-social stimuli and b) investigate the relationship between ERP responses and social-behavioral phenotypes in non-ASD ASIBs.

Methods: Twenty-six participants, ranging from 4 to 8 years old, were included in this study (non-ASD ASIBs: *n* = 11, 81.8% male, *M*age = 5.96 years; TD controls: *n* = 15, 100% male, *M*age = 5.60 years). Non-ASD ASIBs had an older sibling with a diagnosis of ASD but were not diagnosed with ASD themselves. TD controls had no family history of ASD. Participants completed an EEG experiment in which they passively viewed upright faces, inverted faces, upright houses, and inverted houses. The latency and amplitude of P1 was measured at the central occipital (OZ) electrodes. The latency and amplitude of N170 was measured at right posterior lateral electrodes (P8). Participants completed a battery of social-behavioral measures that included the Autism Diagnostic Observation Schedule – Second Edition (ADOS-2), the Childhood Autism Rating Scale (CARS), and the Social Responsiveness Scale (SRS). ERP component latencies and amplitudes were examined across conditions and groups in repeated measures ANOVAs. Correlations between ERP responses and social-behavioral variables were investigated using Pearson correlations.

Results: No main or interaction effects were observed for P1 latency or amplitude. For N170 latency, no main or interaction effects were observed. For N170 amplitude, the main effect of condition was significant, $F(3, 69) = 10.22$, $p < .001$, with faces eliciting larger amplitudes than houses, $ps < .037$, but no main effect of group or group by condition interaction was present. In TD controls, P1 and N170 latencies and amplitudes were not significantly correlated with any social-behavioral measures. In non-ASD ASIBs, several significant correlations emerged. Shorter N170 latency to upright faces was associated with higher ADOS-2 Social Affect severity score, $r = -.71$, $p = .021$ and marginally correlated with higher CARS total score, $r = -.620$, $p = .056$ and SRS total score, $r = -.63$, $p = .068$. Greater (i.e., more negative) N170 amplitude to inverted faces was correlated with higher ADOS-2 Social Affect severity score, $r = -.66$, $p = .050$ and higher SRS total score, $r = -.80$, $p = .009$, whereas greater N170 amplitude to upright faces was marginally correlated with higher ADOS-2 Social Affect severity score, $r = -.62$, $p = .057$, and higher SRS total score, $r = -.62$, $p = .076$.

Conclusions: These results indicate that ERP responses to social and non-social stimuli are similar in non-ASD ASIBs and TD controls. In contrast, correlations between ERP responses and BAP symptoms in non-ASD ASIBs suggest distinct relationships among neurophysiological functioning and behavior in ASD-related behavior in those at elevated genetic risk for ASD relative to TD controls.

317 **246.317** Early Visual Processing Indicates E/I Imbalance in Adults with Autism and Schizophrenia

T. Winkelman[1], *A. Naples*[1], *T. McAllister*[1], *E. Jarzabek*[1], *J. Wolf*[1], *J. Foss-Feig*[2], *V. Srihari*[3], *A. Anticevic*[3] *and J. McPartland*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Division of Neurocognition, Neurocomputation, and Neurogenetics (N3), Yale University School of Medicine, New Haven, CT*

Background:
Visual Evoked Potentials (VEP) are robust and well characterized EEG responses that index the integrity of the visual system with amplitudes that reflect the ratio of excitation and inhibition (E/I) in the brain. Past research has shown attenuated P1-N1 amplitude in disorders with sensory features, including autism (ASD) and schizophrenia (SZ); these disorders share a neural phenotype of attenuated VEP P1-N1 amplitudes and overlapping behavioral phenotypes of social and communicative difficulties, termed *negative symptoms* in schizophrenia. The use of VEPs as a transdiagnostic measure of cortical function and a neural correlate of behavior may lead to a better understanding of the neurobiological underpinnings of these disorders with implications for prognostic evaluation and treatment selection.

Objectives:

Determine shared features of low-level visual processing as a metric of E/I imbalance in adults with autism and schizophrenia and explore the relationship of these neural markers with social and communicative severity.

Methods:

Participants were 18-40 year old adults with ASD (*n*=23; mean IQ=105), SZ (*n*=15; mean IQ=99), and typical development (TD; *n*=29; mean IQ=114), matched for age (mean age=24.6 years). All participants were extensively behaviorally characterized, including the Autism Diagnostic Observation Schedule (ADOS) and Positive and Negative Symptom Scale (PANSS). EEG was recorded with a 128 sensor Hydrocel Geodesic Sensor Net while participants viewed a black and white checkerboard reversing at a rate of 1 Hz. EEG was filtered from 0.1-30 Hz, re-referenced, segmented from -150 to 300 ms, artifact detected, and averaged. Peak amplitudes and latencies were extracted for the N1 (60-100 ms) and P1 (80-180 ms) components at electrode 75 (Oz). The difference in N1 and P1 amplitudes was calculated for all participants. One-way ANOVAs tested for differences in P1 and N1 latency and P1-N1 amplitude. Pearson correlations were used to assess relationships of ERP components with social abilities as measured by the ADOS and the negative symptom scale of the PANSS.

Results:

No main effects of diagnosis were seen for N1 [$F(2, 64)=2.57$, $p>.05$] or P1 [$F(2, 64)=.32$, $p>.05$] latency. There was a significant main effect of diagnosis on P1-N1 amplitude [$F(2, 64)=5.37$, $p=.007$]. Post hoc tests revealed the difference was driven by greater P1-N1 amplitude in the ASD group as compared to the TD group [$t(29)=2.9$, $p=.007$]; no differences were seen between the SZ group and either group ($ps>.1$). Collapsing across clinical

groups (ASD, SZ) revealed a significantly greater P1-N1 amplitude compared to the TD group [$t(57)=-2.9$, $p=.004$]. P1-N1 amplitude was positively correlated with ADOS calibrated severity scores ($r=.291$, $p=.017$) and PANSS negative symptom total score ($r=.31$, $p=.012$) across all participants.

Conclusions:

Differences in the P1-N1 amplitudes of the VEP in adults with ASD and SZ are consistent with intact visual processing circuitry but atypical E/I balance. P1-N1 amplitude is associated with clinician-reported social symptomatology in both ASD and SZ, demonstrating a link between objective neural responses and social function. These findings suggest a degree of shared pathophysiology between SZ and ASD and demonstrate the promise of transdiagnostic research for informing social-communicative biomarker development in neurodevelopmental disorders.

318 **246.318** Event-Related Brain Dynamics of Auditory Cognitive Control in Adults with Autism Spectrum Disorder

***D. S. Karhson**, Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*

Background:

Atypical sensory reactivity in autism spectrum disorder (ASD) is a core diagnostic feature. It is also one of the earliest and most persistent indicators to be behaviorally observed in this clinical population. Yet, a basic understanding of the neural mechanisms that mediate these behaviors remains unclear. Event-related neural oscillatory activity plays a key role in brain function and is easily evaluated by electroencephalography (EEG), which provides a high-temporal resolution of brain dynamics. Specifically, theta- (4-8 Hz), alpha- (8–12 Hz), and gamma-band (25-50 Hz) activity, are important for sensory processing, sensory integration, and working memory. Additionally, these bands have been observed as atypical in ASD and have been associated with deficits in cortical inhibition. In neurotypical controls, event-related spectral dynamics associated with target detection in the oddball paradigm have been used to examine the functional integrity of brain circuits. However, this relationship has not been well-characterized among adults with ASD.

Objectives:

In participants with ASD and age- and IQ-matched neurotypical controls, event-related spectral dynamics during attentional processing in an auditory oddball task will be evaluated. The relationship between sensory reactivity and average band power will also be examined.

Methods:

Adults with ASD (N=12) and age- and IQ-matched control controls (N=12) completed a modified 3-stimulus (target, non-target, and distractor) oddball task, as well as being assessed by the Adolescent/Adult Sensory Profile (AASP) and Kaufman Brief Intelligence Test (KBIT-2). During the oddball task, scalp-level EEG was recorded as the stimuli was binaurally presented, this included: randomly infrequent pure tone targets (1000 Hz, probability = .12) presented at 0° midline and frequent non-targets/distractors (probability = .88) with an inter-stimulus interval of 2000ms (~60dB, 200ms duration, 200 stimuli/block, 8 blocks total). EEG data was filtered, segmented into 2-s epochs, and edited for artifacts. Time/frequency analysis was performed using the standard frequency band ranges: Delta: 1- 4 Hz; Theta: 4 - 8 Hz, Alpha: 8 - 12 Hz; Beta: 12 - 25 Hz; Gamma: 25 - 50 Hz; and High Gamma: 50 - 80Hz. A 2x5 ANOVA (threshold $p<.05$) was used to compare power spectra across bands and between groups.

Results:

Average power at low perceptual loads were significantly different between groups ($p=0.015$). Adults with ASD demonstrated decreased theta and alpha-band power as well as increased gamma-band power ($p=0.0127$, $p=0.06$, $p=0.044$). Changes in spectral power in those with ASD were correlated with atypical reactivity ($r=0.851$).

Conclusions:

In adults with ASD increased sensory reactivity were related to changes in spectral power in low-and high-frequency bands compared to neurotypical controls. This atypical EEG pattern in auditory target detection is a potentially distinct profile of neural circuits functionality in sensory processing and top-down cognitive control between in adults with ASD.

319 **246.319** Externalizing Behaviors in Autism Spectrum Disorder Modulate Neural Responses during a Novel Interactive Social Paradigm

***M. Zhou**, A. Naples, T. Winkelman, M. R. Altschuler, D. Stahl, E. Jarzabek, J. Wolf and J. McPartland, Child Study Center, Yale University School of Medicine, New Haven, CT*

Background:

Aberrant development of attention is indicated in both autism spectrum disorder (ASD) and disorders associated with externalizing behavior (e.g., conduct disorder). Attention modulates electrophysiological (EEG) neural responses elicited by visual social stimuli, and atypical patterns of these neural responses are seen in individuals with both ASD and maladaptive behavior. However, there have been few investigations into the potential influence of externalizing behaviors on neural responses to social information in ASD.

Objectives:

To examine whether externalizing behavior modulates event-related potentials (ERPs) to social information in individuals with ASD compared to typically developing (TD) controls.

Methods:

Preliminary EEG and eye tracking data were collected from children with ASD (n=49, mean age=14.17 years, mean IQ=107.41) and age/IQ matched TD controls (n=44, mean age=13.39 years, mean IQ=108.52); data collection is ongoing. Participants viewed an experimental paradigm in which onscreen faces responded contingently to participant gaze (monitored with eye tracking) with direct or averted gaze. The amplitudes and latencies of the N170, a face sensitive ERP, and the P100, an ERP associated with early sensory processing, were extracted from selected electrodes over the occipitotemporal scalp of the right and left hemispheres (RH; LH), segmented to the gaze shift. Externalizing symptomatology was measured using parent-report on the Child Behavior Checklist (CBCL). Group differences were examined using t-tests. Effects of diagnosis and gaze on ERPs were examined with two-way ANOVAs. Linear regression analyses were used to test whether externalizing behaviors significantly predicted neural responses.

Results:

Participants with ASD exhibited significantly greater parent-reported externalizing behavior than TD participants, as determined by the CBCL's Externalizing T-Scores [$t(88)=4.30$, $p<0.001$]. Analysis of N170 peak amplitude revealed that there was a significant main effect of gaze [LH, $F(1,158)=4.48$, $p=0.04$] such that the N170 was enhanced to direct gaze compared to averted gaze. There was no main effect of diagnosis and no interaction between diagnosis and gaze ($ps>0.05$). In ASD but not TD, externalizing behaviors predicted N170 latency to averted gaze [LH, ($b=1.36$, $p=0.04$), ($R^2=0.10$, $F(1,43)=4.53$, $p=0.04$)]. The analysis of P100 peak amplitude and latency indicated no main effects of diagnosis or gaze and no interaction between diagnosis and gaze ($ps>0.05$). Similar to the N170, externalizing behaviors predicted in ASD but not TD P100 latency to averted gaze [RH, ($b=0.81$, $p=0.02$), ($R^2=0.13$, $F(1,43)=6.22$, $p= 0.02$)], and P100 amplitude to direct gaze [RH, ($b=-0.07$, $p=0.01$), ($R^2=0.11$, $F(1,39)=4.96$, $p=0.03$)].

Conclusions:

Results of this novel interactive gaze paradigm indicate enhancement of the face-sensitive N170 to direct gaze across diagnostic groups, suggesting similar response to mutual gaze at initial stages of face perception. Externalizing behaviors were associated with gaze perception in children with ASD but not TD. In children with ASD, more severe externalizing behaviors were associated with slowed visual and facial processing in an avoidance-oriented social context and with more impaired visual processing in an approach-oriented one. These findings suggest that externalizing behavior may be useful in guiding strategies to stratify a heterogeneous ASD population to advance the objective of individualized, targeted therapies.

320 **246.320** Genetic Correlates of Electrophysiological Responses to Repeated Auditory Stimuli in Phelan-Mcdermid Syndrome

E. Isenstein[1,2], *H. Grosman*[2], *Y. Zhang*[2], *M. Mulhern*[2], *C. McLaughlin*[2], *A. R. Durkin*[2], *E. Wilkinson*[2], *P. M. Siper*[2], *S. De Rubeis*[3], *J. Buxbaum*[4], *L. E. Ethridge*[5], *A. Kolevzon*[2] *and J. Foss-Feig*[2], *(1)University of Rochester, Rochester, NY, (2)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (5)Pediatrics, University of Oklahoma Health Science Center, Norman, OK*

Background:

Phelan-McDermid Syndrome (PMS) is a rare disorder caused by a loss-of-function point mutation in the *SHANK3* site or a deletion at site 22q13.3, which includes the *SHANK3* site, that alters synaptic and glutamatergic function. PMS is characterized by global developmental delay, hypotonia, and generalized sensory hyporesponsiveness. The presence of PMS confers approximately a 75% likelihood of a comorbid Autism Spectrum Disorder (ASD) diagnosis. Sensory differences including both hyporesponsiveness and hyperresponsiveness are a common feature of ASD.

Objectives:

We investigated whether the hyporesponsiveness observed behaviorally in individuals with PMS can be recorded in electrophysiological (EEG) responses to repeated auditory stimuli. Additionally, we examined whether deletion size at the 22q13.3 locus in individuals with PMS correlated with degree of neural hyporesponsiveness and habituation to repeated auditory stimuli, as compared to typically developing (TD) controls.

Methods: EEG was recorded from 19 participants with PMS and 21 with TD, all 9-30 years of age, while a series of four consecutive 1000Hz tones was repeatedly presented. Within trials, each 50ms tone was separated by 616ms; inter-trial interval was 4000ms. Amplitudes of N1, P2, and N2 event-related potentials (ERPs) were extracted and compared between groups. Genetic reports for all PMS participants were assessed for base pair deletion length at the 22q13 gene. Individuals with a loss of function mutation at *SHANK3* were assigned a deletion size of 58571 base pairs, the size of the entire *SHANK3* gene.

Results: The PMS group showed a significantly lower mean P2 amplitude to the first tone relative to controls (p=.045). Habituation of the mean P2 amplitude was significantly larger in the TD group than the PMS group between tones 1 and 2, tones 1 and 3, and tones 1 and 4 (p=.038, p=.003, p=.018, respectively). Larger deletion size was associated with smaller mean P2 amplitude (r=-.43, p=.06) to the initial tone. Increased deletion size also correlated significantly with lesser habituation of mean P2 amplitude between tone 1 and 2 (r=-.51, p=.023), and approached significance for habituation between tones 1 and 3 as well as tones 1 and 4 (r=-.36, p=.12; r=-.38, p=.10; respectively).

Conclusions:

Our results indicate relative electrophysiological hyporesponsiveness to auditory stimuli in the PMS group as compared to the TD group, consistent with global behavioral observations of under-reactivity in this group. Results also suggest lower levels of habituation of the P2 ERP component in the PMS group, with a robust negative relationship to base pair deletion size at the 22q13.3 locus. Results also demonstrate a strong relationship between degree of neural hyporesponsiveness and base pair deletion size; further investigation in necessary to parse the relationship between these variables.

321 **246.321** Increased Inter-Trial Variability in Sensory Processing of Social Stimuli in Children and Adolescents with ASD

C. Luckhardt[1], *A. Kröger*[1], *H. Cholemkery*[1], *L. Elsuni*[1], *S. Bender*[2] *and C. M. Freitag*[1], *(1)Autism Research and Intervention Center of Excellence Frankfurt, University Hospital Frankfurt, Frankfurt am Main, Germany, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University of Cologne, Medical Faculty, Cologne, Germany*

Background:

In Autism Spectrum Disorder (ASD) neural correlates of sensory processing differ from matched typically developed controls (TDC). Most studies have focused on differences in group means but have not compared intra-individual variability of neural processing. The model of reduced sensory precision posits that sensory processing abnormalities in ASD may be caused by increased variability in the neural response patterns to sensory information (see Baum et al., 2015 for an overview). First studies have already indicated increased variability in neural markers of sensory processing (Dinstein et al., 2012; Haigh et al., 2014; Milne, 2011).

Objectives:

The objective of the current study was to test the hypothesis of reduced sensory precision during the processing of social stimuli. For this purpose the variability of a neural marker of sensory processing, namely the P100, was compared between children and adolescents with ASD and TDC. Furthermore, the correlation of this variability with performance in social perception tasks was explored.

Methods:

In a sample of 21 children and adolescents with ASD and 15 age, IQ and gender matched TDC EEG was recorded during the viewing of emotional facial expressions. EEG data were analysed on the single trial level, identifying P100 amplitude and latency for 60 trials. The median absolute deviation (MAD), which reflects the degree of variability across trials (Milne, 2011), as well as mean amplitude were computed for each participant. Mean and MAD were compared across groups using univariate ANOVA.

Results:

No between-group difference for mean P100 amplitude was found ($F(1,34)=.450$ $p=.507$). In contrast, MAD of the P100 amplitude was increased in ASD compared to TDC ($F(1,34)=4.616$ $p=.039$). Higher variability in P100 amplitude correlated with poorer performance ($r(36)=-.387$ $p=.010$) as well as increased reaction times ($r(36)=.351$ $p=.018$) in an emotion discrimination task.

Conclusions:

Results confirm increased variability in sensory processing of emotional facial expressions in children and adolescents with ASD. Importantly, the analysis of inter-trial variability seems to provide information on neural processing differences between ASD and TDC which do not become evident by a comparison of mean amplitudes. Furthermore increased variability is linked to deficits in facial emotion processing. These findings indicate that reduced sensory precision indeed contributes to social perception deficits in ASD. Further replication is needed to confirm this hypothesis. Preliminary analyses of P100 variability during biological motion processing indicate similar patterns also apply to other areas of social perception.

322 **246.322** Machine Learning Methods Reveal Improved EEG Biomarkers in an Autism Clinical Trial

*Y. Li[1], M. Murias[2], S. Major[2], G. Dawson[3] and **D. Carlson**[4], (1)Duke University, Durham, NC, (2)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (3)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (4)Department of Civil and Environmental Engineering, Duke University, Durham, NC*

Background:

Clinical trials for autism spectrum disorder (ASD) frequently utilize electroencephalography (EEG) measurements to track and evaluate neural dynamics. The utility of these measurements is determined by the efficacy of the biomarkers (or features) extracted from the EEG. Novel methods to *learn* improved biomarkers from clinical trial data can increase this efficacy and statistical power. A particular challenge for machine learning is the "little big data" structure, where there are many EEG samples but only a small number of participants. We introduce a new framework to address this challenging structure in conjunction with an interpretable deep network.

Objectives:

Our objective is to evaluate whether there are significant changes in neural activity in an open-label clinical trial designed to evaluate the efficacy of a single infusion of autologous cord blood for ASD. Specifically, the goal is to uncover improved EEG biomarkers using a machine learning algorithm to capture neural differences based on EEG recordings taken while watching social and non-social stimuli in longitudinal data.

Methods: The study involves secondary analysis on 22 children with ASD from ages 3 to 7 years who participated in this clinical trial and had available EEG recordings. High-density EEG recording (EGI, Inc) were collected at baseline (T1), 6 months post treatment (T2), and 12 months post treatment (T3). The EEG was recorded while watching a total of three one-minute long videos designed to measure responses to dynamic social and nonsocial stimuli. To learn EEG biomarkers, an interpretable convolutional network was applied to clean one-second data chunks to predict whether an EEG sample was from T1, T2, or T3. The "little big data" structure of the recordings was addressed with a novel multi-domain adaptation approach by explicitly learning and using similarities between patients. By examining the features, we can track how neural changes correlate to treatment stages. The learned features were evaluated with a leave-one-patient-out cross-validation scheme.

