Results: The need for social support has been strongly expressed. An online platform seemed very relevant for them to get support from other parents. The most important conditions were confidentiality, accessibility, complementarity with existing services, needs-based content and the relevance of a moderator, which one can be a peer worker.

Conclusions: This research raises the need to develop population interventions in a comprehensive approach including in the form of online social support. Such a platform could help parents develop a sense of social support and improve their coping skills and sense of self-efficacy. This innovative platform could help meet the informational and emotional support needs of parents based on peer support.

123 **140.123** Setting Families up for Success: Parent Perspectives on a Toolkit to Enhance the Autism Spectrum Disorder Diagnostic Evaluation Process

R. Haine-Schlagel[1,2], *C. M. Corsello*[3], *T. Holt*[4], *L. Brookman-Frazee*[1,5] *and H. Gould*[6], *(1)Child and Adolescent Services Research Center, San Diego, CA, (2)San Diego State University, San Diego, CA, (3)Psychiatry, UNC TEACCH Autism Program, Raleigh, NC, (4)Psychiatry, UCSD Psychiatry, San Diego, CA, (5)Psychiatry, University of California, San Diego, San Diego, CA, (6)UCSD, San Diego, CA*

Background: Serving children with Autism Spectrum Disorder (ASD) is a significant public health concern (CDC, 2014). The first step in accessing services is often the ASD diagnostic evaluation. Unfortunately, receiving a diagnosis alone does not guarantee that services will be initiated. Parents report challenges with the evaluation process, such as providers recommending services not consistent with what is available and communication gaps between families and providers (Rous et al., 2008). Each parent brings a unique set of characteristics to the evaluation that may influence the evaluation's impact on a child's service use trajectory. For example, studies have documented that parental beliefs about the causes and chronicity of ASD can impact treatment choices (Dardennes et al., 2011; Mire et al., 2017), and parent perceptions of ASD symptom severity can impact follow-through with evaluation recommendations (Moore & Symons, 2009).

Objectives: To: 1) describe the development of a toolkit to enhance psychologists' communication and tailoring skills during the ASD diagnostic evaluation process; and 2) preliminarily evaluate the impact of the toolkit on parents' perceptions of the evaluation and recommendation follow-through efforts.

Methods: The ASD evaluation enhancement toolkit was developed with input from psychologists providing ASD diagnostic evaluations at a regional children's hospital and the parents they serve. More specifically, parents (n=10) whose children were diagnosed with ASD by participating psychologists (n=7) were interviewed one month post-evaluation about the diagnostic report, recommendations, and feedback portion of the evaluation. The interview protocol included both close-ended and open-ended questions. Another group of parents (n=6) whose children received an ASD diagnosis from participating psychologists were interviewed after the toolkit training had taken place, and responses between the two groups of parents were compared. The majority of children with ASD of these participating parents were male (87.5%), Hispanic (50%), and Medicaid-insured (43.8%) with a mean age of 3.4 years. Close-ended responses were analyzed using SPSS; open-ended responses were coded using an open-coding process (Haine-Schlagel et al., 2013).

Results: Effect size estimates from t-tests indicated that parents who received their evaluation after the toolkit training reported higher satisfaction with feedback. Across the two groups, there were no differences in understanding the evaluation results and confidence in next steps after the evaluation. There were also no differences in the likelihood of obtaining the report or percentage of recommendations initiated by the time of the interview. Qualitative data indicate that barriers to following through with recommendations differed for those who received their evaluation before versus after toolkit training. For example, some parents interviewed before the training discussed the need for more support after the evaluation to help obtain recommended services. Parents interviewed after the training did not articulate any need for additional support to obtain recommended services from their evaluator.

Conclusions: Results indicate some promising signals that this toolkit may address some barriers that facilitate parents' follow-through with recommendations following an ASD diagnostic evaluation. A larger-scale test of the toolkit's effectiveness with a much larger sample of parents across a more heterogeneous group of psychologists is a critical next step.

124 **140.124** The Impact of Community-Implemented Esdm on Parents' Ratings of Parenting Reward and Providers' Sense of Competence

M. R. Talbott[1], *G. S. Young*[2], *M. E. Miller*[1], *A. C. Stahmer*[1] *and S. Rogers*[3], *(1)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA*

Background: Infants and toddlers at-risk for ASD frequently receive early intervention through federally regulated Part C services, which typically address family needs and general developmental and heath needs of children via transdisciplinary assessment and parent guidance, rather than disability-specific interventions. While research studies have demonstrated positive effects for parent-implemented ASD-specific interventions, none of these empirically supported approaches have been adapted and tested in existing community Part C service systems. A randomized controlled trial analyzing the efficacy of one such model, Community-Early Start Denver Model (C-ESDM), is currently underway to fill this gap. Here, we examine the effects of this model on the providers receiving training and on the families being served.

Objectives: To evaluate the effects of C-ESDM on 1) parents' ratings of parenting reward and child developmental progress, and 2) community-based early intervention providers' sense of competence.

Methods: Agencies and providers serving toddlers at-risk for ASD in low resource communities were recruited across 4 states: Alabama, California,

Colorado, and Pennsylvania. Participating providers assisted with recruitment of families on their caseload. Agencies were randomly assigned to receive training in C-ESDM or a general developmental education program. The research team used telehealth to disseminate intervention materials to providers in both groups. Training consisted of: (1) provider webinars (general review of child development for the control group and training in C-ESDM strategies and autism for the experimental group); and (2) access to web-based materials for families (videos describing strategies to encourage general child development across domain areas for control group or a smartphone app, called Help is in Your Hands with multimodal materials to help parents implement key features of the C-ESDM at home). At intake and exit (6 months), providers completed a Sense of Competence Scale (PSOC) and parents completed Ratings of Parenting Reward (RPR) and Parent Rating of Child Progress (PRCP).

Results: To date, 32 providers (19 C-ESDM) and 33 parents (19 C-ESDM) have completed data for at least one time point (Provider: T1 *n* = 31; T2 *n* = 9; Parent: T1 *n* = 31; T2 *n* = 9). Preliminary findings suggest no differences between the randomization groups at baseline on any measure (PSOC, RPR, PRCP, all *p's* >.4). There are no significant main effects of time for any measure (all *p's* >.1), but non-significant differences between the groups over time in the expected direction (more positive improvements for C-ESDM group) are observed for the PSOC and PRCP measures. Time 2 data are expected to be available for all 32 providers and 33 families prior to the meeting.

Conclusions: These preliminary findings highlight the need to consider the effects on practitioners and parents when adapting laboratory-based empirically-validated interventions for use in existing early intervention service systems. Positive effects of an adapted intervention on providers and parents will support implementation and sustainment of evidence-based strategies in the community.

125 **140.125** A New Way to Help Parents? Exploring the Impact of School-Based Interventions on Parenting Outcomes

D. Swain[1], *L. Anthony*[2], *M. Troxel*[2], *B. J. Anthony*[2], *L. Kenworthy*[3], *A. Verbalis*[3] *and Y. Myrick*[3], *(1)Virginia Polytechnic Institute and State University, Blacksburg, VA, (2)University of Colorado, Denver, Aurora, CO, (3)Children's National Health System, Washington, DC*

Background: Increased levels of parenting stress are well documented in parents of children with neurodevelopmental disorders in comparison to parents of typically developing children, with parents of children with Autism Spectrum Disorder (ASD) and Attention Deficit Hyperactivity Disorder (ADHD) reporting the highest scores (Craig et al., 2016a). Parenting stress impacts individual beliefs and behaviors (e.g., parent self-efficacy) as well as the family system and can lead to diminished outcomes on child-focused therapy. In turn, child behavior has been shown to influence parenting stress and practices. Executive dysfunction, or difficulties with behavioral, emotional or cognitive regulation, has been suggested to serve as an endophenotype in neurodevelopmental disorders (Craig et al., 2016b), and may play an important underlying role in parenting stress and self-efficacy. Although not the primary target of treatment, analyzing the secondary impact of a school-based intervention on parents can help examine family impact, which in turn can lead to greater maintenance of child skills.
Objectives: Determine the impact of a school-based intervention on parenting strain and self-efficacy and explore moderators of change.

Methods: Participants included 148 parents (79.1% mothers) of children diagnosed with ASD (*n* = 50) or ADHD (*n* = 98) from Title 1 eligible schools in Washington, D.C. and northern Virginia. Children were randomly assigned to either Unstuck and On-Target or Parents and Teachers Supporting Students. Parent strain (Caregiver Strain Questionnaire-Short Form 7 (CSQ-7; Brannan et al., 2012)), parenting self-efficacy (subscale from Family Empowerment Scale (FES; Singh et al., 1995)), and child executive dysfunction (two subscales from the Behavior Rating Inventory for Executive Function (BRIEF; Gioia et al., 2000) were measured at pre, post, and follow-up.

Results: There was a significant decrease in subjective parenting strain from pre to post-treatment ($t(91) = 3.08$, $p = .003$) and maintained to follow-up ($t(73) = 2.10$, $p = .039$). A significant decrease in objective parenting strain was noted from pre- to post-treatment ($t(90) = 3.15$, $p = .002$), but effects did not extend to follow-up ($t(72) = 2.10$, $p = .265$). Although parent self-efficacy increased from pre- to post-treatment, it was not a significant change ($t(85) = -.80$, $p = .425$). After controlling for baseline levels of parenting strain and child executive dysfunction, only change in metacognition significantly predicted change in subjective parenting strain ($\beta = .413$, $p = .002$). Changes in metacognition ($\beta = .276$, $p = .027$) and not behavioral regulation ($\beta = .189$, $p = .094$) significantly predicted change in objective parenting strain.

Conclusions: The current study builds on the encouraging findings in relation to both treatments demonstrating positive changes in child executive functioning and behavioral flexibility. Results demonstrate significant changes in parenting strain and not parenting self-efficacy as a consequence of participating in these school-based treatments. Interestingly, only change in metacognition, or increases in child's ability to plan, organize, and initiate tasks) significantly predicted change in both subjective and objective strain. Neither changes in classroom observation nor number of parent training sessions attended impacted change in parenting strain or self-efficacy.

126 **140.126** Predictors and Moderators of Parenting Stress in Youth with Autism Spectrum Disorder and Their Typically-Developing Siblings

E. Kang[1], *A. H. Gerber*[1], *M. D. Lerner*[2] *and M. E. Tudor*[3], *(1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY, (3)UC David MIND Institute, Davis, CA*

Background: Mothers of children with autism spectrum disorder (ASD) experience a particularly elevated level of stress (Schieve et al., 2007) and depression than mothers of children with other developmental disabilities or typically-developing (TD) children (Abedduto et al., 2004; Davis & Carter, 2008). Increased rates of problem behaviors in children with ASD contribute to parenting stress more than ASD symptoms (Peters-Schefferet al. 2012). A less studied component of parenting stress is the clinical functioning of TD siblings in the context of ASD. Mothers may also respond differently to child characteristics, including sex-based differences (Sameroff, 2009). A better understanding of factors contributing to parenting stress, including clinical functioning in children with and without ASD and across genders, is crucial for developing interventions that enhance well-being of families affected by ASD.
Objectives: Examine whether the relationships between clinical functioning in children and parenting stress are moderated by maternal depression or child's gender, in children with ASD and in TD siblings.

Methods: Mothers (*N*=256) with one child with ASD (M_{age}=11.82, SD_{age}=3.02; 84% male) and a TD child (M_{age}=11.24, SD_{age}=3.18; 47% male) completed a measure of clinical functioning in their children (BASC-2; Reynolds & Kamphaus, 2004), as well as a measure of parenting stress (PSI-4SF; Abidin, 2012) and their own depressive symptoms (BDI-II; Beck, Steer, & Brown, 1996).

Results: PSI total score positively correlated with externalizing, internalizing, behavioral symptoms (r>.30, p<.001), and negatively with adaptive skills (r=-.52, p<.001) in children with ASD. BDI moderated the relationship between the child with ASD's internalizing behaviors and PSI (B=-.02,

p=.012), such that the relation was present only when BDI was low or average (Fig 1A). The gender of children with ASD moderated the relationship between child externalizing behavior and PSI (*B*=-.85, *p*=.006), such that these relationships were only present for with boys (Fig 1B). TD children's behavioral symptoms (*r*=.17, *p*=.016) and adaptive skills (*r*=-.14, *p*=.025) related to PSI. These relationships were not moderated by BDI, but the relationship between adaptive skills and PSI was moderated by gender (*B*=-0.35, *p*=.041), such that the relation was only in TD girls (*B*=-0.25, *p*=.015).

Conclusions: Results suggest that both children with ASD and their TD siblings' clinical functioning contribute to parenting stress, supporting bidirectional relations along with parenting stress predicting child psychopathology (Anthony et al., 2005; Bauminger et al., 2010). Surprisingly, these relations were not seen in highly depressed mothers. Given that parenting stress predicts depressive symptoms above and beyond child characteristics (Weitlauf et al., 2014), it is possible that depressed mothers may experience elevated parenting stress regardless of child behaviors. Moderation by gender suggests that mothers' differential expectations of behavior, such as perceiving externalizing behaviors in boys with ASD and low adaptive skills in TD girls as more stressful, may affect mothers' sense of parenting efficacy. As parental stress has a negative impact on treatment outcome (Osborne et al., 2008), these findings highlight the importance of addressing emotional and behavioral problems in both children with ASD and TD siblings, and considering maternal (depression) and child-specific (gender) factors to reduce parental stress.

127 **140.127** Autistic Adults' Views and Experiences of Stimming

***S. K. Kapp**, University of Exeter, Exeter, United Kingdom*

Background:

'Stereotyped or repetitive motor movements' are characterised as core symptoms in the diagnosis of autism and treatments to control them remain popular (Jaswal & Ahktar, 2018). Diverse therapeutic perspectives have regarded these behaviours as self-stimulatory acts that shut out external stimuli and interfere with the person's (and others') focus (Lilley, 2018). In contrast, many autistic adults (and the neurodiversity movement) have reclaimed them as 'stimming', arguing they may serve as useful coping mechanisms and decrying practices such as "quiet hands" (e.g. Bascom, 2012). Yet only one empirical study has directly elicited autistic adults' views about stimming, a pilot online survey presented by Steward at IMFAR (2015) that found most participants viewed stimming as a coping mechanism to reduce distress or overstimulation. Furthermore, most reported they generally or sometimes enjoyed stimming, yet had been told not to do it.

Objectives:

We sought to extend the study by Steward (2015) through more in-depth data collection and purposive sampling for a diverse range of support needs among autistic adult participants. We aimed to examine autistic adults' perceptions and experiences of stimming, including: (1) the reasons they stim, (2) any value doing so may hold for them, and (3) their perceptions of others' reactions to their stimming.

Methods:

We conducted semi-structured interviews and focus groups with a participatory team of autistic and non-autistic researchers. Thirty-two autistic adults (20 male, 11 female, one non-binary), between the ages of 21 to 56 years (μ = 36.4) participated in the study (20 in one-to-one interviews and six each in two facilitated focus groups). Recruitment took place through the existing networks of research teams in the Southwest of England and London, including residential homes and a training centre for autistic adults, producing a sample with a diverse range of support needs. Interviews and focus groups had a similar topic guide and prompts to encourage active participation.

Results:

Using thematic analysis (Braun & Clarke, 2006), we identified two themes, including stimming as: 1) a self-regulatory mechanism, and 2) lacking in social acceptance, but can become accepted through understanding. For the first theme, participants reported external causation of stimming through overwhelming environments that cause sensory overload, as well as internal causation through noisy thoughts. Stimming always involved uncontainable emotion, but it could be a positive emotion such as joy or a negative one such as anxiety. For the second theme, we observed a dynamic of (de)stigmatisation in which others usually devalued participants' stims, especially when they were harmful and as participants got older, but stims could become socially accepted through others' understanding.

Conclusions:

Autistic adults highlighted the importance of stimming as an adaptive mechanism that helps them to soothe or communicate intense emotions or thoughts and thus objected to treatment that aims to eliminate the behaviour. The point of intervention could therefore be shifted to dysfunctional causes of stimming, such as the overwhelming environment and possibly distressing thoughts and emotions. Future research might investigate the possibility that everyone stims by comparing stimming to the fidgeting ubiquitous among non-autistic people.

128 **140.128** Should Heritage Languages be Incorporated into Interventions for Bilingual Individuals with Neurodevelopmental Disorders?

***N. Lim**[1], M. O'Reilly[2], J. Sigafoos[3], K. Ledbetter-Cho[4] and G. Lancioni[5], (1)The University of Texas at Austin, Austin, TX, (2)UT Austin, Austin, TX, (3)Education, Victoria University of Wellington, Wellington, New Zealand, (4)University of Texas at Austin, Austin, TX, (5)Università degli studi di Bari Aldo Moro, Bari, Italy*

Background: Bilingualism is becoming increasingly prevalent in today's rapidly globalizing world, and this increase is also seen among children with disabilities. A core characteristic of individuals with neurodevelopmental disorders like intellectual disability (ID), global developmental delay (GDD), communication disorders (CDs), and autism spectrum disorder (ASD) is a deficit in language. Concerns that dual language exposure may hinder language development often lead to many language-minority parents being advised against speaking in their heritage languages. According to special education policies, the heritage languages of individuals with disabilities should be developed and preserved. However, practice does not seem to align with these policies. Does research support incorporating the heritage languages of bilingual individuals with neurodevelopmental disorders into interventions?

Objectives: Research syntheses are key when determining evidence-based practices. Previous reviews on this topic were unregistered narrative reviews with methodological weaknesses. Consequently, the purpose of this review was to evaluate the effects of incorporating heritage languages into interventions for bilingual individuals with neurodevelopmental disorders using more systematic methodology and meta-analytic

procedures. The quality of research designs was also evaluated.

Methods: This systematic review was registered with the PROSPERO international prospective register of systematic reviews. Procedures used followed PRISMA guidelines. A total of 18 studies met predetermined inclusion criteria (i.e., used an experimental design, implemented an intervention, included individuals with ID, GDD, CDs, and/or ASD who were bilingual, and investigated the effects of languages of instruction). Participant characteristics, interventions delivered, languages of instruction used, and study outcomes were summarized. Study quality was evaluated using the What Works Clearinghouse (WWC) Standards Rating. Effect sizes for studies that met WWC standards were also calculated.

Results: Nine out of 18 studies were conducted with participants with CDs. The other nine studies were conducted with participants with diagnoses of ID, GDD and/or ASD. Findings indicate a small effect favoring interventions that incorporated participants' heritage languages versus interventions that were delivered solely in the majority language. Additionally, most studies met WWC standards and were found of be of high quality.

Conclusions: Overall, findings support the incorporation of heritage languages of bilingual individuals with neurodevelopmental disorders into interventions. More than half of the studies conducted with participants with CDs favored interventions delivered in participants' heritage languages, but the same was only found for a third of studies conducted with participants with ID, GDD, and/or ASD. This may be due to a discrepancy in heritage language supports provided to participants. Specifically, 80% of participants with CDs were reported to be receiving some amount of heritage language instruction in school. However, this was only the case for less than 10% of participants with ID, GDD, and/or ASD. Thus, due to previous exposure, participants with CDs may have developed preferences for heritage language instruction and/or been more familiar with receiving formal instruction in heritage languages. Suggestions for future research include assessing social validity, involving stakeholders when designing and implementing interventions, and investigating strategies for overcoming language barriers between therapists and clients.

129 **140.129** Bringing School Home: Understanding the Interactional Resources of a Bilingual Child with ASD

S. R. Cohen[1], *J. Miguel*[2], *K. Bottema-Beutel*[3], *G. Oliveira*[4] *and R. Osoria*[5], *(1)University of California - San Diego, La Jolla, CA, (2)UC San Diego, San Diego, CA, (3)Lynch School of Education, Boston College, Chestnut Hill, MA, (4)Boston College, Chestnut Hill, MA, (5)UC San Diego, La Jolla, CA*

Background: Children with autism spectrum disorder (ASD) engage in social interactions differently from their typically developing peers. The ways in which bilingual children with ASD socially engage with others is not well understood. Bilingual language practices may be shaped by families' contexts and childrearing practices (Yu, 2016). We utilized Bakhtin's notion of heteroglossia - varied speech voices in context -- to examine the interactional implications of code-switching within an immigrant, bilingual family that includes a child with ASD.
Objectives: The purpose of this study was to examine how code switching is used as an interactional resource during parent-child interactions among immigrant parents and their child with ASD.

Methods: To understand certain features of code-switching -- the alternation between two languages -- we examined transcripts to answer the following questions: (1) Who initiated code-switching; (2) What was the activity context during code-switching; (3) How was code-switching used in conversation; and (4) What did code-switching appear to do for the interaction? Over three hours of video data were collected from an immigrant, predominantly Spanish-speaking family who lives in a rural border town. The primary caregiver was Beatriz (names are pseudonyms), a 32 year-old unemployed mother working on her bachelor's degree. The child, Herman, was a 5 year-old boy with autism. The father, David, was a 31 year old merchant.

Results: Beatriz initiated code-switching 21 times; David, 4 times; and Herman, 46 times. The alternation primarily occurred from Spanish to English during structured interactional activities like book reading, homework, or in conversations about animals and colors. Code-switching also occurred during pretend play like play-doh, car play, and preparing pretend meals.

The form of code-switching included single word insertions -- a second language word inserted into a primary language sentence (Moyer, 2013). Herman inserted a single English word (e.g., red, dinosaur, pirate) into a Spanish conversation. Alternations -- secondary language sentences or clauses utilized within a speaker's turn -- were also utilized. Herman asked his mother a question in English and the mother responded in Spanish.

To understand interactional implications, code-switching was used as a contextualization cue (Gumperz, 1982). After playing with play-doh, Beatriz asked the children to clean up. Herman sang the "clean up song" in English as he cleaned up the play doh. Herman enacted a song that he learned outside of home (likely at school) within a similar interactional context at home. Code-switching brought school interactional contexts into the home. Code-switching was also used as a metalinguistic pedagogical tool to encourage Herman to learn new words and practice the second language (Waring, 2009). During a book reading activity, David and Herman communicated in English to describe the pictures. When Herman did not know an English translation for a word (i.e.,"disfraz") he asked David to translate it to English ("costume").

Conclusions: This case study exemplifies how Herman and his parents used code-switching as an interactional resource within family interactions. These findings indicate the need for interventionists to capitalize on the linguistic strengths of bilingual families to support language and communication.

130 **140.130** Question-Response-Evaluation Sequences in the Home Interactions of a Bilingual Child with Autism Spectrum Disorder

K. Bottema-Beutel[1], *G. Oliveira*[2], *S. R. Cohen*[3] *and J. Miguel*[4], *(1)Lynch School of Education, Boston College, Chestnut Hill, MA, (2)Boston College, Chestnut Hill, MA, (3)University of California - San Diego, La Jolla, CA, (4)UC San Diego, San Diego, CA*

Background: Early interventions for children with autism spectrum disorder (ASD) rely on caregivers as interventionists, and leverage family routines as intervention contexts (e.g., Kasari, 2015). However, families in most intervention research are monolingual. There is little research on the interactional routines of bilingual families that could be drawn upon to aid in the implementation of family-centered intervention practices. To fill this gap, we examined naturally occurring interactions in a Spanish-English bilingual, immigrant bilingual family with a 4-year old child with ASD.
We focused on interactions involving parent questions directed toward their child. Child-directed questions are often *pedagogical*, ostensibly designed to teach the child about the world, social interaction, and language itself (Snow, 1972; Yu, Bonawitz, & Shafto, 2017). When answers to questions are known to the adults who pose them (i.e., *known-answer* questions; Grosse & Tomasello, 2012; Schegloff, 2007), they culminate in

question-response-evaluation (QRE) sequences. These sequences have been examined classroom contexts (e.g., Waring, 2009), but few studies have examined these sequences in family interactions that involve children with ASD.

Objectives: to determine (a) the question formats that were used to launch QRE sequences, (b) the types of third-turn evaluations used to close these sequences, and (c) the larger action trajectories in which the QRE sequences were embedded.

Methods: We used Conversation Analysis, a micro-analytic approach to examining interaction that focuses on the sequence organization of talk. Parents were given a video camera, and instructed to turn it on during times of the day that family members engaged in routine interactions. We focused on one family in our data corpus, comprised of ~4 hours of recordings. Recordings were transcribed in Spanish, and then translated into English. After an initial pass through the dataset, we developed a code book to identify segments of transcript that included the provision of known-answer questions. These segments were then coded to determine the question format, the evaluation format, and the action trajectory within which the QRE sequence was embedded.

Results: Known-answer questions were posed using several question formats, with q-word (who, what, why, etc.) questions being the most prevalent. We also found that parents formatted evaluations in a variety of ways; by initiating repair, repeating the child's utterance to confirm the acceptability of the response, moving to the next question is a series of topically organized questions, and by offering affirmative tokens (e.g., yes) or evaluative phrases (e.g., wow, that's great). In terms of action trajectories, our analyses showed that QRE sequences were *not* designed solely to test child knowledge. Instead, they worked to: (a) repair prior responses, (b) move play routines forward, and (c) launch an extended, topically connected series of questions. See Table 1 for descriptions and examples.

Conclusions: This study offers a characterization of QRE routines in a Spanish-English, immigrant family with a child with autism. Our findings suggest that QRE sequences were a rich interactional resource for the child and his parents, and could potentially be a space for maximizing high level engagement to encourage social-communication development.

131 **140.131** Using Community Advisory Boards to Inform Interventions for Latinx Children with ASD.

K. Lopez *and J. M. Marroquin, Arizona State University, Phoenix, AZ*

Background: Data from the Arizona Developmental Disabilities Surveillance Program 1 in 71 8-year children have autism spectrum disorder (ASD) in Arizona. When considering race and ethnicity, White or black non-Latinx children are more likely to be identified with ASD than Latinx children in Arizona. For those Latinx children who are diagnosed, they are more likely to receive a later diagnosis and receive fewer services compared to non-Latinx white children. A plethora of socio-cultural individual, family, healthcare systems, educational systems, community systems factors impact access to diagnosis and services for Latinx children. Thus, to reduce ASD disparities among Latinx children it is critical to engage in interprofessional collaborations to engage relevant stakeholders and promote social justice through collaborative work. Community advisory boards provide a platform for interprofessional and community engagement to enhance the inclusiveness of the target community perspectives and advisement. The purpose of this presentation is to discuss the development and utility of a community advisory board to inform the scope of the problem, outreach, and participant recruitment for the pilot of a culturally informed intervention combined with pivotal response training for Latinx families of children with ASD.

Objectives:

1) increase awareness of ASD disparities for Latinx children in AZ.

2) identify effective collaborations among service providers and Latinx families in the autism community

3) highlight opportunities to engage Latinx families raising children with autism in intervention programs

Methods: A geographic area within Maricopa County was identified to be the targeted area for the pilot intervention project. An engagement and relationship-building phase followed. After which, key stakeholders within the community were invited to serve on a community advisory board to guide the pilot intervention project. The community advisory board responsibilities included 1) identify barriers Latinx families experience in the diagnostic process and challenges after diagnosis; 2) collaborate with the program by incorporating their knowledge of resources in the community; 3) describe strategies within the community that have been successful for outreach and recruitment of Latinx families.

Results: Six community members (three Latina mothers of children with ASD, three providers) served on the community advisory board. The community advisory board provided information and advisement about the problem, outreach strategies, retention considerations, appropriate and reliable community resources, and offered space for assessments. This information contributed to the successful recruitment of 10 parent-child dyads for the intervention program.