Results:

Our learned features distinguished between trial stages at a significantly higher rate than traditional approaches. Specifically, our features determined the correct stage 67.8% of the time. We compared this to a number of existing methods, with the next best performance giving 58.4% accuracy from a Multi-Channel Deep Convolutional Neural Network, suggesting that our novel methodology captures improved EEG information ($p<.001$, Wilcoxon signed-rank test). One confound on predictive ability was age, but age only captured a small amount of variability. The EEG was more predictive for trial stage compared to using age alone ($p<.001$, paired t-test). Visualization of learned features showed that particular frequency bands and sections of the brain were important to distinguish among trial stages. Neural similarities of participants can be revealed by using a graph visualization.

Conclusions:

Our machine learning methods empirically learned improved biomarkers related to clinical trial outcomes. By enhancing discrimination by a non-trivial margin, the statistical power of EEG biomarkers was significantly enhanced. The learned EEG biomarkers are a powerful tool to identify changed neural patterns in a longitudinal study, which we will soon be evaluating in a larger, placebo-controlled study.

323 **246.323** Maturation of Face-Sensitive MEG Responses in 6-24 Months Old Infants

*M. Slinger[1], E. S. Kuschner[2], M. Kim[2], J. C. Edgar[2], L. Bloy[2], H. L. Green[2], T. Chiang[2], H. Huang[2], T. P. Roberts[2] and **Y. Chen**[3], (1)The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Children's Hospital of Philadelphia, Philadelphia, PA, (3)University of Pennsylvania/The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Failure to detect or respond to faces is a predictor of autism spectrum disorder (ASD), with most research showing altered brain networks and abnormal fusiform gyrus (FFG) activity to face stimuli in adult or school-age children with ASD. Although orienting to face stimuli is an ability that emerges in the first year of life, little is known about how the brain processes social face stimuli in young populations.
Objectives: The present study employed magnetoencephalography (MEG) to study the development of face processing in infants and toddlers. The primary study goals were: (1) identify brain areas showing differences when processing Face versus Non-Face stimuli in typically-developing (TD) infants 6-12 months old (Time 1); (2) evaluate the developmental trajectory of face processing by obtaining MEG measures 12 months after the

participants' initial visit (Time 2; 18-24 months old). Associations between FFG peak latencies and age were also examined to evaluate whether the latency of the face FFG response decreases as a function of age.

Methods: MEG responses to Face and Non-Face stimuli were obtained from 35 infants aged 6-12 months. Follow-up MEG data (Time 2) were obtained from 12 TD infants 12 months after their initial visit. MEG data were obtained using an infant MEG system (Artemis 123™). MEG data were co-registered to a one-year-old MRI template. Artifact-free epochs 200 ms pre- to 500 ms post-stimulus were averaged according to stimulus type. Distributed source modeling via dSPM estimated activity throughout the brain at each digitized time point.

Results: A within-subject paired t-test showed stronger Face than Non-Face activity in multiple brain regions across time, with greater activity to Face than Non-Face stimuli most evident in right FFG at ~300 ms. Right FFG latencies in response to Face stimuli decreased as a function of age (R^2 = 0.43, p < 0.001). For the 12 infants with a follow-up MEG exam, the average right FFG latency difference between Time 1 and Time 2 was 110 ms (range 0 – 260 ms).

Conclusions: Face-sensitive brain activity was identified in TD infants in left and right FFG at ~300 ms post-stimulus, with right FFG activity occurring on average 110 ms earlier after a year interval. The above suggests that the face-sensitive FFG response (right hemisphere) evolves to an adult-like FFG face response (~170 ms post-stimulus) by 3 years of age. With a better understanding of face processing in infants, longitudinal studies are now needed to characterize neural responses to social stimuli during the first year of life in infants at-risk for ASD. It is expected that via such studies early brain markers that predict future (and possibly atypical) brain function will be identified, with these functional markers eventually used to identify children at risk for conversion to ASD.

324 **246.324** Modeling the Connections of BRAIN Regions in Children with Autism Using Evolutionary Algorithms and Electroencephalography Analysis.

E. Grossi, *Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy*

Background: Recent studies with neuroimaging methods like diffusion tensor imaging, functional connectivity, and graph theoretic methods have showed atypical development of neural connectivity in ASD, with excessive local connectivity within neural assemblies and deficits in long-range connectivity between functional brain regions. In this paper we present a new pre-processing approach of EEG data based on a novel algorithm applied to raw data and to quantitative EEG features able to pick-up abnormal connections.

Objectives: The aim of this study is to focus brain connections abnormalities in ASD using novel algorithms applied to EEG data.

Methods: Twenty children diagnosed with ASD (DSM-V criteria) and 20 children diagnosed with NPD (ADHD –N.16, mood disorders –N.2, anxiety disorders –N. 2) matched identically for age and male/female ratio, were entered into the study. A continuous segment of artifact-free EEG data lasting 10 minutes in ASCCI format were entered in Cin-Cin algorithm, a new pre-processing method to treat multichannel time series related to brain activity. The algorithm is based on an input vector characterized by a linear composition of city-block matrix distances between 19 electrodes. In this way, each EEG is transformed in a vector of 171 numbers expressing all the one by one distances among the 19 electrodes. Each distance value is assumed to express the connection among the two brain areas below corresponding electrodes. An evolutionary algorithm (a TWIST system based on KNN algorithm) was used to subdivide the dataset into training and testing set and select connections yielding the maximal amount of information. After this pre-processing different machine learning systems were used to develop a predictive model based on a training testing crossover procedure applied to selected connections distances.

Results: The connections subset involving 11 electrodes with nine connections (T4_F3, O2_F4, P3_T3, P3_C3, O1_C4, P3_T5, P4_T5, O1_T5, O1_P3) allowed the maximum degree of predictive performance by Machine Learning Systems used as classificators. Four of these connections are long range (three inter hemispherical and one intrahemispherical) and five short range. Long-range mean distances values resulted higher in ASD group while the opposite was true for short-range distances. The best machine learning system (three-layer feed- forward neural network with 8 hidden nodes) obtained a global accuracy of 96.2% (96.4 % sensitivity and 96.0 % specificity) in differentiating ASD subjects from NPD subjects.

Conclusions: The results of this study indicate the existence of brain connections abnormalities in ASD detected with evolutionary algorithms and Electroencephalography Analysis applied on a linear composition of city-block matrix distances between 19 electrodes. In addition, the model could distinguish the autistic children from the control children with an accuracy rate of 96.2%.

325 **246.325** Neural and Behavioral Predictors of Friendship in Children with Autism Spectrum Disorder

M. R. Altschuler[1], *D. A. Trevisan*[2], *J. Wolf*[1], *A. Naples*[1], *T. Winkelman*[1], *D. Stahl*[1], *E. Jarzabek*[1] *and J. McPartland*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Faculty of Education, Simon Fraser University, Burnaby, BC, Canada*

Background: Peer friendships are fundamental for social and affective functioning throughout the lifespan. In a meta-analysis, Mendelson et al. (2016) proposed a model of friendship success in children with autism spectrum disorder (ASD): efficient social information processing speed (SIPS), social cognition, and social motivation may underlie increased friendship quality and quantity and improve psychosocial functioning in individuals ASD who are able to form and maintain successful friendships. The present study utilized N170 latency to dynamic mutual eye contact as an index of SIPS. We hypothesized SIPS, social cognition, social motivation, and psychosocial functioning would relate to friendship (interest, quantity, and quality) in children with ASD.

Objectives: To empirically investigate and extend a model of successful friendship in ASD by examining the behavioral and neural correlates of friendship.

Methods: Children with ASD and average intelligence participated in a gaze-contingent experiment with co-registered electroencephalography and eye-tracking (N=72, 17 females, mean age=14 years-old, mean IQ=105). Participants viewed faces that responded to their gaze in four conditions: fixate on eyes, eyes open (mutual eye contact); fixate on eyes, mouth opens; fixate on mouth, eyes open; fixate on mouth, mouth opens. The amplitude and latency of the N170 were extracted from selected electrodes over the right and left occipitotemporal scalp. Friendship, social motivation, social cognition, and psychosocial functioning were measured with standardized interviews and questionnaires (see Table 1). Two ordinal regressions were conducted to examine the predictors of friendship quantity and interest, respectively, with N170 latency, social cognition and social motivation entered into the model as independent variables. A third multiple regression was run to assess whether friendship quantity and interest predicted psychosocial functioning. Final analyses will assess friendship quality as measured by coding from the Autism Diagnostic Observation Schedule-2.

Results: The first model significantly predicted friendship quantity over and above the intercept-only model [$\chi^2(3)=16.91$, $p=.001$]. Shorter N170 to mutual eye contact [Wald $\chi^2(1)=12.34$, $p<.001$] and higher social motivation [Wald $\chi^2(1)=4.31$, $p=.04$] significantly predicted greater number of friends. The second model significantly predicted friendship interest over and above the intercept-only model [$\chi^2(3)=11.64$, $p=.009$]. In this model, only higher social motivation emerged as a significant predictor of greater friendship interest [Wald $\chi^2(1)=7.15$, $p=.04$]. A third regression model examined friendship quantity and interest as predictors of psychosocial functioning. The overall regression model was significant [$R^2=.24$, $p=.03$].

Conclusions: Associations between friendship and SIPS, social motivation, and psychosocial functioning in ASD are consistent with the model proposed by Mendelson et al. (2016). Results suggest neural differences in SIPS and social motivation in children with ASD are associated with enhanced ability to form and maintain friendships and thereby positively impact psychosocial functioning. Moreover, this study extends Mendelson et al. (2016)'s model, demonstrating that improved neural SIPS in response to mutual eye contact in ASD is associated with greater number of friendships and that social cognition is not associated with friendship. These clinically significant findings suggest that targeting SIPS and social motivation may lead to improved friendships in ASD and, eventually, improved psychosocial functioning.

326 **246.326** Predictive Processing in Changing Environments in Autism: Electrophysiological, Pupillometric and Behavioral Assays

***S. Tikir**, M. J. Crosse and S. Molholm, Albert Einstein College of Medicine, Bronx, NY*

Background:

The brain continually produces predictions of upcoming sensory inputs rather than passively waiting for input to act upon. Impairments in the ability to flexibly generate and update predictions about upcoming events could be stressful, and it could lead to resistance to even trivial changes in life, which is a major feature in autism spectrum conditions (ASC). In a stable and predictable environment, the neurotypical brain generates expectations with a high level of confidence; while in a volatile and unstable environment where contingencies fluctuate wildly, the predictions earn lower levels of confidence. Thus, the brain not only makes predictions, but also assigns them an expected error rate.

Objectives:

Here we test the hypothesis that individuals with ASC are impaired in the ability to flexibly adjust the confidence level of their predictions according to changes in level of volatility in the environment. This is done by investigating whether & how quickly a new prediction model is adapted upon new experience in environments with different levels of volatility (high, medium, low).

Methods:

Data from 15 high functioning adults with ASC (18 to 25 years, three females) and 15 IQ- and sex- matched neurotypical controls were collected. We first remotely trained subjects to perform a sequence pattern learning task, where three consecutive shapes appearing in a particular order can create a pattern. The subjects were instructed to respond to a target, which is the final item the pattern. On the laboratory day, we then presented conditions with varying levels of pattern violation (environmental volatility), while high-density electroencephalography (EEG), behavioral responses and pupillometry were recorded. To examine how the level of surprise was modulated upon pattern violations in different volatility conditions, we measured changes in pupil dilation. Evoked response potentials (ERPs: CNV, P3, and error related responses) and reaction times were analyzed to infer predictive processing mechanisms.

Results:

In neurotypical subjects, as expected, P3 was present for the target, and increased in amplitude for low volatility through high volatility conditions. Further, there was a graded P3 function for the predictive items leading to the target in all volatility conditions. In the ASC group, a clear target P3 was only seen for the high volatility condition. In both groups, response times (RT) varied according to the level of volatility, showing an increase in RT when the condition switched to a higher volatility, and a decrease as it switched to a lower volatility. Additional analyses will focus on how fast this RT change occurred to determine learning rates of subjects, as well as how the CNV response and pupil dynamics modulate across volatility conditions and differ between groups.

Conclusions:

The P3 data reveal that the level of volatility and predictability had a lower influence on confidence of predictions in ASC, compared to neurotypical controls. This implies that people with ASC are less capable of processing the differences in volatility in the environment, which could make the changes in daily life unexpected and discomforting. Further analyses will show whether the data fully supports these conclusions.

327 **246.327** Psychophysiological Biomarkers of Stress As Predictors of Behavioral Disturbance in Autism Spectrum Disorder

***B. J. Ferguson**[1], T. Hamlin[2], J. Lantz[2], J. Coles[3], T. Villavicencio[2] and D. Q. Beversdorf[4], (1)Radiology & Thompson Center for Autism & Neurodevelopmental Disorders, University of Missouri, Columbia, MO, (2)The Center for Discovery, Harris, NY, (3)CUBRC, Buffalo, NY, (4)University of Missouri, Columbia, Columbia, MO*

Background: Many individuals with autism spectrum disorder (ASD) who are non-verbal and intellectually impaired are unable to effectively communicate their internal stress state, which may manifest as problem behavior during times of high stress. This presents significant challenges for those providing care and services for this population. Psychophysiological measures of arousal, such as skin conductance level (SCL), may provide an early indication of proceeding problem behavior, which may eventually be used to intervene prior to the engagement of problem behavior.

Objectives: The present study examined the feasibility of collecting SCL data from severely affected individuals with ASD during lesson time in a school setting at a residential facility for severely affected individuals with developmental disabilities. SCL was examined prior to the occurrence of problem behaviors to determine if a period of time exists prior to when the problem behavior occurred that could be used to intervene. SCL was also examined after the problem behavior occurred to determine how long it takes on average for an individual in the classroom to return to median baseline levels of SCL after the occurrence of a problem behavior. We also explored whether subtypes of SCL responders within the sample differed regarding types of problem behaviors.

Methods: SCL data from 8 individuals with ASD who are non-verbal and have severe intellectual impairment were collected over a 1-year period. SCL data were analyzed once per month for a year prior to engagement of problem behavior as well as after the problem behavior ceased. Also, the SCL data prior to engagement in problem behavior were visually inspected for the presence of different SCL subtypes in an exploratory

manner.

Results: An anticipatory rise in SCL only occurred 60% of the time prior to the problem behavior, with an average rise time of 10 minutes between the initial rise in SCL and the engagement in problem behavior. Furthermore, SCL levels after a problem behavior returned to median baseline levels only 45% of the time. Additionally, three different subtypes of SCL response were found, suggesting that different treatment strategies may be effective for each SCL response pattern.

Conclusions: It is feasible to utilize SCL as an indicator of stress in severely affected individuals with ASD who are non-verbal and intellectually impaired. A significant window of opportunity for intervention (10 minutes on average) may exist between the initial rise in SCL and engagement in problem behavior in some people with ASD. Further, almost half of the participants did not return to baseline SCL levels after engaging in problem behavior, reinforcing the importance of prediction and intervention prior to the engagement of problem behavior. Finally, distinct SCL patterns were associated with different problem behaviors, which may have implications for treatment strategies (i.e. cognitive/behavioral vs. pharmacological). Taken together, these results may ultimately help caregivers and practitioners create better personalized, precise treatments that will be more efficient and help increase the quality of life for individuals with ASD.

328 **246.328** Reduced Beta and Gamma Band Activity to Auditory Stimuli in Children with Autism Spectrum Disorders.

ABSTRACT WITHDRAWN

Background: Abnormal sensory reactivity is a key feature in the DSM-5 and is related to the most functional impairment in individuals with autism spectrum disorders (ASD). Auditory processing is the most commonly affected sensory domain. Atypical auditory processing is hypothesized to play a role in social, communicative, and cognitive deficits in ASD. However, there is little research examining the basis of auditory processing dysfunction in ASD.

Objectives: To examine brain oscillations during a sensory gating paradigm in children with ASD using electroencephalography (EEG). Based on previous research, we hypothesized that children with ASD will have reduced beta and gamma band activity to the click sounds compared to typically-developing (TD) controls.

Methods: Participants included 21 children with ASD (*M*= 8.6 years, *SD*= 2.14), and 20 age-matched TD children. EEG data were collected during a modified sensory gating paradigm consisting of 100 paired-click stimuli while the participant watched a silent movie. The base-line corrected time-frequency characteristics measured included a) evoked power, representing signal intensity, and b) phase-locking factor, depicting synchronization of signals across trials. The following regions of interest (ROI) were identified 1) Beta: 13–18 Hz from 60-90 ms and 2) Early gamma: 30–50 Hz from 20–60 ms and 3) Late gamma: 30–50 Hz from 60–90 ms. Data from each ROI were analyzed using a 2 (Clicks) by 2 (Group) ANOVA procedure. Caregivers of all participants filled out the Sensory Profile questionnaire.

Results: Evoked power and phase synchronization plots show that children with ASD appear to have less evoked power and reduced synchronization than the TD group to the clicks. (Figures 1 and 2). The ANOVA evaluating evoked beta power indicated a significant group effect, $F_{(1,39)}$= 25.1, p < .0005, η^2_p = .39, with reduced beta evoked power in both clicks in the ASD group compared to controls. Similarly, the ANOVA examining beta phase synchronization indicated significantly reduced beta phase synchrony to both clicks in the ASD group compared to controls, $F_{(1,39)}$ = 27.3, p < .0005, η^2_p = .41. There were no group or interaction effects in *early* or *late* gamma-band evoked power. However, early gamma phase synchronization was significantly reduced in the ASD group compared to controls for both clicks, $F_{(1,39)}$ = 10.5, p = .002, η^2_p = .21. There were no significant group differences in late gamma synchrony. Across all participants, greater sensory processing issues as measured by the Sensory Profile total score was associated with lower click 1 evoked beta power (r=.44, p= .004), lower beta phase synchronization (r=.49, p= .001) and lower gamma synchrony (r=.45, p= .003).

Conclusions: Results shows that children with ASD have reduced evoked power and phase synchronization of beta activity and reduced early gamma phase synchrony during auditory processing compared to controls, specifically in orienting and filtering auditory stimuli. Moreover, neural oscillations of click 1 strongly correlate with sensory processing in everyday activities suggesting that the sensory processing deficits observed in children with ASD may arise from atypical neurophysiological functioning specifically when orienting to an auditory stimulus.

329 **246.329** Respiratory Sinus Arrhythmia, Parenting, and Externalizing Behavior Problems in Children with Autism Spectrum Disorder

J. K. Baker[1], *R. M. Fenning*[2], *S. A. Erath*[3], *B. R. Baucom*[4], *D. S. Messinger*[5], *J. M. Moffitt*[6], *A. Kaeppler*[3] *and A. N. Bailey*[7], *(1)Center for Autism; Dept. of Child & Adolescent Studies, California State University, Fullerton, Fullerton, CA, (2)Center for Autism, Child and Adolescent Studies, California State University, Fullerton, Fullerton, CA, (3)Human Development and Family Studies, Auburn University, Auburn, AL, (4)Psychology, University of Utah, Salt Lake City, UT, (5)University of Miami, Coral Gables, FL, (6)Center for Autism, California State University, Fullerton, Fullerton, CA, (7)Psychology, Auburn University, Auburn, AL*

Background: Children with autism spectrum disorder (ASD) exhibit significant difficulties with emotion regulation. Respiratory sinus arrhythmia (RSA) is a biomarker for processes related to emotion regulation, with higher baseline levels generally linked to beneficial outcomes. Although reduction in RSA in response to challenge (RSA reactivity) can index adaptive engagement in community samples, excessive reactivity may suggest loss of regulatory control among children with clinical concerns. Psychophysiological risk for dysregulation may be protected against or exacerbated by parenting environments more or less supportive of the development of children's regulatory competence.

Objectives: The current study examined RSA in relation to externalizing problems in children with ASD, and considered positive and negative parenting as moderators.

Methods: From an original sample of 77 children, usable RSA data were obtained from an ethnically- and developmentally-diverse subgroup of 61 children with ASD (74% male; 47% Hispanic, IQ range = 47-121) aged 6 to 10 years (*M* = 7.95, *SD* = 1.48). RSA was measured with MindWare acquisition equipment and analysis software during a laboratory baseline and challenge task. Positive parenting included warmth as coded from a recorded speech sample, and observers' ratings of parental scaffolding. Negative parenting was comprised of critical comments from the speech sample and parent report on a measure of harsh discipline. Children's externalizing scores were indexed by parent report on the Child Behavior Checklist, and symptom ratings of oppositional defiant disorder (ODD) on a structured diagnostic interview.