Conclusions: The community advisory board supported the implementation of a culturally informed intervention for Latinx families raising children with ASD. Through this inclusive practice the community perspective of challenges Latinx children and families face in access to ASD diagnoses, treatment services in the targeted region. The community advisory board assisted the researcher in identifying inclusive strategies in outreach, modifications of the intervention delivery, and culturally appropriate resources. This presentation is particularly relevant, given the variety of providers and disciplines involved in the lives of individuals diagnosed with ASD. Implications for outreach, recruitment, inclusion, and retention of Latinx children and families in ASD research will be discussed.

132 **140.132** "Had a Good Cry, then Went Online": Factors Associated with Parent Reactions to Diagnostic Disclosure Sessions

E. I. Anderberg[1]*, M. South*[2]*, T. P. Gabrielsen*[3]*, J. Cox*[4] *and R. A. Lundwall*[2]*, (1)Psychology, Brigham Young University, Provo, UT, (2)Psychology & Neuroscience, Brigham Young University, Provo, UT, (3)Counseling & Special Education, Brigham Young University, Provo, UT, (4)Counseling and Career Center, Brigham Young University, Provo, UT*

Background:

Receiving a diagnosis of an autism spectrum disorder (ASD) is often an important event in the life of a family. The diagnostic disclosure session can produce strong emotions and stress, but also can help families learn about autism and access helpful resources. To date, most of the research literature focuses on the broader diagnostic process or on qualitative data from a small number of families. Little is known about how providers can improve their diagnostic disclosure sessions to better serve families.

Objectives:

This study aims to better understand positive and negative parent experiences with diagnostic disclosure sessions, with the goal of understanding how providers can improve client outcomes by maximizing the benefit of these sessions.

Methods:

Information was gathered through a mixed-methods study including interviews with diagnosing professionals of various disciplines (n=6), a focus group of parents (n=11), and surveys from U.S. parents with children diagnosed with ASD in the past 3 years (n=160). The survey was developed for this study using currently available research and asked parents about their attitudes and knowledge coming into the disclosure session, their experiences during the disclosure session (e.g., provider characteristics, information received), and their experiences following the session (e.g., knowledge and confidence, emotional responses, actions taken). The survey also included open response questions about their experiences receiving the diagnosis and how the session could be improved.

Results:

Parent satisfaction with the diagnostic disclosure session was best predicted by having a provider who parents felt was warm and empathetic, really "got" their child, and was competent. They also felt more satisfied if providers adequately explained why their child had ASD, described treatment options, and gave strategies they could use at home. In qualitative responses, parents emphasized that recommendations for at-home strategies were extremely helpful, and that they would like more step-by-step recommendations that were rank-ordered in terms of priority. Parents who entered the session feeling more nervous about receiving an autism diagnosis were more likely to leave the session feeling shocked, worried, upset, and sad about the loss of the future they imagined for their child. Parents felt most hopeful after the session if they had a provider who addressed their child's prognosis, explained the diagnosis, and was warm and empathetic. Immediately following the session, parents report crying, and then accessing services right away, with most parents seeking informal social support and provider-recommended treatments first.

Conclusions:

Providers who diagnose ASD can help support parents by making sure that parent expectations are adequately addressed during the disclosure session. Attending to parents' emotional states at the time of the session may improve outcomes afterward. Parents especially value step-by-step information on how the diagnosis was decided and instructions on how to access specific resources. Empathic and warm diagnosticians are valued and trusted most.

133 **140.133** "We Are Mama and Papa Bears": A Mixed Methods Study of the Outcomes of Parents of Transition-Age Youths with ASD

***V. Hang**, University of Kentucky, Lexington, KY*

Background:

The negative transition outcomes and transition experiences do not only impact students with ASD, but also their families because many individuals with ASD continuously rely on their caregivers' intensive support, even through adulthood (Smith et al., 2010). A successful transition should be based on how well the family is doing and how parents perceive the transition process (i.e., family-centered approach; Neece et al., 2009). However, the transition process often fails to empower caregivers or measure family-level outcomes (Cameto & colleagues ,2004).

Objectives:

To provide a detailed account of the experiences associated with the transition process from a family-centered approach and answer three questions: (1) What are the stressors, external and internal support, coping strategies, and parent transition outcomes from a parent's perspective?; (2) What are the predictors of parent transition outcomes?; and (3) Does resources and coping strategies mediate the relationship between stressors and outcomes as proposed by the ABCX model?

Methods:

An exploratory sequential mixed methods study was conducted:

Part 1–Qualitative study

Participants. 13 parents of transition-age youths with ASD were interviewed. The analysis of the qualitative data was guided by the thematic analysis approach (Daly, Kellehear, & Gliksman, 1997).

Part 2–Quantitative study

Participants. 252 parents of transition-age youths with ASD was recruited. According to the qualitative results generated by phase 1, four regressions and a structural equation model were developed to identify predictors that influence parent transition outcomes at indicator and structural levels.

Results:

Qualitatively, parents identified four stressors at three levels (family, parent, child), seven resources, five perception/coping strategies used, and five current/desirable outcomes. These themes were categorized using the ABCS model (see figure 1). These parents were angry, fearful, and worry, but were hopeful at the same time. They shared thoughts about the meaning of being a parent, aging, and their own dream. A father shared, "I am a prisoner." Another mother said, "I just want to read a book on a beach." These parents' powerful sharing sheds light on their areas of need and gives us a deeper understanding of the intersection of aging and parenting an adult with ASD.

The quantitative study added information about the factors that impact parents' transition outcomes to the literature. At the indicator level, two child-related factors (i.e., autism severity; mental health crisis/challenging behaviors), two parent-related factors (i.e., filial obligation; efficacy), two school related factors (e.g., transition planning quality; parent-teacher alliance), coping strategies (problem-focused coping; avoidance-focused coping; optimism) predicted at least one of the parents' transition outcomes. At the structural level, optimism, emotion-coping strategies, and resources mediated the relationships between stressors and parental outcomes (see Figure 2).

Conclusions:

The current project provided insights into the complexity of the transition process experienced by parents of adolescents and young adults with ASD. The results also shed light on variables for further development and study of family-centered transition interventions. Parents are crying for help and support is far from sufficient. Clinical and research implications will be discussed.

134 **140.134** "What We Need from the U.K Healthcare System for Our Children with Autism": Voices of Parents / Carers Captured through Qualitative Interviewing.

A. Bratt[1] *and S. Chantziara*[2]*, (1)Medway School of Pharmacy, Kent, United Kingdom of Great Britain and Northern Ireland, (2)Medway School of Pharmacy, Universities of Kent and Greenwich, Chatham, United Kingdom*

Background: Children with Autistic Spectrum Conditions (ASCs) often require access to multiple areas of healthcare provision through the course of their development, due to increased presentation of both physiological and psychiatric co-morbidities. It is hoped that this medical support is delivered in a timely, fully integrated, and appropriately individualised way to adequately support autistic individuals and their families.
Objectives: No published data are available in the U.K. reporting how satisfied parents / carers are with the level of health-related support that their dependents with ASC receive. This qualitative interview study aimed to collect those views in addition to parental suggestions for possible improvement of future health care provision, with a focus on the use of hospital passports (dossiers of integrated patient information).
Methods: Data were obtained from 24 voice-recorded, semi-structured interviews (mean duration 60 minutes) with parents / carers of children with ASC, aged between 0-18 years. Interviews took place predominantly in participants own homes (3 took place in a quiet interview room in the Medway School of Pharmacy). Parents were asked to describe specific past experiences of healthcare provision for their children with autism and to define factors which led to overall level of satisfaction. The services surveyed were General practitioners (GP's), Paediatric services, Child & Adolescent Mental Health services (CAMHS), Accident & Emergency and inpatient hospital admissions. Parents were asked to offer suggestions to improve future practice. Finally parents were asked if they were aware of hospital passports, and if they could improve provision. Interviews were anonymised and transcribed, and thematic analysis was used to identify, analyse and report thematic frequency within the data.
Results: Parents gave examples of both positive and negative experiences with healthcare provision in all sectors. The dominant theme to emerge which appeared to discriminate positive & negative experiences was the amount of autism-related knowledge parents felt that healthcare professionals (HCPs) demonstrated in their practice, along with the depth of their understanding of the range of possible individual presentations of ASC. A secondary theme highlighted a need for the appropriate level of communication and interaction between the health care professional and the child, and for the HCP to actively listen to the parents and to treat them as "experts" regarding their child. Parental suggestions for improvement aimed at optimising the holistic health outcome for the child, and overall family satisfaction will be discussed.
Conclusions: The suggestion of use of the hospital passport for children with autism was met with overwhelmingly positive reviews as parents felt it could be used in an integrated way across a variety of healthcare settings to improve information dissemination and communication between health care professionals and families.

135 **140.135** "and Yet, I Still Hope": Parenting Self-Efficacy in ASD

J. Kurzrok[1]*, E. McBride*[2] *and R. Grossman*[3]*, (1)Communication Sciences and Disorders, Emerson College, Boston, MA, (2)Institute of Liberal Arts and Interdisciplinary Studies, Emerson College, Boston, MA, (3)CSD, Emerson College, Boston, MA*

Background: Children with ASD are often involved in multidisciplinary, complex therapy programs, requiring significant caregiver management, participation, and strain (Ruble & McGrew, 2007; Kandolkar & Kenchappanavar, 2014). Parenting self-efficacy, i.e. the expectations caregivers have about their abilities to successfully parent their children, has previously been shown to predict a parent's ability to cope with the unique challenges of raising a child with ASD (Pastor-Cerezuela et al., 2016; Kuhn & Carter, 2006). High parental self-efficacy has been shown to mediate parental stress (Bayat, 2007). Despite a recent focus on family-centered care and parental involvement in therapy for children with ASD, little research has investigated the impact of various components of a child's therapy programming on parental ratings of confidence and self-efficacy.
Objectives: We aim to assess the effects of intervention intensity, parental therapy involvement, and parent training on ratings of parenting self-efficacy. This study seeks to answer two questions: (1) To what extent do intervention-level factors (e.g. degree of parental involvement in intervention, training from professionals, intervention frequency, number of different interventions) modulate autism-specific parenting self-efficacy?; (2) Does perceived level of caregiving burden mediate the predictive power of these intervention-level factors on parental self-efficacy ratings?

Methods: Parents of children with ASD (N=439) across 47 states completed an online questionnaire on parenting self-efficacy for autism (PSEa). The survey was designed to capture parental confidence in advocating for their child with ASD, confidence in navigating the complexities of autism intervention, and perceived level of social and financial strain associated with raising their child. It also captured basic demographic information and details of intervention frequency, modality, and number and type of clinical interventions.

Results: We used linear regression with PSEa as the outcomes measure. Result show that time since diagnosis, parental rating of involvement across all therapies, and parental rating of satisfaction with training significantly predict PSEa. We also grouped participants by high vs. low parental strain and found that for individuals who rated the strain of raising their child as low, parental involvement in therapy significantly predicted 32.3% of the variance in PSEa and parental satisfaction with intervention training significantly predicted 30.3% of the variance in PSEa. Conversely, among parents with a high rating of strain, parental involvement predicted only 18.7% of PSEa ratings and training satisfaction did not significantly predict PSEa. PSEa was not significantly predicted by number of therapies, total number of therapy hours per week, severity of child's ASD symptoms, or child language level.

Conclusions: Data collected from 439 caregivers of children with ASD indicate that parental self-efficacy can be improved through parental involvement and positive training experiences, as long as perceived burden is low. However, when parents indicate high perceived burden, practitioners may need to prioritize working with families to counsel, refer to other professionals, and engage community resources in order to decrease burden and enable parents to derive maximal benefit from training and involvement. Interestingly, these effects seem to be independent of intensity of intervention, severity of child's ASD symptoms, or child language level.

136 **140.136** ASD Support Networks and the Services Cliff: Mappings Social Capital Inequalities for Young Adults with ASD Post-Transition

E. McGhee Hassrick[1]*, C. Sosnowy*[1]*, P. Shattuck*[1]*, C. Friedman*[1] *and J. L. Walton*[2]*, (1)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (2)AJDAI, Drexel University, Philadelphia, PA*

Background: Over 66% of young adults with Autism Spectrum Disorder (ASD) are disconnected from opportunities for work or schooling in the first few years after high school. [1] Unequal access to social capital (resources and connections) from work, community and school contexts could adversely impact their transition to employment and other lifecourse outcomes. [2-4] Our study represents the first attempt to use modern social network methods to investigate the social networks of transition-age youth with autism to investigate social capital inequalities during transition.
Objectives: To conduct a preliminary investigation of the social capital of youth with ASD post transition by using pilot data from self-report egocentric social network surveys to identify resources and connections and investigate variation across gender.

Methods: A purposeful sample of 17 young adults between the age of 19-28 were asked to identify up to five important people and the supports they provided to the young adult. The young adults also identified network connections among identified supporters. Using ORA [5], we computed the density of the team of identified supporters, the percent for each role type and the percent for each support type of supporter. Descriptive statistics suggest that participants represented a racially homogenous (88% white), relatively advantaged group of 17 young adults, with a mean age 23.25. Overall, 82% had ever attended college and 35% were living independently. 59% were male (n=10), 29% female (n=5), and 12% were gender non-conforming (n=2) (Table 1).

Results: Pilot data suggest that youth were not isolated, with mean networks size = 4.88. Few support networks included professionals (n=2). Types of supports provided by network members varied. Friendship (75%), emotional support (74%) and advice (73%) were more frequent while employment support was less frequent (24%). Median network density for males was 100%, while female or gender non-conforming persons median density was 60% (Mann–Whitney U = 13, p = .03, two-tailed). (Figure 1) Role types of supporters varied by gender. Family members were marginally more present in males' support networks (median 68%) than female and gender non-conforming persons' (median 40%; Mann–Whitney U = 17.5, p = .09, two-tailed). In contrast, community members were more present in the support networks of females and gender non-conforming persons (median 40%) than in the support networks of males (median 12.5%) (Mann–Whitney U = 53, p = .08, two-tailed). Family friendship also varied by gender, where males had on average a marginally greater percentage of family members who provided friendship (median 60%) than females and gender non-conforming persons (median 40%) (Mann–Whitney U = 15.5, p = .06, two-tailed).

Conclusions: Pilot data suggests that youth were not isolated and that gender is salient for diverse sources of social capital acquisition, as male young adults with ASD in this study relied primarily on family network members, while females and gender non-conforming persons had more diverse networks that included family and community members. The lack of professionals present in support networks illustrates the adverse impact of the service cliff, as identified in previous studies.[1]

137 **140.137** Adjustment in Typically Developing Siblings of Children with ASD: The Impact of Sex, Age, and Birth Order

M. L. McNair[1], *M. Coffman*[2], *N. Kelso*[3], *J. McPartland*[1] *and J. Wolf*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Virginia Tech, Blacksburg, VA, (3)University of Maryland, College Park, College Park, MD*

Background: The current literature investigating adjustment and behavior challenges in typically developing siblings of children with ASD (TD-Sibs) reports inconsistent findings. Some studies report TD-Sibs demonstrate adjustment problems compared to normative samples, while others report no significant differences. However, the inconsistent literature may reflect the influence of modulating factors that impact sibling adjustment. While some modulating factors, such as maternal stress and affected sibling's ASD severity, have been investigated with mixed results, other potential modulators (e.g. birth order) have yet to be fully explored. Recent literature suggests TD-Sibs younger than their affected sibling may exhibit problem behaviors because of increased stress from birth due to the presence of a sibling with ASD or modeling sibling behavior.
Objectives: To investigate the impact of modulating factors such as sex, age, and birth order on TD-Sib adjustment. We hypothesized that TD-Sibs younger than their sibling with ASD will exhibit more adjustment challenges compared to older TD-Sibs and age-based norms.

Methods: Thirty-four families with at least one TD-Sib (N=34, 6-12 years, mean age=8.9 years) and one child with ASD were recruited through a larger study investigating the effectiveness of a sibling support group. Prior to support group participation, one parent completed the *Child Symptom Inventory-4* (*CSI-4*) and *Behavior Assessment System for Children, Second Edition* (*BASC-2*) to measure the TD-Sib's emotional and behavioral adjustment. To investigate the difference in clinical/subclinical occurrences in adjustment difficulties between TD-Sibs and normative samples, binomial *t*-tests were conducted for each *CSI-4* and *BASC-2* subscale. Within the TD-Sib sample, independent sample *t*-tests were used to compare subscale scores between males and females, TD-Sibs younger or older than the affected sibling, and TD-Sibs younger than eight (<8) or eight and older (8+; cutoff selected to correspond to *BASC-2* normative age groupings).

Results: On the *CSI-4,* male and female TD-Sibs showed no significant differences in adjustment and scored in the normative range on all subscales. However, the proportion of female TD-Sibs with subclinical Depression subscale scores was lower than population norms ($p<0.05$). TD-Sibs younger than their affected sibling had greater challenges than older TD-Sibs on *BASC-2* Daily Living Skills subscale ($t(29)=-2.06$, $p<0.05$). Compared to TD-Sibs 8+, TD-Sibs <8 exhibited worse adjustment on *BASC-2* Functional Communication ($t(32)=2.55$, $p<0.05$) and marginally more impairment on *BASC-2* Attention ($t(32)=2.01$, $p=0.053$) and Conduct ($t(32)=1.10$, $p=0.054$) subscales. Likewise, the proportions of TD-Sibs <8 with subclinical adjustment difficulties on the *BASC-2* Depression subscale was higher than population norms ($p<0.05$). The proportions of TD-Sibs 8+ with adjustment challenges on all *CSI-4* and *BASC-2* subscales were comparable to or less than population norms (*BASC-2* Somatization, Withdrawal, Leadership, Functional Communication, *p*-values<0.05).

Conclusions: TD-Sibs did not exhibit difficulties in their parent-reported adjustment and scored in the normative range on both adjustment measures. However, our findings suggest an effect of birth order and developmental age, such that TD-Sibs younger than their affected sibling or younger than eight showed more adjustment challenges. Understanding the psychological well-being of TD-Sibs may help inform family and sibling support groups as well as sibling-mediated interventions for children with ASD.

138 **140.138** An Autism Friendly Hospital Initiative: Measuring Distress in Children with ASD during Vital Signs

D. P. Carroll[1], *R. C. Schmitt*[1], *J. Benwait*[2], *P. Vittner*[2] *and S. J. Spence*[1], *(1)Autism Spectrum Center, Boston Children's Hospital, Boston, MA, (2)Neurology, Boston Children's Hospital, Boston, MA*

Background: On average, children with autism spectrum disorder (ASD) have more medical visits than those without this diagnosis (Liptak et al., 2006; Shimabukuro et al., 2008) and have more difficulty tolerating procedures due to rigid behaviors, sensory seeking behaviors, and difficulty coping with change (Davignon et al., 2014). Vital signs (e.g., height, weight, HR, BP) are routinely collected across healthcare settings to provide essential information for care. When vitals are missed, there may be significant implications for the timeliness, quality, and safety of care provided. Little is known about how children with ASD tolerate these exams and to what extent vital signs are missed or delayed.
Objectives: We aimed to determine (1) the likelihood that patients with ASD are unable to complete vital signs exams and (2) the frequency and severity of distress behaviors in those who are able to complete the procedure. To explore if distress behaviors were specific to ASD we utilized a comparison group of patients with other developmental/neurological diagnoses.

Methods: Participants included 56 patients with ASD and 45 without ASD (ages 4-17) who presented for routine care in the neurology and developmental medicine outpatient clinics. We included equal numbers of children with and without intellectual disabilities in each group. An adapted version of the Brief Behavioral Distress Scale (BBDS; Tucker et al., 2001) was administered to measure the frequency and severity of distress behaviors during vital signs collection. Interrater reliability on the BBDS was established utilizing a separate cohort of patients recruited from the neurology outpatient clinic. BBDS scores for each procedural step were calculated and total BBDS score was computed. Total time to completion was recorded and it was also noted when patients could not complete the procedure.

Results: There were no significant differences in baseline characteristics when comparing the two groups (Table 1). Total BBDS scores were significantly higher for patients with ASD than for patients without ASD, after controlling for baseline characteristics ($F(8,91)=6.63$, $p<0.001$). Additionally, age and intellectual disability were unique predictors of higher total BBDS scores in the ASD group ($p<0.001$). The average time required to complete vital signs was significantly longer for the ASD group compared to the non-ASD group (4.9 vs. 3.5 minutes; $p<0.001$). Children with ASD were also found to be twice as likely to be unable to complete vital signs compared to children without ASD.

Conclusions: Patients with ASD exhibited significantly more behavioral distress during the vital signs exam compared to patients without ASD. Additionally, children with ASD had significantly longer exams and were more likely to miss the exam altogether. To our knowledge, this is the first study to demonstrate that children with ASD have difficulty tolerating one of the most routine and important procedures in healthcare, the vital signs exam. These findings highlight the need for additional behavioral supports to improve patient experience as well as the quality and efficiency of patient care for children with ASD.

139 **140.139** An Examination of Life Satisfaction of Caregivers and Typically Developing Siblings of Children with Autism Spectrum Disorder

K. K. Baker[1], *T. Tomeny*[2], *S. W. Eldred*[3], *C. A. Paisley*[2] *and J. A. Rankin*[2], *(1)University of Alabama, Tuscaloosa, AL, (2)The University of Alabama, Tuscaloosa, AL, (3)Department of Psychology, University of Alabama, Tuscaloosa, AL*

Background:
Having a child with ASD can present unique challenges for other family members. Research on parents of children with ASD has found increased risk of negative outcomes associated with parenting a child with ASD, including heightened parental stress (e.g., Dabrowska & Pisula, 2010) and depression and anxiety (e.g., Sharpley et al. 1997). With respect to outcomes for typically-developing (TD) siblings of children with ASD, results are mixed (e.g., Meaden et al., 2010). Recently, research has begun to also focus on more positive outcomes for parents of children with ASD, such as life satisfaction (e.g., Ekas & Whitman, 2010). Given that life satisfaction and subjective well-being have been shown to be positively related to better health outcomes (Diener et al., 2017), further examining correlates of these positive outcomes is particularly important for family members of children with ASD.

Objectives:

The present study sought to 1) explore life satisfaction in caregivers and TD siblings of children with ASD, 2) examine relations between symptom severity of the child with ASD and life satisfaction of caregivers and TD siblings, and 3) examine relations between parental distress and life satisfaction of TD siblings.

Methods:

Participants included 106 families of children with ASD ages 3 to 17 years (M = 11.47, SD = 4.00), with at least a primary caregiver (M = 41.40, SD = 5.12) and a TD sibling (ages 11 to 17 years; M = 13.76, SD = 1.91) serving as respondents. Of these 106 families, 68 families had a secondary caregiver (M = 42.87, SD = 6.91) who also participated. Caregivers completed measures to assess ASD symptom severity in their children with ASD, a self-report measure of overall distress, and a self-report measure of overall life satisfaction. TD siblings completed a self-report measure of their emotional/behavioral difficulties and a self-report measure of life satisfaction.

Results:

Regarding life satisfaction, for both primary and secondary caregivers rated their average life satisfaction rating fell in the “slightly satisfied” range. Results indicated no significant relation between autism symptom severity in children with ASD and life satisfaction for primary caregivers (r = -.12, p = .230) or secondary caregivers (r = -.09, p = .468). TD siblings’ average life satisfaction rating fell in the “mostly satisfied” range, almost reaching the “pleased” range. Again, results revealed no significant correlation between autism symptoms severity in children with ASD and life satisfaction for TD siblings (r = -.14, p = .144). Results also indicated no significant association between primary caregivers’ distress and TD siblings’ life satisfaction (r = -.16, p = .106).

Conclusions:

In general, caregivers and TD siblings in the current sample reported relatively high levels of life satisfaction. Moreover, their overall life satisfaction was unrelated to autism symptom severity of their family member with ASD. This study highlights that family members seem to be displaying resiliency regardless of the level of autism symptom severity. Additionally, the present study emphasizes the importance of researchers continuing to explore positive outcomes for family members of children with ASD.

140 **140.140** Aspirations and Needs for Successful Post-Secondary Transitions: Stakeholder Voices

ABSTRACT WITHDRAWN

Background:
ASD is a lifelong disorder requiring continual services and supports to ensure success. Despite the best efforts of special education, the outcomes for individuals with ASD after high school are bleak. Of particular concern is a sub-group of adolescents with high-functioning autism (HFA). Although these individuals have the potential to fully participate in mainstream community activities, outcomes for many adults with HFA are surprisingly poor in the areas of secondary education, employment, independent living, and social participation. These individuals are three times more likely to have no daytime activity compared to adults with an intellectual disability (Taylor & Seltzer, 2011). The transition process is a time of great opportunity and risk for these adolescents and their families. Without adequate supports, families lack awareness of and access to services *and* adolescents often do not achieve their full potential.

Objectives:

Adolescents' and parents': (a) goals and aspirations for adult life; (b) views of transition areas they feel most and least prepared for; and (c) views of needed services and supports to support the transition to adult life will be identified.

Methods:

Parents and adolescents (ages 13-18) participated in separate focus groups. Parents completed the Social Responsiveness Scale Version 2 (Constantino & Gruber, 2012) to document their child's functioning level. In the focus groups, 36 parents and 26 adolescents (ages 13-17) from both rural and urban areas were asked about their goals after high school, and the services and supports they have used *and* need to facilitate a successful transition to adulthood. Using a card sort activity, participants provided information about transition areas for which they felt most and least prepared. Focus groups were audio taped and transcribed verbatim. A constant comparative method and consensus coding process were used to validate the major themes highlighted by parents and adolescents.

Results:

The parents were generally positive about their youth, highlighting strengths while acknowledging their individual challenges. While the adolescents had aspirations for independence, they expressed concerns regarding future employment, education, and relationships. Interestingly, parents and adolescents' views were often similar but different in subtle ways. The similarities and differences will be described in terms of goals for adult life, concerns regarding independence, and perceived needs for services and supports. Parents' goals focused on successful employment and independent living whereas adolescent goals related to employment focused on their specific interests such as computers or fantasy novels. While parents' major concerns related to social interaction (e.g., having friends to do things with), getting a job, and living independently, adolescents' major concerns related to being financially secure, and having a safe place to live and the social skills needed to maintain employment. Both parents and adolescents identified needs for continued supports.

Conclusions:

The adolescent and family perspectives indicated a need for capacity building supports tailored to *what really matters* to stakeholders for achieving successful adult outcomes. Those supports include social support for the adolescent and family, accessible and useble information about the adult service system, and continued professional supports according to adolescent's individualized needs.

141 **140.141** Autistic Traits in Transgender Youth: Dysphoria, Stigma, and Barriers to Care

E. Sadikova[1], *A. Verbalis*[1], *M. Mohajerin*[2] *and J. F. Strang*[3], *(1)Children's National Health System, Washington, DC, (2)Children's National Healthy System, Washington, DC, (3)Center for Autism Spectrum Disorders, Children's National Health System, Washington, DC*

Background: There is an apparent over-occurrence of Autism Spectrum Disorder (ASD) and Gender Dysphoria (GD; e.g., de Vries et al., 2010; Strang et al., 2018[a]). In qualitative interview, youth with the co-occurrence describe challenges related to being both autistic and transgender, as well as experiences of having their gender dysphoria questioned (e.g., providers and family members dismissing their experience as a symptom of ASD; Strang et al., 2018[b]).

Objectives: Examine the relationship between ASD traits (as reported by parent and self) and: self-reported intensity of gender dysphoria, LGBTQ-related stigma, and specific perceived barriers to obtaining gender care.