Results: Parents were generally rated moderate (63%) or high (30%) on warmth and average scaffolding was in the moderately-high range. Critical comments and harsh discipline were relatively low. The positive and negative parenting composites were uncorrelated, r = -.05, *ns*. Almost one-

third of the children (30%) fell within the clinical range on externalizing problems and 34% met criteria for ODD. No main effects for RSA baseline or reactivity were observed after controlling for child age, IQ, and ASD symptom level; however, RSA reactivity interacted with both positive, *B* = -.26, *t* = -2.07, *p* = .044, and negative parenting, *B* = .30, *t* = 2.18, *p* = .034. Simple-slope analyses revealed that moderate-to-high levels of positive parenting buffered the association between higher RSA reactivity and children's externalizing problems (low positive parenting, *t* = 2.34, *p* = .022, others were non-significant), while high negative parenting appeared to strengthen this risk, *t* = 2.35, *p* = .022. Alternative follow-up analyses with RSA reactivity as the moderator suggested a dual-risk model wherein less optimal parenting was particularly problematic for children with high RSA reactivity (low positive parenting, *t* = -2.32, *p* =.025; high negative parenting, *t* = 2.26, *p* =.028).

Conclusions: Findings suggested a dual-risk model wherein children with both high RSA reactivity in response to challenge *and* less-optimal parent support (low positive or high negative parenting) were uniquely at risk for higher externalizing problems. Differential susceptibility was not supported in that high reactivity did not similarly sensitize the children to more positive environments. Implications for tailoring parenting interventions for different children with ASD will be discussed.

330 **246.330** Sex Differences in Neural Response to Emotional Faces in Children with ASD

***L. H. Singer**, T. Winkelman, M. R. Altschuler, E. Hamo, E. Jarzabek, J. Wolf, B. Lewis, A. Naples and J. McPartland, Child Study Center, Yale University School of Medicine, New Haven, CT*

Background:

Previous studies indicate that males and females with autism spectrum disorder (ASD) exhibit different social behaviors. School-aged girls with ASD tend to be more socially motivated and mimic peers in social interactions more frequently than boys with ASD (Sedgewick et al., 2016; Dean et al, 2016). Event related potential (ERP) recordings show promise in clarifying the neural basis of sex differences in ASD. One study found that in response to static, neutral faces, girls with ASD showed weaker neural activity than boys at the N170, an ERP marker of face perception (Coffman et al., 2015). However, a general population study indicates that autism-like traits are associated with poorer performance on emotion recognition tests in boys, but not girls (Kothari, 2013). While the body of ERP research focuses on response to static faces, the current study is unique both in that it utilizes dynamic faces and that the faces exhibit emotional expressions.

Objectives:

The study aims to assess potential sex differences in N170 and P100 amplitudes in response to dynamic, emotional faces in typically developing (TD) children and children with ASD.

Methods:

The current study included 30 children with ASD (24 male, 6 female) and 24 TD children (14 male, 10 female) matched on age (ASD: *M* = 13.78 , *SD* = 2.83; TD: *M* = 12.83, *SD* = 2.94) and IQ (ASD: *M* = 107.38, *SD* = 28.56; TD: *M* = 109.75, *SD* = 11.31). Participants were presented with photorealistic faces with neutral facial expressions. When a participant fixated directly on a face, as measured by eye-tracking, the facial expression changed to happy or fearful. Data were filtered, re-referenced, epoched from -100 to 500 ms, baseline corrected, artifact detected, and averaged for each stimulus (happy and fear). ERP latencies and amplitudes were extracted from left and right occipitotemporal electrodes. Amplitude difference scores were calculated as fear minus happy condition.

Results:

A two-way ANOVA indicated a significant interaction between diagnosis and sex, $F(1, 63) = 5.57$, $p = .022$, $\eta^2 = 0.10$, with a medium effect size, on amplitude difference. Post-hoc independent samples T-tests were performed with Bonferroni correction (.050/2: $p < .025$). Among the ASD group but not the TD group, males showed significantly attenuated N170 amplitudes in the left hemisphere in response to emotional faces (*M* = -.41, *SD* =1.91) relative to females (*M* = 2.37, *SD* = 3.58), $t(28) = -2.66$, $p = .013$.

Conclusions:

These findings highlight sex differences in neural activity when viewing emotionally salient stimuli that may underlie sex differences between social difficulties in children with ASD, which may help to identify new, specific therapeutic targets for individuals with autism of both sexes. Analyses in progress examine relationships among sex differences in neural response and clinical phenotype.

331 **246.331** Sex-Related Differences in Youth with ASD: Alpha EEG Power in Eyes-Open and Eyes-Closed Conditions from the ACE Gendaar Network

***E. Gahr**[1], A. Kresse[1], E. Neuhaus[2], R. Bernier[3] and S. J. Webb[3], (1)Seattle Children's Research Institute, Seattle, WA, (2)Seattle Children's Hospital, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background:

The EEG alpha frequency band (8-12 Hz) is thought to reflect levels of cortical excitability, with greater alpha power indicating lower cortical activity. Prior studies have demonstrated that individuals with ASD have decreased alpha power at rest (with eyes open) compared to control but comparable alpha power in eyes-closed (for review: Wang et al., 2013). The disparity in eyes-open vs eyes-closed alpha power is attributed to failure of individuals with ASD to increase cortical activity in preparation for visual input (e.g., Mathewson et al., 2012). Additionally, sex differences in resting EEG have been demonstrated in neurotypical participants, with females spend demonstrating lower power (greater attentional processes) compared to males (Tomescu et al, 2018). Little is known about sex-based difference in brain functioning in individuals with ASD, as most studies enroll males with ASD.

Objectives:

This study will evaluate resting-state EEG alpha power in youth with ASD, comparing alpha power during eyes-open and eyes-closed resting conditions. Analyses will focus on exploring sex differences within youth with and without ASD.

Methods:

EEG was collected as part of the ACE GENDAAR network. EEG data were collected while the participants passively watched screen-saver-like videos (eyes-open) and while sitting with eyes closed (eyes-closed). To be included in the analysis, youth had to provide artifact free data in both

conditions. EEG data was available from 61 youth with ASD (males=35, females=26), 24 siblings of the youth with autism (males=12, females=12), and 94 neurotypical youth with no family history of autism (males=50, females=44). A fast fourier transformation (FFT) was performed on artifact-free EEG data to assess alpha power averaged across mid-posterior electrodes. Linear regressions were used to evaluate the effects of sex and diagnosis on alpha power.

Results:

Regression models with group, sex, and age as predictors of eyes-open frontal alpha power were significant for the eyes-open calm viewing alpha power at all regions (Fs>9.698, ps<.001, R2=.111-.137). Higher power (less activation) was found in the ASD group compared to NT (ps<.05) and for younger participants compared to the older (ps<.01). For eyes-closed frontal alpha power, the regression model was significant for eyes-closed at all regions (F≥2.62, ps≤.05, R2=.033-.39). Higher power was found in the ASD group compared to NT (ps<.05) and for the females compared to the males (ps<.05).

Conclusions:

EEG resting brain activity significantly differed between youth with ASD and youth with NT development. In the eyes-open condition, EEG power also differed for age; while for the eyes-closed condition, power differed by sex. These analyses extend previous findings to a sample of youth with ASD. Additional analyses will examine the relation between eyes-open and eyes-closed, include the interaction between these main effects, and the relation to phenotypic characteristics.

332 **246.332** Social Reward Circuit Dissection in the Rat Valproate Model of Autism

*G. D'Urso, P. Schoenenberger, R. Lütolf, J. Tampe, P. De Luna, S. V. Gornati, M. Schmitt, M. Bainier, M. Maco, L. Aubert, B. Biemans, R. L. Redondo and **C. Grundschober**, Neuroscience Discovery, Roche Pharma Research and Early Development, Roche Innovation Center Basel, F. Hoffmann-La Roche, Basel, Switzerland*

Background: The Ventral Tegmental Area (VTA) is a heterogeneous region that plays a key role in the control of rewarding activity, motivation and social behavior. It is mainly composed of dopaminergic neurons (> 60%), intermingled with GABAergic neurons (~30%) and glutamatergic neurons (2-3%). Activation of dopaminergic or GABAergic VTA neurons can induce reward or aversion. VTA prominently sends dopaminergic projections to the Ventral Striatum (VS), another region actively involved in processing motivation, decision making, and reward. It has been shown that VS activation following dopamine neurons stimulation in VTA has rewarding effects. Moreover, in humans, diminished fMRI BOLD striatal responses to social reward have been reported in autism spectrum disorder.
In humans, prenatal exposure to valproic acid (VPA) is known to increase the probability to develop autism in children up to ten-fold. Similarly, rats prenatally exposed to VPA display impairment in social behavior, increased anxiety and hyperactivity.

Objectives: In this study, we used the rat VPA model of autism to dissect the VTA-VS circuitry and its link to social behavior. We recorded local field potential and unit activity in freely behaving VPA-exposed and vehicle (VEH) control rats during social behavior. Our goal was to measure brain activity during social interaction to detect differences in social reward signaling between VPA and VEH control rats. In a second step, we wanted to test if treatment with a vasopressin V1a receptor antagonist was affecting this circuitry.

Methods: VPA-exposed (N=5) and VEH rats (N=5), implanted with single wires electrodes in both VTA and VS, were free to explore an open field arena with two Plexiglas boxes placed at opposite corners. The two insert boxes had three rows of holes to facilitate social interactions. The test was composed of three different time blocks for a total duration of 35 minutes. The first block consisted of 10 minutes of exploration with empty Plexiglas boxes. During the second time block, an unfamiliar conspecific was placed inside one of the two boxes and an object was inserted in the other for 15 minutes. In the third time block, the boxes were empty again for 10 minutes. Video tracking of the task allowed for segmentation of electrophysiological brain activity according to the position of the nose of the experimental animal in the different zones (object, animal and neutral zone).

Results: In VEH control rats, we found that the VS showed higher 80Hz Gamma Oscillation power in proximity to social cues compared to inanimate objects or empty environments. We are further characterizing differences in VPA rats and interactions with V1a antagonist treatment.

Conclusions: This work will add to our understanding of the brain circuits involved in social behavior in the rat VPA model of autism and how they may be affected by V1a antagonism, a mode of action which is currently being tested in Phase III studies in adults with autism.

333 **246.333** Spatiotemporal Electrophysiologic Responses to Linguistic Stimuli in Children with Low Language and Cognitive Ability

***L. Bloy**[1], T. P. Roberts[1], K. Shwayder[1], H. L. Green[1], L. Blaskey[1], M. Kim[1], E. S. Kuschner[1] and D. Embick[2], (1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)University of Pennsylvania, Philadelphia, PA*

Background:
Autism Spectrum Disorder (ASD) is a heterogeneous neurodevelopmental disorder often including impairment to language ability. Previous work investigating auditory speech processing with magnetoencephalography (MEG) has found event related desynchronization (ERD) in auditory cortex between 5-20Hz sensitive to a variety of linguistic factors such as semantic congruity, word frequency and word repetition. Recent work suggests that, in higher functioning children with ASD, ERD following linguistic stimuli is correlated with language ability.

Objectives:

In order to better understand the neural responses to language stimuli in the approximately 30% of the ASD population categorized as minimally-verbal/non-verbal (MVNV), we used MEG to measure ERD of the auditory cortex in response to linguistic stimuli (Words, NonWords, ReversedWords) in two cohorts: 1) MVNV children with ASD, 2) lower Intelligence Quotient (IQ) Intellectual Disability/Developmental Disability (ID/DD, non-ASD) clinical controls.

Methods:

Nineteen participants (aged 8-12yrs) were included in the final analysis (MVNV children with ASD, n=12, 9.6±1.1yrs; lower IQ ID/DD (non-ASD) clinical controls, n=7, 10.7±1.4yrs). MEG data were obtained using a 275-channel whole-cortex CTF magnetometer (CTF MEG, Coquitlam, Canada). Subjects listened to three types monosyllabic stimuli with different linguistic properties (100 each type): words (low age of acquisition), pronounceable nonwords, and acoustically reversed words. Bilateral ERD of the auditory cortex was measured between 5-20Hz and 200-1650ms. Cognitive ability

was assessed using the Nonverbal IQ (NVIQ) of the Leiter-3. Language ability was assessed using the Peabody Picture Vocabulary Test 4th edition (PPVT).

Results:

No significant group differences in age or NVIQ were observed (p>0.05), while significantly lower PPVT scores (p<0.01) were observed in MVNV children with ASD (33.0±11.0) compared with the ID/DD group (60.4±10.3). Higher NVIQ was significantly correlated with higher PPVT scores (R^2=0.27; p<0.05). Linear mixed models with subject entered as a random effect found significantly less ERD in MVNV+ASD children compared to ID/DD (p<0.01) and a significant interaction between hemisphere and group. No main effects of age, hemisphere, stimulus type, or other interactions (ps>0.1) were observed. Post-hoc analysis of each hemisphere found significant (p<0.01) bilateral decreases in ERD in MVNV+ASD children with a larger magnitude difference in the Right Hemisphere (Left: ID/DD 8.2±3.3; MVNV+ASD 5.7±1.9 Right: ID/DD 9.5±3.3; MVNV+ASD 5.2±1.6). Hierarchical regression was used in an attempt to disentangle the effects of group and PPVT. When entered first, both variables explained significant amounts of variance (group 42%; PPVT 40.8%; ps<0.01). When entered second neither variable explained significant amounts of variance (group 5.7%, PPVT 4.1%; ps>0.1).

Conclusions:

These findings suggest a correlation between the ERD and the behavioral classification of MVNV in children with ASD. These children exhibited little to no expressive linguistic ability, and their brain responses show little of the ERD previously linked to processing linguistic input. As suggested by hierarchical regression, the observed decreases in ERD in this study could be due to either ASD or poor language ability. Future work will potentially disambiguate these effects. Finally, the fact that no differences were observed between stimuli types in any group suggests that semantic differences between word types are processed outside of early auditory cortex.

334 **246.334** The Atypical GAMMA Range EEG Is NOT Explained By Developmental Delay in Young Children with Autism Spectrum Disorder

T. M. Helminen[1], *S. Pihlajamaa*[1], *S. Yrttiaho*[1], *K. Eriksson*[2], *J. M. Leppanen*[1] *and A. Kylliainen*[1], *(1)Tampere University, Tampere, Finland, (2)Tampere University and Tampere University Hospital, Tampere, Finland*

Background:

It has been suggested that the cortical brain activity of children with autism spectrum disorder (ASD) would show an imbalance between excitation and inhibition, which is reflected in atypically high baseline gamma activity. The previous research have showed abnormalities in gamma band activity in children with ASD when compared with typically developing children. However, there are age-related changes in gamma band activity during the development, and the developmental level of children with ASD has been shown to correlate with abnormalities in gamma band activity. Thus, it is not clear, whether the abnormalities found in previous studies could be better explained by developmental delay than ASD.

Objectives:

This study aimed at investigating whether the baseline gamma band EEG is atypical in children with ASD, when compared with typically developing children, and with children with developmental delay without ASD. In addition, the aim was to investigate whether the level of autistic behaviour correlates with gamma band EEG.

Methods:

Fifteen children with ASD (2.5–5.3 years, developmental age 1.2–4.2 years), 16 typically developing children (TD) matched with chronological age, and 14 children with developmental delay (DD) matched with developmental age, participated in the study. The baseline EEG was recorded when the children were watching a 3 minute video, where a person was calmly building a block tower. Only segments without movements or other distractions were analyzed, based on video analysis. The gamma band activity (24.4-44.0 Hz) was analyzed in central and parietal areas, which are least likely to be contaminated by of myogenic artefacts. The level of autistic behaviour was measured with ADOS-2 and ADI-R.

Results:

The split-plot ANOVA [Brain area (2) x Group (3)] on gamma activity showed a significant main effect of Group [$F(2,42)=3.276$, $p=.048$, $\eta p^2=.135$]. The gamma activity was significantly higher in ASD Group, when compared to TD ($p=.029$) or DD group ($p=.036$). The gamma activity between TD and DD groups did not differ. Activity was higher on parietal than on central areas [$F(1,42)=5.709$, $p=.021$, $\eta p^2=.120$], but there was no interaction between brain area and the Group. The correlation between gamma activity on central brain areas and ADOS-2 comparison scores in ASD group was marginal ($r_s = .487$, $p=.066$). The more autistic symptoms the child exhibited in ADOS-2, the higher was the gamma activity. No significant correlations were found between gamma activity and ADI-R scores.

Conclusions:

The present study supports previous studies by showing that the gamma band activity is higher in children with ASD than in typically developing children. Moreover, this finding seems to be specific to autistic psychopathology and not related to developmental delay per se, as according our results, the children with ASD showed higher gamma activity also when compared to children with developmental delay but without ASD. Some indications were found that the severity of autistic symptoms might be associated with gamma band activity. These findings suggest that the gamma band activity could be considered as one potential diagnostic marker for autism.

11:30 AM - 1:30 PM - Room: 710

335 **247.335** Thalamic GABA:Glutamate Ratio Is Related to Severity of Sensory over-Responsivity in ASD

E. T. Wood[1], *K. K. Cummings*[2], *J. O'Neill*[3], *J. Guo*[4], *M. Dapretto*[1], *S. Y. Bookheimer*[1] *and S. A. Green*[1], *(1)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)Division of Child & Adolescent*

Psychiatry, UCLA Jane & Terry Semel Institute For Neuroscience, Los Angeles, CA, (4)Department of Psychiatry & The Zuckerman Institute, Columbia University, New York, NY

Background: A better understanding of the underlying neurochemistry of Sensory Over-Responsivity (SOR) is vital for developing potentially groundbreaking and life-altering psychopharmacological interventions for the 50-75% of children with ASD who experience SOR. Parents report that SOR symptoms, ranging from tactile discomfort to distress in loud or complex environments, are among the most disruptive in their children's everyday life (Ben-Sasson *et al.*, 2007), but the biological mechanisms underlying SOR remain poorly understood, leaving a dearth of effective treatments. Genetic studies of GABA receptor function, biochemical analyses of GABA synthesis and degradation and computational models have suggested that core features of ASD are driven by an excitatory-inhibitory imbalance of neuronal activity (Rosenberg *et al.*, 2015). Neuroimaging research from our laboratory shows reduced modulation of thalamocortical connectivity in autism in response to mildly aversive sensory stimulation, further suggesting that an imbalance of excitation and inhibition in thalamic neuronal populations may play a role in SOR.
Objectives: Examine how GABA, Glutamate, and GABA/Glutamate ratios in the thalamus 1) differ between youth with and without ASD; and 2) correlate with behavioral measures of SOR within children with ASD.

Methods: Single-voxel edited ^{1}H-MR spectra and SOR measures were acquired from 19 youth with ASD (17 males; age (mean±SD) 16.0±2.0 years) and 8 typically developing (TD) youth (4 males; age 13.8±2.1 years). MRS GABA levels were measured in the bilateral thalamus with a midline voxel (8750mm^{2}) using a Siemens prototype MEGA-PRESS sequence (TE/TR 68/2000ms; 256 averages). Post-processing in MATLAB (Guo *et al.*, 2018) consisted of spectra phase and frequency correction, difference editing, and frequency-domain peak fitting with a simulated basis-set yielding high accuracy GABA and Glutamate+Glutamine (Glx) concentrations. Child sensory responsivity questionnaires were completed by parents including the Short Sensory Profile (SSP; Dunn, 1999) and the Sensory Over-Responsivity (SenSOR) Inventory (Schoen *et al.*, 2008).

Results: Student's t-tests did not demonstrate significant differences between ASD and TD groups in MRS GABA measurements. Pearson's correlations were used to characterize associations between GABA:Glx ratio and SOR measures where higher scores indicate greater severity of SOR symptoms. In the ASD group, negative correlations were found between GABA:Glx ratio and SOR scores on both the SenSOR and the SSP. (SenSOR Total r=-0.68, p<0.01; SSP Tactile Sensitivity r=-0.71, p<0.01; SSP Auditory/Visual Sensitivity r=-0.79, p<0.001).

Conclusions: These preliminary results relate lower thalamic GABA (inhibitory) to Glutamate (excitatory) ratios to greater severity of SOR symptoms within autism, suggesting that in ASD youth, SOR is associated with a deficit in thalamocortical inhibition. These correlations within the ASD group – despite the lack of significant differences between ASD and TD groups in GABA levels – may reflect the considerable phenotypic and etiologic heterogeneity of ASD. Abnormalities of the thalamic excitatory/inhibitory neurochemical balance could interfere with the role of the thalamus in integrating, relaying, and inhibiting attention to sensory information. Further analyses will correlate these spectroscopic findings with thalamocortical connectivity as measured by resting state fMRI.

336 **247.336** Making Sense of Sensory Sensitivity: New Evidence and a New Framework

ABSTRACT WITHDRAWN

Background: Atypical sensory sensitivity in autism is a puzzle. Its definition and measurement is essentially subjective, and it is unknown how it maps on to behavior: is it linked to perceptual abilities (e.g. local processing) or dysfunction? Similarly, it is unclear how an individual can be both hyper-sensitive and hypo-sensitive. Does it change over time, depend on context, or do hyper- and hypo- refer to different things (e.g. high sensitivity v. low responsivity)? Finally, although increased sensory sensitivity is assumed to reflect increased neurophysiological responses to sensory stimuli we don't know which neural circuits are crucial, including the relative importance of sensory and affective regions.
Objectives: I will present a new framework for exploring these issues which, whilst not directly answering these questions, provides a roadmap for how they can be tackled by future research. Specifically, I will discuss how different facets of sensory sensitivity (subjective, neural, behavioral) can be understood within a signal detection framework and how existing theories fit within this (including ideas from other panel speakers). I shall present unpublished data from psychophysical studies and brain stimulation that explore the idea that individual differences in neural noise contributes to adaptation and hyper-excitability.

Methods: Adaptation (measured in terms of subjective discomfort, or subjective neutrality) to visual stimuli is measured in several paradigms. Variability in TMS phosphene thresholds from visual cortex stimulation is considered (with motor thresholds as a control). These objective measures are regressed again subjective sensory sensitivity and autistic trait measures (with the AQ).

Results: Findings show a relationship between high sensory sensitivity and low adaptation (aversive visual patterns become less aversive through repetition in most people, but this is diminished in people with high sensory sensitivity), and a negative relationship between phosphene thresholds and sensory sensitivity (low phosphine thresholds linked to high sensory sensitivity).

Conclusions: Different accounts of sensory sensitivity are not mutually exclusive and future research needs to bridge the gap between implementational theories (e.g. excitation:inhibition ratio) and those couched in cognitive/computational terms (e.g. predictive coding).

337 **247.337** Acoustic Startle Response in Children with Autism Spectrum Disorder with and without Co-Morbitiy of Attention Deficit Hyperactivity Disorder

*R. Phillips[1], **S. Schmid**[2] and R. Nicolson[3], (1)University of Western Ontario, London, ON, Canada, (2)Anatomy and Cell Biology, Western University, London, ON, Canada, (3)Western University, London, ON, Canada*

Background: Parents of children with Autism Spectrum Disorder (ASD) and or Attention Deficit Hyperactivity Disorder (ADHD) often report that their children have trouble "tuning out" sensory stimuli. It is estimated that over 96% of children with ASD have difficulties filtering sensory information. Typically, no objective physiological measures of sensory filtering are assessed for those with ASD nor for those with ADHD and clinicians must rely on subjective reports of behaviours and symptoms. Though many symptoms overlap between ASD and ADHD and some estimates of comorbidity are as high as 50%, there is evidence that the underlying causes of these conditions may differ. An objective method for assessing sensory filtering ability is to study the eye-blink component of the startle reflex (SR) in response to unexpected startling sounds. The subject's ability to habituate to these random noises can be quantified and compared to traditional diagnostic tools.
Objectives: This study sought to quantify the differences and similarities in sensory filtering among individuals with ASD, ADHD, both ASD and

ADHD (Dual), and those with neither ASD nor ADHD (Control). A second objective was to compare EMG SR data to current clinical measures of sensory-related behaviours currently.

Methods: Data from 32 participants aged 9-17 years were grouped according to diagnostic status into one of the four groups mentioned above. All individuals were assessed using pencil and paper standardized tests for characteristics of ASD, ADHD as well as the Raven's Progressive Matrices as a measure of non-verbal intelligence. Orbicularis occuli electromyograph (EMG) measurements were recorded during an acoustic startle protocol that included input/output function, and habituation. Baseline EMG SR amplitude, and response latency were compared between groups. Welch's Anova and Games-Howell post-hoc analysis was conducted to determine statistical significance of findings.

Results: Baseline average EMG voltage of participants with ADHD was significantly higher than the baseline voltage for those with ASD or those who were dually diagnosed ($p<0.05$). The ASD group's average amplitude of startle response was significantly higher than Controls and included a period of sensitization. The degree of habituation over the course of the session was not strongly correlated to the subjective reporting measures of ASD nor ADHD symptoms nor did it correlate strongly to age, or IQ. No differences between groups was seen for the latency of the startle response. Latency was not effected by the age of the participant.

Conclusions: The results of this work demonstrate that there are differences between the population of individuals who have ASD with ADHD and those that have ASD without ADHD. The correspondence of the EMG data to subjective measures indicates limitations in relying on third-party subjective assessments for diagnostic purposes. The EMG SR of the groups will inform the validity of animal models of autism currently being used in basic research and further develop the neuroscience models of sensory filtering pathways.

338 **247.338** Changes in Muscle Strength, Static Balance and Dynamic Plantar Pressures in Autism Spectrum Disorder

T. Honsberger[1], *M. Mitchell*[2], *C. Honsberger*[3] *and M. Fernicola*[1], *(1)The Learning Academy at The Els Center of Excellence, Jupiter, FL, (2)Health and Human Performance, Palm Beach Atlantic University, West Palm Beach, FL, (3)Els for Autism Foundation, Jupiter, FL*

Background: Individuals with autism spectrum disorder (ASD) show affected sensorimotor skills that impair postural control and static balance, both necessary components of standing and walking without risk of fall and injury. Muscle strength, body composition and reaction time are known to effect injury risk from falls.

Objectives: To examine the extent of alterations in static balance, gait alterations within individuals with ASD.

Methods: Forty-eight subjects (14.3 ± 4.3 years) participated in this study. Height (62.8 ± 6.1 inches), weight (133.5 ± 50.9 pounds), body mass index (23.0 ± 6.4), fat deposition (25.9 ± 9.8 % body fat), grip strength (11.4 ± 6.4 kg), upper body strength, standing balance and reaction time were measured. Correlations with Childhood Autism Rating Scale (CARS-2) and other incidence reports were also investigated. Plantar forces, pressures and oscillations during walking were also analyzed and compared to a control group of non-ASD subjects.

Results: Compared to normative values, arch index was decreased (pes cavus) in subjects with ASD. Plantar force distribution surface area distribution during walking was significantly different in individuals with ASD. During static balance assessment, center of pressure distances and speed of deviations were significantly greater in subjects with ASD.

Conclusions: Overall, these findings are consistent with clinical observations that abnormalities of movement performance and cognitive performance are an associated feature of ASD in children and young adults. These abnormalities may contribute to the increased rates of injuries that individuals with ASD experience. Implications for intervention to potentially mitigate these deficiencies are discussed.

339 **247.339** Clinical & Genetic Subtypes of Sensory Processing Sensitivities in Autism

G. Dumas[1], *A. Lefebvre*[2], *F. Cliquet*[2], *F. Amsellem*[3], *T. Bourgeron*[4] *and R. Delorme*[5], *(1)Human Genetics and Cognitive Functions Unit, Institut Pasteur, Paris, France, (2)Institut Pasteur, Paris, France, (3)Pasteur, Paris, France, (4)University Denis Diderot Paris 7, Paris, France, (5)AP-HP, Robert-Debré Hospital, Child and adolescent Psychiatry unit, Paris, France*

Background:

Sensory processing sensitivities are critical cornerstone for characterising and understanding Autism Spectrum Disorder (ASD). These prevalent symptoms correlate with symptoms severity and cognitive impairments, suggesting shared biological mechanisms. Understanding these mechanisms may shed light not only on sensory processing deficits but also on ASD.

Objectives:

This study characterises extreme cases of high and low sensory sensitivity among subjects and investigate their correlation with mutations in pathways related to ASD.

Methods:

The analysis was done on 420 subjects of the C0733 cohort including 165 with ASD, 210 first-degree relatives & 97 controls. Low- and high-sensitive participants were selected based on the Short Sensory Profile [SSP; Dunn, 1999]. We used GRAVITY (http://gravity.pasteur.fr) for the analysis of all exonic variants.

Results:

Preliminary analysis showed a normal distribution of scores in all groups but with statistically significant differences in variance. The exploration of the GABA and GLUT pathways suggests that likely gene disruptive mutations in GABA have stronger impact on Perceptual Sensibility than GLUT. For Missense mutations, there was no difference between groups.

Conclusions:

These results show how hypo/hyper-sensitivity in ASD may be caused by the higher clinical heterogeneity, with deleterious genetic mutations as one underlying cause.

340 **247.340** Pain Anticipation in High Functioning Autism: Physiological Evidence from a Skin Conductance Study

J. De Angelis[1], *A. Maravita*[1], *M. Palladini*[1] *and* ***P. Ricciardelli***[2], *(1)Psychology, University of Milano-Bicocca, Milano, Italy, (2)Psychology, University of Milano - Bicocca, Italy, Milano, Italy*

Background:
Previous research showed the existence of brain areas dedicated to pain processing in self and others. These areas were demonstrated to respond both to actual pain stimulation and to pain anticipation (i.e. when the painful stimulus approaches participant skin without touching it). A very few studies have investigated pain anticipation patterns in people with High Functioning Autism (HFA), even though hyper/hyporeactivity to sensory input has become one of the key DSM-5 criteria for Autism Spectrum Disorders diagnosis.

Objectives:

The present study was aimed at investigating psychophysiological responses in people with HFA when observing a painful stimulus approaching their or other participants skin.

Methods:

Skin Conductance Responses (SCR) were measured in a group of participants with HFA diagnosis and a control group including participants without any psychiatric or neurological diagnosis. All the HFA participants obtained ADOS - 2 scores above the diagnostic cut-off (Level 1). Moreover, both the HFA and the control group participants filled out the Autism Quotient before taking part in the study, which served as an additional group manipulation check. During the experimental session, participants observed, respectively, a painful (sterilized needle) or a neutral (cotton bad) stimulus that could approach their own hand, the hand of another person or the hand of a robot.

Results:

SCR results showed that – regardless of the experimental condition – in general HFA participants exhibited greater physiological responses than control group participants. Interestingly, we also found that HFA participants showed greater pain anticipation responses when observing the painful stimulus approaching the skin of the human hand. In addition, lower responses in HFA compared to control group participants were observed when the robotic hand was approached by the needle.

Conclusions:

Taken together, our results indicate a substantial physiological hyperactivation in HFA participants when observing a noxious stimulus approaching another human being compared to the control group participants, who exhibited a lower activation pattern. These findings are in line with previous evidence showing that the affective component of empathy would be preserved in HFA and it might at the basis of an overreaction when observing others in pain. These results are expected to shed light on the pain processing patterns in people with HFA and to better clarify how social signals coming from the social world are processed by this population.

341 **247.341** Sleep Problems and Sensory Sensitivities Are Strongly Related in Children with ASD

I. Dinstein[1], *O. Tzischinsky*[2], *M. Ilan*[3], *H. Flusser*[4], *A. Michaelovski*[5], *M. Faroy*[5], *O. Zivan*[6], *I. Menashe*[7], *G. Meiri*[5] *and L. Manelis*[8], *(1)Negev Autism Center, Ben Gurion University of the Negev, Beer Sheba, Israel, (2)Yezreel Valley College, Yezreel Valley, Israel, (3)Department of Psychology, Ben-Gurion University of the Negev, Beer Sheva, Israel, (4)Child Development / Pediatric, Ben Gurion University in the Negev, Be'er Sheva,, Israel, (5)Soroka Medical Center, Beer Sheba, Israel, (6)Soroka Medical Center, Beer Sheva, Israel, (7)Public Health Department, Ben-Gurion University, Beer Sheva, Israel, (8)Negev Autism Center, Ben Gurion University of the Negev, Beer Sheva, Israel*

Background: Previous research has suggested that sleep problems and sensory processing are associated in both typically developing children and those with Autism Spectrum Disorders (ASD).
Objectives: To examine whether a relationship between sleep and sensory processing is also apparent during early ASD development (below the age of 36 months) and whether longitudinal changes in sleep problems are associated with changes in sensory processing.
Methods: 195 children with ASD (mean age 3.77±1.54 years old, 45 females) were recruited at the Negev Autism Center (www.negevautism.org). All children fulfilled DSM 5 and Autism Diagnostic Observation Schedule (ADOS) criteria for ASD. Parents filled out the Children Sleep Habits Questionnaire (CSHQ), a caregiver questionnaire that quantifies the severity of sleep problems, and the Sensory Profile (SP)**,** a caregiver questionnaire that quantifies sensory processing. In 44 of these cases, both questionnaires were filled out again (after ~1.5 years) by parents during an annual follow-up visit. The relationships between sleep and sensory measures were examined at both time-points.
Results: ASD children exhibited abnormally high rates of sleep disturbances (75% had total sleep disturbance scores >41 on the CSHQ) and sensory processing (52%) in comparison to typical development norms. Total sleep disturbance scores were most strongly associated with sensory sensitivity and avoidance scores in children under 36 months old (avoiding: r=0.56, p<0.001, sensitivity: r=0.59 p<0.001) and in older children with ASD (avoiding: r=0.47 p<0.001, sensitivity: r=0.56 p<0.001). Most importantly, changes in sleep disturbance scores over a period of 1.5 years were positively correlated with changes in sensory sensitivity and avoidance (avoiding r=0.39 p=0.04, sensitivity: r=0.45 p=0.01).
Conclusions: These results demonstrate that ASD children exhibit relatively large sleep and sensory abnormalities, which are strongly associated. This association is apparent not only in cross-sectional assessments, but also when examining longitudinal changes in sleep and sensory measures. We speculate that sleep problems and sensory sensitivities enhance one another in a vicious cycle that is likely to have considerable impact on the family's well-being and on the efficacy of behavioral interventions. Specific targeted interventions for these particular children are currently lacking.

342 **247.342** The Association between Sensory Behaviors and Heart Activity in Preschool Children with Autism Spectrum Disorder and Fragile X Syndrome

J. A. Ezell[1], *E. A. Will*[2], *K. Hills*[1] *and J. E. Roberts*[2], *(1)University of South Carolina, Columbia, SC, (2)Psychology, University of South Carolina, Columbia, SC*

Background:
Fragile X syndrome (FXS), the most common heritable genetic cause of autism spectrum disorder (ASD), is characterized by abnormal social behavior and intellectual disability (ID). Children with FXS or ASD are at risk for physiological dysregulation, atypical sensory processing, and anxiety (Sinclair, et al, 2017). Sensory processing difficulties are linked to anxiety in ASD (Green & Ben-Sasson, 2010; Lane, et al, 2012). Further, children with FXS or ASD often show autonomic dysregulation, resulting in lower respiratory sinus arrhythmia (RSA), which may contribute to increased vulnerability to anxiety (Klusek et al, 2015; Roberts et al, 2012). Dysregulated startle response to an auditory stimulus is one example of

atypical sensory processing (Kohl et al, 2014; Friedman, 2007). Understanding the influence of sensory processing on physiological regulation can provide insight into early risks and features of anxiety in these children.

Objectives: The purposes of this study are to employ a multi-method approach to (1) compare parent-reported sensory behaviors in FXS, ASD, and typically developing (TD) controls, (2) characterize and test group differences in the association between sensory processing difficulties and RSA during an anxiety-provoking task across preschoolers with FXS or ASD, and TD controls.

Methods:

Participants included 29 children with FXS, 26 TD children, and 25 children with non-syndromic ASD between the ages of 3-6 years old. The FXS and ASD groups had ID. The Sensory Experiences Questionnaire total score (SEQ) measured sensory processing. RSA was measured throughout the auditory startle task, which is comprised of the pre-startle (30 seconds), 100 dB, white-noise startle (1 second), and post-startle (30 seconds).

Results: One-way ANOVA results identified significant differences in SEQ scores across ASD, FXS, and TD children ($F(2, 78) = 22.75$, $p < .001$), with ASD highest and FXS next highest. Sensory processing and post-startle RSA were significantly correlated within the entire sample ($r = -.357$, $p = .001$). A moderated regression model showed that sensory processing predicted post-startle RSA, but only in the FXS group ($b = -2.09$, $p < 0.01$). FXS and ASD groups significantly differed on post-startle RSA, holding SEQ scores constant ($b = -4.25$, $p = 0.02$). Results also indicated a significant difference in the effect of SEQ on post-startle RSA between the FXS and ASD groups ($b = 2.09$, $p = 0.01$), in that the predicted effect of sensory difficulties on post-startle RSA is stronger for the FXS group. There was no such difference between FXS and TD groups.

Conclusions:

Consistent with prior work, these findings demonstrate greater sensory processing difficulties in both ASD and FXS groups than the TD group. A significant association between post-startle RSA and sensory behaviors was found only in the FXS group, suggesting that the more atypical sensory behaviors, the lower or more blunted RSA for the FXS group only. Further, the association between RSA and sensory processing differed between the FXS and ASD group, suggesting that these mechanisms are a unique aspect of the FXS phenotype. Future steps include evaluating the relationship between sensory processing, RSA, and anxiety symptoms.

343 **247.343** Thermal Detection Thresholds Are Not Elevated in Children and Adults with Autism Spectrum Disorder

Z. J. Williams[1], *S. L. Davis*[2], *C. D. Okitondo*[3], *L. E. Mash*[4,5], *B. H. Heflin*[6], *A. S. Weitlauf*[7] *and C. J. Cascio*[8], *(1)Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Psychiatry Department, Vanderbilt University Medical Center, Nashville, TN, (4)Brain Development Imaging Laboratories, Department of Psychology, San Diego State University, San Diego, CA, (5)Joint Doctoral Program in Clinical Psychology, SDSU / UC San Diego, San Diego, CA, (6)Florida International University, Miami, FL, (7)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (8)Vanderbilt University School of Medicine, Nashville, TN*

Background: In recent years, sensory features, including an “apparent indifference to pain/temperature” (American Psychiatric Association, 2013) have been included in the diagnostic criteria for autism spectrum disorder (ASD). However, most evidence of atypical pain/temperature perception in ASD is based on clinical descriptions or parent reports rather than experimental studies (Moore, 2015). The few studies to date examining warm and cold detection thresholds in this population have produced mixed and contradictory results (Cascio et al., 2008; Duerden et al., 2015; Fründt et al., 2017; Yasuda et al., 2016). Nevertheless, all prior studies utilized small sample sizes (≤20 ASD participants), and none explicitly controlled for covariates such as age and IQ when comparing groups.

Objectives: To assess thermal detection thresholds in a large sample of children and adults with ASD, comparing them to typically-developing (TD) controls and adjusting for a number of covariates.

Methods: Participants included 143 individuals with average or above-average intelligence (WASI-II FSIQ > 70): 32 ASD adults (22 males, mean age 28.76 years), 24 TD adults (13 males, mean age 29.0 years), 51 ASD children (41 males, mean age 11.24 years), and 36 TD children (26 males, mean age 10.03 years). In the experimental task, a thermode on the palm increased or decreased in temperature at 1°C per second until the participant indicated a sensation of warmth or cold via mouse click. This procedure was repeated over four alternating blocks of five warm or five cold trials (counterbalanced across participants). Warm and cold detection thresholds were estimated using the Harrell-Davis median (Harrell & Davis, 1982) of threshold temperatures from warm and cold trials, respectively. Participants or caregivers also completed measures of IQ (WASI-II), autistic traits (SRS-2), and sensory reactivity (Sensory Profile). Threshold values were analyzed using proportional odds regression models (Liu et al., 2017), with baseline models including ASD status, age, sex, and counterbalance order as predictors. Additional predictors were added to the model using a best-subset approach based on BIC values.

Results: ASD and TD groups in the full sample and child/adult subsamples were matched on age, sex, and performance IQ ($ps > 0.118$), although verbal IQ was higher in the TD group ($p < 0.001$). Baseline regression models that included ASD status, age, sex, and counterbalance order as predictors failed to find any significant associations with warm or cool detection thresholds in the combined sample or any subgroup ($ps > 0.05$). In the best-subset regression, performance IQ was consistently included in all best-fitting models, with higher performance IQ predicting lower warm thresholds and higher cool thresholds ($ps < 0.025$). Questionnaire measures of autistic traits and sensory reactivity were not found to significantly predict warm or cool thresholds in any model.

Conclusions: Warm and cool detection thresholds did not differ between individuals with ASD and TD controls. Performance IQ was the only consistent predictor of sensory threshold across temperature conditions and age groups. These findings suggest that the “hyposensitivity” to thermal stimuli observed in some individuals with ASD is likely not related to a quantitatively higher sensory threshold.