Methods: Thirty-nine transgender youth, age 13-21 years, were recruited across the neurodiversity spectrum: transgender youth with confirmed ASD diagnoses (N=16); transgender youth with suspected, but unconfirmed ASD or autistic traits (N=10); and transgender allistic (i.e., non-autistic) youth (N=13). Measures of autistic traits were given: parent-reported Social Responsiveness Scale-2 (SRS-2; Constantino et al., 2012) and self-reported Broader Autism Phenotype Questionnaire (Hurley et al., 2007). Youth participants completed the Utrecht Gender Dysphoria Scale (UGDS; Cohen-Kettenis & van Goozen, 1997) and the LGBT Stigma Scale (Weinhardt et al., 2017, Logie & Earnshaw, 2015). Youth also answered questions regarding gender affirmation barriers including barriers related to executive function, and barriers related to social anxiety/reactions of others. Spearman correlation analyses were conducted to examine the relationship between ASD traits and GD intensity, barriers and stigma. FDR corrections for multiple comparisons were applied.

Results: Positive correlations were observed between gender goal barriers related to executive function and both SRS-2 and self-reported BAPQ scores (r=.463(p=.012) and r=.434(p=0.012) respectively). No significant correlations were found between ASD trait measures and the UGDS (intensity of gender dysphoria), the LGBT stigma scale, or other barriers.

Conclusions: Results suggest transgender people with increased autistic traits may require additional levels of executive function support to help them meet their gender related needs and goals. The lack of relationships between level of autistic traits and experienced gender dysphoria provides further evidence that gender diversity experiences of transgender autistic individuals are similar to those of transgender people in general.

142 **140.142** Barriers to Healthcare in an Insured Latino Population with ASD

M. L. Massolo, *N. P. Gordon, H. J. Cerros, C. K. Yoshida and L. A. Croen, Division of Research, Kaiser Permanente, Oakland, CA*

Background:
In the United States, ethnic minorities are more likely to receive inferior mental health care than Whites. The disparity extends to autism spectrum disorders (ASD) where Latino children experience critical delays in diagnosis and treatment. These health care disparities are partially

explained by structural barriers, such as lack of insurance, or limited availability of services. However, even when controlling for structural factors, ethnic minorities underutilize available health care services. This exploratory study will identify barriers to accessing resources and recommended assessment, diagnostic, and treatment services for ASD among Latino children receiving healthcare at Kaiser Permanente Northern California (KPNC).

Objectives:

To describe how socioeconomic and language factors affect access to healthcare resources and utilization of behavioral and mental health services among Latino children with ASD across target subgroups defined by insurance type (Commercial vs. Medicaid) and primary language (English vs. Spanish).

Methods:

We identified all Latino children with ASD among the membership of KPNC (N=3263). English and Spanish survey materials were mailed to 1164 parents in the 4 target subgroups with the goal of obtaining 100 completed surveys per subgroup. Three weeks after the initial mailing, we called non-responders to invite them to complete the survey by phone. The survey covered parental access to information about ASD services and resources, barriers to use of ASD services (e.g., cost, lack of awareness, logistics, language barriers), parent literacy and health literacy, and social determinants of health and healthcare access (e.g., food insecurity, trouble paying for different basic necessities, transportation difficulties, social support). Data collection began in 2018 and is ongoing. Differences by language and insurance type were examined for the first 50 completed surveys in each subgroup (total N=200).

Results:

Significant differences by language were seen regarding low educational attainment (76% of Spanish vs, 19% of English speakers had no education beyond high school and 36% vs. 3%, respectively, had not completed high school), health literacy (34% of Spanish vs. 3% of English speakers lacked confidence filling out health related forms by themselves), receiving unpaid help with their child from friends/family (71% of Spanish vs. 44% of English speakers), never or rarely getting enough social and emotional support (52% of Spanish vs. 38% of English speakers), and use of the patient portal to communicate with their child's clinical care team (18% of Spanish vs. 75% of English speakers). Significant differences by insurance type were seen for household income < $35,000 (48% of Medicaid vs. 11% of Commercial), trouble paying for housing (18% of Medicaid vs. 8% of Commercial), and trouble paying for ASD services (7% of Medicaid vs. 35% of Commercial). Approximately 1/3 of the sample was food insecure, with notable differences in prevalence between English-speaking Commercial (16%) and English-speaking Medicaid (50%).

Conclusions:

Preliminary results indicate that in this population of insured Latino children with ASD, family social and economic risk factors such as low income, low health literacy, and lack of social support may limit parents' ability to utilize developmental evaluations and specialty ASD care for their children.

143 **140.143** Caregiver Perspectives on Treatment for Challenging Behaviors in School-Age Children with Autism Spectrum Disorder

J. E. Tschida[1], *J. R. Bertollo*[1,2], *E. S. Kuschner*[3], *B. B. Maddox*[1], *J. S. Miller*[4] *and B. E. Yerys*[1], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Virginia Polytechnic Institute & State University, Blacksburg, VA, (3)Children's Hospital of Philadelphia, Philadelphia, PA, (4)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Children with autism spectrum disorder (ASD) are at risk for challenging behaviors, including aggression, oppositional behaviors, and tantrums or meltdowns. Despite the effectiveness of pharmacological and behavioral interventions for challenging behaviors in a considerable number of children with ASD, there is little information on stakeholder perspectives about the available treatments. Increasing knowledge about stakeholder perspectives may help providers better understand preferred approaches within the ASD community and support greater treatment acceptability and compliance.

Objectives: To characterize caregiver perspectives on challenging behavior treatment for school-age children with ASD.

Methods: A survey about challenging behavior treatment use was sent to an autism research center mailing list of ~10,000 individuals. 346 caregivers of children with ASD aged 7 to 17 years who had undergone treatment to address challenging behaviors completed the survey. Kruskal-Wallis rank-sum tests and subsequent pairwise comparisons using a Wilcoxon rank-sum test with False-Discovery Rate-adjusted p-values ($q<0.05$) were conducted for caregiver ratings of treatment satisfaction, helpfulness, and amount of improvement maintained over time. Analyses were completed separately for children with a caregiver reported IQ≥70 and children with a caregiver reported IQ<70.

Results: Caregivers reported attempting distraction (n=214), identifying triggers and using reward systems not as part of an ABA program (hereinafter, "triggers/rewards") (n=211), medications (n=208), Applied Behavior Analysis (ABA) (n=187), Collaborative Problem Solving (CPS) (n=101), Zones of Regulation (ZOR) (n=67), Parent-Child Interaction Therapy (PCIT) (n=42), and Unstuck and On Target (UOT) (n=19). For children with an IQ≥70, the omnibus test was significant for caregiver ratings of treatment satisfaction ($\chi^2(8)=16.147$, $q=0.040$); pairwise tests revealed no significant differences among treatments. The omnibus test was also significant for caregiver ratings of treatment helpfulness ($\chi^2(8)=38.065$, $q<0.001$) with medications rated significantly more helpful than PCIT, ABA, distraction, triggers/rewards, and ZOR; and CPS more than triggers/rewards. The omnibus test was significant for caregiver ratings of amount of improvement maintained over time ($\chi^2(8)=45.56$, $q<0.001$) with medications rated significantly higher than PCIT, ABA, distraction, triggers/rewards, and ZOR; CPS higher than PCIT, distraction, triggers/rewards, and ZOR; and ABA higher than triggers/rewards. For children with an IQ<70, the omnibus test was significant for caregiver ratings of treatment helpfulness ($\chi^2(8)=19.845$, $q=0.011$); pairwise tests revealed no significant differences between treatments. The omnibus test was not significant for caregiver ratings of treatment satisfaction ($\chi^2(8)=13.811$, $q=0.087$), or amount of improvement maintained over time ($\chi^2(8)=5.709$, $q=0.680$).

Conclusions: This is one of the first studies to examine caregiver perspectives on treatments for challenging behaviors in school-age children with ASD. For children with an IQ<70, there were no significant differences among caregiver ratings of treatment types. However, for children with an IQ≥70, medications, Applied Behavior Analysis (ABA), and Collaborative Problem Solving (CPS) received significantly higher caregiver ratings than other treatments. While medications and ABA treatments are standard-of-care interventions, CPS is an evidence-based treatment for targeting challenging behaviors in Oppositional Defiant Disorder that relatively few caregivers in our study have tried with their children. CPS may be a preferred and efficacious treatment option that is underutilized for a subgroup of children with ASD and challenging behaviors.

144 **140.144** Caregiver-Reported Use of Autism-Related Services in the Dallas-Fort Worth Metroplex and Associated Satisfaction

Ratings

***A. Ganesh**, S. Mupparapu and H. L. Miller, University of North Texas Health Science Center, Fort Worth, TX*

Background:

The prevalence of Autism Spectrum Disorder (ASD) has risen rapidly to 1 in every 59 children. Being one of the fastest growing developmental disorders, the need for services outpaces availability for individuals with ASD. Texas is ranked 50th (out of the 51 states included) in providing community-based services for people with developmental disabilities. In order to make community- and state-level policy recommendations to address this issue, it is important to understand the specific landscape of met and unmet needs of individuals with ASD. By identifying gaps in service availability and use of services, policymakers, healthcare providers, and community advocates will be better equipped to design programs that facilitate access to appropriate and timely interventions.

Objectives:

We aimed to identify patterns of service utilization among individuals with ASD and their families in the Dallas/Fort Worth (DFW) area, a large population center in northeast Texas. We predicted that service navigation and financial burden would be among the most difficult challenges caregivers faced.

Methods:

We conducted a cross-sectional study to assess the services used by individuals with ASD in the DFW area, and satisfaction with these services. We created the Autism Service Utilization and Satisfaction survey by combining new items with adaptations of two existing instruments, the Pathways in ASD and the Community Services Outcomes for Families and Children with ASD. The survey was delivered to caregivers of individuals with ASD and adult self-advocates with ASD using REDCap, an online secure project management service. The survey captured family demographics, services utilized (e.g., type, setting), and associated satisfaction. Preliminary analysis included 26 caregiver respondents; demographics are presented in Table 1.

Results:

Preliminary qualitative analysis revealed several notable trends in caregivers' self-reports of the most challenging issues they faced after a diagnosis was made. Caregivers reported difficulty navigating services: 47% struggled to find the appropriate services for their child, 29% did not know where to start, and 24% had difficulty scheduling and maintaining appointments with providers. Overall, 29% reported that affording services and qualifying for help was one of their three most challenging issues. Additionally, 82% of caregivers affirmed that they identified a resource but could not pay for it, 67% were satisfied with the diagnostic services provided by their school district, and 71% were satisfied with education programs meeting the recipient's behavioral and emotional needs. Finally, 88% either disagreed or were neutral about overall satisfaction with available services and providers.

Conclusions:

Preliminary examination of responses suggests that caregivers in the DFW area have difficulty navigating their child's diagnosis and case management. Participants confirmed our hypothesis that they were satisfied with the diagnostic and educational services the school provided; however, they had trouble paying for the services and qualifying for help through insurance and other means. This further emphasizes the importance of identifying resources that families are using, and where the gaps lie in their access to these resources. Data collection is ongoing through partnership with clinics, schools, and community organizations in Dallas-Fort Worth.

145 **140.145** Change in the Use of Request Strategies over Time in Parents of Toddlers with ASD

***A. M. Dimachkie**[1], N. Libster[2], J. Yang[3], A. Gulsrud[4] and C. Kasari[5], (1)Human Development and Psychology, UCLA, Los Angeles, CA, (2)UCLA Center for Autism Research and Treatment, Los Angeles, CA, (3)Department of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA, (4)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (5)University of California, Los Angeles, Los Angeles, CA*

Background:

Compliance to parental requests is considered a developmental hallmark in early childhood, and is related to a range of positive outcomes for children with and without developmental disabilities (Kuczynski & Kochanska, 1990). The way parents communicate with their children plays an important role in eliciting their compliance (Radley & Dart, (2016). Various child factors may contribute to how parents communicate with their children, namely children's maladaptive behavior (Ostfeld-Etzion et al., 2016). It is important to understand how these factors may change how parents communicate with their children over time.

Objectives:

This study aims to explore predictors of change in parental request strategies over time.

Methods:

Participants were part of a randomized efficacy trial of a parent-mediated social communication intervention (JASPER; Kasari et al., 2015). 86 toddlers with ASD (CA = 24 - 36 months) and their primary caregivers completed a video-taped clean-up task at entry and, 10 weeks later, at exit. Parents were also asked to complete the Infant Toddler Social Emotional Assessment (ITSEA; Briggs-Gowan & Carter, 2000), a measure of children's maladaptive behavior. Parent's use of request strategies during the task was coded in 10-second intervals to include 6 types of requests: Unclear command, direct command, indirect command, reprimand, positive incentive and reasoning. Proportions of each request strategy used during the task was calculated for parents at both time points. Change scores between entry and exit were calculated for the three subdomains of ITSEA - internalization, externalization and dysregulation - and the proportion of each request strategy. Paired sample t-tests were conducted to determine that there were no differences between the treatment groups on any of the outcome variables. Separate linear regressions were conducted to predict the 4 most used request strategies: Unclear commands, direct commands, indirect commands and reprimands. Change scores for each ITSEA subdomain were entered as predictors, and the regression model controlled for treatment group assignment.

Results:

At entry parents used, on average, 0.05 unclear commands, 0.45 direct commands, 0.26 indirect commands, and 0.05 reprimands per interval. At exit, parents used, on average, 0.07 unclear commands, 0.32 direct commands, 0.32 indirect commands, and 0.10 reprimands per interval. Linear regressions predicting the change in the proportion of each strategy used, controlling for treatment group, revealed that change in ITSEA

dysregulation (b = -0.243, p < 0.01), ITSEA internalizing (b = 0.181, p < 0.05) and ITSEA externalizing (b = 0.172, p < 0.05) scores predicted change in the proportion of unclear commands used by parents. Only change in ITSEA dysregulation scores (b = 0.420, p < 0.05) predicted change in the proportion of indirect commands. The regressions predicting change in direct commands and reprimands did not emerge as significant.

Conclusions:

Children's internalizing, externalizing and dysregulation, as reported by parents, emerged as a significant predictor of change in parental request strategy use over time. This emphasizes the transactional nature of parent-child interactions, and indicates the need for parent education curriculums that teach parents how to address maladaptive behaviors and optimize communication with their children with ASD.

146 **140.146** Changes in Autism Nosology: Stigma, Knowledge, Contact, and the Removal of Asperger's Syndrome from the DSM-5.

L. A. Katz[1], *K. Nayar*[2], *C. Schieszler-Ockrassa*[1], *A. Garagozzo*[1] *and J. Paxton*[1], *(1)Psychology, Roosevelt University, Chicago, IL, (2)Feinberg School of Medicine, Department of Psychiatry and Behavioral Sciences, Northwestern University, Evanston, IL*

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder diagnosed in one in every 59 eight-year-olds (CDC, 2014). Further insights into the heterogeneous nature of ASD have contributed to the revised diagnostic criteria. Research has documented evidence to classify the disorder as a spectrum with severity ranges (Lord & Jones, 2012; *DSM-5,* American Psychiatric Association, 2013) instead of a categorical system comprising Pervasive Developmental Disorder—Not Otherwise Specified, Asperger's Syndrome, and Autistic Disorder (*DSM-IV-TR*, American Psychiatric Association, 2000). However, classification under an umbrella diagnostic label represents individuals with a wide range of symptoms and may assume homogeneity (Lord & Jones, 2012). This conceptualization can promote stigma and pessimistic attitudes (Corrigan, 2007). Indeed, individuals previously diagnosed with Asperger's Syndrome have raised concerns regarding stigma that may be associated with ASD (Linton et al., 2014).

Objectives: This study examined undergraduate students' perceptions of a label of ASD compared to Asperger's syndrome or no diagnosis. It was hypothesized that participants would associate increased stigma with ASD compared to Asperger's syndrome. Additionally, no diagnostic label would promote greater stigma than assigned diagnostic labels.

Methods: Raters included 71 undergraduate students from Roosevelt University. Participants were randomly assigned to read a vignette adapted from prior research (Ohan et al., 2016) about a student with one of three labels (i.e., ASD, Asperger's Syndrome, No Diagnosis). Participants also completed questionnaires, including an adapted Social Distance Scale (SDS) (Bogardus, 1925), which assessed their comfort level with the individual, the ASK-Q (Harrison et al., 2017), which assessed participants' knowledge of ASD in general, and additional questions regarding level of contact with ASD.

Results: Differences in comfort level ratings between the three conditions were assessed using one-way ANOVAs. Post-hoc comparisons were conducted following significant multivariate differences. Results revealed more positive ratings for the Asperger's compared to the ASD condition on a number of SDS items. Participants rated being more comfortable residing in the same hall as an individual with Asperger's than an individual with ASD (p=.01). When asked about comfort as a child's caretaker, group differences revealed higher ratings for the Asperger's condition compared to the ASD condition (p<.05). No group differences emerged between the Asperger's and ASD groups when asked about going to dinner or a sporting event (ps>.72). Significantly higher positive ratings were associated with both ASD and Asperger's conditions compared to No Diagnosis (ps<.05). All results remained significant when covarying for ASK-Q and contact scores.

Conclusions: Results demonstrate the impact of diagnostic labels in different social contexts, and support the need for education surrounding the change in diagnostic criteria. Having greater responsibility and more prolonged exposure increased stigma in the ASD condition compared to the Asperger's condition. Short-term interactions did not raise the same concerns and were rated similarly between the ASD and Asperger's conditions. Diagnostic ambiguity may result in greater discomfort than concrete diagnostic labels, suggesting the benefit of obtaining a diagnosis. Additional research on the perception of the ASD label should be conducted to better understand stigma associated with ASD.

147 **140.147** Characterizing Challenging Behaviors in Preschoolers with ASD: Home and School Contexts

L. M. Baczewski[1], *C. K. Toolan*[2], *A. Holbrook*[3], *R. Landa*[4] *and C. Kasari*[2], *(1)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA, (3)University of California Los Angeles, Los Angeles, CA, (4)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD*

Background:

94% of children with ASD exhibit challenging behaviors (CBs; Jang et al., 2010). CBs impact the wellbeing of parents (Davis & Carter, 2008; Hayes & Watson, 2012) and burnout rates in teachers (Hastings & Brown, 2002). A greater understanding of situations in which CBs commonly occur would allow for the development of tailored, situation-specific interventions, helping to reduce parent stress and teacher burnout. However, there is little information on contexts where CBs are most prevalent and most severe from the perspectives of parents and teachers. Additionally, many studies that examine CBs are cross-sectional (Lecavalier et al., 2006), with few examining CBs longitudinally.

Objectives:

1) Determine in which situations parents and teachers: a) most commonly report child CBs and b) report high severity CBs. 2) Examine change in parent-reported CBs over 12 months.

Methods:

This study used data from a social communication RCT collected across three timepoints (entry, exit, 6-month follow-up). Preschoolers (n=145) using <30 spontaneous words at entry received 6 months of behavioral intervention (JASPER or DTT). At each timepoint parents completed the Home Situations Questionnaire-PDD (HSQ), which assesses behavioral noncompliance in everyday contexts. Parents were asked to report whether their child exhibits CBs across a variety of settings, and if so, how severe they perceive those behaviors to be (1=mild to 9=severe). Teachers completed the School Situations Questionnaire (SSQ), which assesses child noncompliance within the school context.

Results:

Across all three timepoints, parents reported that children most frequently displayed CBs while attending group events, playing with other children, transitioning between activities, and being out in public places (Table 1). They reported that the most severe CBs occurred when children

were taken to appointments, attended group events, when repetitive behavior was interrupted, and when out in public places (Table 1).

Across all timepoints, teachers most commonly endorsed that students displayed CBs during small group activities, individual desk work, and during lessons (Table 2). Teachers reported most severe CBs across timepoints were while on field trips, during small group activities, and during lessons (Table 2).

Linear mixed models were used to investigate change in parent-reported CBs over time (entry, exit, follow-up). Analyses controlled for treatment group, ADOS total score, chronological age, and Mullen visual reception scores. The treatment x time interaction was not significant and was removed from subsequent analyses. HSQ severity differed significantly from entry to exit (B=-.32, p=.014), but not from entry to follow-up.

Conclusions:

These results provide rationale for targeting of CBs in behavioral interventions for preschoolers with ASD, illustrating in which situations parents and teachers may benefit from supports. Parents most commonly endorsed severe CBs during routine changes and in social situations, while teachers reported that CBs occurred during lesson times. Parents and teachers may benefit from training in managing CBs around these specific situations.

Results also indicate that CBs reduce over time with intervention, but the reduction is not maintained. This finding suggests that parents may benefit from intervention booster sessions once social communication interventions have ended to help maintain the reduction in CB severity.

148 **140.148** Community Engagement in Deafness and Autism Research: Organizer Experiences

I. M. Eigsti[1], *M. Coppola*[1], *K. Coulter*[1], *B. Lory Hector*[2], *J. Henner*[3], *E. G. Keenan*[4], *M. D. Lerner*[5], *K. Porto*[1] *and R. J. Steiner*[1], *(1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Center for Neurodiversity, Denver, CO, (3)Univ of North Carolina-Greensboro, Greensboro, NC, (4)Human Development & Psychology, University of California, Los Angeles, Los Angeles, CA, (5)Psychology, Stony Brook University, Stony Brook, NY*

Background: Research with marginalized groups increasingly aims to include representatives from the groups studied not just as data-generators, but as key contributors in developing and executing the research. The scientific community is shifting in kind: 1) with improvements in access to education, researchers who study neurodiverse populations are more often themselves members of those communities; 2) an understanding that research should respect the needs of stakeholders; 3) a recognition that research requires extensive community collaboration. Certainly, the process of scientific inquiry requires training and expertise; but what is the role of researchers who are *not* members of the community they research? Community engagement is particularly complex when the very nature of human interaction is under investigation, with studies involving consent and the emergence and use of conventional communication skills.

Scientific research with deaf people and autistic people (and people who are both deaf and autistic) exemplifies the challenge of navigating community, culture, and marginalization. Over the past sixty years, research on Deafness has led to watershed advances in our understanding of the fundamental building blocks of human language. Deaf researchers have made strides in persuading the scientific community to jettison the "medical model" in which deafness was construed as something that needed to be *fixed* rather than accepted as part of the diverse spectrum of humanity. These changes came about primarily because non-researcher and researcher members of the Deaf community were engaged as partners in the research enterprise.

Objectives: To present lessons learned from a 2018 workshop.

Methods: Drawing on our collective expertise (personal and scientific), and on the experiences of autism community organizations (e.g., ASAN), a team of scientist and non-scientist Deaf, Autistic, and neurotypical (i.e., individuals who are not autistic) people gathered in October, 2018 to discuss the challenges of engaging non-scientist Deaf and autistic communities in research. Steve Silberman, author of *Neurotribes*, was an invited speaker. Facilitated discussions and shared meals created spaces for exchanging ideas. The planning process was itself challenging, as Organizing Committee members struggled with difficulties in communication, differing expectations about how to accommodate individual needs, and with shifting and differing goals.

Results: Important similarities and differences characterize the Deaf and Autistic communities, including questions about who speaks for the community, the importance of labels, and the utility of community members raising their voices to affect public policy. We also learned firsthand that Deaf individuals *with autism* are grossly underserved; the rapidly growing number of Deaf autistic individuals in the US have very limited access to services, research, and a community.

Conclusions: Given that many others may wish to include non-scientist community members in a group enterprise, we share the collective wisdom that our group takes away from this meeting. While many others have engaged in a similar process, the historical and experiential parallels between the Deaf and Autistic communities provide a unique foundation for improving on the process; with others, we will build on this momentum in planning future meetings.

149 **140.149** Community-Partnered Participatory Research in Autism: Engaging Underresourced African American, Korean and Latino Communities

H. S. Lee[1], *F. Jones*[2], *F. A. Castellon*[1], *J. Smith*[1], *A. Lucas-Wright*[2,3], *S. Kataoka*[4], *I. A. Channa*[1] *and C. Kasari*[1], *(1)University of California, Los Angeles, Los Angeles, CA, (2)Healthy African American Families, Los Angeles, CA, (3)Charles R. Drew University of Medicine and Science, Los Angeles, CA, (4)Psychiatry, University of California, Los Angeles, Los Angeles, CA*

Background: Despite the advancement in ASD research, engaging underresourced minorities remains a challenge. In addition to financial barriers, cultural factors contribute to these families' low research participation. For example, many African Americans (AA) who have experienced history of research abuse distrust research; Korean Americans, the majority of whom are first-generation immigrants, are excluded from most ASD studies due to language barriers. Community members who understand cultural barriers can help motivate families to participate in research. In community-partnered participatory research (CPPR), community members share power equally with academic partners in all research phases and ensure research prioritizes community needs. CPPR utilizes community engagement conferences to educate the community and build research-community trust. CPPR conferences have shown success in engaging underresourced communities in other disciplines, but have not been examined in ASD.

Objectives: The goal of the study was to examine whether a CPPR conference can engage underresourced AA, Korean, and Latino communities and

increase attendees' perceived ASD knowledge and trust toward research.

Methods: The conference, held in a Los Angeles church for four consecutive years, was part of the AIR-B III Network's larger CPPR study. Academic and community partners met monthly to plan the conference and multicultural staff reached out to diverse communities. Conference attendees were verbally consented to participate in demographic, perceived ASD knowledge and research trust, and conference evaluation surveys. English, Korean, and Spanish materials and simultaneous interpretation were provided. Community and academic partners co-led conference sessions, directed attendees and collected data together.

Results: Excluding staff (>50), 153 participants attended. More than half (51%) were caregivers of individuals with ASD, with 21% earning $9,999 or less annually. Races included Latino (49%), Asian (24%), AA (18%) and others (8%); 39% reported their primary language as non-English (Table 1). Bonferroni-adjusted repeated measures t-tests were conducted to examine score changes on the 15-item perceived ASD knowledge and research trust survey pre- and post-conference. Attendees showed increases in perceived knowledge in core deficits of ASD ($t(94)=3.04$, $p=.003$)), finding effective therapies ($t(94)=5.19$, $p<.001$)), and trust in community agencies ($t(94)=3.50$, $p=.001$)) and ASD research ($t(93)=5.21$, $p<.001$)) (Table 2). Analyses by race also revealed Latinos' increased understanding of research participants' rights. However, AA showed no change in any items, in part due to their higher baseline scores; Asians showed an increase in perceived knowledge in core deficits of ASD only. No decreases in scores were found. Attendees agreed that the conference increased their knowledge about autism and services (99%), advocating for individuals with autism (98%), transitions (100%), and that the conference helped them make new connections (99%). AA and Latinos rated the conference higher than Asians.

Conclusions: The CPPR conference successfully engaged diverse underresourced communities, increased attendees' perceived ASD knowledge and research trust, and was highly rated. Findings highlighted the need for culturally-tailored information; the conference's impact and ratings differed by race. Each group's baseline knowledge, culture-specific attitudes, and native language likely contributed to differential results. Future research should consider incorporating culturally-adapted contents in CPPR conferences and examine research-community partnerships' long-term impact on the autism community.

150 **140.150** Comparison of Parental Stress, Parental Efficacy, and Child Problem Behavior between ASD and Non-ASD Youth: A Multi-Group Confirmatory Factor Analysis

K. Pedersen[1,2], *B. J. Taylor*[3], *M. Siegel*[4], *S. L. Santangelo*[5] *and W. L. Cook*[6], *(1)Department of Psychiatry, Maine Medical Center, Portland, ME, (2)Department of Medicine, Tufts University School of Medicine, Boston, MA, (3)Psychiatry, Maine Medical Center Research Institute, Portland, ME, (4)Maine Medical Center - Tufts School of Medicine, Westbrook, ME, (5)Psychiatry, Maine Medical Center and Tufts University School of Medicine, Portland, ME, (6)Dyadic Data Consulting, Portland, ME*

Background: Several studies have examined the role of parental stress and child outcomes in autism spectrum disorder (ASD). However there is little research examining positive parental characteristics, such as self-efficacy, that may reduce the impact of stress in families with a child with ASD. Whether the relationships between parental stress, parental self-efficacy, and child problem behavior outcomes have the same measurement characteristics across groups (ASD/non-ASD), known as measurement invariance, is also unclear.
Objectives: To examine the relationships between parental stress, parental self-efficacy, and child problem behavior using confirmatory factor analysis (CFA). To examine differences in the measurement of these latent variables between ASD and non-ASD samples.

Methods: Participants were 1035 hospitalized children and adolescents, 937 with an Autism Diagnostic Observation Schedule-2 (ADOS-2) confirmed ASD diagnosis, and 98 participants with non-ASD developmental delay, admitted to one of six specialized inpatient psychiatry units and prospectively enrolled in the Autism Inpatient Collection (AIC) study. Parents completed the Aberrant Behavior Checklist Irritability (ABC-I) subscale, Parent Stress Index Short Form (PSI-SF-4) and Difficult Behavior Self-efficacy Scale (DBSS) at admission. The measurement model contained three latent variables – parental stress, parental self-efficacy, and child problem behavior – which were measured using observed variables of each as indicators (see Figure 1). A multi-group CFA was conducted using AMOS version 25.

Results: Individual model results indicated the three latent variables were significantly correlated with each other in a manner that supported the validity of each for the ASD sample only: parental efficacy was negatively correlated with both parental stress and child problem behavior and parental stress was positively correlated with child problem behavior (all p-values ≤ .001). In the non-ASD sample, only parental stress and child problem behavior were positively correlated with each other (p ≤ .001). Group differences were also found among the observed variables used as indicators to measure the child problem behavior latent variable. Specifically, self-injurious behavior items did not contribute to the measurement of child problem behaviors in the non-ASD sample, β= 0.104, p=0.25. Multi-group CFA results indicated differences between group correlations ($\chi^2 = 57.5$, $df = 13$, $p = 0.001$) and means of the observed variables ($\chi^2 = 44.5$, $df = 7$, $p = 0.001$) between ASD/non-ASD groups, however we did not find differences between group factor loadings, that is, how well the observed variables measured the underlying latent variable.

Conclusions: Relationships between parental stress, parental self-efficacy, and child problem behaviors differed between parents of children with ASD compared to those without. Measurement invariance was not found across groups. By applying CFA we're able to obtain more reliable measures of the underlying constructs of parental stress, parental self-efficacy, and child problem behaviors and the correlations between them. Of clinical importance, while parental stress is correlated with child problem behaviors in both samples, self-efficacy in parents of children with ASD may be a positive characteristic for reducing both parental stress and child problem behavior. Interventions targeting parental self-efficacy could be a novel treatment target with downstream effects on both members of the parent-child dyad.

151 **140.151** Comparison of Parenting Stress, Efficacy, and the Home Environment Among Families of Youth with ASD, ADHD, and ASD with ADHD Features

H. K. Schiltz[1], *K. Gonring*[1], *A. J. McVey*[1], *A. D. Haendel*[2], *S. Pleiss*[3], *K. Willar*[4], *A. Gerdes*[1] *and A. V. Van Hecke*[5], *(1)Marquette University, Milwaukee, WI, (2)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (3)Great Lakes Neurobehavioral Center, Edina, MN, (4)Stanford University, Stanford, CA, (5)Psychology, Marquette University, Milwaukee, WI*

Background: Given the persistent and pervasive nature of Autism Spectrum Disorder (ASD) and Attention Deficit Hyperactivity Disorder (ADHD), difficulties often extend beyond the child resulting in challenges regarding parental and family functioning. Parents of youth with ASD or ADHD commonly report heightened parenting stress, decreased parental efficacy, and disruption in the home environment (e.g., Hayes & Watson, 2013;

Theule, Wiener, Tannock, & Jenkins, 2013).

Objectives: While many studies have compared experiences of parents of youth with ASD or ADHD to parents of typically developing children, a paucity of research has explored differences in parenting and household experiences between families of youth with ASD, ADHD, and those presenting with symptoms of both disorders. Therefore, the present study aimed to begin to address this gap in the literature.

Methods: 124 youth were included in the current analyses; subgroups reflect ASD alone (ASD- n= 76), ADHD alone (ADHD- n= 29) and ASD with clinical levels of ADHD via the Child Behavior Checklist (ASD+ n= 19). Adolescents presented for participation in the PEERS® intervention; data collected prior to the intervention is used here. Presence of ASD was confirmed with the ADOS-G (Lord et al., 2000), and a composite IQ greater than or equal to 70 was required for the ASD participants (KBIT-2; Kaufman & Kaufman, 2004). Youth presenting for ADHD provided documentation of an established diagnosis and demonstrated clinically-significant ADHD symptoms on the Disruptive Behavior Disorder scale (DBD; Pelham, Gnagy, Greenslade, & Millich, 1992). Parental and family functioning was assessed using the Stress Index for Parents of Adolescents (Sheras, Abidin, & Konold, 1998), Parent Sense of Competency Scale, Efficacy Subscale (Johnston & Mash, 1989), and the Confusion Hubbub and Order Scale (Matheny, Wachs, Ludwig, & Phillips, 1995).

Results: Results of ANOVA and MANOVA analyses indicated that total parenting stress and subscales of parent-domain stress (restrictions on life and social alienation) were significantly greater in the ASD+ group compared to the ASD- and ADHD- groups (Table 1). Subscales of the adolescent-domain parenting stress (adolescent moodiness, delinquency, and failure to achieve), as well as overall home disruption were significantly greater in the ADHD and ASD+ groups compared to the ASD- group (Table 1). Parental efficacy was marginally greater in the ASD- group compared to the ADHD group (Table 1).

Conclusions: Findings from the present study revealed significant differences in parenting stress and home disruption, but less robust differences in parental efficacy among parents of youth with ASD, ADHD, and ASD with ADHD features. The pattern of differences appears to be driven by either a compounding effect of ADHD and ASD or the presence of ADHD symptoms. The results highlight the importance of screening for comorbidity among these populations as varying neurodevelopmental presentations appear to be associated unique parental and family functioning and, in turn, likely impact treatment recommendations. While a strength of this study is the comparison between multiple clinical groups, lack of a typically developing control sample, small sample sizes, and reliance on parent-report limit the interpretation and generalizability of these findings.

152 **140.152** Cultural Adaptation of an Evidence-Based Social Skills Intervention for Latino Families in the Inland Empire: A Feasibility Study

***E. Veytsman**, A. M. Martin, L. A. Alba, J. Blacher and K. K. Stavropoulos, Graduate School of Education, University of California Riverside, Riverside, CA*

Background:

Obtaining stakeholder feedback when adapting interventions for autism is integral to assure culturally sensitive practices (Hwang, 2009). The Program for the Education and Enrichment of Relational Skills (PEERS), a parent-assisted social skills intervention for adolescents with autism spectrum disorder (ASD), has been found to be effective in eight randomized controlled trials conducted across multiple sites (Laugeson et al., 2009; Laugeson et al., 2012; Schohl et al., 2013; Yoo et al., 2014; Matthews et al., 2018; Jagersma et al., 2018; Shum et al., 2018; Rabin et al., 2018). While PEERS has been adapted for Asian and European populations, most studies on the effectiveness of PEERS in North America have been conducted with primarily Caucasian families of middle to high socioeconomic status. The effectiveness of PEERS for low-income Latino families has yet to be examined. The Inland Empire (I.E.) area of Southern California is an ideal place to expand the PEERS intervention to families who have been historically left out of intervention research. As a first step in the cultural adaptation of PEERS for underrepresented families in the I.E., we obtained parent perspectives on the practicality of the intervention.

Objectives:

The current study examines stakeholder perspectives on the feasibility of the PEERS intervention with primarily low-income Latino families in the I.E.

Methods:

Three 90-minute focus groups were conducted with 19 parents of youth with ASD in the I.E. (Latino=16, Caucasian=3, Spanish-speaking=9, English-speaking=10). Parents were recruited from local school districts, community organizations, parent groups, and flyers posted in the community. Parents completed questionnaires and engaged in a group discussion regarding the feasibility of the PEERS intervention. Our main questions were: 1) Is the original format of the program (weekly 90-minute sessions for 16 weeks) feasible? 2) What is the preferred timing of the program? 3) What are the barriers to participation? Data were analyzed through quantitative (i.e., responses on questionnaires) and qualitative (i.e., group discussion themes) methods.

Results:

The majority of parents reported that the original 16-week format of the program is feasible (*n*=13), while some parents reported that a shorter length of the program would be preferable (*n*=5). Most parents preferred sessions to be on weekdays from 6-8 pm (*n*=15) or on weekends (*n*=10), and fewer parents preferred weekdays from 4-6 pm (*n*=6). The greatest barriers to participation were childcare issues (*n*=7) and work schedules (*n*=5). Other barriers included getting to the groups (*n*=4) and the length of the program (*n*=4). The main theme that emerged from the group discussion was that parents perceive a lack of services and a need for evidence-based interventions for adolescents with ASD in the I.E.

Conclusions:

This preliminary study aimed to increase the accessibility of an evidence-based social skills intervention for underresourced Latino families in the I.E. Overall, results suggest that parents endorse the feasibility of the PEERS intervention and have a desire to participate in it. Implications for decreasing disparity in autism intervention research are discussed.

153 **140.153** Depression, Self-Efficacy, and Family Functioning Reported By Mothers of Children with Autism Spectrum Disorder

***S. Z. Jackson**[1], R. C. Boyd[2,3], J. A. Pinto-Martin[4], J. A. Deatrick[1] and M. C. Souders[5], (1)University of Pennsylvania School of Nursing, Philadelphia, PA, (2)Department of Child and Adolescent Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)Perelman School of Medicine, The*

University of Pennsylvania, Philadelphia, PA, (4)University of Pennsylvania, Philadelphia, PA, (5)University of Pennsylvania/The Children's Hospital of Philadelphia, Philadelphia, PA

Background: Clinically significant depressive symptoms are reported in 30-50% of mothers of children with autism spectrum disorder (ASD), compared to 10% of mothers of typically-developing (TD) children. Improving our understanding of the prevalence and relationship of depressive symptoms to family functioning and child outcomes is needed to support professional practices as well as national and state policy decisions. Understanding the burden of depression requires rigorous study involving validated instruments, large heterogeneous samples, and comparison groups. In other populations, maternal depression is associated with lower family functioning and lower maternal self-efficacy. Evidence exists that maternal self-efficacy mediates the relationship between maternal depression and child behavior. The nuances of the relationships among these variables, however, have not been studied in ASD. Understanding these relationships will help researchers design tailored interventions to improve outcomes in families with a child on the autism spectrum.

Objectives: (1) Compare mean depression score and prevalence of depressive symptoms in mothers of children with ASD to mothers of Down syndrome (DS) children and TD children. (2) Describe the mediating role of maternal self-efficacy in the relationship between depressive symptoms and child behavior, controlling for family functioning.

Methods: Convenience sample of mothers 18 and older living with a biological child under 18, diagnosed with ASD, DS, or TD, completed an online survey with SCQ, ABC, PHQ-9, Family Assessment Device General Functioning Scale, Maternal Self-Efficacy Scale, Demographics.

Results: 245 mothers : 101 ASD, 101 DS, and 43 TD (power=0.8). Mean PHQ-9 score was higher in ASD group compared to DS and TD groups (6.6 vs 4.0 vs 2.0, respectively, $p<0.001$).

Significantly more mothers in ASD group screened positive for depression than the DS and TD groups (23.8% vs. 11.9% vs. 0% respectively, $p<0.001$).

A higher proportion of mothers of children with ASD met cutoff for poor family functioning compared to DS and TD groups (42.6% vs. 19.8% vs. 18.6%, respectively, $p<0.001$). Better family functioning is significantly associated with fewer maternal depressive symptoms ($r=0.408$, $p<0.0001$), better maternal self-efficacy ($r = -0.410$, $p<.0001$), and fewer child problem behaviors of irritability ($r=0.255$, $p<0.0001$), social withdrawal ($r=0.310$, $p<0.0001$), stereotypy ($r=0.236$, $p=0.0002$), hyperactivity ($r=0.217$, $p=0.0006$), and inappropriate speech ($r=0.350$, $p<0.0001$).

Controlling for family functioning, maternal self-efficacy statistically significantly mediated the relationship between maternal depressive symptoms and child behavior. The Sobel test revealed the percent of total effect mediated as follows: irritability (43%, $t=5.72$, $p<0.0001$), social withdrawal (29%, $t= 4.61$, $p<0.0001$), stereotypy (30%, $t= 4.12$, $p<0.0001$), hyperactivity (41%, $t= 5.13$, $p< 0.0001$), and inappropriate speech (43%, $t= 5.72$, $p< 0.0001$).

Conclusions: Significantly higher proportion of mothers of children with ASD screen positive for depression, compared to mothers of children with DS and TD. Associations among depressive symptoms, maternal self-efficacy, and family functioning were found. Parenting self-efficacy partially mediates the relationship between maternal depressive symptoms and child problem behaviors, controlling for family functioning. Interventions that (a) increase parenting self-efficacy and (b) improve how the family unit functions to support the needs of all family members may be helpful in addressing depression in mothers of children with ASD.

154 **140.154** Understanding the Oral Health Beliefs and Experiences in Latino Families of Children with ASD and Typically Developing Children

L. I. Florindez[1]*, D. H. Como*[1]*, D. C. Florindez*[2]*, D. Hudak*[2] *and S. A. Cermak*[3]*, (1)Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)University of Southern California, Los Angeles, CA, (3)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA*

Background:

Oral care is related to overall health and quality of life. Oral health of children is of particular importance because those with early childhood caries are at higher risk for developing gingivitis, periodontal disease, and other adverse health problems as they age. Culturally influenced factors that affect dental care utilization may include behaviors, beliefs, attitudes, and values, such as diet, infant feeding practices, care of primary teeth, concern for oral health, and dental knowledge. Research has shown that Latinos are less likely to believe in the need for regular professional dental care, more likely to have misperceptions about oral health, and less likely to have access to dental care than the general population. Similarly, children with Autism Spectrum Disorder (ASD) have also experienced oral care related disparities regarding access to trained dentists and receiving sub-standard care. To date, minimal research has explored oral health beliefs in Latino families with ASD and typically developing children, and little is known about how these families experience oral care.

Objectives:

Using a qualitative description methodology, this study examined oral health attitudes, beliefs, and practices in Latino families with and without children with Autism Spectrum Disorder (ASD).

Methods:

Participants were 18 English or Spanish-speaking Latino families with children aged between 6 and 12 years. Of the total, eight families had typically developing (TD) children, and 10 families had a child with ASD. The qualitative description approach consisted of conducting one-on-one, semi-structured interviews. Each family participated in three interviews: two caregiver interviews (36 total parent/caregiver interviews), and one child interview (18 total child interviews) for a total of 54 interviews. One of two bilingual study team members, both with extensive interview experience, conducted interviews in either English or Spanish. Parent/caregiver interviews lasted 30-180 minutes, and child interviews lasted 2-20 minutes. All interviews were audio-recorded, transcribed verbatim by a professional service, and translated if necessary. Transcripts were iteratively coded using thematic analysis by two coders, with the research team providing input on the coding scheme in order to reach a final consensus regarding findings.

Results:

Three themes arose from the interviews including *Vulnerability and Mistrust*, *Putting Children First,* and *Acculturation and Cultural Practices*. The Latino families described dissatisfaction with dental treatments and costs. They highlighted fear of the dentist and health care providers, due to their ethnic minority status, as key factors inhibiting receipt of dental care. Additionally, families discussed prioritizing other occupations of daily

living over oral care routines. Finally, they shared cultural influences on oral care habits that were passed on from their varied upbringing.

Conclusions:

These findings contribute to the literature discussing barriers to oral care among underserved Latino families. Understanding the importance of social and cultural influences on patients' health beliefs and behaviors, and considering how these factors interact at multiple levels of the health care delivery system, will assist in devising future interventions. Future programs need to take these issues into account to assure quality health care delivery to diverse patient populations

155 **140.155** Provider Feedback on the Integration of Parent Engagement Strategies into an Evidence-Based Parent Coaching Intervention for Toddlers at-Risk for ASD

ABSTRACT WITHDRAWN

Background: State-of-the-art evidence-based treatments for children with autism spectrum disorder (ASD) include parent coaching interventions (e.g., Schreibman et al., 2015) that require active parent participation. One implementation challenge with parent coaching interventions is community providers' level of training and comfort working directly with parents (Bailey et al., 1992). Little is known about how providers perceive training specific to parent engagement, in particular as part of an intervention for children with ASD.

Objectives: To use mixed-methods to characterize both agency trainer and therapist perspectives on parent engagement strategies integrated into a parent coaching intervention, Project ImPACT for Toddlers (PI^T; Stahmer et al., 2016), within a community-based train-the-trainer pilot study. The engagement strategies, referred to as Alliance, Collaboration, and Empowerment (ACEs), were adapted from a toolkit designed for child mental health services (Haine-Schlagel et al., 2016).

Methods: Fifteen community agencies serving toddlers with ASD each identified an agency leader to learn PI^T and become an agency trainer (n=14), who subsequently trained interventionists (n=24) within their agencies. Trainers were 21% Hispanic/Latinx; interventionists were 29% Hispanic/Latinx. 29% of trainers and 33% of interventionists had a special education credential. Training was delivered over 12 weeks and included two sessions focused on ACEs. After an additional three months utilizing PI^T independently, trainers and interventionists received an intervention feedback survey (1=strongly disagree to 5=strongly agree) and were invited to participate in an interview. The survey and interview guide questions specifically about ACEs are the focus of this study. Quantitative data were analyzed using SPSS; qualitative data were coded using an iterative grounded theory approach (Glaser & Strauss, 1967).

Results: The four ACEs survey items were combined into one attitudes score (Cronbach's alpha=.82; higher scores more positive). Overall, attitudes were positive (M=4.06; SD=.66). Demographic and background characteristics of trainers and interventionists were examined as predictors of ACEs attitudes. Provider age and ethnicity were not associated with attitudes. Experience working with children with ASD had a modest positive association (r=.34) and caseload had a modest negative association (r=-.39), but neither were statistically significant. ACEs attitudes did not vary for trainers versus interventionists, but providers with a general background (child development, early intervention) had significantly more positive ACEs attitudes (p=.041) compared to providers with a specialist background (SLP, PT, OT). Interview results indicated both trainers and interventionists agreed on the usefulness of the ACEs, their appropriateness for providers, and reported some sustainment in current practice. Trainers indicated high acceptability of ACEs and appropriateness for parents, and suggested placement of ACEs information earlier in training.

Conclusions: Results indicate that across service roles, providers consider training on parent engagement strategies to be useful and generalizable. Providers in supervisory positions had more positive attitudes about engagement strategies in their interviews but not in the survey data. Survey results preliminarily suggest that background (generalist versus specialist) may play a role in readiness to receive training on parent engagement strategies. Future research should examine whether provider use of parent engagement strategies improve both parent engagement and child outcomes.

156 **140.156** Supporting Autistic Children to Successfully Transition to Primary School: Perspectives from Parents and Early Intervention Professionals

N. T. Chen[1,2], S. Miller[1,3,4], B. T. Milbourn[2], M. H. Black[1,2], K. Fordyce[5], G. Van Der Watt[3,4], T. Alach[1,3,4], A. Masi[1,6,7], G. Frost[8], M. Tucker[9], V. Eapen[1,6,10] and ***S. J. Girdler****[1,2], (1)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Brisbane, Australia, (2)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia, (3)Autism Association of Western Australia, Perth, Australia, (4)Autism Specific Early Learning and Care Centre, Bedford, Australia, (5)North West Tasmania Autism Specific Early Learning and Care Centre, St Giles Society, Burnie, Australia, (6)School of Psychiatry, University of New South Wales, Sydney, Australia, (7)KU Marcia Burgess Autism Specific Early Learning and Care Centre, Liverpool, Australia, (8)Anglicare SA Daphne St Autism Specific Early Learning and Care Centre, Prospect, Australia, (9)Queensland Autism Specific Early Learning and Care Centre, AEIOU Foundation, Nathan, Australia, (10)Academic Unit of Child Psychiatry, South West Sydney (AUCS), ICAMHS, Mental Health Centre, L1, Liverpool Hospital, Liverpool, Australia*

Background:

The transition to primary school is an important social and developmental milestone which may evoke significant anxiety and uncertainty for both children and families, as it is coupled with changes to existing supports. This transition can be particularly difficult for children diagnosed with Autism Spectrum Disorder (ASD) who face significant barriers to developing school readiness and experiencing a positive transition to school. There is a need to better understand how to support families and children diagnosed with ASD during this crucial time.

Objectives:

This study aimed to explore the perceptions of parents and early intervention staff on the factors contributing to school readiness and a successful school transition for children diagnosed with ASD.

Methods:

Focus groups and interviews exploring school readiness and transition for children diagnosed with ASD were conducted with 58 early intervention staff and 15 parents of children diagnosed with ASD who transitioned to school from autism specific early learning and care centres (ASELCC) at the beginning of 2018. Thematic analysis was undertaken to explore factors influencing school readiness and transition at both system and individual levels.

Results:

At the system level both early intervention staff and parents discussed the need for better communication and collaboration between early intervention staff, receiving teachers and parents. Both groups also noted that teachers receiving children must build a relationship with the child and have an adequate understanding and knowledge of ASD. Early intervention staff and parents also emphasised the need to utilise a strengths-based approach, incorporating a child's interests and skills to facilitate a successful transition to school. Early intervention staff noted that support provided by early intervention staff and parents advocating for the child was important for success. At the individual level, key issues highlighted were assisting children to develop independence, beginning the transition early to provide time to adjust, developing routines and structure, providing tools to facilitate transition, developing strategies to manage anxiety and individualizing the transition process.

Conclusions:

Findings indicate a number of factors which must be considered to facilitate the transition to school for children diagnosed with ASD. This study highlights the need for clear, collaborative and ongoing communication between parents, teachers and early intervention staff to support children diagnosed with ASD during the transition to school. Early intervention staff must provide support to families and work with receiving teachers to develop knowledge and understanding of ASD to facilitate better school outcomes for children diagnosed with ASD. Using a strengths-based approach, collaboration between all stakeholders and individualizing the transition process are essential for success.

Poster Session
141 - Interventions - Non-pharmacologic - Infant, Toddler, and Preschool
5:30 PM - 7:00 PM - Room: 710

157 **141.157** Effectiveness of Parent Training for Disruptive Behavior of Children with Autism Spectrum Disorder in a Clinic Setting

B. Cavanaugh[1], *K. Zanibbi*[2] *and L. Silverman*[1], *(1)University of Rochester Medical Center, Rochester, NY, (2)University of Rochester, Rochester, NY*

Background: The Research Units on Pediatric Psychopharmacology (RUPP) Autism Network developed a parent training (PT) manual for children with autism spectrum disorder (ASD) and disruptive behavior. Randomized clinical trials suggest that manualized PT is an efficacious treatment for disruptive behavior in children with ASD (Johnson et al., 2007; Aman et al., 2009; Handen et al., 2015; Bearss et al., 2015). However, little is known about the effectiveness of this intervention when conducted in clinical settings, and in general results of studies evaluating the external validity of manualized psychotherapy treatments in community settings are inconclusive (Weisz, Donenberg, Han, and Weiss, 1995; Shadish, Matt, Navarro, and Phillips, 2000). We implemented an adaptation of the RUPP manual in a clinic setting. Administration differed from previous RCTs in that clinicians were encouraged to administer the treatment manual flexibly, with the primary goal of the clinic being to meet the unique needs of each patient.

Objectives: (1) Evaluate differences between implementation of the PT manual in a clinic setting to implementation in a previous RCT (Bearss et al., 2015); and (2) Compare the effects of the intervention conducted in a clinic setting to the previous RCT.

Methods: Participants included were children whose caregivers completed the parent training program and pre- and post- treatment questionnaires in the current outpatient behavioral health clinic (N=50). We analyzed data on child characteristics (age, gender, race, ethnicity, and diagnoses) and intervention characteristics (length of treatment, number of sessions attended, session content covered). We also conducted paired sample T-tests and calculated effect sizes for pre- and post-treatment questionnaires: the Home Situations Questionnaire, Autism Spectrum Disorder (HSQ-ASD; Chowdhury et al., 2015), Brief Assessment of Mealtime Behavior in Children (BAMBI; Lukens and Linscheid, 2008), and Children's Sleep Habits Questionnaire (CHSQ; Owens, Spirito and McGuinn, 2000). Data from the current clinical sample was compared to data reported in Bearss et al. (2015).

Results: Child Characteristics: Children in the current sample tended to be older (M=6.3) and less likely to have a diagnosis of ASD (48 percent) compared to the prior RCT. Intervention Characteristics: On average, caregivers attended treatment for 12.48 sessions over 15.33 weeks. Session topics covered in treatment differed some from the previous RCT. Outcome Measures: We saw a 40 percent reduction in HSQ-ASD Total Mean Severity Scores from pre- to post- treatment, yielding a large effect size, comparable to reductions exhibited on pre-treatment and 12-week follow up in the prior RCT. Small effects were observed on the BAMBI and CSHQ.

Conclusions: Overall, we found some differences in the children who were served and the sessions that were administered in our current clinical sample. Despite differences, decreases in disruptive behavior (assessed by the HSQ-ASD) were comparable to the previous RCT.Many individuals who participated in our parent training program were not included in the current analysis, due to missing/incomplete questionnaires. Therefore, the current sample may be biased. However, the current investigation provides preliminary support for PT for children with developmental disabilities and disruptive behavior in a clinical setting.

158 **141.158** Parent Training for Medicaid-Enrolled Families of Children with ASD

D. Straiton[1], *B. R. Ingersoll*[1], *K. Casagrande*[1] *and B. S. Groom*[2], *(1)Psychology, Michigan State University, East Lansing, MI, (2)Mid-State Health Network, Lansing, MI*

Background: Parent training, in which providers teach parents to address their child's maladaptive behavior or skill development, is considered best practice in the treatment of autism spectrum disorder (ASD). However, it is underutilized in community settings, particularly for traditionally underserved families of children with ASD.

Objectives: Little is known about the use of parent training with families from lower-resourced backgrounds. The present study utilized Medicaid claims data and a survey of applied behavior analysis (ABA) providers to describe the parent training service use landscape for children receiving ABA services through the Michigan Medicaid Autism Benefit.

Methods: Six months of Medicaid claims for 879 youth receiving the Autism Benefit in a 12-county region were examined to determine the number of encounters of ABA parent training received per child. Child characteristics (age, gender, race, and ethnicity) were examined as potential predictors of number of parent training encounters. ABA providers who service Medicaid-enrolled children with ASD (n = 97) were asked to provide

a written description of parent training, and then asked to report how frequently they provide parent training for an average client per month and the content of their parent training sessions. Content analysis was used to code provider descriptions of parent training.

Results: Youth received an average of 1.5 parent training sessions (range 0-19 encounters), which was less than 2% of the total number of ABA encounters that they received. Only 1.6% of children received at least 8 encounters (consistent with lower intensity evidence-based models), and 44.9% received no encounters. Gender and racial minority status were not associated with number of parent training encounters, but Hispanic/Latino ethnic status and age were; thus, these two predictors were entered into a multiple regression model. The model was significant (R^2 = .01, F (2,876) = 4.49, p = .012), with Hispanic/Latino status predicting fewer parent training encounters (β = -.069, p = .043) and younger age predicting more (β = .077, p = .023).

The majority of providers reported delivering 1-2 encounters of parent training per month (74.2%). Providers reported that the content of their parent training sessions primarily included principles of ABA (90.8%), communication skills (87.8%), self-care skills (85.7%), and play skills (70.4%). When defining parent training, most providers described it as an opportunity to discuss the child's progress with caregivers or to provide psychoeducation. Providers infrequently mentioned the use of evidence-based strategies like modeling an intervention strategy or providing time for caregiver practice with feedback.