344 **247.344** Weaker Neural Suppression during Visual Perception in Autism Spectrum Disorder

M. P. Schallmo[1,2], *T. Kolodny*[2], *A. M. Kale*[2], *J. Gerdts*[3], *R. Bernier*[3] *and S. Murray*[2], *(1)Psychiatry and Behavioral Science, University of Minnesota, Minneapolis, MN, (2)Psychology, University of Washington, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background:

It has been proposed that autism spectrum disorder (ASD) is associated with an imbalance of excitation and inhibition. While this is supported by specific animal models of ASD, there is little direct experimental support for this hypothesis from studies in humans.

Objectives:

Using a visual motion paradigm, we tested whether mechanisms that regulate neural activity may be disrupted among individuals with ASD.

Methods:

Within the visual system, a powerful suppressive regulatory effect occurs in neurons when a stimulus is presented that is larger than that neuron's classical receptive field – information from the surround suppresses the neural response to the stimulus in the center. We used a well-known behavioral paradigm that reflects this spatial suppression by measuring the amount of time required to perceive the motion direction of stimuli at various sizes. In addition, we used fMRI to measure neural suppression in the motion sensitive brain area called human MT complex (hMT+). We further tested the mechanism of this suppression by measuring levels of the inhibitory neurotransmitter GABA in the hMT+ region using MR spectroscopy. Participants included 28 young adults with ASD (10 male, 8 female) with diagnoses confirmed through ADOS, ADI and clinical judgment using DSM-5 criteria, as well as 35 age-, gender-, and IQ- matched neurotypical controls (21 male, 14 female).

Results:

In both the behavioral and fMRI measurements, we found strong evidence of reduced suppression among young adults with ASD compared to neurotypical controls (Supplemental Figures 1 & 2). However, MR spectroscopy measurements in the region of hMT+ showed no difference in GABA levels between ASD and control groups.

Conclusions:

Our results suggest that differences in suppressive regulatory mechanisms in ASD reflect changes in neural activity, but are not driven by a specific difference in GABA concentration.

Panel Session
Adult Outcome: Medical, Cognitive, Behavioral, Social, Adaptive, Vocational
249 - Autism, Sexuality and Romance: From a Better Understanding to Attuned Support
1:30 PM - 3:30 PM - Room: 516ABC

Panel Chair: Jeroen Dewinter, *GGzE, Eindhoven, Netherlands, GGzE, Eindhoven, Netherlands*

Discussant: Laura Graham Holmes, *Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA*

Our insight in autism, sexuality and relationships has improved over the last four decades, yet questions remain relating to themes that impact the daily lives of autistic adolescents and adults. The presentations in this panel focus on directions for future research on autism, sexuality and relationship, and highlight recent findings relating to these priorities. In the first presentation, a research agenda on autism, sexuality and romantic relationships developed with researchers, autism advocates, and stakeholders at INSAR 2018 and additional groups of autistic adults is presented and discussed. The second speaker discusses sexuality in autistic women. Data from an online survey on sexuality in autistic women compared to autistic men and women in the general population, revealed a lower desire for sex, notwithstanding higher levels of experience and more negative sexual experiences. The third presentation offers insight in on how autistic individuals experience the role of sensory processing in dating and sexuality. Our last speaker discusses the experiences and needs of professionals in working with autistic adults presenting with gender identity questions. This study revealed the need for knowledge on gender issues in professionals working with autistic people in order to provide them with attuned support.

1:30 **249.001** Autism, Sexuality and Relationships: Defining Themes and Priorities for Future Research Based on a Participatory Approach.

J. Dewinter[1,2], *L. Graham Holmes*[3] *and A. I. van der Miesen*[4], *(1)GGzE, Eindhoven, Netherlands, (2)Tilburg School of Social and Behavioral Sciences - Tranzo, Scientific Centre for Care and Welfare, Tilburg University, Tilburg, Netherlands, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Child- and Adolescent Psychiatry, VU University Medical Center, Amsterdam, Netherlands*

Background:

In 2018, a special interest group (SIG) was initialized at INSAR 2018 to discuss research priorities resulting in the development of a research agenda relating to autism, sexuality and romantic relationships.

Objectives:

To explore research priorities relating to sexuality and romantic relationships in and together with autistic people, in order to develop a research agenda that contributes to the well-being of autistic adolescents and adults.

Methods:

The nominal group technique (NGT), reliable to define healthcare priorities, was applied in eight groups (n=65, 31 self-identified as autistic). Five of these groups were mixed groups consisting of researchers, autism advocates, clinicians and students (n=39, group range n=5-10, all professionals or students, 5 autistic). In order to warrant the input of autistic adolescents and adults, three additional groups were organized; two in collaboration with a Dutch LGBT$^+$-group (Lesbian, gay, bisexual, trans and inclusive to all other groups) for autistic people (n= 20, group range n= 8-12) and one with a self-organization (Persons on the Autism Spectrum; PAS) for autistic adults (n=6). Themes were grouped based on thematic analysis. All participants selected 5 themes they found having the highest priority. Priorities were calculated and compared over all groups and in autistic participants.

Results:

Three general themes emerged, overarching 17 thematic clusters, based on 222 topics collected during the group meetings. The first, '*Getting a better understanding*', included questions relating to sexual development across lifespan, sexuality and intellectual disability, cultural differences, experiences and needs in autistic LGBT+'s, sexual identity development, gender differences, relationship characteristics and experiences, pregnancy and parenthood, healthcare, sensory issues, well-being, and the influence of medication use. Second, '*Improving support and treatment*' included the need for evidence on ways to support and promote sexual well-being and healthy romantic relationships, preventing

offending and victimization, improve healthcare experiences and needs, and involving and supporting families, partners and professionals. Finally, '*Changing societal views and practices by a participatory approach*' referred to the need for a participatory approach in research and ways to influence societal views on autistic people, their sexuality and romantic relationships. Using the priority scores as indicated by all participants, ways to support romantic relationships (1), sexual well-being (2) and getting a better insight in sexual development across lifespan got the highest priority scores (3). The autistic participants ranked insight in lifespan issues higher than education and support.

Conclusions:

This research agenda relating to autism, sexuality and romantic relationships can guide the design of future research in this field. Highest priorities are promoting and supporting sexual well-being and positive relationship experiences and prevent victimization. Therefore, increasing our insight in sexual development across lifespan, with attention to the influence of autistic information processing characteristics in relationship experiences and types, and in sexual identity development and the needs of autistic LBGT+'s is needed. Gaining knowledge should benefit and support autistic people directly, and indirectly by influencing societal views and stereotypic ideas on autism, sexuality and romance. A participatory approach could guarantee that research is valuable to the daily lives of autistic people.

1:55 **249.002** Characterizing the Sexuality and Sexual Experiences of Autistic Women

M. A. Stokes[1], *L. Pecora*[2] *and G. Mesibov*[3], *(1)Deakin University, Burwood, Australia, (2)School of Psychology, Deakin University, Burwood, VIC, Australia, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: There is limited understanding of the sexuality and sexual experiences of autistic women. While preliminary insights have been drawn from few anecdotal and qualitative reports, findings have begun to identify a profile marked by increased sexual risks and vulnerabilities. These initial observations require further exploration via quantitative means.

Objectives: This study aimed to expand upon initial understandings of the sexuality of autistic women to examine the prevalence and nature of sexual functioning and experiences for individuals in this group.

Methods: A total of 459 autistic (*N*=232) and typically developing (*N*=227) adults completed the SBS-III online. Self-reported levels of sexual interests, behaviours, and negative experiences of 135 autistic women (*M*=26.2 years, *SD*=8.7) were compared between autistic males (*N*= 96 [*M*=24.2 years, *SD*=7.4]) and TD females (*N*=161 [*M*=22.0 years, *SD*=4.6]).

Results: Despite reporting less interest in sex ($p<.05$), compared to autistic males, proportionally more autistic females reported having had sexual experiences ($p<.05$). Autistic females also reported more instances of negative sexual experiences, including the engagement in sexual behaviours that were later regretted ($p<.001$), unwanted ($p<.001$), or being the victim of unwanted sexual advances by others ($p<.001$) than male counterparts. Age trends were also observed, where reported instances of negative sexual experiences increased with age in the TD group, yet decreased in the autistic sample from 41 years.

Conclusions: Results indicate that due to a mismatch between low levels of sexual interest, yet increased engagement in sexual behaviours, autistic women are at greater risk of being subject to negative sexual experiences including victimisation and abuse. These results highlight the need for further research to identify the factors leading to these increased vulnerabilities. Additionally, these findings affirm the growing need to deploy gender specific programs that educate and support autistic women to reduce these risks and facilitate a healthy sexual life.

2:20 **249.003** Sensory Processing and Autistic Experiences of Sex and Relationships

A. V. Kirby[1], *L. Graham Holmes*[2] *and S. Gray*[3], *(1)University of Utah College of Health, Salt Lake City, UT, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Life Skills Clinic, University of Utah, Salt Lake City, UT*

Background:

Autistic individuals often process sensory information differently than neurotypical people. Dunn's Model of Sensory Processing is commonly used to understand sensory processing and outlines four main types of processing differences including sensory sensitivity, sensory avoiding, low registration, and sensation seeking. Sensory processing plays a critical role in many life roles and activities, including sexuality and dating. However, prior research on sexuality and relationships for autistic people has focused on social communication aspects, with limited research and understanding about the effects of sensory processing. This study addressed this gap by considering both positive and negative effects of sensory processing on sexuality, and how autistic people address these experiences.

Objectives:

To understand autistic sexuality and relationship experiences as related to sensory processing.

Methods:

Two methodological approaches were used to address the research objective. First was qualitative analysis of publicly-available narratives from autistic adults including books by autistic authors, quotes attributed to other autistic adults in those books, movies, and online forums. Second was qualitative analysis of open-ended responses from 59 autistic adults on an online survey about sexuality and relationship experiences. Text segments related to sensory experiences and sexual activity or romantic experiences were retained for analysis. Qualitative thematic analyses included deductive theoretical coding using Dunn's Model of Sensory Processing. Inductive coding was also used to generate additional themes from the text data. Multiple approaches were used to strengthen trustworthiness of the analyses and results including investigator triangulation, data triangulation, an audit trail, and researcher reflexivity.

Results:

Identified narratives written by self-identified autistic adults revealed that some perceive sensory processing as influencing their experiences of sexuality and romantic relationships. Some of the experiences were described as beneficial or positive, while many others were uncomfortable or negative. All four of Dunn's sensory patterns were observed in the narratives, with sensory avoiding being the most frequently identified pattern. Individuals described a variety of ways of addressing negative experiences including avoiding physical contact or dating, increased communication with partners, and various adaptations. Some individuals indicated that intense or overwhelming sensory experiences decreased or altered their desire, ability, or willingness to participate in partnered sexual activity or other relationship-related activities (e.g., going on dates in traditional noisy or crowded settings, cohabitating). On the other hand, some participants discussed positive sensory experiences as a benefit

of being autistic.

Conclusions:

Sexuality and relationships provide opportunities for connection and fulfillment, and are important factors in adult health and well-being. The results of this study suggest that sensory processing plays an important role in these experiences for many autistic adults. Some of these experiences are positive—warranting no intervention. Other sensory experiences may be limiting individuals' desired relationships—warranting support. Understanding autistic experiences of sexuality and relationships can inform self-advocacy, education, resources, and/or services to support autistic people in the pursuit of healthy and fulfilling sexual experiences and romantic relationships.

2:45 **249.004** Clinicians' Perspectives on the Co-Occurrence of Gender Dysphoria and Autism Spectrum Disorder: A Pilot Study

***A. I. van der Miesen**, Child- and Adolescent Psychiatry, VU University Medical Center, Amsterdam, Netherlands*

Background: The co-occurrence of gender dysphoria (GD) and autism spectrum disorder (ASD) is an area of inquiry by researchers with the vast majority of publications reporting an increase in (symptoms of) ASD in individuals diagnosed with (symptoms of) GD and vice versa. All clinicians may therefore encounter individuals with the sometimes challenging co-occurrence of ASD and gender identity questions. But how comfortable are these clinicians in assessing and/or working with individuals with both GD and neurodiversity and what is their approach?
Objectives: This pilot study assesses experiences, perspectives and needs of clinicians working with neurodiverse and gender diverse individuals.

Methods: A questionnaire with both multiple choice as well as open ended questions was used to assess the views of clinicians working with individuals with (symptoms of) GD and ASD on their feelings of competence, their ideas and hypotheses on the co-occurrence, the topics they consider important to discuss during assessment, and their professional needs in improving their approaches. This pilot study included 44 mental health professionals working with different age-groups.

Results: While none of the participants worked in a specialized gender identity service, all had at least some experience with assessment of individuals with (symptoms of) GD and 95.5% had at least some experience with individuals with ASD. A total of 72.7% had experience with assessment of individuals with ASD for (symptoms of) GD. A total of 22.7% of clinicians would discuss similar topics with neurotypical as well as with neurodiverse individuals. But there were also clinicians (22.7%) who had no idea which topics they should discuss with neurodiverse individuals. Others mentioned that they would take specific aspects of autism during the counseling into account such as rigid thinking, problems with abstract thinking, and the difficulties during social transition and treatment. Some clinicians were able to mention hypotheses about why neurodiversity and gender diversity could co-occur, but others had no idea. Of the clinicians, 51.2% considered themselves competent to talk about gender/GD with neurodiverse individuals because of experience and specific education. A total of 23.3% felt incompetent and 25.6% felt as well competent and incompetent.

Conclusions: Being an expert in the separate fields of neurodiversity or gender diversity alone doesn't seem to be enough for clinicians to feel competent in working with neurodiverse and gender diverse individuals, especially with regard to scientific background and clinical approach. Clinicians assessing and treating neurodiverse and gender diverse individuals stated that they want to broaden their knowledge of the current state of literature and the different views that exist on co-occurring GD-ASD. Being well-equipped with these scientific findings would enable the clinicians to adapt their clinical guidance on a case to case basis, thereby improving the assessment and care for neurodiverse and gender diverse individuals. In the present talk, specific implication for clinical practice will be discussed.

Panel Session
Biomarkers (molecular, phenotypic, neurophysiological, etc)
250 - Human and Animal Models: Impact of High-Risk Copy Number Variants on Brain Structure, Functional Connectivity, and Sexual Development.
1:30 PM - 3:30 PM - Room: 517C

Panel Chair: Ana Silva, *Neurosciences & Mental Health Research Institute, Cardiff University, Cardiff, United Kingdom*

An increased burden of rare copy number variants (CNVs), structural variations of the genome, has been associated with neurodevelopmental and psychiatric disorders, including intellectual disability, autism spectrum disorders and schizophrenia. Given their relatively high penetrance, a significant impact on brain structure and function is anticipated but studies within brain structure are still relatively scarce. This panel of senior and early-career researchers brings together exciting multidisciplinary evidence on the impact of some of these rare variants using different imaging modalities (MRI, rs-fMRI, DTI, TEM) and functional measures in both human and animals. Results on the effects of 1q21.1, 15q11.2, and other rare CNVs on brain structure using big data from large collaborative efforts will be presented. Next, we will focus on mirror effects associated with 16p11.2 and 22q11.2 in functional connectivity (FC) and how these deletion-FC-signatures are specifically enriched in a large idiopathic autism sample. Next, mirror effects of 16p11.2 CNVs on sexual development will be explored by looking at 16p11.2 CNV carriers, patient cells, and animal models. Finally, using a novel Cyfip1 haploinsufficiency rat line, we will address how this gene in 15q11.2 BP1-BP2 affects white matter microstructure, which starts to unravel the cellular mechanisms contributing to 15q11.2 associated phenotypes.

1:30 **250.001** Enigma-CNV: Unraveling the Effects on Brain Structure of Rare Copy Number Variants Involved in Autism and Other Neurodevelopmental Diseases

***I. E. Sønderby**[1], D. van der Meer[2], S. Djurovic[3], I. Agartz[4], L. T. Westlye[3], S. Jacquemont[5], P. M. Thompson[6], O. A. Andreassen[7] and .. for the ENIGMA-CNV working group[8], (1)CoE NORMENT, University of Oslo, Oslo, Norway, (2)Oslo University, Oslo, Norway, (3)NORMENT, Oslo, Norway, (4)Dep of Psychiatric Reseach, Diakonhjemmet Hospital, Oslo, Norway, (5)CHU Sainte Justine, University of Montreal, Montreal, QC, Canada, (6)Stevens Neuroimaging & Informatics Institute, University of Southern California, Los Angeles, CA, (7)NORMENT, KG Jebsen Centre for Psychosis Research, Institute of Clinical Medicine,, University og Oslo, Oslo, Norway, (8)UCLA, Oslo, CA*

Background: Many recurrent copy number variants (CNVs) dispose to autism, including the 16p11.2 proximal and distal CNV, 1q21.1, 15q11.2 and 16p13.11 CNV. Although many CNVs are highly penetrant, their low frequency makes them challenging to study. ENIGMA-CNV is an international

effort launched to create the statistical power to identify the effect of CNVs on brain MRI measures. The study currently includes n~17,000 participants with CNVs and structural brain data. The 1q21.1 CNV predisposes to e.g. delayed development, autism and schizophrenia. Deletion carriers display microcephaly and duplications carriers macrocephaly. Frequency of the deletion in UK biobank: 0.027 %.
Objectives: Our aim is to identify the effect of CNVs on brain MRI measures.

Methods: Structural T1-MRI data from ENIGMA-CNV and the UK biobank were analyzed (FreeSurfer) and CNVs called (PennCNV). Subcortical volumes, cortical area and thickness were normalized correcting for age, age squared, gender, scanner and intracranial volume (ICV). Dose response (deletion = 1, non-carrier = 2, duplication = 3) was analyzed in a linear model on the normalized brain values.

Results: We found a positive dose-response effect of copy number on intracranial volume (β=1.52, P=1.4E-26) and total surface area (β=0.81, P = 1.5E-08) with the highest effect on the frontal lobe and a small, significant negative dose response on caudate and hippocampus (β=-0.44, P=0.0026; β -0.5, P=0.00064) (deletion=30, non-carriers=24,575, duplications=19). In addition, in the largest analysis to date on 15q11.2 (119 deletions, 154 duplications, 37,871 non-carriers), we showed a positive dose response for cortical surface area (β=0.19, P=2.9E-3) and a negative dose response for average cortical thickness (β=-0.25, P=1.3E-4).

Conclusions: The mechanism behind the head circumference change in 1q21.1 distal CNV carriers seems to be an increase in cortical surface area which may indicate an effect on early development of the (dorsal) telencephalon. Together with other results both from ENIGMA-CNV and others, this indicates that each recurrent CNV has its own specific brain structural signature independent of its phenotypic outcome. These results underline the value of large-scale collaboration such as ENIGMA-CNV for studies of rare genetic variants implicated in autism and brain pathology.

All contributors to ENIGMA-CNV working group can be found at: http://enigma.ini.usc.edu/ongoing/enigma-cnv/enigma-cnv-co-authors/.

1:55 **250.002** Mirror Effects of 4 Neurodevelopmental CNVs on General Functional Connectivity and Implications for Idiopathic Autism

C. Moreau[1,2], *S. Urchs*[2,3], *C. Shramm*[1,4], *A. Lin*[5], *L. Kushan*[5], *A. C. Evans*[3], *C. Bearden*[5], *P. L. Bellec*[2] *and S. Jacquemont*[1,6], *(1)CHU Sainte Justine, University of Montreal, Montreal, QC, Canada, (2)Centre de Recherche de l'Institut Universitaire de Gériatrie de Montréal, Montreal, QC, Canada, (3)Montreal Neurological Institute, McGill University, Montreal, QC, Canada, (4)Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, QC, Canada, (5)University of California, Los Angeles, CA, (6)Service of Medical Genetics, CHUV, Lausanne, Switzerland*

Background: Copy number variants (CNVs) at the 16p11.2 and 22q11.2 loci are among the most frequent risk factors for autism and schizophrenia. Almost nothing is known, however, on the alterations of functional connectivity (FC) associated with these genomic variants. fMRI studies of ASD (Autism Spectrum Disorder) have resulted in heterogeneous findings yet there is a paucity of research into homogeneous groups of individuals that share the same genetic ASD risk factors.
Objectives: Our aims are : 1) To characterize the functional impact on brain connectivity of 4 CNVs at the 16p11.2 and 22q11.2 loci. 2) To investigate whether these CNV-associated patterns are observed in a heterogeneous group of idiopathic autism at a level consistent with the risk conferred by each genetic variant. 3) To explore the similarity of spatial patterns of FC alterations associated with each CNV.

Methods: To this mean, we have analyzed rs-fMRI data from n=105 deletion and duplication carriers and 128 controls from the Simons VIP dataset and UCLA. We then correlated the pattern of connectivity of each CNV to patterns observed in n= 276 autism and n=290 control subjects from the ABIDE dataset. fMRI data were preprocessed with NIAK pipeline and FC was estimated as the pairwise correlation between the average time series of 64 brain regions. A linear model was fitted to each connection with genetic status, subject motion, sex and site as explanatory factors. The effect of the 4 genetic groups were then tested by post-hoc contrasts. Each contrast was controlled for false discovery rate (FDR) across all connections at q < 5%. The 16p11.2 and 22q11.2 connectivity patterns were compared to the autism cohort using spatial correlation of the individual connectome with the CNV derived pattern of connectivity alterations.