Conclusions: Parent training is infrequently provided to this population, with younger children receiving significantly more sessions. Hispanic/Latino individuals received significantly less parent training sessions, possibly due to language and cultural barriers. Providers reported a substantially higher rate of parent training than what was reflected in the claims data, with session content targeting a range of relevant skills. Yet providers appear to be largely unaware of evidence-based parent training components and use critical components infrequently; thus, additional pre-service and in-service training is needed to increase community use.

159 **141.159** Community Interventionists' Perspectives Toward Using Parent Coaching

M. Pellecchia[1], *R. Beidas*[1], *D. S. Mandell*[2], *A. C. Stahmer*[3] *and M. Gizaw*[1], *(1)University of Pennsylvania, Philadelphia, PA, (2)Center for Mental Health, University of Pennsylvania, Philadelphia, PA, (3)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA*

Background: University-based randomized trials demonstrate that parent-mediated early intervention for children with autism spectrum disorder (ASD) results in improved child outcomes across a range of developmental domains, as well as improved parental self-efficacy and treatment engagement (Green et al., 2010; Kasari et al., 2014; Rogers et al., 2012; Wetherby & Woods, 2006). The manner through which interventionists coach parents is a critical component of all parent-mediated interventions. Effective parent coaching requires the therapist to actively teach the parent techniques to improve their child's development. However, preliminary evidence shows that community therapists infrequently implement parent coaching strategies (Aranbarri, Miller, Stahmer, & Rogers, 2017; Salisbury, Woods, & Copeland, 2009); especially in under-resourced settings. An in-depth understanding of the barriers and facilitators to using parent coaching in community-based treatment settings is a necessary first step towards improving the implementation of this approach in the community.

Objectives: The objective of this community-partnered study is to learn directly from community interventionists working with families of young children with ASD about their experiences with, and perspectives toward, using parent coaching during usual practice. We identified barriers and facilitators to using parent coaching within community-based early intervention (EI), the primary service setting for young children with ASD, in order to inform the development of an implementation strategy toolkit designed to improve the use of parent coaching in EI.

Methods: Semi-structured interviews were conducted with 15 interventionists employed within a publicly-funded EI system, which encourages the use of family-based interventions such as parent coaching. Interview questions asked about the interventionists' experiences using a specific set of evidence-based parent coaching strategies, barriers and facilitators to using each strategy, as well as attitudes, self-efficacy, and intentions to implement parent coaching. All interviews were audio recorded and professionally transcribed for analyses. Transcripts were analyzed in an iterative process based upon an integrated approach that incorporates both inductive and deductive features, which provides a rigorous and systematic approach to analyzing qualitative data.

Results: Analyses are ongoing. Preliminary results provide important insights into community-based interventionists' perspectives toward the acceptability and appropriateness of parent coaching. Common themes are consistent with constructs described in the Consolidated Framework for Implementation Research (CFIR: Damschroder et al., 2009) and include barriers related to the outer setting (parental expectations for a direct service model; busy, chaotic, and challenging home environment) and inner setting (inconsistencies in treatment approach across interventionists), as well as facilitators related to the outer setting (parental buy-in; flexible approach to implementing strategies within home settings), and individual characteristics (interventionist self-confidence). Distinct barriers and facilitators for different coaching strategies were described by interventionists.

Conclusions: This study is one of the first to provide first-hand perspectives regarding community interventionists' use of parent coaching. The findings highlight the unique challenges to implementing parent coaching within publicly-funded service systems and point to the need to develop strategies to support the widespread implementation of parent coaching within these systems.

160 **141.160** Comprehensive Meta-Analysis of Early Intervention Research for Young Children with ASD

M. Sandbank[1], *S. Crowley*[2], *T. Woynaroski*[3] *and K. Bottema-Beutel*[2], *(1)The University of Texas at Austin, Austin, TX, (2)Lynch School of Education, Boston College, Chestnut Hill, MA, (3)Hearing & Speech Sciences, Vanderbilt University Medical Center, Nashville, TN*

Background: Early-intervention research for young children with ASD has been rapidly proliferating, partly owing to the assumption that intervention provided before school entry will have the largest impacts on later outcomes. However, there are marked differences between early intervention approaches, and there is currently no consensus on the 'best' strategies for supporting developmentally important outcomes for this group of children. Meta-analysis is a useful tool for sorting and synthesizing extant research, to gain a holistic understanding of research evidence.

Objectives: The purpose of this project is to generate summary effect sizes and tally quality indicators from all available studies that investigated the effect of early interventions on any outcome for young children (ages 0-8) with ASD.

Methods: To gather peer-reviewed literature and dissertations/theses, we searched nine online databases. The initial search yielded 12,933 records. In an effort to gather "grey literature", or studies not published in a peer-reviewed journal, investigators who received federal grants to

study autism were emailed and asked to provide unpublished data that would fit our inclusion criteria. A preliminary screen of abstracts was first completed using Abstrackr software. Studies that met the following inclusion criteria: (a) published in English, (b) published from 1970 - present, (c) group design that includes both an intervention and control group, (d) participants received a confirmed ASD diagnosis, and (e) participants were within the 0-8 year old range, went on for a full-text reading. Following screening, two coders extracted relevant information and effect sizes from each study. Discrepancies were resolved by consensus. We used robust variance estimation (RVE; Hedges, Tipton, & Johnson, 2010) to synthesize Hedge's g effect sizes within each intervention and outcome type. The RVE approach accounts for the nesting of multiple effect sizes within a single study sample, allowing us to take all available effect sizes from each study without violating independence assumptions.

Results: The search and screening process yielded 1,615 effect sizes gathered from 347 studies/databases. The RVE approach requires that at least five studies contribute to the generation of effect sizes. This criteria was met for six intervention categories; traditional behavioral (8 outcomes), naturalistic developmental behavioral (7 outcomes), developmental (2 outcomes), computer-based (1 outcome), sensory (1 outcomes), and TEACCH (2 outcomes). Significant summary effects ranged from 0.25 to 0.44. Coefficients, standard errors, and confidence intervals for each summary effect is listed in Table 1. However, a high percentage of behavioral studies were quasi-experimental in design, and all of the intervention types had high risk of bias for at least one study quality indicator.

Conclusions: In this comprehensive meta-analysis, we computed 21 summary effects across 6 intervention types. Results indicate at least some support for behavioral, NDBI, developmental, and computer-based interventions across several outcome types, and no support for any outcomes for sensory and TEACCH interventions. Future intervention research should include studies with randomized controlled designs, and low risk of bias across the full set of quality indicators. These findings have implications for best practices within the early intervention period.

161 **141.161** Impact Reduces Social Hyporesponsiveness and Translates to More Optimal Spoken Language Outcomes Infants at Heightened Risk for Autism

T. Woynaroski[1], *J. I. Feldman*[2] *and P. Yoder*[3], *(1)Hearing & Speech Sciences, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt University, Nashville, TN, (3)Department of Special Education, Vanderbilt University, Nashville, TN*

Background: Infant siblings of children affected by autism spectrum disorder (Sibs-ASD) are at high risk of receiving a future diagnosis of ASD or language delay and may show hyporesponsiveness (i.e., reduced or absent responding to sensory stimuli), in particular to social stimuli, such as a name call, tap on the shoulder, or wave. It has been proposed that such social hyporesponsiveness, especially early in life, may produce cascading effects on the development of higher-level skills, such as spoken language. In an early intervention called ImPACT, parents are taught to use a number of strategies that might reduce social hyporesponsivity (e.g., well-timed animation, face to face positioning, behavioral responsivity) and support language acquisition (e.g., language responsivity, communication temptations, direct communication teaching) in Sibs-ASD.
Objectives: The present study sought to evaluate whether an early intervention called ImPACT may reduce social hyporesponsiveness and translate to more optimal spoken language outcomes in Sibs-ASD.

Methods: At entry to the study (T1), 39 infants (17 male, 22 female; chronological ages 12-18 months) were randomly assigned to receive ImPACT vs a business as usual (BAU) control at Vanderbilt University. Families assigned to ImPACT received 24 sessions of parent training over 3 months by an ImPACT-certified speech-language pathologist (SLP) or someone trained and supervised by the certified SLP in the home setting. Social hyporesponsiveness was measured at immediate post-treatment (3 months post study entry; T2) with the Sensory Experiences Questionnaire. Infants' spoken language was measured at the final follow-up period (9 months post study entry; T3) using the average of z-scores for the (a) raw number of words infants were reported to say on the MacArthur-Bates Communicative Development Inventories (MBCDI), (b) Mullen Scales of Early Learning expressive language age equivalency, and (c) number of different words spoken in the context of Communication and Symbolic Behavior Scales: Developmental Profile and Brief Observation of Social Communication Change samples. Assessors and coders were blind to treatment assignment. T2 social hyporesponsiveness and T3 MBCDI expressive raw scores were log 10 and square root transformed, respectively, to correct for positive skew.

Results: ImPACT was superior to BAU for effects on T2 social hyporesponsiveness for infants with parents who entered treatment with more formal education (*p* value for parent formal education * treatment group parameter in regression model testing moderated effect = .0015). The effect of ImPACT on social hyporesponsiveness translated to more optimal T3 spoken language outcomes for this subgroup of infants, 95% CI for conditional indirect effect of treatment on spoken language outcomes via midpoint social hyporesponsiveness according to parent formal education [.0001, .7774].

Conclusions: This study is the first to our knowledge to demonstrate that an early "preventative" intervention may impact social hyporesponsiveness in infants who are at heightened risk for autism. Results suggest ImPACT has the greatest potential to reduce social hyporesponsiveness and translate to more optimal language outcomes when parents have a relatively high level of formal education and perhaps are best positioned to learn strategies to be applied in the course of everyday interactions with their infant.

Background:
Infant siblings of children affected by autism spectrum disorder (Sibs-ASD) are at high risk of receiving a future diagnosis of ASD or language delay and may show hyporesponsiveness (i.e., reduced or absent responding to sensory stimuli), in particular to social stimuli, such as a name call, tap on the shoulder, or wave. It has been proposed that such social hyporesponsiveness, especially early in life, may produce cascading effects on the development of higher-level skills, such as spoken language. In an early intervention called ImPACT, parents are taught to use a number of strategies that might reduce social hyporesponsiveness (e.g., well-timed animation, face to face positioning, behavioral responsivity) and support language acquisition (e.g., language responsivity, communication temptations, direct communication teaching) in Sibs-ASD.

Objectives:

The present study sought to evaluate whether ImPACT may reduce social hyporesponsiveness and translate to more optimal spoken language outcomes in Sibs-ASD.

Methods:

At entry to the study (T1), 39 infants (17 male, 22 female; chronological ages 12-18 months) were randomly assigned to receive ImPACT vs a business as usual (BAU) control at Vanderbilt University. Families assigned to ImPACT received 24 sessions of parent training over 3 months by an ImPACT-certified speech-language pathologist (SLP) or someone trained and supervised by the certified SLP in the home setting. Social

hyporesponsiveness was measured at immediate post-treatment (3 months post study entry; T2) with the Sensory Experiences Questionnaire. Infants' spoken language was measured at the final follow-up period (9 months post study entry; T3) using the average of z-scores for the (a) raw number of words infants were reported to say on the MacArthur-Bates Communicative Development Inventories (MBCDI), (b) Mullen Scales of Early Learning expressive language age equivalency, and (c) number of different words spoken in the context of Communication and Symbolic Behavior Scales: Developmental Profile and Brief Observation of Social Communication Change samples. Assessors and coders were blind to treatment assignment. T2 social hyporesponsiveness and T3 MBCDI expressive raw scores were log 10 and square root transformed, respectively, to correct for positive skew.

Results:

ImPACT was superior to BAU for effects on T2 social hyporesponsiveness for infants with parents who entered treatment with more formal education (*p* value for parent formal education * treatment group parameter in regression model testing moderated effect = .0015). The effect of ImPACT on social hyporesponsiveness translated to more optimal T3 spoken language outcomes for this subgroup of infants, 95% CI for conditional indirect effect of treatment on spoken language outcomes via midpoint social hyporesponsiveness according to parent formal education [.0001, .7774].

Conclusions:

This study is the first to our knowledge to demonstrate that an early "preventative" intervention may impact social hyporesponsiveness in infants who are at heightened risk for autism. Results suggest ImPACT has the greatest potential to reduce social hyporesponsiveness and translate to more optimal language outcomes when parents have a relatively high level of formal education and perhaps are best positioned to learn strategies to be applied in the course of everyday interactions with their infant.

162 **141.162** Longitudinal Indirect Effect of Parent Responsiveness and Vocal Complexity on Expressive Language Outcome in Toddlers at Risk for ASD

S. R. Edmunds[1], *P. Yoder*[2] *and W. L. Stone*[3], *(1)University of Washington, Seattle, WA, (2)Department of Special Education, Vanderbilt University, Nashville, TN, (3)Psychology, University of Washington, Seattle, WA*

Background: Up to 40% of later-born siblings of children with ASD are diagnosed with ASD (7-19%) or other language and/or cognitive delays (14-20%) by age three. Vocal complexity, a measure of the quality and maturity of vocal communication, is a strong predictor of later expressive language in typically developing children and children with ASD, but no studies have examined this relation for toddlers at high familial risk (HR) for ASD.

Parent responsivity to toddlers' vocalizations may facilitate children's complex vocal communication, which in turn may provide the basis for expressive language. ImPACT is a parent-implemented, naturalistic developmental behavioral intervention (NDBI) that teaches parents to respond contingently to toddlers' vocalizations, which could facilitate complex vocal communication and expressive language.

Objectives: (1) To examine whether parents' verbal responsiveness (PVR) indirectly predicted expressive language through vocal complexity in an ongoing longitudinal RCT of the ImPACT intervention; and (2) To explore longitudinal indirect effects of ImPACT on expressive language through PVR or HR toddlers' vocal complexity.

Methods: Participants were 54 HR toddlers and parents randomly assigned to receive 3 months of ImPACT (*n*=28) or to business-as-usual (*n*=26). Toddlers were 12-18 months old at study entry (*M*=14.32 months; *SD*=2.03 months). PVR was measured at Time 2 (immediately post-ImPACT). Vocal complexity was measured at Time 3 (3 months post-ImPACT). Expressive language was measured at Time 4 (6 months post-ImPACT).

Parents' verbal responsiveness (PVR) to children's vocally complex communication acts was coded from a parent-child free play and snack time task using observational coding definitions from previous research. Vocal complexity, an aggregate of canonical syllable frequency and consonant inventory in communication acts, was coded from the Communication and Symbolic Behavior Scales (CSBS-DP) and the Brief Observation of Social Communication Change (BOSCC). Expressive language was an aggregate of T4 MCDI expressive vocabulary, number of word roots used during the CSBS-DP, and MSEL expressive language subscale. Indirect effects were assessed using bias-corrected bootstrapping.

Results: For toddlers in both treatment conditions, there was a significant indirect effect: Time 2 PVR significantly predicted T4 expressive language, in part, through Time 3 vocal complexity, *ab*=1.74, 95%CI [0.64, 3.19] (Table 1; Figure 1). This indirect association did not vary by treatment group. Participation in the ImPACT intervention did not significantly affect Time 4 expressive language indirectly through Time 2 PVR or Time 3 vocal complexity.

Conclusions: To our knowledge, this was the first study to assess whether the relation between parental verbal responsiveness and children's later expressive language is partly due to intermediate increases in the maturity of children's vocalizations. Although this preliminary analysis did not find a significant effect of the ImPACT intervention on PVR or vocal complexity, it *did* find that regardless of treatment condition, PVR predicted an increase in the proportion of HR toddlers' communication acts that were vocally complex, which in turn predicted later expressive language ability. Parents' verbal responsiveness and children's vocal production clearly influence each other in a transactional manner over time, a phenomenon that could have cascading implications for HR children.

163 **141.163** A Pilot Study on the Impact of Group-Delivered Parent Training on Parental Self-Efficacy and Stress

N. Quintana[1], *S. Zheng*[2], *M. Park*[2], *W. Ence*[3] *and G. Lyons*[4], *(1)University of California, San Francisco, San Francisco, CA, (2)Psychiatry, University of California, San Francisco, San Francisco, CA, (3)University of California San Francisco, San Francisco, CA, (4)Psychiatry, UCSF, San Francisco, CA*

Background: Parent-implemented, naturalistic behavioral intervention using a group-based parent training format represents a unique and efficient service-delivery model. Research suggests these interventions positively impact the social, communication, and language skills of young children with autism spectrum disorder (ASD; Hardan et al., 2015; Laugeson et al., 2016; Minjarez et al., 2010). Given their primary role, parent factors may influence child changes in parent-mediated approaches. Though researchers have studied family empowerment and parental stress outcomes in group parent-implemented models (Minjarez et al., 2013), parental stress has been considered more prominently in the broader parent training literature and with inconclusive results. Another parent factor warranting investigation is parental self-efficacy (Steiner et al., 2012), an underrepresented construct in the ASD parent training literature. Changes in parental self-efficacy following group-delivered parent

training programs may be integral to understanding variability in proximal and maintained treatment outcomes and may be linked to parental stress. As such, it is valuable to study the impact of group parent training on parental self-efficacy.
Objectives: This study highlights the understudied construct of self-efficacy in the context of group-delivered, parent-mediated interventions for young children with ASD by examining changes in parental self-efficacy and whether such changes are related to changes in parent stress.

Methods: As part of an ongoing clinical study, we are enrolling 30 total parents of children with ASD under the age of 5, with 15 parent-child dyads in each intervention group: (1) Pivotal Response Treatment (PRT) and (2) Preschool PEERS, two empirically supported, group-delivered parent training programs targeting social communication skills. Parents are asked to report on their levels of parenting self-efficacy (Early Intervention Parenting Self-Efficacy Scale, EIPSES) and stress (PSI-Short Form 4 or Caregiver Strain Questionnaire) before and after their participation in their respective intervention. At present, we have collected completed preliminary pre- and post-treatment self-efficacy and stress data on seven participants. Table 1 displays the data for our preliminary descriptive analysis.

Results: Based on our pilot sample, families both increased and decreased in self-efficacy and stress. Three of seven parents reported increases in self-efficacy (average increase of 0.33 points on the EIPSES), with two of those parents also reporting concomitant decreases in stress levels, and one of them reporting little change. The remaining four parents reported decreases in parental self-efficacy (average decrease of 0.58 points on the EIPSES), with three of those parents reporting increases in stress levels and one reporting a decrease.

Conclusions: Despitethe overall mixed results suggested by these preliminary findings, there may be an emerging pattern of negative relationships between changes in parental self-efficacy and changes in parental stress, whereby increases in self-efficacy are accompanied by decreases in stress and vice versa. Importantly, variability in our small dataset is prominent, with some families reporting less self-efficacy and more stress at post. As we continue to enroll families in our ongoing study, a larger sample will allow us to inferentially examine the mechanism of intervention changes in parental self-efficacy and stress across and between the two intervention groups.

164 **141.164** Changes in Adaptive Behaviour in 3-5-Year-Old Children with Autism Spectrum Disorder Following a Motor Skill Intervention: Preliminary Results

A. T. Ibbitson[1], *T. Runge*[1] *and M. Lloyd*[2], *(1)Faculty of Health Science, University of Ontario Institute of Technology, Oshawa, ON, Canada, (2)Kinesiology, University of Ontario Institute of Technology, Oshawa, ON, Canada*

Background: Children with Autism Spectrum Disorder (ASD) experience significant challenges in socialization and communication in addition to repetitive and restricted behaviors. In addition to these core characteristics, delays in the development of fundamental motor skills (FMS) are often observed from a young age. These challenges can lead to reduced opportunities to engage in active play which is an important venue for the development of social and behavioral skills. Adaptive behavior refers to an individual's typical performance of the day-to-day activities required for social and personal sufficiency. Active play is considered to be the occupation of children and if children with ASD have limited ability to engage in active play due to their motor skills this might have an impact on adaptive behaviour as well.
Objectives: To determine the impact of a 12-week motor skill intervention in 3-5-year-old children with ASD on FMS and adaptive behavior.

Methods: 14 children with ASD (11 male, 3 female, Mean age = 3.51 ± .52) were recruited for a 12 week, 2 hours/week, wait-list controlled fundamental motor skill intervention. Participants were randomly assigned to the intervention (n = 7, Mean age = 3.74 ± 0.69) or control group (n = 7, Mean age = 3.38 ± 0.13). The Test of Gross Motor Development-2 (TGMD-2) was used to measure motor skills before and after the intervention and determine the Gross Motor Quotient (GMQ). The Vineland Adaptive Behavior Scales (2nd ed.) was used to score overall adaptive functioning. The Adaptive Behavior Composite (ABC) is a composite score that summarizes the individual's performance across four domains related to adaptive functioning: Communication, Daily Living Skills, Socialization and Motor Skills.

Results: There were no significant differences between the groups at the pre-test. Group 1: the ABC standard score (mean = 71.86 ± 8.26), GMQ (mean = 81.57 ± 19.09) and Group 2: ABC Standard Score (mean = 80 ± 11.11), GMQ (mean = 77.29 ± 12.59) at the pre-test. After the 12-week intervention, scores for post-test in Group 1: ABC (mean = 79.29 ± 12.02), GMQ (mean = 91.86 ± 20.91), and Group 2: ABC (mean = 75.29 ± 8.34) and GMQ (mean = 87.57 ± 14.33). There was a significant effect for the group by time interaction (p= 0.003) for the ABC but no significant effect for time. For the GMQ, there was a significant effect for time (p = 0.002) but the group by time interaction was not significant.

Conclusions: These preliminary results indicate that a fundamental motor skill intervention may have a positive impact on adaptive behaviour in 3-5-year-old children with ASD. This intervention was an age appropriate, skill-based intervention focusing on the skills needed for active play. Overall, the results are promising and indicate the need for further research in this area.

165 **141.165** Community Implementation of Social ABCs: Program Description, Feasibility, and Acceptability

I. Drmic[1], *J. A. Brian*[2], *C. Roncadin*[1], *C. Shaver*[3], *E. M. Dowds*[4], *A. Solish*[2], *L. Conry*[5], *M. Pase*[5], *K. Paul*[5], *N. Rugajs*[5], *C. Calinescu*[5], *L. Zwaigenbaum*[6] *and S. E. Bryson*[7], *(1)Autism Spectrum Disorder Service, McMaster Children's Hospital - Hamilton Health Sciences, Hamilton, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Hamilton Health Sciences, Hamilton, ON, Canada, (4)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital-Autism Research Centre, Burlington, ON, Canada, (5)Ron Joyce Children's Health Centre, Hamilton, ON, Canada, (6)University of Alberta, Edmonton, AB, Canada, (7)Dalhousie University, Halifax, NS, Canada*

Background: Naturalistic Developmental Behavioral Interventions (NDBIs) have been shown to be effective in toddlers with confirmed or suspected ASD in well-controlled research settings. The Social ABCs is an evidence-based caregiver-mediated NDBI involving in-home live-coaching for toddlers. Next steps involve implementation in community settings.
Objectives: To describe a collaborative effort between the Social ABCs developers and community team to implement Social ABCs with confirmed or suspected ASD in a large community program. Information about the program, sample, training model, referral/service delivery model, feasibility, acceptability, and key factors related to implementation will be described. Effectiveness data will be described in a linked submission (Parent and Toddler Outcomes...).

Methods: Social ABCs is one of four NDBI models involved in a government-funded pilot demonstration initiative underway in Canada. Community implementation took place at Ron Joyce Children's Health Centre in Hamilton, Ontario, where parents received 12 weeks of one-on-one coaching. Implementation included engagement with community stakeholders to understand local needs. *Participants:* a) Social ABCs developers ("expert team"): program developer (J.B.), psychologist, lead trainer, and additional trainers; b) Community team: 5 coaches, program coordinator,

psychometrist, and psychologist; and c) Family participants: toddlers aged 12 to 30 months and one caregiver. *Training/supervision:* A positive and collaborative training approach included: a) week-long workshop (didactic, practice, video review); b) training phase (direct implementation, coaching supported by lead trainer); and c) ongoing training/supervision by lead trainer tapering over time (onsite/video review in individual/group format) and expert team (via Telemedicine). *Evaluation:* Caregivers completed a Caregiver Diary and satisfaction survey. Fidelity measures for caregivers and coaches were obtained, as well as child responsivity to parents' prompts. Implementation facilitators were recorded during supervision sessions.

Results: Five front-line staff ("coaches") have been trained; mean time for fidelity of implementation and coaching was 119 days. Mean supervision hours during training was 4.8 hours/week per coach. To date, of the 215 toddlers referred, 159 have been enrolled (111 boys, 48 girls); age range: 15-34 months (*M* age = 25.4 months, *SD* = 4.16). Of 159 enrolled, 109 completed, 18 still completing, 23 waiting, and 9 dropped out. Caregivers reported child improvements, and child responsivity doubled from week 1 to 12 (from 33% to 66%). Caregivers reported increased adherence and competence, and 93% achieved the pre-established rate of 75% fidelity by weeks 8-12. Caregivers reported high satisfaction. Engagement of community stakeholders led to improvements in internal and external referral processes, including decreases in age at time of referral (from *M* = 30.8 to *M* = 22.7 months) and earlier referral for diagnostic assessment. Drivers of success included a careful and collaborative planning approach, shared decision-making, consideration of contextual issues, an opinion leader, institutional support, and a program coordinator with clinical training.

Conclusions: The Social ABCs intervention was successfully implemented in a large community program. Parent coaches achieved fidelity in a timely manner, caregiver- and child-level improvements were obtained, with positive feedback from coaches, caregivers and community partners. Findings highlight the feasibility and acceptability of the Social ABCs for implementation within a community service-delivery model.

166 **141.166** Content and Process of Communication Intervention for Toddlers with Autism: Trends and Current Status

H. Schertz[1], *K. Lee*[1], *X. Liu*[2] *and L. Sun*[2], *(1)Indiana University, Bloomington, IN, (2)Indiana University - Bloomington, Bloomington, IN*

Background:

Intervention models for toddlers on the autism spectrum have emerged and evolved since 2000. While subsequent research has focused largely on outcomes, the communication-focused content and intervention processes that influenced those outcomes are relatively unexplored.

Objectives:

The study's aim was to explore intervention content and process variables described in recent studies of communication-focused intervention for toddlers with autism and to assess their alignment with recommendations from extant reviews of early intervention for this population.

Methods:

A search of intervention studies of toddlers with autism yielded 23 intervention descriptions as reported in 31 original studies (some duplicated). Studies were limited to peer-reviewed publications since 2010 that reported on communication-focused interventions with all participants under age 36 months. The intervention descriptions were coded for intervention content (primary outcomes and communication focus/level) and process (strategies, setting, agent, and learning framework). A parallel search of published reviews of interventions for toddlers with autism yielded seven reviews, which were ordered chronologically with findings classified by their component studies' approaches, foci, agents, and settings as well as by overall identified needs. Original studies and reviews were independently coded with consensus on coding reached by the full team (all presenters).

Results:

Viewed chronologically, the seven reviews revealed a decreasing use of exclusively behavioral and a commensurate increasing use of developmental and combined approaches, an increasing focus on preverbal social communication with a decreasing focus on verbal language, an increasing use of natural environments, and minimal change over time in the use of parent- versus professional-implemented interventions. Needs cited by multiple reviews included more developmentally grounded intervention focusing on prelinguistic social communication, more implementation in natural environments, and greater use of family-centered/capacity-building practices with parent implementation. The parallel review of the 23 recent communication intervention descriptions showed interventions focused on social communication (8), general communication (6), or a mixture (9) that targeted pre-symbolic (8), symbolic (4), or mixed (11) levels. Interventions were relatively evenly distributed between home-only (12) and preschool/clinic/lab/mixed (11) settings and between implementation exclusively by parents (12) and fully/partially by professionals (11) with the majority of home-only interventions implemented by parents and non-home-only at least in part by professionals. A review of intervention strategies revealed theoretical mechanisms assumed to guide child learning: These included response to reinforcement, modeling, and/or prompting (7), reciprocal contributions to learning (4), response to environmental arrangement (1) or a mixture (11).

Conclusions:

Paralleling recommendations from the seven reviews, analysis of 23 recent intervention descriptions revealed that, while progress toward developmentally grounded content and recommended practices is evident, continued advancement toward a primary emphasis on social communication at the preverbal level, active facilitation of the parent role in implementation, and delivery in natural environments is needed. A number of recent interventions relied primarily on external reinforcement strategies or prompting/modeling while fewer relied primarily on reciprocal learning processes that might promote child active engagement and initiations. Future investigations should explore the role that interventions driven by differing underlying learning assumptions might play in promoting meaningful interactive social engagement on the toddlers' own volition.

167 **141.167** Diminished Responsiveness to Parental Tutoring in Preschoolers with ASD: Implications for the Guided Participation Relationship

J. A. Hobson[1], *F. Larkin*[2], *L. Hollaway*[3] *and M. Garlington*[4], *(1)Sonoma State University, Santa Rosa, CA, (2)Psychology, University of York, York, United Kingdom, (3)Occupational Therapy, University of Central Arkansas, Conway, AR, (4)Preschool, Pediatrics Plus, Conway, AR*

Background:
In a Guided Participation Relationship (GPR), parents scaffold children's performance during instructional activity to promote competence and autonomy (Rogoff, Ellis, & Gardner, 1984) within their children's Zone of Proximal Development (Vygotsky, 1978). Mothers of securely attached preschool children tend to provide more sensitive feedback, and are unlikely to use physical guidance (Meins, 1997). Feedback and responsiveness from their children help parents provide sensitive scaffolding. Children with Autism Spectrum Disorder (ASD) and their caregivers face challenges negotiating the GPR as measured by the Dyadic Coding Scales (DCS: Beurkens, Hobson, & Hobson, 2013).

Objectives:

We aimed to assess whether caregivers and their preschool-aged children with ASD differed from those without ASD during free play and parental tutoring. We predicted differences in the quality of the GPR. We studied whether there was change in a subset of the children with ASD who (with their parents) received an intervention designed to foster the GPR (Relationship Development Intervention, RDI).

Methods:

In addition to language testing and a confirmation of diagnoses with the ADOS-2, 30 children (16 with ASD) and their caregivers were administered the Relationship Development Assessment – Research Version (RDA-RV: Larkin, Guerin, Hobson, & Gutstein, 2013) at the beginning and end of the preschool year. Two sets of coders, blind to the study design, rated the RDA-RV according to the DCS and also caregivers' ability to tutor their children within the 'region of sensitivity to instruction' (Meins, 1997).

Results:

At baseline, children with ASD were more likely to ignore or fail to adjust their behavior in response to parental feedback, t(28) = - 2.72, p = .011. Children in the comparison group were more likely to accommodate to parental suggestions, t(28) = - 2.43, p = .022. Parents in both groups provided equally sensitive responses, although those with children with ASD were more likely to use physical prompts. Parent-child dyads containing children with ASD were rated significantly lower on the Dyadic Coding Scales, t(28) = 3.68, p < .001. Child negative responsiveness was inversely correlated with dyadic scores on the DCS, even after taking into account variability associated with verbal mental age, partial-r = -.49, p = .008. Scores on the DCS improved significantly over the course of the school year for dyads participating in RDI, F (1,14) = 9.04, p = .009.

Conclusions:

Children with ASD and their parents showed impairments in aspects of the GPR as assessed with the RDA-RV applying the Dyadic Coding Scales (Beurkens, Hobson, & Hobson, 2013; Hobson, Tarver, Beurkens, & Hobson, 2015). Despite children with ASD being more resistant to parental tutoring strategies, parents remained sensitive to their child's needs. However, higher resistance to parent input in children with ASD was related to lower quality of dyadic relatedness on the DCS. Although ASD may present challenges for the child-caregiver GPR, results of the present study reveal the potential for improvements in the GPR when this is a treatment focus.

168 **141.168** Disparities in the Amount of Early Intervention Services Received By Toddlers with ASD: The Role of Demographic Factors

N. Portillo[1], *L. Buitrago*[2], *L. P. Thammathorn*[3], *A. Eisenhower*[4] *and A. S. Carter*[5], *(1)University of Massachusetts, Boston, Boston, MA, (2)Boston Children's Hospital, Boston, MA, (3)University of Massachusetts, Boston, MA, (4)Psychology, University of Massachusetts Boston, Boston, MA, (5)University of Massachusetts Boston, Boston, MA*

Background: Early access to a diagnosis of ASD can lead to earlier, more intensive intervention, which has been shown to result in optimal developmental outcomes (Peters-Scheffer et al., 2012; Warren & Stone, 2011). However, disparities in the age of diagnosis have been documented, with children of racial/ethnic minority backgrounds being identified much later than White children (Mandell et al., 2009). Less research has extended this work to consider whether such disparities persist, beyond the age of initial diagnosis, to the intensity and amount of early intervention (EI) received.

Objectives: To examine whether demographic factors (parental education, poverty, English proficiency, race/ethnicity, US-born status) predict the amount of early intervention services received by children with ASD. We consider these predictors in the context of a screening and evaluation program that is designed to minimize health disparities in the initial age of diagnosis; as such, our study enables us to consider whether, even in the context of relative equity in the age of ASD diagnosis, health disparities persist in the intensity of EI services received by young children with ASD.

Methods: 381 children (ages 14-36 months) were diagnosed as part of an EI-based, multi-stage screening and university-based diagnostic assessment protocol designed to reduce health disparities. 51% of this sample were of families living below the poverty line, 34% English learners, 50% immigrants, 45% White, 46% Hispanic, 26% Black, and 6% Asian. Follow up interviews were then conducted with 130 of the families of children to ascertain the amount of EI services received post-diagnosis. Next, using a latent class analysis (LCA), we identified six demographic clusters of families to predict ASD service receipt.

Results: First, the six demographic clusters of families revealed that these families were primarily distinguished by their race and US-born status. Additionally a one-way between subjects ANOVA indicated that across all six classes, on average, families from classes holding multiple marginalized identities were receiving significantly fewer hours of weekly services than families with more privileged identities [F(5, 124) = 4.36, p = 0.001]. However, the two classes that were distinguished as being White, differed in immigration status yet still had the same mean hours of weekly intervention services (White immigrants = 13.7 hrs; U.S. born non-Hispanic White = 13.7 hrs). Across other classes, U.S. born Black parents reported receiving significantly fewer hours (m = 6.3) than White immigrants and U.S. born non-Hispanic Whites. Latinx immigrants reported receiving fewer hours (m = 7.2) than White immigrants and U.S. born non-Hispanic Whites.

Conclusions: Despite having a timely access to an ASD diagnosis, disparities continued to persist in subsequent receipt of post-diagnosis intervention services. Our class solutions suggest that these demographics play a significant role in service attainment. Findings may help properly address and identify groups in need of additional support when it comes to service attainment and suggests that there may be systemic barriers at play.

169 **141.169** Effect of Project Impact on Social Imitation in Children with ASD: A Randomized Controlled Trial

S. Van der Paelt*, P. Warreyn, A. Piatti and H. Roeyers, Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: Children with ASD show deficits in imitation skills, which are especially pronounced in a social-interactive context (Rogers et al., 2003). Research has shown that social imitation during play is related to language, social reciprocity and symbolic play in children with ASD (Ingersoll & Meyer, 2011). Project ImPACT (Ingersoll & Dvortcsak, 2010) is a parent-implemented intervention, focusing on social communication in children with ASD. One of the intervention targets is the increase of social imitation through the use of interactive and behavioural strategies during daily routines. Previous studies have shown positive effects on language and communication (e.g., Ingersoll & Wainer, 2013; Stadnick et al., 2015). Studies on the effect of Project ImPACT on social imitation are lacking. Moreover, as yet no RCT's have been published.
Objectives: The goal of the present study was to test the effect of Project ImPACT in a community setting on the spontaneous imitation skills of children with ASD.

Methods:

Participants: 29 children between 22 and 49 months (two girls) were recruited through two services for home guidance for children with ASD. Clinical diagnoses were confirmed using the ADOS-2. Participants were randomly assigned to either an ImPACT intervention group (n = 14) or a treatment as usual (TAU) condition (n = 15). The mean age in both groups was 37 months. There was no significant difference in the developmental index on the Mullen between ImPACT (M = 68.54, SD = 21.80) and TAU (M = 61.93, SD = 16.19), $t(25) = 0.90$, p = .38.

Intervention: Children in the ImPACT group received 18 weekly individual parent training sessions. Children in the TAU condition received regular home guidance, with a frequency of one session every 2-3 weeks, mainly targeting daily living skills.

Procedure: Imitation skills were assessed with the spontaneous imitation task (Ingersoll, 2008) before and after receiving Project ImPACT (M = after 5.86 months, SD = 1.23) or after a similar time interval (M = 5.60 months, SD = 0.74) in the TAU group. Administrators were blind for group assignment. Imitation skills were coded afterwards from video by coders who were blind for group assignment and testing moment.

Results: A repeated measures ANOVA showed no main effect of time, $F(1,27) = 2.03$, p = .17. However, there was a significant time*group interaction, $F(1,27) = 4.29$, p = .048, $\eta p2$ = .14. Children in the ImPACT group showed a marginally significant improvement in their imitation skills from pre (M = 5.64, SD = 3.20) to post intervention (M = 8.71, SD = 5.66), $t(13) = 2.11$, p = .055, while children in the TAU group did not show this improvement from pre (M = 6.00, SD = 4.39) to post intervention (M = 5.43, SD = 4.07), $t(14) = 0.56$, p = .59.

Conclusions: Project ImPACT seems to improve social imitation skills of children with ASD through parent training. This is an important finding, given the association of imitation with other social-communicative skills. Results on a larger sample, including follow-up data will be presented at the meeting.

170 **141.170** Effectiveness of a Parent-Mediated in-Home Feeding Intervention for Families with Children with Autism Spectrum Disorders

***K. K. Ausderau**, B. St John, S. Kant and J. Muesbeck, University of Wisconsin-Madison, Madison, WI*

Background: Up to 89% of children with autism spectrum disorder (ASD) have feeding challenges impacting their development, health, social interactions, and parent–child relationships. Feeding challenges are heterogeneous in presentation and include a range of behavioral, sensory, and health problems that put children at risk for decreased/excessive caloric intake, abnormal growth patterns, atypical social interactions, and difficulty participating in peer and family activities. Current evidence for intervention is limited even though the prevalence and negative effects on the family have been clearly established.
Objectives: The purpose of this pilot study was to examine the feasibility, acceptability and evaluate the preliminary effectiveness of an in-home parent-mediated intervention for children with ASD and feeding challenges.

Methods: A convenience sample of seventeen children diagnosed with ASD ages 2 to 7 years participated in a parent-mediated intervention that occurred in the home. A quasi-experimental pre-test/post-test design was used. Families received approximately 32 visits over six-months that included a combination of parent training, direct intervention, and parent coaching. Intervention was delivered by occupational therapists, a dietitian, and graduate students. Measures of feasibility were collected from parents and interventionists. Goal Attainment Scales (GAS), the primary outcome, were used to assess intervention effectiveness using a paired-sample t-test. GASs were collaboratively set with families at the initiation of the intervention following standardized GAS procedures. Parents did not view the GAS during or upon completion of the study. Parents were interviewed prior and post intervention along with videotaped mealtimes.

Results: The parent-mediated intervention was feasible to implement and acceptable to parents and interventionists. Fifteen children/families (88%) completed the intervention with two families withdrawing due to significant parent schedule changes. 100% of parents completing the intervention reported being satisfied. However, they described different aspects of the intervention (e.g., parent training versus direct intervention) as being most beneficial for their child and family. Results identified significant positive changes in GAS scores ($p<.05$). GAS for the families fell into three primary categories of mealtime behaviors, self-help skills, and selective diets. The most challenging goal to achieve across families was adding portion-sized vegetables to their diet. However, other common goals such as decreasing mealtime behavior, improving nutritional content of meals, adding food to the child's food repertoire, and improving self-help skills were more likely to be achieved. Parent report indicated increased self-efficacy and decreased stress. At the close of the intervention, parents also expressed an increased knowledge base and skills to address future mealtime challenges and feeding difficulties with their children.

Conclusions: The parent-mediated intervention to address feeding challenges for children with ASD was feasible and viewed positively by families in the study. Interventionists and families collaborated to achieve goals directly related to the child's health and nutrition, eating behaviors, and family mealtime. Families met the majority of their goals for their children. Although not all goals were met and families expresses their children still had inconsistent eating patterns at times, they expressed an increased knowledge and confidence of know how to approach their child's feeding challenges in the future.

171 **141.171** Effects of Early Social-Communicative Intervention on the Brain Activity of Toddlers with ASD: An ERP Study.

***A. Piatti**, S. Van der Paelt, P. Warreyn and H. Roeyers, Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background:
There is large consensus that objective and insightful evaluations of autism interventions should include neurophysiological measures.

Objectives:

This randomised controlled trial tests the effects of Project ImPACT, an early parent-run intervention targeting social-communicative skills, on the behaviour and brain activity of toddlers with Autism Spectrum Disorder (ASD).

Methods:

Toddlers with ASD have been randomised to receive either Project ImPACT or treatment as usual (TAU), which does not specifically focus on social-communicative abilities. Researchers involved in data acquisition and analysis were blind to group assignation. Outcome measures include event related potentials (ERPs) in response to standard and deviant voice and non-voice stimuli.

The ImPACT (n=12, 1 girl, mean age: 3.1 ±.6, mean IQ: 62.67 ± 24.42) and TAU groups (n=8, 1 girl, mean age: 3.5 ±.5, mean IQ: 59.38 ± 22.5) were compared at baseline and outcome separately to typically developing (TD) children (n=16, 4 girls, mean age: 3.0 ±.9) in the P1, N2, P3 and N4 time windows. Sample size will increase to n = 20 or higher per group before the INSAR meeting. A 2 X (voice/non-voice standard sound) X 2(voice/non-voice deviant sound) X 2 (group) interaction was tested using permutation-based t-test (n=5000) over differences between levels and between factors. Time was added as a two-level factor when comparing ImPACT and TAU.

Results:

This section highlights the most prominent findings of this study (complete overview in Table 1).

A significant main effect of group was found over N2 mean voltages when comparing the ImPACT group at baseline and the TD group ($t(1,26) = 1.849$, $p = .031$), as well as the TAU group at baseline and the TD group ($t(1,22) = 1.759$, $p = .048$).

For the ImPACT group, the difference with TD became non-significant after the intervention ($t(1,26) = .576$, $p = .279$). For the TAU group, the difference with TD was still significant after the intervention ($t(1,22) = 1.937$, $p = .033$). A paired samples t-test within the ImPACT group confirmed the effect of treatment on the N2 component ($t(1,11) = 3.256$, $p = .005$), which became less negative (Figure 1).

The differential effect of intervention over the N2 response to deviant stimuli was further supported by the time X group interaction approaching significance when comparing the ImPACT and TAU groups ($t(1,18) = 1.412$, $p = .085$).

Exploratory analysis suggests that a larger N2 in children with ASD correlates with worse response to joint attention ($r = .442$ [.017 767], $p = .049$). We will further investigate whether the treatment effect on the N2 ERP component is associated with improved response to joint attention.

Conclusions:

Initial group differences, as well as treatment effects, were mostly observed on the N2 ERP component. A larger N2 response at baseline in children with ASD may reflect hypersensitivity to sound change or a more effortful attentional disengagement, with possible repercussions on the children's social behaviour. These preliminary results suggest a deeper effect of early intervention focused on social-communicative skills training compared to intervention that does not primarily focus on social communicative abilities.

172 **141.172** Effects of Family Factors on Joint Engagement in a Caregiver Mediated Intervention

S. R. Crabbe[1], *S. Iadarola*[2], *W. I. Shih*[3], *D. E. Linares*[4], *L. Hauptman*[3], *C. Lord*[5], *R. Landa*[6], *B. King*[7], *A. Wetherby*[8] *and C. Kasari*[3], *(1)University of Pennsylvania, Philadelphia, PA, (2)University of Rochester Medical Center, Rochester, NY, (3)University of California, Los Angeles, Los Angeles, CA, (4)Maternal and Child Health Bureau, Office of Epidemiology and Research, Health Resources and Services Administration, Rockville, MD, (5)University of California Los Angeles, Los Angeles, CA, (6)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (7)UCSF, San Francisco, CA, (8)Florida State University Autism Institute, Tallahassee, FL*

Background: Intervention research in autism spectrum disorder (ASD) primarily focuses on child outcomes; however, increasing literature addresses caregiver well-being and its impact. Consideration of caregiver experiences related to intervention is critical, as factors such as low resources and stress can negatively impact outcomes (Obsborne et al, 2008; Gabriels et al, 2001). Stressors include increased time demands for caregivers and financial strains. These effects may be exacerbated in low resource families because of the additional demands of travel and time away from work that they may not be able to afford. The literature exploring the impact low resources have on outcomes is limited while the literature on caregiver stress is conflicting. Examining these underexplored factors could elucidate how intervention affects families and inform implementation modifications to maximize impact.

Objectives: Examine how family factors (i.e., resources and stress) affect joint engagement (JE) in a caregiver-mediated intervention for young children with ASD from predominately low resource families.

Methods: Children aged 2-5 (N=112) and their caregivers were randomized to a caregiver education module (CEM) or caregiver mediated module (CMM) informed by JASPER (Joint Attention, Symbolic Play, Engagement, and Regulation) intervention. This home based intervention lasted 12 weeks. Measures were administered at baseline and exit. In our sample, 66% were a racial/ethnic minority and 61.6% were low-income. Measures included the Parenting Daily Hassles (PDH) and Family Resource Scale (FRS); the PDH evaluates both the frequency and intensity of stressful daily events. JE was assessed from a 10-minute videotaped interaction between the caregiver and child, using a validated coding scheme. Linear mixed models were used to examine the association between PDH and FRS on JE and whether the associations differ by intervention.

Results: As noted previously, JE was significantly improved in the CMM group over the CEM group (Kasari et al, 2014). In this study, baseline hassle *frequency* positively predicted joint engagement ($F(1,96)=4.38$, $p=0.039$) at all time points, but baseline hassle *intensity* did not. There was a strong trend toward significant moderating effect of baseline hassle intensity (i.e., low versus high) on treatment effects on JE from baseline to exit ($F(1,94)=3.75$, $p=0.056$). Specifically, improvement in JE was more favorable in the CMM group regardless of having low or high hassle intensity. Overall hassle *frequency* positively predicted increases in JE in the CMM group, but hassle *intensity* did not predict improvements in JE from baseline to exit in either group. Chi-square analyses indicated that race/ethnicity was associated with baseline JE, but income and family resources were not.

Conclusions: Improvements in joint engagement were predicted by higher frequency and intensity of daily caregiver stress pre-intervention. While not consistent with our prediction, this relationship may suggest that families who encounter more caregiving stress are poised to benefit more from intervention focused on engagement. These results mirror other psychotherapy literature indicating that individuals with higher mental health symptoms can benefit most from treatment. Overall, results suggest that community interventions targeting this population, and with consideration of structure and schedule to ease time and financial burdens, can impact parent/child engagement.

173 **141.173** Effects of Parent-Mediated Intervention Coaching Vs. Psychoeducation on Social Communication Development of Lower-Resourced Young Children with Autism Spectrum Disorder: A Feasibility Study

S. Dufek[1], *A. DeGeorge*[2], *A. Pickles*[3] *and C. Lord*[4], *(1)Psychiatry, University of California, Davis, Sacramento, CA, (2)Psychiatry, Weill Cornell Medicine, New York, NY, (3)Biostatistics and Health Informatics, King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (4)University of California Los Angeles, Los Angeles, CA*

Background: As children with autism spectrum disorder (ASD) are identified at increasingly younger ages, parent-focused intervention has become an essential component of comprehensive early intervention programs. However, the implementation and effectiveness of these parent-focused intervention programs varies widely across intervention providers, particularly for lower-resourced families. This study examined how traditional parent-focused intervention programs for young children with ASD may be modified to be more practical for lower-resourced families (i.e. those with limited resources and education, low incomes).

Objectives: The purpose of the proposed project was to adapt and evaluate a modified version of an early intervention program working with caregivers from a lower-resourced population. We hypothesized that a parent-mediated intervention (PMI) would demonstrate greater change in child language and social communication behaviors, as well as increased effectiveness in parents' use of specific treatment strategies when compared to a parent psychoeducation intervention consisting of information, education, and support(IES). Further, it was hypothesized that the design and modifications to the protocol (i.e., liberal cancellation and rescheduling policy, individualized home visits, case management and advocacy, and crossover design) would promote engagement in the treatment and decrease attrition compared to previous studies.

Methods: Six mother-child dyads participated in a randomized crossover design in which PMI was compared to IES over 3 months of treatment. Parent outcome was measured using parent fidelity of implementation (FI) of treatment techniques. Child outcome was measured using the Brief Observation of Social Communication Change (BOSCC), a new social communication behavior measure.Account was taken of the repeated measures on estimated confidence intervals and significance by fitting random effects models.

Results: Parent and child outcomes did not differ by type of parent-focused intervention (PMI vs. IES) in our sample. However, overall parent FI scores measured across both conditions improved significantly over the course of treatment [5.18 per month (95% CI 1.88 to 8.49; p=.002)], and was mirrored by nonsignificant but similar changes in the children's scores on the BOSCC [-1.88 per month (95% CI -4.06 to 0.31; p=.093)]. In addition, rich qualitative data gathered during the study concerning parent experiences, as well as feedback regarding the research protocol are discussed and recommendations for implementing parent-focused intervention programs with lower-resourced families are proposed. Four major themes emerged regarding the importance of 1) the intervention strategies and psychoeducation information learned, 2) parent coach flexibility and social support, 3) case management and advocacy, and 4) the relationship between the child and the parent coach.

Conclusions: This study provides preliminary evidence that parent-focused intervention programs can be carried out in a positive fashion with families with few resources in order to teach parent intervention techniques to support the social communication development of their young children with ASD. Parents of children with ASD are generally stressed and overscheduled, especially lower-resourced families. Partnering with families to provide a parent-focused intervention program based on the needs of the families they serve would help practitioners get the most "bang for their buck", particularly when implementing evidence-based programs within resource-poor community settings.

174 **141.174** Effects of a Parent-Mediated Intervention on Expressive Language Among Toddlers with Autism: A Randomized Controlled Trial

K. Baggett[1], *B. Barger*[2], *C. Beacham*[2], *A. L. Patterson*[2] *and B. DiPetrillo*[2], *(1)Mark Chaffin Center for Healthy Development, School of Public Health, Georgia State University, Atlanta, GA, (2)Georgia State University, Atlanta, GA*

Background: The purpose of this presentation is to report results of a randomized controlled trial pilot study of a parent-mediated intervention, focused primarily on enhancing parent support of toddler joint attention (Schertz et al., 2011). The Joint Attention Mediated Learning (JAML) program is a relationship based, developmentally oriented intervention that does not directly target expressive language promotion, but has consistently demonstrated large effects on joint attention (Schertz et al., 2013; 2017). Prior research has shown a relationship between establishment of joint attention and language development in young children with ASD (Markus et al., 2000; Bottema-Beutel, 2017). However, for preverbal toddlers with autism, it is not clear whether receipt of brief parent-mediated interventions, which do not intentionally target expressive language, are sufficient for improving expressive language outcomes.

Objectives: The current study examines effects of the Joint Attention Mediated Learning intervention on expressive language of toddlers with autism.

Methods: Participants included 30 toddlers diagnosed with autism. Participants were randomly selected from a larger sample (Schertz et al., 2017) to include a subset of 15 families who received the JAML program and 15 control group families. Demographics of the subset of 30 families are presented in Table 1. Pre- and post-intervention assessment videos of parent-child interactions at home were coded using the Early Communication Indicator (ECI; Greenwood, Walker, & Buzhardt, 2010). Based on direct observation, gestures, vocalizations, single words, and multiple words are coded for occurrence based on six minutes of direct observation of parent-child interactions in family homes. Coders were naïve to treatment condition and time point. Interobserver agreement (IOA) was examined for 20 percent of the videos. Mean IOA was 88%, ranging from 80% to 100% (SD=5.14). Analysis consisted of General Linear Mixture Models (GLMM), using lme function of the R nlme package, for parametric data (gestures). GLMM (Poisson, quasi-Poisson, and negative binomial) analyses were conducted with the glmmPQL function from the MASS package for non-parametrically distributed data, evidencing zero-inflation (single-words and multiple word). GLMM logistic regression, using lme4's glmer function, analyses were conducted on whether or not any word was uttered.

Results: Analyses of gestures, single words, and multiple words did not show significant treatment by time differences within this low powered sample. However, there was a significant treatment X time interaction wherein any word utterance (Z=3.31, p < .001) increased significantly for the JAML group (Pre= 20%, Post=67%; OR=8.0[95%CI=1.52-42.04] p<.001), but not the control group (Pre=33%, Post=40%; OR=1.33[95%CI=0.30-5.91], p=.71). See Figure 1.

Conclusions: In contrast to families in the control condition, families receiving the JAML intervention showed significant pre- to post- assessment gains in any word utterance during interactions with their parents at home. Although the JAML program does not directly target language acquisition, it had large effects on expressive language of toddlers with autism. These results are encouraging and warrant sufficiently powered analyses with the full study sample and other studies. Limitations of this study as well as considerations for future study will be presented.

175 **141.175** Encouraging Toddlers with ASD to Request: An Exploration of Expectant Pausing and Engagement Strategies

M. Maye[1], *A. S. Carter*[2] *and V. E. Sanchez*[3], *(1)Psychiatry, University of Pennsylvania, Philadelphia, PA, (2)University of Massachusetts Boston, Boston, MA, (3)Division of Developmental Medicine, Boston Children's Hospital, Boston, MA*

Background: Deficits in requesting are an early social communication risk factor for ASD in toddlers (Barbaro & Dissanayake, 2009) and are successfully targeted through intervention (Leung, 1994). Evidence-based interventions address a number of social communication deficits. However, little is known about how specific interactional strategies (i.e., ways interventionists interact with children to elicit or respond to behavior within an intervention session) function individually, and in combination, on requesting.

Objectives: The current study evaluated examiner use of two levels of two interactional strategies (i.e., positive affect, expectant pausing) on child requesting. Positive affect was defined as examiner use of animated facial expressions and expressive vocal intonation (levels: consistently positive affect, low affect with contingent positive affect). Expectant pausing was defined as the amount of time between an examiner's prompt before s/he delivered the next prompt on a hierarchy of increasing support (levels: 2 seconds, 7 seconds). Child interest (none, moderate, high) was examined as a potential moderator of child requesting. Child expressive language and ASD symptom severity were considered as covariates of child requesting.

Methods: As part of a larger screening study, toddlers were recruited and randomized to one of four conditions (positive affect by expectant pausing) following confirmation of an ASD diagnosis made with gold-standard assessment tools and clinical judgment (n=58, M=28.24 months [4.61]). Within the assigned condition, unfamiliar examiners led children through a series of 5 hierarchical prompts in an attempt to elicit requesting.