Results: The 16pDel is associated with an overall increase in connectivity while the 22qDel is associated with an overall decrease in connectivity compared to control. An enrichment of their individual profiles is reported in an idiopathic ASD sample in 4 seed regions (Putamen, Thalamus, perigenual anterior Cingulate, and dorsomedial Prefrontal Cortex). Finally, a functional covariance pattern between 16pDel and 22qDel is observed in the Fronto-parietal, Limbic, and Anterior DMN networks.

Conclusions: Deletions and reciprocal duplications are associated with a mirror effect at the global and individual connection level for both the 16p11.2 and 22q11.2 CNV loci. In addition, FC alterations exhibit opposing relationships for DEL (and DUP) carriers at both loci: 16p11.2 DEL is characterized by overall over-connectivity while the reverse is true for 22q11.2 DEL carriers. Striato-striatal and striato-cortical over-connectivity in the DEL carriers is consistent with previous reports of aberrant functional connectivity in ASD. Despite the opposing pattern of FC alteration exhibited by DEL carriers of each locus, we find an enrichment of both in an idiopathic autism sample. This is likely conferred by the similar relative distribution of FC alterations (convergence of covariance connectivity patterns between 16p11.2 and 22q11.2 deletions).

2:20 **250.003** Using Rare Variants, Animal Models and Mendelian Randomization to Pinpoint Causative Genes

A. Reymond, *Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland*

Background: Although accumulating evidence suggests that rare CNVs are a common health problem in the population, their phenotype spectrum have largely only been investigated in clinical (often pediatric) patients.
Objectives: Our aim is to pinpoint causative genes within the 16p11.2 region influencing sexual development in general population.

Methods: We combined data from a comprehensive set of clinically ascertained 16p11.2 families (n=660 affected individuals) with unselected adult population cohorts (>470,000 individuals recruited to the UK and EGCUT biobanks) to assess adult phenotypes.

Results: We uncovered that the 16p11.2 BP4-BP5 dosage, one of the most frequent genetic causes of mental disorders, was oppositely associated with age at menarche (AaM) in the UK Biobank ($p=7.8e^{-05}$; ANOVA, corrected for BMI and birth year). Compared to controls AaM was decreased in deletion (Δ=-1.5 years, p=0.01) and increased in duplication carriers (Δ=+1.5; $p=7.8x10^{-5}$). We replicated these associations in EGCUT ($p=2.4e^{-05}$) and in two unrelated cohorts of 16p11.2 clinical patients ($p=7.7e^{-05}$; $p=3e^{-03}$). We observed a directionally consistent trend for pubertal onset in male 16p11.2 CNV carriers. These features were accompanied by various diagnoses related to function of reproductive organs and fertility, with up to half of deletion and two-third of duplication female carriers presenting at least one diagnosis related to hormonal problems or function of genital organs. We validated the human results by detecting changes in timing of first ovulation, estrous cyclicity and uterine size in females and reduced

anogenital distance in males 16p11.2 mice. Corroboratively, genes differentially-expressed in 16p11.2 patients cells and mice model cortices were enriched for urogenital disease genes. We unraveled a negative correlation between the 16p11.2 dosage and hypothalamus volume both in human (p_{FWE}<0.05) and mice ($p<1x10^{-04}$), suggesting that perturbation of the gonadotropin-releasing hormone (GnRH) axis could contribute to the observed phenotypes. Whereas Mendelian Randomization (MR) suggested *INO80E* and *KCTD13* as potential causal genes for AaM, an agnostic modulation of all 16p11.2 genes dosage in *gnrh3:egfp* transgenic zebrafish larvae pinpointed to *ASPHD1* a gene specifically expressed in brain and pituitary gland. Pairwise interaction experiments in zebrafish revealed epistasis between the *ASPHD1* "driver" and the *INO80E* and *KCTD13* “modifiers”.

Conclusions: Our findings highlight how identification of traits associated with rare variants, such as CNVs, in the general population provides valuable unbiased insight into disease etiologies. Our data also demonstrate how rare variants combined with MR can be utilized to pinpoint causal genes within GWAS loci as the common SNPs within the 16p11.2 interval were previously associated with AaM.

2:45 **250.004** Impact of Cyfip1 Haploinsufficiency on White Matter Microstructure in a Rat Model

***A. I. Silva**, J. E. Haddon, Y. A. Syed, D. E. Linden, M. J. Owen, J. Hall and L. S. Wilkinson, Neurosciences & Mental Health Research Institute, Cardiff University, Cardiff, United Kingdom*

Background: The 15q11.2 BP1-BP2 deletion has been associated with learning and motor delays, autism and schizophrenia. This region includes a gene that codes for the cytoplasmic FMRP interacting protein 1 (*CYFIP1*). *CYFIP1* haploinsufficiency is considered to be a likely significant contributor to the 15q11.2 BP1-BP2 deletion psychiatric phenotype due to its known involvement in a number of key brain plasticity-related functions. *CYFIP1* gene plays a crucial role in actin remodeling, where dysregulations could result in changes in white matter microstructure by influencing axonal density, organisation, and myelination.

Objectives: Our aim is to identify possible cellular changes underlying white matter effects at 15q11.2 BP1-BP2 region.

Methods: We used a novel CRISPR/Cas9-engineered hemizygous-null *Cyfip1* (*Cyfip1*$^{+/-}$) rat line. All the rats used in this experiments were males and 6-8 months old. Diffusion tensor imaging (DTI) data were collected in a cohort of 24 rats (wild-type (WT) n=12, *Cyfip1*$^{+/-}$ n=12) and analyzed using Tract-Based Spatial Statistics (TBSS) available in FSL. To investigate the cellular nature of the DTI changes we used transmission electron microscopy (TEM) to measure the number of myelinated and unmyelinated axons, the axon diameter, and the myelin thickness and g-ratio (myelin thickness relative to axon diameter) of each myelinated axon. The experiment used a new cohort of rats (WT n=5, *Cyfip1*$^{+/-}$ n=4). We then quantified the number of oligodendrocytes lineage and mature cells using immunofluorescence technique, where sections were stained for Olig2 and Cc1 proteins. This experiment used rats taken randomly from the same group of rats providing the DTI data (WT n=7 and *Cyfip1*$^{+/-}$ n=7). Linear mixed effects (LME) models were used to analyze the effect of genotype on axon diameter, g-ratio and myelin thickness, considering variation across animals, whereas a two-tailed unpaired t-test was used to compare the number of axons and number of oligodendrocytes between groups.

Results: A main finding of DTI were significant decreases in fractional anisotropy (FA) in the *Cyfip1*$^{+/-}$ rats that were most pronounced in the corpus callosum and external capsule. TEM showed that decreased FA was associated with thinning of the myelin sheath in the corpus callosum (LME: $X^2(1)=14.63$, $p<0.001$), where no differences were found in the number of unmyelinated ($t=0.39$, $df=5.15$, $p=0.71$) and myelinated ($t=-0.63$, $df=5.72$, $p=0.55$) axons, or in the diameter of the axons (LME: $X^2(1)=0.05$, $p=0.83$). Immunofluorescence showed a reduction in the number of mature oligodendrocytes ($t=2.48$, $df=11.99$, $p<0.05$) in the corpus callosum of the *Cyfip1*$^{+/-}$ rats.

Conclusions: Altogether, our study suggest that haploinsufficiency in the *Cyfip1* gene results in changes in white matter microstructure associated with thinning of the myelin sheath. The reduction in oligodendrocyte cells suggests that this might be caused by an insufficient supply of myelinating oligodendrocytes. Insufficient myelination can result in impaired cognitive processing, which can lead to deficits in tasks of higher cognitive demand and contribute to the cognitive deficits seen in 15q11.2 BP1-BP2 deletion carriers.

Panel Session
Diagnostic, Behavioral, Sensory and Intellectual Screening and Assessment
251 - Clinical Presentation of ASD and Access to Care Among Girls
1:30 PM - 3:30 PM - Room: 517B

Panel Chair: Allison Ratto, *Children's National Health System, Washington, DC*

Discussant: Sharon daVanport, *Autistic Women & Nonbinary Network, Lincoln, NE*

There is a rapidly expanding field of research showing that ASD may manifest differently across the sexes, particularly among individuals with intact core language and intellectual abilities. Girls may have important socio-communicative strengths that “camouflage” their challenges and deficits related to ASD, which in turn places them at risk for under-diagnosis, delays in diagnosis, and reduced access to treatment. Although there is a growing sense among both researchers and self-advocates that autism may be camouflaged in girls, there is not yet a clearly established set of diagnostic differences by sex, necessitating further research in this area. The presentations in this panel will focus on differences by sex among autistic youth in performance on standard diagnostic tools used in research in and clinical practice for identifying ASD and co-occurring conditions, as well as associated disparities in access to care. Sex differences in both core domains of ASD and related areas of emotional-behavioral functioning will be explored. Data from the National Survey on Children’s Health will also examine disparities in psychotropic medication prescription rates as possibly related to differences in clinical conceptualization of co-occurring conditions.

1:30 **251.001** Sex Differences in Youth with ASD: Language Phenotype and Relation to Autism Behaviors from the ACE Gendaar Network

***S. J. Webb**[1], A. Kresse[2], V. Y. Kang[3], E. Neuhaus[4], S. Corrigan[2] and R. Bernier[1], (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Seattle Children's Research Institute, Seattle, WA, (3)Special Education, University of Illinois at Chicago, Chicago, IL, (4)Seattle Children's Hospital, Seattle, WA*

Background:
The GENDAAR study is a multisite collaboration focused on understanding sex-based differences in youth with ASD using multimodal behavioral measures, neuroimaging, and genetics. This analysis specifically focuses on sex-based language differences in youth with ASD and neurotypical development, and the relation to autism behaviors (as reported by parents or observed by clinicians). In this abstract, we focus on the Word Class Expressive (WC-E) domain of the Clinical Evaluation of Language Fundamentals (CELF), in which the participants explain why words go together; this task involves both word knowledge and social/cultural-understanding of similarities between words.

Objectives:

To understand sex differences in language ability in verbal youth with ASD and how these sex based differences in language ability impact assessment of autism symptoms.

Methods:

8- 18-year-old individuals participated at four sites as part of the ACE GENDAAR Network. This analysis included 157 youth with ASD (71 female) and 158 youth with neurotypical development (NT; 80 female). All individuals with ASD met criteria on the ADOS, ADI, and DSM and had Verbal IQ > 70. Participants with NT had no family history or concerns about ASD and had scores £ 11 on the SCQ and £ 60 on the SRS. Language was assessed using the DAS II (Word Definitions, Verbal Similarities) and the CELF-5 subdomains. Analyses used ANOVA and regression to investigate effects of participant sex and diagnosis on language skills; and the contribution of language ability to observed and reported autism behaviors.

Results:

On all standard language measures, the NT group had higher scores than the ASD group (ps<.05). There were no sex differences within the ASD group on the DAS Word Definitions or Verbal Similarities; but there were sex differences on the CELF, with ASD females demonstrating better language skills than ASD males (Total Score; Recalling Sentences; Formulating Sentences; WC-E; Word Definitions; ps<.05). In the ASD group, WC-E was predicted by the sex (t=1.96) but not age, autism symptoms, executive functioning (EF) or parental education. Within the ASD group, parent report of autism behaviors (via SCQ) was predicted by sex (t=-1.7), with additional variability explained (FD=5.0) by language WC-E scores (t=-2.5), EF (t=2.5), and parental education (t=-3.9). In contrast, observed autism severity (ADOS calibrated severity score) was predicted by sex (t=-2.7) with no additional contribution from language and other variables (FD=.84).

Conclusions:

In this preliminary analysis, female youth with ASD had better verbal skills than males with ASD but only on the CELF, suggesting that even when "similar" language domains are being assessed, subtle differences in the measures may identify different sex related functioning within ASD (and may account for previous inconsistencies in sex-based findings in ASD). Sex and language were related to parent report of autism behaviors but not clinician observation of autism severity. Additional analyses will explore sex differences in other aspects of language and probe why differences were observed on the CELF but not the DAS; discussion will focus on implications for identifying sex-based differences in other autism samples.

1:55 **251.002** Social Strengths of Autistic Girls: Sex Differences in Clinician-Rated and Parent-Reported Autistic Traits

A. B. Ratto[1], *C. E. Pugliese*[1], *L. Kenworthy*[1], *S. J. Webb*[2], *R. Bernier*[2] *and K. A. Pelphrey*[3], *(1)Children's National Health System, Washington, DC, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)University of Virginia, Charlottesville, VA*

Background: Females are diagnosed with autism spectrum disorder (ASD) at significantly lower rates than males, with particularly discrepant rates among those without co-occurring intellectual disability (ID; Loomes et al., 2017). A growing body of research indicates that females with ASD without co-occurring ID may have important social strengths that "camouflage" autistic traits, making the condition harder to capture (Lai et al., 2016). We have previously found sex differences in parent-reported autistic traits among school-age children with ASD, but not on gold-standard diagnostic measures (Ratto et al., 2017).
Objectives: The aim of the present study was to further investigate sex differences in autistic traits among school-aged children on a clinician-rated and parent-report to extend prior findings.

Methods: The sample was composed of participants ages 8-18 years enrolled in the Gender Exploration of Neurogenetics and Development to Advance Autism Research (GENDAAR) study. From a total sample of 523 participants, a subsample of 196 children (n=85 female) were identified who had been administered the Module 3 of the Autism Diagnostic Observation Schedule-2 (ADOS-2) and had a clinician-confirmed diagnosis of ASD. There were no significant differences by sex in age [$t(194)= -.22$, $p=.83$] or full-scale IQ [$t(194)= -1.11$, $p=.27$]. Independent samples t-tests and chi-square analyses were used to evaluate sex differences in ADOS-2 performance, as well as parent report on the Social Responsiveness Scale (SRS) and the Vineland Adaptive Behavior Scales-II. Chi-square analyses were used to examine differences on select items on the ADOS-2, which prior literature suggested may be strengths for girls with ASD. Social items included Conversation, Facial Expressions, Empathy, Social Insight, Imaginative Play, and repetitive items included Stereotyped Language, Restricted Interests, and Compulsive Behaviors.

Results: Overall, girls were significantly less likely to meet criteria on the ADOS-2 [$X^2(1, N=196)= 4.80$, $p=.03$], though there were no significant sex differences in total scores on the diagnostic algorithm. Socially, girls showed better conversation skills [$X^2(2, N=196)= 5.85$, $p=.05$], empathy [$X^2(2, N=196)= 18.00$, $p<.0001$], and imaginative play than males [$X^2(3, N=196)= 14.63$, $p=.002$], but no differences in facial expressions or social insight. With respect to repetitive features, girls showed fewer compulsive behaviors [$X^2(2, N=196)= 7.19$, $p=.03$], but no differences in stereotyped language or restricted interests. Parents of girls reported greater communication [$t(179)= -3.01$, $p=.003$] and social [$t(180)= -2.10$, $p=.04$] skills on the Vineland-II, though not on the SRS. All results retained significance after controlling for multiple comparisons using the Benajmini-Hochberg procedure.

Conclusions: Although there is a growing literature indicating that non-intellectually disabled girls with ASD may show more subtle autistic traits, most prior studies have not identified differences in performance on gold-standard diagnostic measures. The sample used in this study was specifically recruited to be sex-balanced and thus better able to assess possible sex differences. Girls in this study showed important social strengths in both clinician and parent ratings, as well as reduced compulsive behavior. Despite comparable average algorithm scores, girls were less likely to meet ADOS criteria, suggesting that an adjusted cut-off score may need to be explored in future studies.

2:20 **251.003** Gender and Psychiatric Symptoms Among Youth with ASD and ADHD

A. Verbalis[1], *A. C. Armour*[1], *G. L. Wallace*[2], *E. Sadikova*[1] *and L. Kenworthy*[1], *(1)Children's National Health System, Washington, DC, (2)The George*

Washington University, Washington, DC

Background: Gender-related differences have been studied in ADHD for many years (e.g., as early as Gaub & Carlson, 1997), but inquiries in autism spectrum disorders (ASD) are relatively new (Bargiele, 2016). An important line of research is investigation into gender differences within and between developmental disabilities. This current study, using a large clinical sample of youth with diagnoses of ASD or ADHD, investigates potential gender-related differences in emotional and behavioral symptoms.
Objectives: To examine potential gender and diagnosis driven differences on the Child Behavior Checklist (CBCL).

Methods: 945 parents of youth with developmental disability diagnoses (440 with ASD and 505 with ASD) reported on their child's emotional and behavioral functioning using the CBCL. Youth age 6-18 with IQ > 50 were included in the analyses. Altogether there were 690 males and 255 females in the study. The diagnostic groups did not differ in age or IQ. A mixed-model ANOVA was used to investigate internalizing and externalizing symptoms (CBCL t-scores) across gender and diagnostic group, with post-hoc analyses following.

Results: The ANOVA revealed a main effect for diagnosis group ($F(1,941)=8.238$, $p=.004$), with ASD children exhibiting overall higher symptoms then ADHD children. Further, an interaction was identified between CBCL domain and diagnosis group ($F(1,941)=5.587$,$p=.020$), as the ASD children exhibit greater internalizing problems then ADHD children (post-hoc T-test: $t(943)=4.455$, $p<.001$), but similar levels of externalizing problems (post-hoc T-test: $t(943)=0.559$, p=ns. Additionally, this interaction was further driven by gender (ANOVA 3-way interaction $F(1,941)=4.066$, $p=.040$), with ASD girls being higher than ASD boys on externalizing problems specifically (post-hoc T-test: $t(438)=-1.984$, $p=.04$), but no differences between ASD boys and girls on internalizing problems, nor differences between ADHD boys and ADHD girls on internalizing or externalizing problems (p-values all = ns).

Conclusions: In a large sample of youth clinically diagnosed with ASD or ADHD, differences were observed with the parents of ASD children reporting higher overall symptoms then parents of ADHD children. This was primarily caused by higher levels of reported internalizing problems, rather then externalizing problems. However, within diagnostic groups, gender differences were noticed in the ASD children, but not the ADHD children, specifically for externalizing problems. It is important to note that these findings are based on standardized scores that have been normed according to both age and gender, suggesting that while ADHD children follow these norms more closely, the ASD children may exhibit discrepancies from these norms. These findings are in line with a growing literature of notable gender-related differences and risks within developmental disabilities, particularly ASD. It is also possible that the findings of this study might be driven by the fact that ASD girls who get referred for evaluations have increased overt symptoms. Studies in both ADHD and ASD have identified under-referral of girls for diagnostic evaluations. Finally, the finding of increased internalizing symptoms in ASD as compared to ADHD, without any effect of gender, is notable for potentially increased anxiety and depression specific to the autistic condition beyond developmental disability status.

2:45 **251.004** Evidence for Undertreatment of ADHD in Girls with ASD in the National Survey of Children's Health

***K. A. Register-Brown**, A. B. Ratto, S. I. Habayeb and L. Kenworthy, Children's National Health System, Washington, DC*

Background: Numerous studies have established that pharmacological treatment of ADHD is more effective than behavioral intervention alone for ADHD symptom improvement, although effect sizes are typically lower in children with autism spectrum disorders. Untreated ADHD has been associated with worse long-term outcomes in a wide range of functional domains. **Objectives:** To elucidate national patterns in ADHD medication use among girls and boys with and without autism in the US. **Methods:** The 2016 National Survey of Children's Health (NSCH), conducted by the US Census Bureau from June 2016 to February 2017, provides state-level and nationally representative data of parent report on the health and wellbeing of noninstitutionalized children aged 0-17 with and without special healthcare needs. The 2016 NSCH surveyed the parents/caregivers of 50,212 children in all 50 states and the District of Columbia. Data were adjusted and weighted by the survey team to create state and nationally representative samples of noninstitutionalized children aged 0-17. The overall weighted response rate was 40.7%. Weights were adjusted to account for nonresponse, and a nonresponse bias analysis is available on the survey website. In the current study, chi-square and logistic regression analyses were performed examining rates of ADHD diagnosis and medication use among children with and without ASD. SPSS Version 25 Complex Samples Module with subpopulation routine was use to estimate variance per the study documentation. **Results:** For boys, unweighted N=917 for current ASD and 430 for current ASD+ADHD; for girls, unweighted N=214 for current ASD and 91 for current ASD+ADHD. ASD children were age 3-17 (mean age 10.04). Race/ethnicity distribution was 53.3% white, 24.1% Hispanic, 14.4% black, and 8.2% "other." There was not a significant difference by gender of ADHD diagnosis among children with ASD (OR 0.575, 95%CI 0.327-1.010, 51.2% of ASD boys and 37.6% of ASD girls); girls who currently had both ASD and ADHD diagnoses had lower odds of currently using medication for ADHD (OR 0.318, 95% CI 0.149-0.677, 69.1% of ASD+ADHD boys and 41.5% of ASD+ADHD girls) compared to boys. Non-ASD girls had lower odds of ADHD diagnosis (OR 0.439, 95% CI .381-0.507) versus boys; there was not a significant difference by gender of medication use among children with ADHD but not ASD (OR 1.156, 95% CI 0.868-1.539). In logistic regression, the odds ratio for ASD girls' ADHD medication use remained at 0.311 (95% CI 0.128-0.757, $p<0.01$) even after controlling for race/ethnicity, household income, service use (current mental health therapy [$p<0.05$] and special education services), and parent rating of ADHD severity and three ADHD behaviors (finishing tasks, doing all homework, and staying in control when challenged [$p<0.05$]). **Conclusions:** This nationally representative dataset indicates that girls with both ASD and ADHD are being undertreated for ADHD. The one-third of ASD girls with ADHD diagnoses therefore might have improved long term outcomes in academic and occupational achievement, antisocial behavior, unsafe driving, drug/alcohol use, obesity, services use, and self-esteem, social functioning if their ADHD were treated in accordance with practice guidelines.