Results: Generalized estimating equation (GEE) analyses revealed a significant three-way interaction between positive affect, child interest in materials, and trial number when controlling for expressive language (See Figure 1). In high child interest trials in which children were randomized to the consistently high engagement versus the low with contingent high engagement condition, children were more likely to request in earlier trials than in later trials. In contrast, in medium child interest trials, in which children were randomized to the low with contingent high engagement versus the consistently high engagement condition, children made more requests independent of trial number. Low child interest trials rarely resulted in a request, irrespective of engagement condition or trial number. Pause length was not associated with requesting. Children with higher levels of expressive language were more likely to request.

Conclusions: A major finding to emerge from this study is that a child's level of interest in materials is an important consideration when attempting to elicit a request. This study provides initial evidence that children with varying levels of interest in materials may respond better to different levels of clinician use of positive affect (i.e., consistently high, versus low with contingent high). Further, beyond child interest in materials and clinician engagement condition, child developmental factors matter. Children with higher levels of expressive language were more likely to request. Additionally, the present study demonstrates a novel method for evaluating potential active ingredients of intervention in an experimental manner. Further exploration of individual interactional strategies may lead to both more personalized interventions for toddlers with ASD and more directive guidelines for clinicians.

176 **141.176** Examining Coaching Outcomes in the Social ABCs Parent-Mediated Intervention

E. M. Dowds[1], *A. Solish*[2], *T. McCormick*[3], *S. Macwilliam*[4], *L. Zwaigenbaum*[5], *S. E. Bryson*[6] *and J. A. Brian*[2], *(1)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital-Autism Research Centre, Burlington, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)IWK Health Centre, Halifax, NS, CANADA, (4)IWK HEALTH CENTRE, HALIFAX, NS, CANADA, (5)University of Alberta, Edmonton, AB, Canada, (6)Dalhousie University, Halifax, NS, Canada*

Background: The *Social ABCs* is a parent-mediated intervention (Brian et al., 2016; 2017) based on empirically supported Pivotal Response Treatment (PRT; Koegel & Koegel, 2006). The main targets of the *Social ABCs* are functional early (vocal/verbal) communication and positive affect sharing between child and caregiver for infants/toddlers who have suspected or diagnosed Autism Spectrum Disorder (ASD).

Objectives: The present study examines the training for *Social ABCs* parent coaches with a focus on the training of parent coaches across multiple Canadian sites in both research and clinical contexts. We present data on the consistency of coaching fidelity across training sites, and highlight that the success of training coaches, will increase community capacity for implementation.

Methods: Our team has trained a total of 15 coaches, with a range of educational, clinical, and research backgrounds, across 4 major Canadian cities in 3 provinces; Toronto and Hamilton (Ontario), Halifax (Nova Scotia), and Edmonton (Alberta). From this population of coaches, we have 3 identified trained-trainers, and 3 trained supervisors who are PhD-level clinical psychologists. Using video-coded indices, fidelity of the parent coaches has been analyzed using (1) a measure of coaching fidelity across 3 separate parent/child dyads and (2) fidelity of parent implementation for 3 separate parent/child dyads, across 15 coaches. The parents' implementation served as a proxy measure for the overall success of the coaches' skill level.

Results: Coaching fidelity and parent implementation fidelity were consistently high across research sites, and slightly higher in the community cohort of coaches, with parent fidelity ranging from 80-100% by week 12 of the intervention, demonstrating that the coaches are highly skilled at training parents in the Social ABCs. The length of time required to train parent coaches has decreased significantly over time. In the Social ABCs pilot study (Brian et al 2016) the training of the first coaches took 1 year of intense supervision until independent coaching began. Currently, training takes half the time (about 6 months), a training process which has been maintained from our initial Randomized Control Trial (Brian et al., 2017). This has remained as a successful model for training within a large community demonstration project currently underway. More recently, in a group-based clinic-delivery model, our team has trained two experienced Speech-Language Pathologists to provide parent-coaching in a shorter, 3-month period.

Conclusions: We define coaching within the Social ABCs as providing live, moment-to-moment, positive coaching strategies. These positive strategies are defined as the verbal acknowledgement of correct in-the-moment behaviours exhibited by the caregivers with the child, and setting families up for success in using the techniques. It is this positive coaching which supports caregivers in learning the Social ABCs strategies. All 15 parent coaches have achieved a high level of coaching fidelity across research sites and community settings. Our increased efficiency in training coaches contributes to the feasibility and sustainability of this model.

177 **141.177** Feasibility and Acceptability of Using an Online Platform to Deliver Training in Evidence-Based, Parent-Mediated

Interventions for ASD

A. Pomales[1], *R. L. Gruen*[1], *E. A. DeLucia*[1], *L. L. Booth*[1] *and P. E. Ventola*[2], *(1)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT*

Background:

Access to intervention for Autism Spectrum Disorder (ASD) is limited. The high cost, frequent sessions, and distance of reputable medical centers create barriers that prevent families from gaining access to empirically validated interventions, such as Pivotal Response Treatment (PRT). PRT is a naturalistic intervention that targets social communication skills. Previous findings have shown that caregivers can readily implement PRT (Vernon, Koegel, Dauterman & Stolen, 2016). More recently, studies have aimed to explore methods of using technology to deliver behavioral interventions and training for parents of children with ASD (Lindgren et al., 2016). MindNest Health is a digital behavioral health tool that delivers parent education and training in evidence-based, parent-mediated interventions through didactic instruction and animated demonstrations of key concepts.

Objectives:

To examine the feasibility and acceptability of using MindNest to deliver training in PRT principles.

Methods:

MindNest provides eight online training modules that include didactic information, as well as demonstrations of behavioral strategies using animated simulations. For example, the simulations illustrate how a parent can prompt their child to ask or respond to questions. Additionally, participants completed four one-hour videoconferencing sessions with a clinician. The duration of the study is ten weeks, and videoconferencing sessions are scheduled during the first, third, seventh, and tenth week. During sessions, clinicians provided direct instruction and feedback on parents' PRT implementation.

Parents acceptance of MindNest was assessed using the Client Credibility Questionnaire (CCQ) at week 2. The CCQ is an eight-point scale that asks parents how logical the training seems, how confident they are in its success, how confident they feel in recommending it, and how confident they feel that it will improve other areas of development, such as sadness, anxiety, or school work.

Results:

To date, 15 families with children with ASD between the ages of 2-7 have enrolled in the program. All families independently completed the online enrollment process and gained access to the training platform. Six families are in the process of completing the program and 2 families withdrew from the study. Seven families successfully completed all training modules and videoconferencing sessions.

Parents rated items on the CCQ on an 8-point scale ranging from 0 (*not at all logical/confident*) to 8 (*very logical/confident*), with a total score range of 0 to 32. On average, participants rated a 7.2 on *logical* (*N*=15, *SD*=.941), 5.8 on *confidence* (*N*=15, *SD*=1.42), 6.27 on *recommend* (*N*=15, *SD*=1.75), 4.93 on *other* (*N*=15, *SD*=1.75), and a 24.20 total score (*N*=15, *SD*=5.08).

Conclusions:

MindNest is a novel platform used to attain scalable education and training in PRT. This addresses the need for improved access to affordable evidence-based interventions, and reduces the economic burden of providing care to individuals with ASD. Successful completion of the program supports the idea that this program is a feasible option for delivering training in PRT, which will increase accessibility to service. Acceptability ratings reveal that, on average, participants find the program to be very logical. This could result from integrating parent-friendly content on behavioral principles with videoconferencing based support from a clinician.

178 **141.178** How Does the Broader Autism Phenotype Affect Parent-Mediated Interventions for Children with Autism?

H. L. Moore[1], *A. Pickles*[2], *S. Wigham*[3], *J. Green*[4], *A. LeCouteur*[5], *J. R. Parr*[6] *and P. Consortium*[4], *(1)Newcastle University, Newcastle upon Tyne, United Kingdom, (2)Biostatistics and Health Informatics, King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (3)Institute of Neuroscience, Newcastle University, Newcastle upon Tyne, United Kingdom, (4)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (5)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom, (6)Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom*

Background:

The broader autism phenotype (BAP) describes sub-diagnostic threshold traits of autism/autism spectrum disorder (ASD) that are commonly found in family members of people with autism, but also the general population. BAP is associated with a number of difficulties, including language, face processing, cognitive, social, rigidity and psychiatric conditions. Parent-mediated interventions can benefit children with autism; however, very little research has investigated how the presence of parental BAP might influence parent-mediated intervention and consequently affect outcomes. One small pilot study (n=18; Parr et al., 2015) showed a significant negative correlation between BAP and measures of mother-child interaction post-intervention. The authors concluded that this required further investigation using larger samples, including a control group who received treatment as usual (TAU).

Objectives:

The aim was to determine how parental BAP affects outcomes following parent-mediated intervention or TAU. We hypothesised that BAP would impact parent-child interaction and effectiveness of parent-mediated intervention.

Methods:

PACT 7-11 was a follow up (FU) of a parent-mediated social communication intervention RCT for children aged 2–4 years with core autism. FU was conducted at a median of 5.75 years from the original trial endpoint (mean age=10.5 years (SD=0.8)). Parental BAP traits, measured at FU using the Family History Interview-Subject (FHI-S) Factor Score, were assumed stable and applied retrospectively for analysis. The following blinded endpoint and FU outcomes were treated as multivariate pairs: Autism Diagnostic Observation Schedule (ADOS) comparative severity scores (CSS); Dyadic Communication Measure for Autism (DCMA) of the proportion parent acts that were synchronous with child attention (DCMA Parent Synchrony); and DCMA proportion of child initiations when interacting with the parent (DCMA Child Initiations). Full Information maximum likelihood structural equation modelling in STATA was used to make use of the full sample and repeat post-randomisation outcomes. Adjusting for baseline outcome value and treatment group, the effect of FHI-S (square root transformed) on each outcome was examined, both as main effect and moderator of treatment effect.

Results:

121 (80%) of the 152 trial participants (PACT intervention=59 [77%] of 77, TAU=62 [83%] of 75) completed follow up analysis. Of these, FHI-S scores were available for 102 participants (PACT intervention=49, TAU=53). The models on the full sample confirmed the strong group effects on all outcomes (p<.001) reported in previously published work. FHI-S was not correlated with baseline ADOS CSS, DCMA Parental Synchrony, or DCMA Child Initiations. FHI-S had no effect on outcome ADOS CSS or DCMA Parent Synchrony. There was a marginally significant main effect of FHI-S (p=.079), and a marginal moderation effect (p=.097) on DCMA Child Initiations, and no significant interactions.

Conclusions:

In this sample, BAP appears to have a limited role in outcomes following parent-mediated intervention. The finding may be specific to the particular behaviours targeted by the PACT therapy and the relatively low FHI-S scores of the PACT parents. More information is needed to understand how interventions should be tailored to parents, children, and particular environments.

179 **141.179** Implementing an Early Intensive Behavioral Intervention Program (EIBI): Description of Combined Approaches

C. Dionne[1], *A. Paquet*[2] *and J. Joly*[3], *(1)Psychoéducation, Université du Québec à Trois-Rivières, Trois-RIvières, QC, Canada, (2)Psychoéducation, Université du Québec à Trois-RIvières, Trois-Rivières, QC, Canada, (3)Psychoéducation, Université de Sherbrooke, Sherbrooke, QC, Canada*

Background:

Research effort has been made over the past several years to demonstrate the efficacy and the effectiveness of EIBI for young children with ASD (eg., Boyd *et al*., 2014; Smith et al., 2010; Eikeseth, 2009). Despite the fact that a part of the scientific community recognizes that EIBI should be favored as an intervention for young children with ASD, this assumption is nonetheless accompanied by some criticisms regarding the studies conducted. They include a poorly detailed description of the independent variables specifying the curriculum and important intervention elements (Lechago and Carr, 2008). Love *et al*. (2009) drew a more complete portrait of caseworkers' EIBI practices. The authors underscore the great variability of the implemented programs. More specifically, they stress the fact that supervisors report using more than one curriculum manual, thus suggesting that none of the available curriculums meet all the needs.

Objectives:

The objective of this presentation is to describe the choices made by rehabilitation centers in the context of a universal community based on Early Intensive Behavioral Intervention program (EIBI) for 2 to 5 year-old children with ASD in Quebec (Canada). The approaches and strategies used by professionals are investigated to identify the most frequent and the possible combinations.

Methods: The selected model for evaluating the implementation is the one based on the program theory proposed by Chen (2015). According to Chen's (2015) model, one of the essential components of an action plan that targets the implementation of a program and that guides its evaluation is the intervention and service delivery protocol. A questionnaire about implementation (translated and adapted from Love *et al*. (2009) and Gamache, Joly and Dionne (2010)) was completed by 114 stakeholders from 14 rehabilitation centers across the province. A descriptive analysis was used to examine the results obtained through the questionnaire.

Results:

When asked about the approaches used within the EIBI program, stakeholders have multiple responses. One hundred (87%) say they use Applied Behavior Analysis (ABA). Seventy-two people (62.6%) report using PECS and environmental structuring respectively, while 65 (56.5%) use sensory integration and 32 people (27.8%) use Verbal Behavior. Thirty-four respondents (29.6%) report using other intervention approaches that they do not consider to be part of the EIBI program. Among the other approaches and strategies reported, the most common is the naturalistic approach (8.7%). The combination of approaches and strategies is frequently mentioned. For the 100 people who use AAC, 66 use it in conjunction with PECS, 69 with TEACCH, 30 with Verbal Behavior and 62 with sensory integration.

Conclusions:

This study enabled us to describe the choices made by the large majority of the centers mandated by the province of Quebec to offer a free universal EIBI program to children under 6 years of age with ASD. It confirms the diversity of choices. This study thus contributes, albeit modestly, to the advancement of the emerging Implementation Science by describing the organizations' choices, a major, yet barely studied, link in the implementation of such complex programs.

180 **141.180** Improvement in Social Communication Skills Following the PEERS® for Preschoolers Intervention

E. Moulton[1], *M. Park*[2] *and E. A. Laugeson*[1], *(1)Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA, (2)Psychiatry, University of California, San Francisco, San Francisco, CA*

Background: Social impairment is a hallmark feature of neurodevelopmental disorders, and significantly affects individuals with ASD regardless of cognitive and language functioning (Carter et al. 2005). While social challenges emerge early, and are highly impairing across the lifespan (Howlin et al, 2000; Rao et al. 2008), few evidence-based social skills interventions (SSIs) exist, particularly for young children with ASD. Children with generally average cognitive abilities have unique SSI needs; however, even fewer programs exist for this group (Reichow et al. 2013). These children are likely to be socially motivated, and to be aware of their differences, leading to distress if social skills impairments are unaddressed. Objectives: To develop and test a time-limited SSI for young children with ASD with average cognitive abilities. Multiple components which were previously found to bolster treatment gains were included, including active parent education and training, play-based group format, multimodal teaching strategies, and teaching of concrete skills for friendship building. In addition to studying treatment efficacy, predictors of treatment gains were investigated.

Methods: An open-trial (Study 1) and a randomized-controlled trial (Study 2) were completed. Study 1 included 5 children with ASD (mean age = 5.28 years); Study 2 included 11 children with ASD (mean age = 4.89 years). Methods across studies were similar. The PEERS® for Preschoolers intervention is a parent-assisted social skills treatment program that met once weekly over the course of 16 weeks. Each session was 90 minutes; parents and children attended separate and joint concurrent sessions that focused on key strategies for friendship development and maintenance. At baseline, the KBIT-2 and VABS-2 were collected. At baseline and post-treatment, the QPQ, SSiS, SRS-2 and ADOS-2 were collected. Select measures will be discussed here.

Results: Study1: Parent-reported SRS-2 Total Scores decreased by 9.00 T-score points (p=.158, d=.776), indicating a strong trend with a medium/large effect overall. Parent-reported *SSiS* Social Skills scores increased by 5.40 Standard Score (SS) points (p=.633, d =.132) and *SSiS* Problem Behavior scores decreased by 2.20 SS points (p=.782, d=.231); effect sizes were small. Study2: Parent-reported SRS-2 Total Scores decreased by 9.45 T-score points (p=.001, d=1.40), indicating a clinically and statistically significant improvement with a large effect size. From pre- to post-treatment, there was a significant decrease in parent-reported *SSiS* Problem Behavior scores (-5.90 SS points, p=.032, d=.803, large effect). There was a strong trend toward a significant improvement in parent-reported *SSiS* Social Skills. Predictors of treatment gains: Across studies, treatment gains were independent of baseline KBIT-2, VABS-2, and ADOS-2 comparison scores. Treatment gains on the SSiS Social Skills domain were predicted by baseline SSiS Social Skills scores (r=.531; p=.042, r^2=.282). No predictors were identified for improvements in SSiS Problem Behaviors or SRS-2 Total Scores.

Conclusions: Though results should be interpreted with some caution and are limited due to small sample sizes, they suggest social growth and a decrease in problematic behaviors following the PEERS® for Preschoolers intervention. Treatment gains are largely independent of baseline functioning, indicating that the program is likely to be beneficial for many young children with ASD.

181 **141.181** Psychoeducational Intervention in Preschool Age

A. Mira Coelho[1] *and A. I. Aguiar*[2]*, (1)Psychiatry, Hospital S.Joao, Port, Portugal, (2)ELOS, porto, Portugal*

Background: Early and intensive intervention on pervasive developmental disorders such as autism, is regarded by specialists everywhere, as vital for a better prognosis. We developed an intensive and systematic program (Psychoeducational integrated intervention) , with a multidisciplinary team (with psychologists, occupational therapists, speech therapists), for children with ages under 6 years old, with autism spectrum disorders The program takes place at the clinical setting but also in the child's school and home, integrating all the resources of family. Parents are invited to participate in the sessions, to learn daily strategies to promote their child's development at home. The success of the intervention is evident with monthly monitoring and adjusting of objectives.
Objectives: To evaluate the success of this program in ASD children

Methods:

- All children were assessed with ADOS (Autism Diagnostic Observation Shedule and the Psychoeducational Profile III (PEP-III; Schopler, Lansing, Reichler, & Marcus, 2005) in at least two distinct moments. The results obtained in the two evaluation moments were analyzed, with approximately 12 months of interval between the first and second moments.
- In this study 25 children were selected, who attended the program for a period equal to or greater than 12 months; The children selected were aged between 20 and 70 months.

Results:

- As can be seen from the results , from Moment 1 to Moment 2, approximately 12 months apart, great progress was observed in all children. All the children showed evolution, with a greater number of items in which they are successful, as well as a greater number of skills that are emerging.

Conclusions: This early intervention program integrating different resources involving therapists anf parent training may contribute for a better prognosis in ASD

Poster Session
142 - Neuroimaging
5:30 PM - 7:00 PM - Room: 710

182 **142.182** Autistic Traits Are Both Distributed and Localised within Structural and Functional Brain Networks

S. Paul[1]*, A. Arora*[2]*, R. Midha*[3]*, D. Vu*[4]*, P. K. Roy*[5] *and* ***M. Belmonte***[6]*, (1)Institute of Psychiatry, Psychology and Neuroscience; King's College, London, United Kingdom, (2)Universität Salzburg, Salzburg, Austria, (3)National Institute of Mental Health and Neuro Sciences, Bangalore, India, (4)Division of Psychology, Nottingham Trent University, Nottingham, United Kingdom, (5)National Brain Research Centre, Manesar, India, (6)Com DEALL Trust, Bangalore, India*

Background: Autism, the autism spectrum and the broader autism phenotype are behaviourally defined constructs whose physiology remains murky. Impairments in theory-of-mind present a major aspect of autism's 'core' social communicative symptoms, although it's unclear to what extent such symptoms may be fractionable features which interact only later in development (Valla & Belmonte, 2013; doi: 10.1016/j.dr.2013.08.004). Behavioural measurements have tended to be coarse, failing to capture the often subtle variability of theory-of-mind across the autism spectrum, and this limitation holds doubly when it comes to dimensional variation beyond the autism spectrum: Most assays have used a binary outcome- success or failure at the theory-of-mind question- which cannot assess a dimensional continuum, and narrative presentations which can confound theory-of-mind with verbal working memory.
Objectives: We ask whether both psychometric measures of autistic traits and a continuous, reaction-time measure of theory-of-mind, in a visual presentation, might correlate with neural network integrity at whole-brain and regional scales.

Methods: In 30 right-handed normal volunteers (12 females) aged 27.29±2.88, we studied the relationship between anatomical (diffusion tensor imaging (DTI)) and physiological (500 s of 2 Hz eyes-closed rs-fMRI) measures of brain connectivity, and psychometric (Social Responsiveness Scale (SRS), Autism Spectrum Quotient (AQ), Systemising Quotient (SQ)) and behavioural (the Attention Network Test (ANT)), and key-press reaction time difference associated with a computer-game theory-of-mind condition) measures of autistic traits. The AAL-90 atlas was warped to functional scans and to grey/white segmented T1-weighted anatomical scans to label regions. A functional correlation matrix was constructed over mean fMRI time series within each pair of regions. Similarly, segmented T1-weighted anatomical scans and the entire diffusion-weighted

series were rigidly registered to the corresponding first b=0 image, the AAL-90 atlas was warped to these, and probabilistic tractography was conducted from grey-matter voxels to construct an anatomical connection strength matrix over all region pairs. These functional and anatomical correlation matrices produced network measures of clustering coefficient, characteristic path length, and efficiency (Rubinov & Sporns, 2010; 10.1016/j.neuroimage.2009.10.003).

Results: For the functional connectivity data, high SRS scores were associated with strong clustering (r=+.45, p=.008), short path length (r=-.39, p=.018) and high efficiency (r=+.47, p=.006), globally and within regions spanning temporo-parietal and prefrontal cortices. Similar trends manifested for AQ scores. Likewise, delayed orienting of attention (lower orienting effect) in the ANT was associated with strong clustering (r=-.42, p=.0095), short path length (r=+.44, p=.007) and high efficiency (r=-.46., p=.0133). For the structural connectivity data, SQ was associated with strong clustering (r=+.37, p=.023) and efficiency (r=+.38, p=0.018) in a relation driven specifically by temporal pole; theory-of-mind reaction time trended towards relation with strong clustering (r=-.27, p=.0766) and efficiency (r=-.28, p=0.0655) overall, but this relationship became highly significant within right supramarginal gyrus.

Conclusions: Autistic traits as indexed by SRS, AQ and SQ, and slowed attention shifting in the ANT, are associated with more efficient distributed resting-state functional networks. Theory-of-mind, in contrast, relates largely to localised structural integrity within right temporoparietal junction. Measured localisation of function depends not only on the cognitive capacity assayed but also on the assay itself.

183 **142.183** Autistic Traits Predict Individual Differences in Salience Network Connectivity in Absolute Pitch Musicians

ABSTRACT WITHDRAWN

Background: Absolute pitch (AP) and Autism Spectrum Disorder often co-occur in individuals, are both heritable, and are associated with atypical brain connectivity (Mottron, 2013). Previous attempts to explain these similarities in terms of locally-biased perceptual processing have had limited success. Low cognitive flexibility and greater sensitivity to sound may better explain the relation between autistic traits and possession of absolute pitch. Here, we examine to what extent such a profile is associated with atypical functioning of the fronto-insular salience network (Uddin, 2013), which plays a role in integrating external sensory information to coordinate goal-directed behavioural responses and may provide a unifying framework for the co-occurrence of AP and autism.

Objectives: We investigated functional brain connectivity using resting-state fMRI in salience and default-mode networks (DMN) in musicians with and without AP, and investigated individual differences in autistic traits and salience network connectivity.

Methods: 120 musicians completed an online survey about their musical experience, possession of absolute pitch and autistic traits as measured by the Autism Spectrum Quotient (AQ, Baron-Cohen, 2001). A subset (n=32) with and without AP (AP=17, non-AP=15), matched on age (mean=24±6 years) and years of musical training (mean=18±5 years), completed a musical discrimination task (Wallentin, 2010), the Wechsler Adult Intelligence Scale (Wechsler, 1939), and resting-state functional MRI in a 3T scanner while viewing a fixation cross. Connectivity of the salience network (seeded in the fronto-insular region) and DMN, using seed-to-voxel connectivity was estimated using the CONN toolbox in SPM12. Group differences in brain connectivity between AP and non-AP possessors are reported at p<.05, false-discovery-rate corrected (FDR). AQ-connectivity relationships were assessed within (regression) and between (ANCOVA) AP and non-AP groups.

Results: The AP musicians had AQ scores in a higher range (17±7) than the non-AP ones (15±5) although the difference was not statistically different (p=.2). Participants did not differ in melody or rhythm discrimination (mean percent accuracy=84±5, p=.7) nor on full-scale IQ (mean=113±14, p=.5). Seed-based elicitation of salience network connectivity co-occurred with decreased correlations with the posterior default mode network in both groups (Fig.1). The AP group contrasted against the non-AP showed hyperconnectivity of the salience network, particularly with DMN regions in the posterior cuneal and occipital cortex (p<.05-FDR corrected, Fig.2a), but no differences in the DMN itself. These differences in salience network connectivity were positively related to AQ score within the AP group (p=.04, Fig.2b) but not the non-AP group (p=.14).

Conclusions: Individuals with AP show increased connectivity in the fronto-insular salience network which is predicted by their AQ score. The hyperconnectivity of SN occurs in combination with reduced suppression of the DMN. Reduced dynamic switching between these large-scale networks can impair cognitive flexibility (Menon, 2010) and might explain common features of both AP and autism. Although there is tremendous heterogeneity in executive functions in both AP and autism, these findings provide support for further investigation of cognitive flexibility and salience network connectivity to account for their co-occurrence in a subgroup of individuals. This link from physiology to perception and cognition in turn can provide further avenues for fractionating the ASD phenotype.

184 **142.184** Specific Association between at-Rest Alpha Power and Restrictive and Repetitive Autistic Traits: Replication and Extension in a Clinical Sample

V. Carter Leno[1], *A. Naples*[2], *C. Carlos*[2], *T. Winkelman*[2], *D. Stahl*[2], *J. Wolf*[2], *E. Jarzabek*[2] *and J. McPartland*[2], *(1)King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom, (2)Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Previous literature suggests that different domains of autistic traits are associated with dissociable patterns of at-rest neural activity. Better understanding of the neural drivers of specific domains of symptoms may inform the neurobiological basis of behavioural variation and help to parse heterogeneity in autism spectrum disorder (ASD). Recently, a specific association between alpha power and restricted and repetitive traits has been reported in typically developing adults. These findings require replication and testing in clinical samples.

Objectives: We aimed to replicate and extend previous work by: (1) testing for a positive association between alpha power in the parietal region and restricted and repetitive traits in a sample of typically developing (TD) adolescents (N=61; 34 males, mean age= 13.07, mean IQ= 106.97); (2) examining this relationship in a clinical cohort of adolescents with ASD (N=91; 70 males, mean age= 13.67, mean IQ= 101.70) and by differentiating between low (6-8Hz) and high (8-12Hz) alpha.

Methods: ASD traits were assessed using parent-report Social Responsiveness Scale-2 (SRS) subscales (social awareness, social cognition, social communication, social motivation, restrictive and repetitive behaviours (RRB)). Indices of normalized power were extracted from at-rest EEG activity. As the primary goal was to replicate previous findings, analyses focused on traits measured by the RRB subscale.

Linear regression was used to test the association between RRB traits and low and high alpha power in the TD and the ASD samples separately. Where significant associations were found, age, IQ and sex were included as covariates. Following from this, multivariate regression assessed both

topographical and oscillatory specificity. Ongoing analyses examine (1) the relationship between other indices of alpha (e.g., peak alpha frequency) and RRB traits and (2) RRB traits, alpha power and anxiety, measured by the Childhood Behaviour Checklist (CBCL) and Childhood Anxiety Sensitivity Index (CASI).