Panel Session
Interventions - Non-pharmacologic - Infant, Toddler, and Preschool
252 - Lessons Learnt from the Field-Testing of the W.H.O. Caregiver Skills Training
1:30 PM - 3:30 PM - Room: 518

Panel Chair: Erica Salomone, *Department of Psychology, University of Turin, Turin, Italy*

A growing body of evidence, mostly from high-income, research-based settings, supports caregiver-mediated interventions for autism; however, these are rarely available to families. To reduce the treatment gap, the World Health Organization with international partners and Autism Speaks, developed the Caregiver Skills Training (CST) programme for families of children with developmental disorders/delays, which aims to meet affordability and feasibility criteria of low-resource settings. In this panel we present emerging evidence on the implementation of CST across the globe. We first present a global update on the field-testing initiative, highlighting adaptation processes, challenges and lessons learnt from 29 sites. The second presentation reports on the pre-piloting of CST in the low-income context of Ethiopia, exploring perspectives of participating caregivers, facilitators and supervisors through thematic analysis. The third presentation describes findings from the pre-pilot implementation in Kenya, a middle-income country, through quantitative and qualitative methods. The final presentation will report from the adaptation of CST in a high-income country, Canada, using a Community of Practice, a social participative approach to assess barriers and change in practice. In the panel discussion we aim to critically reflect on these findings, to inform the adaptation, implementation and evaluation of scalable caregiver-mediated interventions in real-life settings.

1:30 **252.001** International Field-Test of the Who Caregiver Skills Training for Families of Children with Developmental Disorders or Delays

E. Salomone[1,2], *L. Pacione*[2,3], *T. WHO CST Team*[2] *and C. Servili*[2], *(1)Department of Psychology, University of Turin, Turin, Italy, (2)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland, (3)Department of Psychiatry, Division of Child and Youth Mental Health, University of Toronto, Toronto, ON, Canada*

Background: Despite evidence of significant gains to children and families from parent-mediated early interventions, open-access programs deliverable by non-specialists in low-resource settings are not currently available. To reduce the treatment gap, as part of the mhGAP initiative, WHO, with support from Autism Speaks developed through systematic literature reviews and expert consultation a novel Caregiver Skills Training (CST) program. The CST aims to meet feasibility criteria for implementation in low-resource settings. Its core psycho-education strategies, informed by principles of behavior analysis, developmental science, social-communication interventions, positive parenting and self-care, aim to be cross-culturally valid and acceptable.

Objectives: to compile data on field-testing of WHO CST in a variety of settings and regions

Methods: The CST suite of materials (intervention manuals, adaptation and capacity building tools; Monitoring & Evaluation (M&E) Framework) was made available for field-testing. Sites involved in field-testing (N=29) are located in all world regions: African (n=4), Americas (n=9), Eastern Mediterranean (n=5), European (n=4), South-East Asia (n=2), and Western Pacific Region (n=5). Participating sites progress through four Phases outlined in the M&E framework: 1) Planning and Adaptation (21% of sites); 2) Training of Trainers (ToT) and Post-ToT practice (38%); 3) Pre-pilot field-testing (17%); 4) Pilot testing (24%). Sites representatives completed an online survey including multiple choice and open-ended questions regarding: a) adaptation processes; b) project implementation characteristics; c) challenges and lessons learnt from field-testing.

Results: Program materials have been translated into 18 languages. The majority of sites (n=26) reported adapting the program to the local context, mostly with minor measures: of these, 76% were adaptations of content (e.g. language use, idioms), 17% adaptations to improve feasibility (e.g. childcare) and 7% adaptations of processes (e.g. frequency of group sessions). Major adaptations include: adaptation of the delivery method (technology application; 1 site) and of program contents for participants with low literacy (e.g., simplification of participant booklets, adding additional psychoeducation; 2 sites). Reported frequency of sessions (planned or actual) was generally weekly (72%). Sites reported planned or actual implementation in a variety of settings, often in combination: public health settings (76%), community centers (41%), public or NGO education settings/schools (48%), university/faith-based setting/private (14%). Target diagnostic groups were in most cases autism (83%), developmental delay/intellectual disability (75%) and other neurodevelopmental disorders or concerns. Reported challenges from Phases 1-2 include: difficulties in securing funding and collaboration with stakeholders; need to devise sustainable intervention fidelity support strategies; challenges in selecting site-specific useful and validated outcome measures. Most endorsed challenges from Phases 3-4 include: selection criteria for master trainers and facilitators (clinical experience, motivation); good acceptability but feasibility issues for home visits and videorecording (safety, travel, lack of time); lack of childcare as a barrier to attendance.

Conclusions: Survey data from participating sites indicate good progress on global field-testing of WHO CST. Lessons learnt from the M&E phases are progressively compiled and inform support strategies to field-testing sites. Feasibility, acceptability and effectiveness data are being collected and will inform revision and preparation of the WHO CST programme materials and tools for wider release and dissemination.

1:55 **252.002** Pre-Testing the Who Caregiver Skills Training Programme for Implementation in Urban and Rural Ethiopia

R. A. Hoekstra[1], *B. T. Gebru*[1], *F. G. Bayouh*[2], *M. Kinfe*[2], *R. Abdulrahman*[3], *T. Zerihun Kebede*[4], *M. Tesfaye*[4], *T. WHO CST Team*[5], *E. Salomone*[6], *L. Pacione*[7], *C. Servili*[5] *and C. Hanlon*[8], *(1)Department of Psychology, King's College London, London, United Kingdom, (2)Department of Psychiatry, School of Medicine, College of Health Sciences, Addis Ababa University, Addis Ababa, Ethiopia, (3)Department of Psychiatry, Yekatit 12 Hospital Medical College, Addis Ababa, Ethiopia, (4)Department of Psychiatry, St. Paul's Hospital Millennium Medical College, Addis Ababa, Ethiopia, (5)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland, (6)Department of Psychology, University of Turin, Turin, Italy, (7)Department of Psychiatry, Division of Child and Youth Mental Health, University of Toronto, Toronto, ON, Canada, (8)Addis Ababa University and King's College London, Addis Ababa, Ethiopia*

Background: The World Health Organization (WHO)'s Caregiver Skills Training Programme (CST) aims to teach caregivers of children with developmental disorders (DD) strategies to help them support their child's development and learning. The programme, delivered over nine group sessions and three home visits, is developed to suit low-resource settings. We recently adapted the programme for implementation in Ethiopia (Tekola et al., 2018), characterised by limited autism awareness, high levels of stigma and a severe lack of service provision (Tekola et al., 2016; Tilahun et al., 2016).

Objectives: Pre-test the adapted CST programme in an urban clinical setting and a rural community setting, and explore the perspectives of participating caregivers, CST facilitators and supervisors.

Methods: The programme was pre-tested in: i) one group (n=10) in Addis Ababa, delivered by a specialist CST facilitator; ii) two groups (n=20) in rural Butajira, delivered by non-specialist facilitators under supervision of two specialists. Feasibility and acceptability data were collected, including enrolment and attendance rates and programme fidelity ratings. In-depth interviews were conducted with participating caregivers (n=9 in both settings), CST facilitators (n=3 in Addis Ababa, n=2 in Butajira), and CST observers (n=2 in Addis Ababa); a focus group discussion was held with six trainee facilitators in Butajira. Qualitative data were analysed using thematic analysis.

Results: Both pre-pilots had excellent participation (100% in both locations) and retention rates (90% in Addis Ababa, 100% in Butajira). Participating families completed at least 7/9 group sessions and all home visits. All essential CST training elements were fully or mostly completed. The competencies of the specialist facilitator as rated using the ENACT scale (Kohrt et al., 2015) were higher than those of non-specialist facilitators. Four themes were developed from the qualitative data: 1) Programme acceptability and relevance: Caregivers indicated the programme was highly relevant to their needs. CST facilitators and observers commented on the eagerness of caregivers to attend the training, reflected in high attendance rates and in caregivers arriving at sessions on time. 2) Perceived programme benefits: Caregivers described how the programme helped promote their child's communication and self-help skills and in managing their child's challenging behaviours. Caregivers also indicated the programme improved their own wellbeing and helped them to manage their stress. 3) Challenges and barriers: Caregivers raised that travel and finding childcare were barriers to attending sessions. Facilitators highlighted the long preparation time needed to deliver the group sessions well, especially the role play demonstration activities. Another challenge was the variation in caregivers' level of understanding and education and making sure the caregivers with little education understood all strategies and tips presented in the CST. 4) Suggested revisions: Some suggestions were offered to simplify the materials, including simpler Amharic translations for some key terms and simplifying the role play activities.

Conclusions: The CST programme is highly acceptable to Ethiopian caregivers. It is feasible to deliver the programme in both urban and rural settings. Before the programme can be fully implemented in low-resource settings, further research needs to determine what constitutes 'good enough' fidelity for non-specialist CST facilitators.

2:20 **252.003** The Acceptability, Feasibility and Preliminary Evaluation of the Who Caregiver Skill Training Programme in Rural and Urban Kenya

A. Abubakar[1], *E. Mwangome*[1], *M. Mwangi*[1], *S. Onyango*[1], *P. Kitsao-Wekulo*[2], *T. WHO CST Team*[3], *C. Servili*[3] *and C. Newton*[4], *(1)Neurosciences Department, Kemri -Wellcome Trust Research Programme, Kilify, Kenya, (2)African Population Health Research Centre, Nairobi, Kenya, (3)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland, (4)Kenya Medical Research Institute, Kilifi, KENYA*

Background: The global burden of mental and neurological conditions is increasing and affects more than 10% of the children in the world. In Africa, improved childhood survival has led to increasing numbers of children with neurodisability due to exposure to multiple risk factors including neonatal insult. Despite the significant burden of neurodisability in Africa there are few specialized therapists or services to support children with disabilities and their families.

Objectives: To investigate the feasibility and acceptability of the WHO's caregiver skill training programme to improve behaviour, communication and quality of life of children with disabilities and their families.

Methods: A sequential mixed methods study where qualitative work advised quantitative work was carried out in two sites, Kilifi and Nairobi. In the first stage focus group discussion and in-depth interviews were carried out with key informants and parents of children with disability. In the second stage, 105 children living with a disability and their families were involved in a pilot randomized control trial (RCT) to evaluate the World Health Organization (WHO) Carent Skill Training (CST). While the third phase, some of the parents taking part in the CST programme provided feedback on their experience.

Results: In the first phase of the study both key informants and parents reported that the CST addresses an important need for the parents of children with disability, although there were concerns about its applicability for parents who were illiterate, given the heavy dependency on written materials. A pre-pilot study indicated that even parents with low literacy levels could adequately follow CST. In the pilot RCT, a significant proportion of the parents attended most of the sessions, rates and the preliminary analysis indicated a decrease in behavioural problem scores and depressive symptoms scores for children and families that participated in CST. In the post CST, parents articulated their satisfaction with the programme, however, the salient challenges mentioned by the caregivers mentioned with the program were focused around attendance; for example, problems finding an alternative caregiver to look after their child while they attended training sessions or lack of family support or conflicts with employers. The key challenge with CST, was the requirement for higher skilled staff than originally anticipated.

Conclusions: Our pilot study, indicates that it is feasible and acceptable to implement the CST in both rural and urban settings in Kenya. A full scale RCT is needed to establish efficacy.

2:45 **252.004** Facilitators and Barriers to Implementation of Manualized Interventions in Community Based Settings

M. Elsabbagh[1], *A. Ibrahim*[2], *A. Yusuf*[3] *and T. WHO CST Team*[4], *(1)McGill University, Montreal, PQ, Canada, (2)McGill University, Montreal, QC, Canada, (3)Psychiatry, McGill University, Montreal, QC, Canada, (4)Department of Mental Health and Substance Abuse, World Health Organization, Geneva, Switzerland*

Background: The Caregiver Skills Training (CST) Program aims to provide evidence-based skills training for caregivers of children with autism in community settings. The program was developed by the World Health Organization using a systematic approach engaging stakeholders globally in the design and now field testing and scaling up the program, including community organizations, government, advocates, and researchers in over 30 countries.

Objectives: In the Canadian adaptation of the CST Program, we focused on measuring facilitators and barriers of implementation within community settings. We formed a Community of Practice (CoP), a dynamic social participative approach to learning and discovery previously used in health research. The CoP brought together professionals involved in early intervention.

Methods: Professionals in public sector and community health and educational services involving children with autism (n=15) participated in Community of Practice over a one year period. At baseline, the participants received 35 hours of training on the intervention model and self-rated their confidence in implementation of the intervention in their own setting: (a) continue to train towards fidelity, (b) use the intervention and/or specific strategies in routine practice, or (c) coach others in the same setting. Three follow up sessions were completed with the CoP to assess change in practice and to discuss facilitators and barriers to implementation.

Results: By the end of the follow up period, only one professional had continued to train to fidelity and none of the professionals had implemented the intervention. Qualitative analysis of CoP sessions was conducted to ascertain barriers to implementation. Reported barriers

include limited time to attain fidelity, limited time available with each family to deliver the full intervention, inconsistency in some of the intervention characteristics relative to the target setting, and limited support from management in adopting the new intervention. However, participants reported indirect influence of intervention strategies including improved understanding and capture of "shared engagement" and "play" and increased consolidation of routine strategies reinforced in the intervention.

Conclusions: Despite intention to do so, professionals who trained on a manualized intervention did not exhibit a direct change in practice as a result of the training. In contrast, indirect influence on practice was reported, yielding more general and positive improvements in practice as reported by professionals.

Panel Session
Rare Genetic Disorders
253 - Multi-Site, Direct Comparison of Three Autism Synaptopathies
1:30 PM - 3:30 PM - Room: 524

Panel Chair: Joseph Buxbaum, *Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Discussant: Mustafa Sahin, *Boston Children's Hospital/Harvard Medical School, Boston, MA*

Many of the genes implicated in autism spectrum disorder (ASD) converge on common molecular pathways, particularly those relevant to protein synthesis that contributes to synaptic function. The mTOR pathway is one such example. In this panel, we examine three genetic disorders of the mTOR pathway, all of which have high penetrance of ASD: Tuberous Sclerosis Complex (TSC1 and TSC2 genes), PTEN Hamartoma Tumor Syndrome (PTEN gene), and Phelan-McDermid Syndrome (SHANK3 gene). We will provide a bench-to-bedside perspective on these disorders, with talks describing the molecular and cellular analyses of these disorders using patient-derived stem cells, structural findings on MRI, electrophysiological findings on EEG, and phenotypical characterization. Overall, data from this combination of genetic syndromes provides an opportunity to understand the relationship between genetics, pathological molecular mechanisms, structural and functional findings that provide opportunities for biomarker development, and behavioral symptomatology across these three biologically related but distinct disorders.

1:30 **253.001** Molecular and Cellular Analyses across Three Autism-Associated Genetic Disorders

J. Buxbaum[1], *C. Eng*[2], *A. Kolevzon*[3] *and M. Sahin*[4], *(1)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Genomic Medicine, Cleveland Clinic, Cleveland, OH, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (4)Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background: The Developmental Synaptopathies Consortium (DSC) is studying three rare genetic disorders associated with high risk for autism, specifically Phelan-McDermid Syndrome (PMS), Tuberous sclerosis complex (TSC), and PTEN-hamartoma tumor syndrome (PHTS). Each of these disorders are being studied extensively using biomarkers and clinical assessments, while, in parallel, molecular analyses are being carried out on patient derived samples, in the context of ongoing preclinical research.
Objectives: The purpose of this study was to map out genotype–phenotype correlations, to collect and characterize patient-derived stem cells, to look for genetic modifier loci, and to analyze gene expression data from blood samples and correlate this with phenotypes.

Methods: The study samples comprised 98 participants in the PMS group, 98 with TSC, and 67 with PHTS. Mean age was 8.74 years (SD = 4.74) with no group differences observed. Blood and skin samples were collected where feasible, and induced pluripotent stem cells were derived. Whole exome sequencing and RNAseq in blood samples were carried out in a subset of cases and family controls. Protein lysates from peripheral leucocytes collected from PHTS patients were subjected to Western blotting with antibodies against the signaling proteins of the PTEN-mTOR pathway.

Results: Induced stem cells were derived from over 30 participants. Gene expression analyses in PMS-derived neurons indicate that specific pathways are dysregulated in these human neurons in vitro. Some of these findings suggest potential therapeutic approaches to PMS. Similar studies in TSC and PHTS are ongoing. The greatest genetic variation across the 3 disorders is found in PMS, were point mutations and deletions can contribute to the phenotype. We demonstrate that there is a strong overlap of phenotypes observed with point mutations as compared to deletions; however, the severity of the phenotype is typically greater in the presence of a deletion. For example, language abnormalities are more profound in the presence of a deletion, compared to a point mutation. RNAseq in over 70 blood samples identifies significantly dysregulated genes in cases versus controls. Interestingly, the dysregulation correlates with the severity of the phenotype, as measured by the Aberrant Behavioral Checklist, and particularly the lethargy/social withdrawal subscale. No genetic modifiers were identified to date, although we have identified individuals with more than one deleterious likely pathogenic change. Western blotting was performed for 54 PHTS subjects, which demonstrate altered expression of PTEN-mTOR signaling molecules.

Conclusions: In the first iteration of the DSC, we have made significant advances in relating preclinical research to clinical findings. We have an extensive repository of patient-derived stem cells for ongoing and future studies, and we continue to expand our sample that undergo RNAseq and Western blotting. While still quite preliminary, we will present how some of these first findings suggest pathways that might be therapeutic drug targets in these rare genetic disorders.

1:55 **253.002** Evaluating the EEG Power Spectrum across Three Neurogenetic Disorders of the mTOR Pathway

A. R. Levin[1], *E. Berry-Kravis*[2], *C. Eng*[3], *L. E. Ethridge*[4], *J. Foss-Feig*[5], *A. Y. Hardan*[6], *D. S. Karhson*[6], *A. Kolevzon*[5], *M. E. Modi*[1], *M. W. Mosconi*[7], *C. A. Nelson*[8], *C. M. Powell*[9], *V. Punia*[10], *P. M. Siper*[5], *A. Thaliath*[11] *and M. Sahin*[12], *(1)Neurology, Boston Children's Hospital, Boston, MA, (2)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (3)Genomic Medicine, Cleveland Clinic, Cleveland, OH, (4)Pediatrics, University of Oklahoma Health Science Center, Norman, OK, (5)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (6)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (7)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, (8)Boston Children's Hospital, Boston, MA, (9)Neurobiology, UAB School of Medicine, Birmingham, AL, (10)Cleveland Clinic, Cleveland, OH, (11)Rush University Medical Center, Chicago, IL,*

(12)Boston Children's Hospital/Harvard Medical School, Boston, MA

Background: Neural networks act as a bridge between genotype and phenotype, thus offering clues about how basic biology translates to behaviorally-defined disorders such as autism spectrum disorder (ASD). Electroencephalography (EEG) serves as an index of the synchronous activity of large populations of neurons, and is therefore an ideal tool for measuring the activity of neural networks. Several genetic disorders of the mammalian target of rapamycin (mTOR) pathway confer significantly increased risk of ASD, despite differences in their exact function on the mTOR pathway: Examples include tuberous sclerosis complex (TSC), Phelan-McDermid Syndrome (PMS), and PTEN Hamartoma Tumor Syndrome (PHTS).

Objectives: We evaluate the EEG power spectrum among children with each of these genetic disorders, compared to typically developing controls.

Methods: As part of the ongoing multisite Developmental Synaptopathies Consortium, EEG data are being acquired at baseline (i.e., without a time-locked task) across 6 sites on children and adolescents with TSC (n=11), PMS (n=32), PHTS (n=8), and age-matched typically developing controls (n=23). We used the Batch EEG Automated Processing Platform (BEAPP) to standardized EEG processing across sites. Within BEAPP, preprocessing occurred via the Harvard Automated Preprocessing Pipeline (HAPPE), which was developed specifically for preprocessing of EEG in children with neurodevelopmental disorders. To standardize data length for each participant, 180 seconds of useable data (after processing) were randomly selected for further analysis. Because limited data were previously available on the EEG power spectrum in these disorders, we began by calculating mean power across all electrodes in the 10-20 electrode system. Normalized spectral power was calculated in each frequency band, and we used a Mann-Whitney U test (threshold $p<.05$), corrected for multiple comparisons, to compare power in each group to typically developing controls.

Results: Children with TSC show reduced gamma power, children with PMS show reduced alpha power, and children with PHTS show no significant differences in power compared to typically developing controls (Figure 1). There were no significant differences in EEG power across sites in any frequency band.

Conclusions: Although all of these mTOR pathway disorders increase the risk for ASD, each disorder shows a different pattern of EEG spectral power as compared to controls. This may help to explain the heterogeneity of EEG power findings among children with ASD who are not stratified by genotype. Further studies probing the mechanisms underlying these spectral power differences may offer helpful insights into the biology underlying ASD.

2:20 **253.003** Computational MRI Analysis of Cerebellar Circuitry across Three Different Genetic Forms of Autism and Intellectual Disability

S. Srivastava[1], *A. Prohl*[2], *B. Scherrer*[2], *S. K. Warfield*[2], *A. Kolevzon*[3], *C. Eng*[4], *D. A. Krueger*[5] *and M. Sahin*[6], *(1)Boston Children's Hospital, Boston, MA, (2)Computational Radiology Laboratory, Department of Radiology, Boston Children's Hospital, Boston, MA, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (4)Genomic Medicine, Cleveland Clinic, Cleveland, OH, (5)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (6)Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background:

The genetic landscape of autism spectrum disorder (ASD) and intellectual disabiity (ID) is expanding to include a wide number of single-gene disorders, leading to increased efforts to study ASD and ID through the lens of specific genetic causes. The basis for this approach is that seemingly unrelated genetic disorders associated with ASD and ID may converge on final common pathways. Therefore, better understanding of mechanistic commonalities among distinct causes may shed light on the pathogenesis of ASD and ID, opening the door to potential targeted treatments.

Phelan-McDermid syndrome (PMS), PTEN hamartoma tumor syndrome (PHTS), and Tuberous sclerosis complex (TSC) are three examples of genetic disorders associated with a high prevalence of ASD and ID, with evidence for cerebellar dysfunction in all three. In PMS, cerebellar vermal hypoplasia is commonly reported as a finding on MRI. In PHTS, Purkinje cell-specific knockout of *Pten*leads to autistic-like traits in mice. In TSC, there is overactivity of the mechanistic target of rapamycin (mTOR) pathway leading to Purkinje cell degeneration in the cerebellum.

Objectives:

In order to investigate whether defects in cerebellar circuits may be one of the final common pathways disrupted in ASD and ID, we performed computational volumetric analysis on brain MRIs of individuals with PMS, PHTS, and TSC, focusing on cerebellar regions of interest.

Methods:

Participants were part of the Developmental Synaptopathies Consortium, a multi-site, natural history study of PMS, PHTS, and TSC, collecting neurocognitive data as well as MRI brain data. We used an automated approach based on the PSTAPLE algorithm to carry out automatic MRI segmentation and generate relative volumes (structure volume divided by intracranial contents volume) of the following cerebellar structures: right/left cerebellar white matter, right/left cerebellar cortex, vermal lobules I-V, vermal lobules VI-VII, vermal lobules VIII-X. For each of the three syndromes, we compared relative volumes to different cognitive/adaptive measures depending on age/functioning of the participants using linear regression.

Results:

In this preliminary interim analysis, there were n=11 individuals with PMS (6 females, 5 males, mean age 9.24 [+/-5.29] years); n=15 individuals with PHTS (6 females, 9 males, mean age 9.42 [+/-5.77] years); and n=6 individuals with TSC (3 females, 3 males, mean age 9.49 [+/-1.93] years) who were part of the analysis.

For the PMS group, there was a trend for increasing Vineland Adaptive Behavior Scales (VABS) composite score with increasing relative volume of cerebellar vermal lobules I-V ($p=0.074$) and cerebellar vermal lobules VI-VII ($p=0.068$). For the PHTS group, there was a trend for increasing Stanford Binet-5 full scale IQ with increasing relative volume of left cerebellum white matter ($p=0.095$). For the TSC group, with increasing VABS composite score there was increasing relative volume of the cerebellar vermal lobules VI-VII ($p=0.029$).

Conclusions:

Based on volumetric analysis, the cerebellum may be affected in three different genetic causes of ASD and ID, warranting further investigation into cerebellar circuitry defects in the pathogenesis of ASD/ID.

2:45 **253.004** Initial Phenotypic Characterization across Three Developmental Synaptopathies

L. Soorya[1], *C. Farmer*[2], *E. V. Ocampo*[1], *A. Wainer*[1], *A. Snow*[3], *D. A. Pearson*[4], *P. M. Siper*[5], *A. Kolevzon*[5], *J. Buxbaum*[6], *C. Eng*[7], *E. Berry-Kravis*[8], *C. M. Powell*[9], *J. A. Bernstein*[10], *D. A. Krueger*[11], *M. Sahin*[3] *and A. Thurm*[2], *(1)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (2)National Institute of Mental Health, Bethesda, MD, (3)Boston Children's Hospital/Harvard Medical School, Boston, MA, (4)McGovern Medical School, Univ. TX Health Sci Cntr-Houston, Houston, TX, (5)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (6)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (7)Genomic Medicine, Cleveland Clinic, Cleveland, OH, (8)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (9)Neurobiology, UAB School of Medicine, Birmingham, AL, (10)Pediatrics, Stanford University, Stanford, CA, (11)Cincinnati Children's Hospital Medical Center, Cincinnati, OH*

Background: Pathways involved in synaptic function play a critical role in conditions associated with intellectual disability and autism spectrum disorder (ASD) such as Tuberous Sclerosis Complex (TSC), PTEN hamartoma tumor syndrome (PHTS), and Phelan-McDermid Syndrome (PMS). Defining observable phenotypes within and across related developmental synaptopathies is a fundamental level of analysis to understanding the relationship between underlying genetic causes and behavioral/cognitive expressions in these syndromic conditions.
Objectives: We analyzed baseline data from DSC to characterize and compare patterns of intellectual disability (ID), autism, and behavioral/psychiatric symptoms in TSC, PHTS, and PMS.

Methods: A comprehensive battery was collected at baseline for children ages 3-18 with TSC (n=98), PHTS (n=67), and PMS (n=98). This battery included measures of IQ, adaptive behavior, problem behaviors, mood and psychiatric symptoms, and ASD symptoms. Adaptations to this assessment battery were necessary to facilitate the evaluation of ID, ASD, and behavioral symptoms in these samples and will be detailed in the presentation. Initial results are presented from one-way ANOVAs with Bonferroni's corrections were conducted to analyze group differences on IQ, Vineland Adaptive Behavior Scale-II (VABS-II) Adaptive Behavior Composite (ABC) and domain standard scores standard scores , the ADOS2 Calibrated Severity Score (CSS), Repetitive Behavior Scale-Revised (RBS-R) Total Score, and Child Behavior Checklist 6-18 (CBCL/6-18) Internalizing and Externalizing T-scores.

Results**:** Mean chronological age of 8.74 years (SD=4.74) did not differ across the samples. Intellectual disability (ID) appeared as a characteristic phenotype in all three developmental synaptopathies. In the context of wide within-group variability, significant group differences were found on FSIQ ($F_{(2, 237)}$=93.9, p<.0001) and VABS-II ABC ($F_{(2, 207)}$=14.4, p<.001), such that PHTS>TSC>PMS, corresponding to the following levels of ID: PHTS (Borderline), TSC (Mild to Moderate), and PMS (Severe to Profound). Initial analyses suggesting group differences on ADOS2 CSS require correction for IQ and cohort effects. RBS-R total scores did not differ across groups ($F_{(2, 211)}$=1.9, p=.156). Across groups, mean CBCL scores were in the non-clinical range or cusp of the borderline clinical range. Post-hoc analyses pointed to significantly lower CBCL/6-18 internalizing symptoms in PMS vs. TSC (p=.013) (omnibus $F_{(2, 112)}$=4.8, p=.010) though no differences were found on VABS-II internalizing scale. Higher externalizing problem behavior levels were reported in TSC vs. PHTS on both the CBCL/6-18 (p=.001) (omnibus $F_{(2, 211)}$=6.9, p=.001) and VABS-II (p=.031) (omnibus $F_{(2, 199)}$=4.4, p=.014).

Conclusions: Initial results suggest diverse ID, ASD, and behavioral phenotypes across PTEN, PMS, & TSC, as well as considerable within syndrome variability. Interpretation of findings requires further study given that many of measures were not validated on individuals with moderate to severe ID (e.g., CBCL/6-18). Additional analyses related to within-disorder variability and genotype-phenotype correlations will be presented. In addition, the effect of IQ/ID on autism and behavior profiles and potential age-cohort effects are of interest given evidence that individuals now diagnosed with genetic conditions associated with ASD and ID may not be as severe as those previously identified.

Panel Session
Technological Approaches
254 - Improving Access and Expanding the Reach of Clinical Care and Research in Autism Spectrum Disorder (ASD) through Innovations in Remote Delivery Methods
1:30 PM - 3:30 PM - Room: 517A

Panel Chair: Elizabeth Berry-Kravis, *Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL*

Discussant: Shafali Jeste, *University of California, Los Angeles, Los Angeles, CA*

Research and clinical care for non-syndromic and syndromic ASD have been hampered by limitations in access of families to research and medical centers. Intervention programs require creativity and flexibility in design and implementation to maximize scalability. In this symposium, we present four innovative models of remote clinical care and/or intervention delivery for children with autism and related neurodevelopmental disorders (NDDs). We begin with a presentation by Drs. Connie Kasari and Stephanie Shire which describes the effectiveness of three community partnered effectiveness-implementation hybrid trials of JASPER (Joint Attention, Symbolic Play, Engagement, and Regulation). Next, Dr. Alexander Kolevzon introduces the new ECHO model of clinical care delivery for Phelan McDermid Syndrome (PMS), through the PMS Neuropsychiatric Consultation Group (PMS-NCG). Dr. Hedda Meadan then discusses the Internet-Based Parent-implemented Communication Strategies (i-PiCS) program, which uses telepractice to coach parents in strategies to promote social-communication skills in their children. Finally, Elizabeth Berry-Kravis presents her NeuroNext NN107 trial which will evaluate effects of a pharmacological intervention on language learning from a remotely delivered parent-implemented language intervention in children with Fragile X syndrome. Lessons learned and strategies developed from these innovative studies can greatly inform the development of more scalable models of intervention delivery across NDDs.

1:30 **254.001** Use of Remote Delivery of Language Intervention in a Pharmacological Trial Targeting Learning in Fragile X Syndrome

E. Berry-Kravis[1], *L. Abbeduto*[2] *and A. McDuffie*[3], *(1)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (2)M.I.N.D. Institute, UC Davis, Sacramento, CA, (3)UC Davis, Sacramento, CA*

Introduction: Basic research in fragile X syndrome (FXS) has identified neuronal targets for treatment of the underlying disorder. The best-studied pre-clinical target has been has been reduction of excessive mGluR5 pathway signaling, with over 60 papers showing pharmacological and genetic reversal of synaptic, cellular, cognitive, and behavioral phenotypes in 3 species with 4 mGluR5 negative allosteric modulators (NAMs). Human

trials of mGluR5 NAMs failed to meet primary behavioral outcomes in adolescents and adults with FXS. These trials may have failed due to lack of measurement of core FXS phenotypes of cognition and learning in a sufficiently young population over a long enough period of time.
Objective: To use an innovative exploratory trial design to determine whether mGluR5 NAM AFQ056 can improve language learning in 100 very young (age 3-6 years) children with FXS during participation in an intensive parent-implemented language intervention (PILI).

Methods: The trial uses a double blind placebo-controlled parallel flexible-dose forced-titration design with a 12 month blinded treatment period including randomization to AFQ056 or placebo and titration to maximum tolerated dose (MTD) and 6 months treatment with AFQ056/placebo combined with PILI, followed by an 8 month open-label extension with treatment for all participants with PILI and AFQ056. PILI is delivered remotely by Skype in order to allow sufficient training time without the cost and scheduling constraints of in-person visits, and has been show to promote language learning in patients with FXS without concomitant pharmacological intervention. The study assesses effects of AFQ056 versus placebo on language, developmental functioning and CNS biomarkers (eye tracking and ERP) after language intervention. The primary outcome is the weighted communication scale (WCS), an observational measure of communication synched to the communication/language targeted by PILI. The parent delivering the PILI attends education sessions, is trained by an SLP wearing Bluetooth headphones in training sessions, while working directly with the child, and does videotaped homework sessions which are reviewed in feedback sessions with the SLP, all via communication using Skype. Drug dilution for the placebo/AFQ056 liquid is monitored via Skype or facetime, as another way to avoid frequent study visits.

Results: To date 13 sites have been trained and opened, including 20 SLPs brought to fidelity on delivery of PILI. Thus far, 65 FXS participants have enrolled, and 3 screen failed, with mean age 5.6, 88% male, and 88% white, 7% Hispanic. Adverse events have been mild, with sleep and hyperactivity being most frequent. PILI has been in general quite well received by families. There have been some technology issues which have not yet been limiting. Methodology will be presented as well as many lessons learned regarding implementation of PILI across sites.

Conclusions: Processes developed in this trial for cross-site standardization of PILI, as well as use of Skype and Bluetooth methodology for delivering PILI and monitoring drug dilution, will be available for other trials. If the design is successful, this novel multi-center trial can serve as a model for future trials of mechanistically-targeted treatments operating on neural plasticity in other NDDs.

1:55 **254.002** Reaching Community Early Intervention Providers in Diverse Communities: Application of Remote Training Supports

C. Kasari[1] *and S. Y. Shire*[2]*, (1)University of California, Los Angeles, Los Angeles, CA, (2)University of Oregon, Eugene, OR*

Background. Rare disorders and distance from a University medical center can limit access to evidence based early interventions. In order to increase access, remote access with support from experts may be necessary. However, it is not currently known the extent to which remote training mirrors what can be obtained in person.
Methods. We examine data from three community partnered effectiveness-implementation hybrid trials. Studies 1 and 2 were conducted in a center based US early intervention program (Shire et al., 2018; Shire et al., 2019) and Study 3 was a provincial intervention deployment study delivering publicly funded health services in a Canadian Maritime province (Shire, et al in progress).

Intervention & Training**.** Across studies, children received approximately 3 months of a developmental social communication intervention- Joint Attention, Symbolic Play, Engagement, and Regulation (JASPER: Kasari et al., 2006) from their local providers who were training to achieve implementation fidelity. All trainees received a 5 day intensive introduction to JASPER including discussion, live coached practice, and feedback delivered either by the research team (Study 1&2) or by local senior JASPER trainers who were trained by the same research team (Study 3). Then, due to the geographic distance of the research team and/or local supervisors from the trainees, this was followed by a combination of remote supports including video feedback, clinical supervision calls, and/or real time video conferenced supervision for the remainder of the study.

Participants. Studies 1 and 2 included a diverse sample of toddlers (n= 55/study) and teaching assistants (TAs; n=24/ study) randomized to immediate JASPER intervention. Study 3 included children age 2.0-6.0 years (n=33) paired with 20 community health providers (e.g., speech language pathologists, occupational therapists, psychologists). All children were eligible for community early intervention services based on diagnoses of autism and other rare sensory and genetic disorders (e.g., visual impairment, Down Syndrome).

Measures. Ten-minute interventionist-child interactions at treatment exit were coded for trainee's JASPER implementation, a total score across 32 items each rated 0-5.

Results. After 3 months of support, all three trainee groups made significant gains over their entry implementation scores demonstrated an average of 80.9%, 72.0%, and 82.51% fidelity respectively. Study 3 allowed for the unique comparison of interventionists who received in person supervision and those who received remote supervision. On average, trainees receiving remote supervision scored 89.17% at exit while those receiving in person support on average achieved 80.29% at exit.

Conclusions. Together, these studies demonstrate that community interventionists of a variety of disciplines can learn to deliver JASPER with high quality through training and supervision methods using primarily remote support strategies. This substantial adaptation to the resource intensive in person supervision previously tested in JASPER clinical trials provides promising evidence for the broader deployment of the intervention model within public early intervention settings including those engaging rural and geographically remote communities.

2:20 **254.003** Echo Model for Remote Delivery of Care for Phelan-Mcdermid Syndrome (PMS): The PMS Neuropsychiatric Consultation Group

A. Kolevzon[1]*, T. Kohlenberg*[2] *and M. P. Trelles*[1]*, (1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)University of Massachusetts, Boston, MA*

Background: Patients with Phelan-McDermid syndrome (PMS) may develop complex neuropsychiatric symptoms, including features of bipolar disorder, psychosis and catatonia, regression in language and motor skills, and early dementia. Given the rarity of the diagnosis, and the range of presenting neuropsychiatric symptoms, patients may be cared for by a wide array of physician specialties, most of whom are unlikely to have any previous experience in the special needs of individuals with PMS.
Objectives: The PMS Neuropsychiatric Consultation Group (PMS-NCG) aims to provide multidisciplinary consultation to geographically-dispersed physicians, to support them in providing the best possible care to patients with PMS.

Methods: This initiative will utilize the established model for knowledge dissemination and capacity building called ECHO. The ECHO model

consists of video-conferencing case consultation with teams of experts and local providers meeting regularly to discuss case management. The existing ECHO national infrastructure provides the necessary technology, training, and ongoing technical assistance for implementation of replication projects – all free of charge. The patient management support provided and CME credits are offered for attendance to incentivize participating providers for their time.

Results: The PMS-NCG was convened in January, 2018 and has met monthly to establish treatment algorithms for a wide array of neuropsychiatric symptoms in PMS. The PMS-NCG went live in September, 2018, and meets monthly. The PMS-NCG has since been soliciting consultation requests from the community of providers across the world through web-based advertising, conference announcements, webinars, and word of mouth. One formal consultation has occurred to date. Long terms goals include measurement of clinical outcomes.

2:45 **254.004** Internet-Based Parent-Implemented Communication Strategies: Remote Delivery of Social Communication Interventions

***H. Meadan**, University of Illinois, Champaign, IL 61820, IL*

Background: High-quality early intervention programs are characterized by services that are developmentally appropriate, evidence-based, and delivered by parents and therapists in the child's natural environment. However, there are significant challenges to providing services with needed dosage or intensity to families with young children with autism and other developmental disabilities (DD). Barriers include the time and cost demands of traveling from one home to the next; limited financial resources to support this work; and situational barriers (e.g., serving families in rural areas; serving families living in neighborhoods providers perceive as unsafe; serving transient families). Innovative solutions are needed to positively impact the early development of young children with autism and other DD by providing greater access to research-based interventions.

Objectives: The i-PiCS (Internet-Based Parent-implemented Communication Strategies) program aims to teach and coach parents, via telepractice, to use evidence-based strategies with their young children to promote their social-communication skills.

Methods: The i-PiCS program includes online self-paced modules that are: (a) interactive, rather than delivered as a simple training video or webinar; (b) asynchronous, allowing parents to complete each module at a time, location, and pace that works best for them; and (c) aligned with adult-learning theory. These asynchronous modules are followed by synchronous embedded coaching provided in real time via videoconference, telepractice, to ensure that participants both master the target skills and feel confident in their application in naturally occurring contexts.

Results: Evaluation of the i-PiCS program has included multiple-baseline single-case experimental studies, and the findings are very promising. The parents have acquired the evidence-based strategies, have implemented them with high fidelity, are satisfied with the telepractice service delivery model, and their children's social-communication skills have improved. In addition, the telepractice program was used to teach and coach early intervention service providers to use the i-PiCS program with families on their caseload. Long terms goals include valuating the i-PiCS program with a larger number of families to assess its effectiveness at a larger scale.