Results: No associations were found in the TD group, likely reflecting a restricted range in SRS scores (range of 41-66 in the TD group vs. range of 45-110 in ASD group on the RRB subscale). Consistent with prior work, a positive association between parietal alpha power, specifically in the low frequency band, and RRB traits was observed in the ASD group (p=0.02; Figure 1), which remained when covariates were included in the model (p=0.03). A comparable association between RRB traits and low alpha power to that reported in the parietal region was found in the central (p=0.02), but not in the frontal or occipital regions. No significant associations were found between delta, theta, beta or gamma power in the parietal region and RRB traits.

Conclusions: Consistent with prior findings for autistic traits in adults, we found a positive association between lower alpha power in the parietal region and RRB traits in a clinical sample of youth with ASD. Contrary to our previous work in adults, we did not observe this relationship in the TD sample; this may reflect the constrained range of RRB traits observed in the sample, or it may suggest that the effects represent a developmental phenomenon emerging in later adolescence or early adulthood.

185 **142.185** Atypical EEG in Autism Spectrum Disorder: Comparing a Dimensional and a Categorical Approach

E. Milne[1], *R. Gomez*[2], *A. Giannadou*[2] *and M. Jones*[1], *(1)The University of Sheffield, Sheffield, United Kingdom, (2)University of Sheffield, Sheffield, United Kingdom*

Background: While many studies have found group differences in neural dynamics between people with and without autism spectrum disorder (ASD), the extent to which variation in neural dynamics is related to variation in the autism phenotype across the population is not known. **Objectives:** The aim of this study was to establish whether neural variables, namely inter-trial phase coherence (ITC) and multiscale entropy (MSE), that have previously been shown to differ at a group level between people with and without ASD, also correlate with individual differences in the autism phenotype across the population. ITC and MSE were selected for analysis as they reflect different aspects of neural information processing, including consistency of the neural response (phase coherence) and complexity of the EEG signal (MSE). Furthermore, both variables have been suggested by previous studies to represent either an endophenotype or a biomarker for ASD. **Methods:** Data were obtained from ninety-nine adults, thirty-eight of whom had an ASD diagnosis and sixty-one of whom did not. Phenotypic information was obtained from the Social Responsiveness Scale (Revised), the Repetitive Behavior Questionnaire, the WHO Adult ADHD Self-Report Scale Screener and the Beck Anxiety Inventory (Trait version). Neural dynamics were computed from EEG data acquired during visual stimulation (presentation of 200 black and white checkerboard stimuli) and during a period of eyes-closed rest. **Results:** The phenotypic questionnaires revealed individual differences in autistic traits across the population, reflecting many previous reports that traits and behaviours associated with the autism phenotype are continuously distributed. Individual differences in both ITC and MSE were also found. However, non-parametric correlation analyses indicated that none of the phenotypic variables were related to either ITC or MSE: rho <.200; p >.05, Bayes Factors (BF_{01}) evaluating the strength of evidence for the null hypothesis > 3. Despite finding no relationship between neural dynamics and the autism phenotype, group-level statistics showed that both ITC and MSE were more likely to be reduced in people with ASD than in those without. Discriminant function analyses indicated that associations between group (with ASD, without ASD) and both ITC and MSE were significant, ITC: $\chi^2(1) = 7.99$, Wilks $\Lambda = .825$, p =.005; MSE:, $\chi^2(1) = 4.34$, Wilks $\Lambda = .90$, p =.037, however not all participants with ASD showed reduced MSE or reduced ITC. **Conclusions:** These data suggest that there are likely to be multiple neural profiles underpinning ASD, and highlight that while the autism phenotype is continuously distributed across the population, this distribution is not underpinned by individual differences in these measures of neural dynamics.

186 **142.186** A Better Approach to Measuring Brain Volume in Autism Spectrum Disorder

J. Crucitti[1], *M. A. Stokes*[2], *P. G. Enticott*[3] *and C. Hyde*[2], *(1)Deakin University, Geelong, Australia, (2)Deakin University, Burwood, Australia, (3)Deakin University, Geelong, AUSTRALIA*

Background: Total brain volume (TBV) and intracranial volume (ICV) have been extensively researched in individuals with Autism Spectrum Disorder (ASD). Though, findings are often inconsistent. Additionally, some past studies did not account for age and gender, and were often based on small to moderate sample sizes.

Objectives: Brain volume data from studies examining autistic and typically developing (TD) participants were gathered to develop the Autism Neurophysiological Parameters Atlas (ANPA). Brain volume trends in light of age were compared between these two groups.

Methods: Following a systematic search, 34 and 30 studies measuring TBV and ICV, respectively, were included. Raw data, or the means and standard deviations of brain volume and age, were obtained from 3,316 autistic participants and 2,744 TD participants. ANCOVA's, controlling for age, compared raw data of autistic participants to TD individuals for males and females separately across a number of age groups. The frequency of extreme (±1.5 SD) TBV and ICV were also explored.

Results: Compared to TD males, findings revealed autistic males to have larger TBV and ICV during late childhood and adolescence (p<.05), respectively, as well as smaller TBV during adulthood (p<.05). In contrast, brain volume was not different between autistic and TD females. Extremely small (OR=3.11), and extremely large (OR=7.17), TBV was more common in autistic than TD males aged two to four years. Compared to controls, autistic males were more likely to have extremely large TBV and ICV between nine to 12 years (OR=3.73), and between 13 to 17 years (OR=6.02), respectively. During adulthood, autistic males were more likely to have extremely small TBV than TD males between 18 and 24 years (OR=3.41), and above 25 years (OR=4.04).

Conclusions: We conclude that for those diagnosed with autism, brain volume is dynamic over age, and varies considerably between autistic individuals. Although some mean differences were observed, a greater amount of variance in brain volume was present in autistic than TD males. Future research investigating brain volume in ASD is needed to account for such variance rather than comparing means between groups. Unlike meta-analyses and independent studies, the ANPA properly accounts for outliers by capturing the entire variance in the data. Hence, the ANPA more effectively describes brain volume in ASD compared to previous methods.

187 **142.187** A Clinical and Behavioral Protocol for Obtaining Electrophysiological Data with Children with Low Language and Cognitive

Ability

***E. S. Kuschner**, M. Kim, M. DiPiero, M. Ku, L. Bloy, J. C. Edgar and T. P. Roberts, Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Neuroscience research conducted with individuals with autism spectrum disorder (ASD) has historically been limited to those with age-appropriate cognitive abilities who are considered "high functioning" cohorts. Children who are nonverbal or have intellectual disability have frequently been excluded from research given anticipated barriers such as tolerating loud sounds associated with magnetic resonance imaging and remaining still during an imaging exam (South et al., 2013). Including individuals with lower intellectual and language abilities in neuroimaging research is needed to obtain a more complete understanding of ASD (and associated disorders). As such, there is a need for approaches to: 1) improve data quality across age and performance range; and 2) identify non-pharmacological, non-sedative, and awake recording strategies. Identifying new approaches for individuals previously excluded from neuroimaging research is a critical step in understanding the genetic expression of ASD, and more specifically, language development (Tager-Flusberg et al., 2017).
Objectives: To develop and implement a clinical and behavioral protocol for obtaining electrophysiological data using magnetoencephalography (MEG) with minimally verbal or nonverbal children with ASD (8-12 years).

Methods: Participants were 14 children with ASD (11 males, mean age=9.9 years, SD=1.3; Nonverbal IQ mean=54.9, SD=13.2) meeting the study definition of minimally verbal or nonverbal (i.e., expressive vocabulary of fewer than 30 words used spontaneously, flexibly, and communicatively). With the support of the newly developed *MEG Protocol for Low-language/cognitive Ability Neuroimaging* (MEG-PLAN), all participants completed MEG protocols using a 275-channel CTF MEG system. Paradigms were short (five to fifteen minutes) and were passive and thus did not require task performance. Data are presented from a pure tone paradigm. 150 trials each of interleaved 500Hz and 1000Hz tones were presented at a pseudo-randomized interstimulus interval (ISI) in the range of 1500 to 2000 ms (approximately 5 minute acquisition). Test-retest reliability was evaluated for a subset (n=8) of participants.

Results: Based on stakeholder feedback, MEG-PLAN was developed as an interdisciplinary protocol to integrate clinical/behavioral (presented here) and technical components to be implemented by a team of clinicians, scientists, and MEG technicians (see Figure 1). Clinical and behavioral components focus on using parents as partners, with strategies based on the principles of applied behavior analysis, including systematic desensitization and habituation, differential reinforcement, visual supports, and individual tailoring. MEG-PLAN is implemented in three parts via (1) initial assessment, (2) plan and preparation for the family and team, and (3) *in vivo* support at the MEG Visit. Using MEG-PLAN, a 75% success rate for obtaining evaluable MEG data was achieved. Moreover, results were reproducible; based on data from eight participants who were scanned twice, M50 latency values were found to be reliable (interclass correlation coefficient = 89%).

Conclusions: Results indicate that children with ASD who are minimally verbal or nonverbal, and often have co-occurring intellectual disability, can be effectively and comfortably supported to complete neuroimaging paradigms that yield valid and reproducible results. MEG-PLAN is a protocol that can be disseminated and implemented across research teams, and likely adapted across technologies to collect neuroimaging data in a previously understudied group of individuals.

188 **142.188** A Diffusion Weighted Imaging Tract Based Spatial Statistics Study of Autism Spectrum Disorder in Preschool Aged Children

***D. S. Andrews**[1], J. K. Lee[1], M. Solomon[2], S. Rogers[1], D. G. Amaral[1] and C. W. Nordahl[1], (1)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (2)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA*

Background: The core symptoms of Autism Spectrum Disorder (ASD) are widely theorized to result from altered brain connectivity. Diffusion weighted magnetic resonance imaging (DWI) has been a versatile method for investigating underlying microstructural properties of white matter (WM) in ASD. Despite phenotypic and etiological heterogeneity, DWI studies in majority male samples of older children, adolescents and adults with ASD have largely reported findings of decreased fractional anisotropy (FA) across several commissural, projection, and associative fiber tracts. However, studies in young preschool aged children (<30-40 months) suggest an inverse relationship between WM diffusion properties and ASD earlier in development
Objectives: We sought to characterize WM diffusion properties associated with ASD in a sample of male and female preschool aged children.

Methods: We analyzed 127 individuals with ASD diagnoses (85♂,42♀) and 54 typically developing controls (42♂,26♀), aged 25.1-49.6 months. DWI were acquired in 30 independent directions with five interleaved non-diffusion weighted images. An accompanying phase map image was acquired to correct for field inhomogeneities. Images were preprocessed using MRtrix3 and the FSL diffusion toolbox and included; 1) denoising, 2) Gibbs artifact correction, 3) eddy current correction, 4) between and within volume motion correction, and 5) field distortion correction. Tensor maps were used to calculate corresponding maps of FA, mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD). Whole brain voxel-wise statistical analysis of FA, MD, RD, and AD maps was conducted using tract based spatial statistics (TBSS). Voxel-wise effects of group were estimated by regression of a general linear model including sex, age in months, mean absolute and relative RMS motion parameters as covariates. Interaction effects between group, sex, and age were also tested by adding the appropriate term to the above model.

Results: Males and females with ASD had significantly increased measures of FA in eight clusters (TFCE $p<0.05$) that incorporated several WM tracts including regions of the genu, body, and splenium of the corpus callosum as well as the corona radiata, inferior and superior longitudinal fasciculi, cerebellar peduncles and corticospinal tract. No significant between group differences were observed for measures of MD, RD, or AD. A group-by-sex interaction was observed in measures of AD across six significant clusters (TFCE $p<0.05$) incorporating areas of the body, genu, and splenium of the corpus collosum as well as areas of the right corona radiata and external capsule. In these tracts ASD females showed increased AD compared to TD females while ASD males showed decreased AD compared to TD males. No significant group-by-age, sex-by-age, or group-by-sex-by-age interaction effects were observed.

Conclusions: The current findings support growing evidence that young children with ASD have atypical measures of WM microstructure that appear to differ in directionality from alterations observed in older individuals with the condition. To our knowledge this study represents the largest sample of females with ASD to be evaluated using DWI. Microstructural differences associated with ASD largely overlapped between sexes. However, differential relationships of AD measures indicate that sex likely modulates ASD neural phenotypes.

189 **142.189** Accelerated Decline of Motor Tracts and Links with Symptom Severity in Older Adults with ASDs

J. Hau[1], *R. A. Carper*[2], *R. A. Mueller*[3], *M. Kinnear*[3], *A. J. Lincoln*[4], *A. Baker*[5] *and C. Chaban*[5], *(1)Brain Development Imaging Lab - SDSU, San Diego, CA, (2)Brain Development Imaging Laboratories, Department of Psychology, San Diego State University, San Diego, CA, (3)Brain Development Imaging Laboratories, San Diego State University, San Diego, CA, (4)Alliant International University, San Diego, CA, (5)SDSU, San Diego, CA*

Background: Motor function often declines in healthy aging, with negative consequences for quality of life. In autism spectrum disorders (ASDs), motor deficits are common and can be detected even before core diagnostic symptoms (e.g. socio-communicative deficits) become evident. Much less is known about motor functions in older adults with ASDs. A few studies have suggested impaired motor function and a possible increased risk for Parkinsonism, but little is known about brain changes in the motor system in adults with ASDs past the age of 40 years.
Objectives: To characterize the microstructure of motor and premotor tracts in older adults with ASDs compared with a matched neurotypical group (NT), and identify the relationship between path structure, age, and behavior.

Methods: Diffusion weighted MRI data were collected from older adults (40-65 years): 19 with ASDs (mean age 50.5 years, 2 female, 1 left-handed) and 24 neurotypical (mean age 51.3 years, 3 female, 3 left-handed). Diagnostic groups were matched for gender, age, handedness and head motion. Motor function was assessed with the Bruininks motor ability test (BMAT). The primary motor, dorsal pre-motor, ventral pre-motor, supplementary motor and pre-supplementary motor cortices of the Human Motor Area Template were warped to individual diffusion space and used as seed regions for probabilistic tractography (FSL). Only ipsilateral streamlines passing through the posterior limb of the internal capsule and cerebral peduncles were retained. Left and right tracts were recoded to dominant and non-dominant based on hand dominance. To study group, age and group by age interactions, ANCOVAs were run on tract measures (fractional anisotropy [FA], mean diffusivity [MD], volume) for dominant and non-dominant hemispheres, covarying for head motion and protocol. To investigate relationships between structure and behavior, partial correlations were run between tract measures and BMAT and ADOS-2 scores controlling for age, head motion and protocol.

Results: Only 3 out of 5 tracts were reliably identified (Fig. 1A). We found a significant group by age interaction for MD of the dominant dorsal premotor tract (Fig. 1B, p=.006) using a Bonferroni-corrected threshold. Follow-up partial correlations showed a positive relationship with age for MD in the ASD, but not the TD, group. Behavioral partial correlations revealed a significant positive association between volume of the dominant primary motor tract and ADOS-2 comparison score in ASD (partial r=.814, p<.001), using an FDR-corrected threshold (Fig. 1C). Additional correlations with medium effect size (|r|≥.5) were found between structural measures and the BMAT (summary score, manual dexterity) and ADOS-2 (social affect, restricted and repetitive behavior), in ASDs but did not survive FDR correction.

Conclusions: In older adults with autism, we found atypical decline of the dominant dorsal premotor tract, which may reflect disruption of learning associations between sensory input and action, and could reflect accelerated decline in ASDs. The association between motor tract structural measures and both motor performance and autism symptoms found in older adults with ASDs suggests possible decline beyond the motor system or an at-risk subgroup among those with higher ASD severity.

190 **142.190** Age Related Differences in Hippocampal Anatomy and Correlates with Episodic Memory and Executive Function in Autism Spectrum Disorder

C. Riecken[1], *B. B. Braden*[2], *J. Alvar*[2], *M. Walsh*[3], *L. C. Baxter*[4] *and C. J. Smith*[5], *(1)University of Missouri, Columbia, MO, (2)College of Health Solutions, Arizona State University, Tempe, AZ, (3)Arizona State University, Tempe, AZ, (4)Radiology, Barrow Neurological Institute, Phoenix, AZ, (5)Southwest Autism Research & Resource Center, Phoenix, AZ*

Background: Over the last 30 years, a rise in autism spectrum disorder (ASD) diagnoses has led to a large group of aging individuals with ASD. Little is known about how aging will affect these individuals' neuroanatomy, compared to the neurotypical (NT) population. Recently, our group found that older adults with ASD have reduced executive functioning and smaller hippocampi compared to NT adults (Braden et al., 2017).
Objectives: This study sought to expand on previous findings from our group by segmenting the hippocampus into 12 unique subfields and determine the difference in relationships between the volumes of the individual subfields and age in ASD compared to NT adults. In addition, this study tested whether relationships between hippocampal subfield volumes and measures of executive functioning and episodic memory existed and if they were different in ASD compared to NT adults.

Methods: This project used Freesurfer 6.0 to perform a cross-sectional analysis of 12 hippocampal subfield volumes in adults with ASD (n = 53) and NT (n =39) from structural MRI scans. Using ANOVA with discrete age cohorts (young-adult: ages 18-25 years, n=42; middle-age: ages 40-70 years, n=50). Correlations were examined between subfield volumes and measures of executive function (Wisconsin Card Sorting Task [WCST] and Tower of London [ToL]), as well as episodic memory (Auditory Verbal Learning Task [AVLT]) with a false discovery rate of p=0.05 to correct for multiple comparisons. All participants with ASD had their diagnosis confirmed with the Autism Diagnostic Observation Schedule-2.

Results: There were significant interactions in several hippocampal subfield volumes (e.g. left and right hippocampal tail, subiculum, CA1, molecular layer, dentate gyrus, CA4, and fimbria, right presubiculum, and left hippocampal amygdala transition area) such that adults with ASD showed larger age-related differences compared to NT adults. Correlations with behavioral measures showed that AVLT performance was related to many subfield volumes across all participants. There were no significant relationships between hippocampal subfield volumes and WCST or ToL performance that survived correction for multiple comparisons. Correlations between behavioral measures and hippocampal subfield volumes were not significantly different between ASD and NT participants.

Conclusions: Results indicate that adults with ASD may be at risk for accelerated age-related hippocampal volume loss; however, this warrants confirmation with a longitudinal sample (in progress). Behaviorally, our study suggests hippocampal size is more strongly related to episodic memory than executive functioning performance, and that this relationship does not differ between adults with ASD and NT adults of either cohort age.

191 **142.191** Altered Activation and Functional Connectivity during Implicit Language Learning in 9-Month-Old Infants at Risk for ASD

J. Liu[1], *T. Tsang*[1], *C. Ponting*[1], *S. Jeste*[1], *S. Y. Bookheimer*[2] *and M. Dapretto*[2], *(1)University of California, Los Angeles, Los Angeles, CA, (2)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA*

Background: Word segmentation is a fundamental aspect of language learning, since the identification of word boundaries in continuous speech must occur before the acquisition of word meanings can take place. We previously used fMRI to show that children with autism spectrum disorder

(ASD) are less sensitive to statistical and speech cues that guide implicit word segmentation. Prior studies have shown that neural activity related to language processing can be detected in 2-day-old neonates during natural sleep; to date, however, very little is known about the neural mechanisms underlying language learning during infancy and how this may be associated with risk for developing ASD.
Objectives: We examined the early neural signatures of language-related learning to characterize the neural networks subserving language acquisition in 9-month-old infants at high (HR) and low risk (LR) for ASD. We also related early measures of brain activity to longitudinal behavioral measures of language development and ASD symptom severity.

Methods: During natural sleep, infants were exposed to speech streams consisting of concatenated syllables where the statistical regularities and prosodic speech cues to word boundaries were manipulated across three conditions: 1) Stressed Language containing prosodic cues (i.e., stress; higher pitch, increased amplitude, and longer duration for the first syllable of the trisyllabic words used to created the speech stream) and strong statistical regularities, 2) Unstressed Language containing solely strong statistical regularities, and 3) Random Syllables containing weak statistical regularities and no prosodic cues. Risk status was determined by virtue of having one or more older siblings with a confirmed ASD diagnosis. A linear function was used to model changes that occurred over the course of exposure to each condition to estimate learning-related signal increases and compared these across groups. Next, a psychophysiological interaction (PPI) analysis examined differences in functional connectivity during exposure to the speech stimuli. Lastly, parameter estimates of brain activity and connectivity were correlated with behavioral measures collected at later time points.

Results: Compared to HR infants, LR infants showed more learning-related signal increases in left temporal regions during the Stressed Language condition, which contained both strong statistical regularities and speech cues. During this condition, the PPI analysis revealed greater functional connectivity between bilateral primary auditory cortex and right anterior insula in LR infants compared with HR infants. Interestingly, learning-related signal increases at 9 months correlated with later language outcome (CDI Receptive Advantage; 12 months) as well as ASD symptom severity (ADOS-2; 36 months); in addition, functional connectivity was associated with later language outcome (MSEL Verbal Score; 36 months).

Conclusions: In line with prior evidence in older children with ASD, HR infants already show diminished neural responses associated with implicit language learning by 9 months of age. Compared to the HR group, LR infants show greater brain activity as well as stronger functional connectivity in regions implicated in salience detection. Our findings indicate that early differences in the neural networks underlying language learning may predict altered trajectories in language development and ASD symptomatology before delays in language acquisition can be observed overtly at the behavioral level.

192 **142.192** Anomalous Patterns of Inferior Parietal Lobule Functional Connectivity and Handwriting Impairment in Children with Autism

A. Y. Herstic[1], *N. F. Wymbs*[1], *R. Nicholas*[2], *R. N. Rochowiak*[1], *C. A. Koch*[3], *M. B. Nebel*[1] *and S. H. Mostofsky*[4], *(1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)University of Nottingham, Nottingham, United Kingdom, (3)Developmental Cognitive Neurology, Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (4)Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD*

Background: Children with Autism Spectrum Disorder (ASD) exhibit handwriting impairments, particularly in letter formation. Although multiple studies have examined neural networks involved in handwriting in neurotypical children and adults, the neural features of handwriting in children with ASD are unknown. The inferior parietal lobule (IPL) is a multi-modal association cortex hub that is heavily involved in skilled motor behavior and handwriting. Differences in functional connectivity of the IPL may account for handwriting impairments in ASD.
Objectives: To examine differences in intrinsic functional connectivity of the IPL, as it relates to handwriting letter formation in typically developing (TD) children and children with ASD.

Methods: Resting-state fMRI data was acquired from seventy-six children (38 ASD) aged 8-12 years. Groups were matched on age, gender and framewise displacement. Masked independent components analysis (ICA) estimated functional connectivity of the IPL, separately for left and right hemisphere (5 independent components/hemisphere), followed by dual regression to estimate whole-brain connectivity maps for each IPL subnetwork. Outside of the scanner, participants completed three conditions of the Minnesota Handwriting Assessment (MHA), on a digitizing tablet. Participants first copied a sentence (Copy), traced the same sentence at a comfortable speed (Trace), and lastly, traced the same sentence as fast as possible (Fast Trace, FT). Letter-form was assessed using Large Deformation Diffeomorphic Metric Mapping (LDDMM) to quantify a participant's deviation from a template, where high form scores indicated poor performance. MHA measures were included as covariates in a second-level GLM of dual-regression whole-brain maps, with significant results meeting FWE cluster-correction ($p<.05$).

Results: A significant effect of diagnosis was observed for FT, such that children with ASD demonstrated worse letter formation than their TD peers ($F(1,73) = 7.33$, $p<.01$). There was no effect of diagnosis for Copy or Trace conditions. IPL functional connectivity analyses revealed a significant interaction effect of FT letter formation with diagnosis (ASD vs. TD) on connectivity of the posterior supramarginal gyrus (pSMG) component bilaterally: While better letter formation was associated with greater pSMG connectivity in children with ASD, for TD children better letter formation was associated with lesser pSMG connectivity. Specifically, the diagnosis x FT interaction was observed for: a) left pSMG connectivity with left precuneus, left dorsolateral prefrontal cortex (DLPFC) and bilateral occipital fusiform gyrus, and b) right pSMG connectivity with the right superior lateral occipital gyrus.

Conclusions: The interaction of connectivity between diagnosis and FT letter formation highlights the known role of the pSMG in the cognitive-motor control of everyday goal-directed skilled actions, including handwriting. The autism-specific association of greater pSMG connectivity with better FT letter formation may reflect increased necessity to recruit higher-order cognitive-motor control during speeded tracing of overlearned letters, which taxes internal model output. In contrast, the detrimental impact of pSMG network recruitment for TD children suggests that these children may do best when relying on more efficient primary motor circuitry to guide speeded tracing of highly practiced orthography. These results indicate a promising first step in understanding the neural circuitry underpinning handwriting: a critical developmental skill that is often impaired in ASD.

193 **142.193** Association between White Matter Microstructure and Autistic Traits across the Diagnostic Divide

V. Arunachalam Chandran[1], *J. Neufeld*[1,2], *C. Pliatsikas*[3] *and B. Chakrabarti*[1], *(1)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (2)KIND lab, Karolinska Institutet, Stockholm, Sweden, (3)School of Psychology & Clinical*

Language Sciences, University of Reading, Reading, United Kingdom

Background:
There is growing evidence that suggests autistic traits lie on a continuum in the general population. Many studies have examined the relationship between white matter (WM) microstructural properties and autistic traits with few studies reporting associations [Lidaka et al. 2012; Gibbard et al. 2013] whilst other studies showed lack of associations [Cedric et al. 2015]. The discrepancies in the results of previous studies led us to carry out this study to find whether the autistic traits in the non-clinical population are associated with WM microstructural abnormalities. Moreover, previous Diffusion Tensor Imaging (DTI) studies in Autism spectrum disorders (ASD) compared to healthy controls have consistently shown reduced fractional anisotropy (FA) and increased mean diffusivity (MD) values in the regions including the superior longitudinal fasciculus (SLF), uncinate fasciculus (UF), inferior longitudinal fasciculus (ILF), and inferior fronto-occipital fasciculus (IFOF) [Catani et al., Brain 2016; Boets et al., 2018; Gibbard et al., 2013]. These brain regions play a significant role in acquiring socio-communication skills, emotional recognition and visual processing skills. In this study, we sought to replicate the above findings and to correlate the diffusion indices with Autism spectrum quotient (AQ) scores in a combined sample of neurotypicals and ASD. It was hypothesized to determine the possible relationship between the WM microstructural integrity and autistic traits.

Objectives:

To determine the white matter microstructural correlates of the autistic traits in the combined sample of neurotypicals and ASD.

Methods:

Fifty three adults (28 neurotypicals, 25 ASD: 31 males, 22 females, age 18-50 years) were recruited for this study. This study was approved by University Research Ethics Committee. Siemens 3T MRI scanner was used to acquire the whole brain DTI images with a 32-channel head coil and high resolution MPRAGE at the Centre for Integrative Neuroscience and Neurodynamics, University of Reading. All the participants also completed the AQ questionnaire. Tract based spatial statistics was employed, on the output of which standard space masks were applied to extract all the mean FA and MD values from the bilateral SLF, UF, ILF and IFOF which were then correlated with the AQ scores.

Results:

Pearson correlation (one-tailed) was used to find the associations between FA, MD values and AQ scores in the combined sample of neurotypicals and ASD while controlling for age, gender and IQ. Negative correlation was found between FA and AQ in right inferior longitudinal fasciculus (r = -0.275, P = 0.027) which was the only statistically significant region. No significant positive correlation between MD and AQ was found.

Conclusions:

In this study, the results replicate the significant findings between the white matter microstructural properties and autistic traits in the right inferior longitudinal fasciculus. This finding is consistent with previous reports of case-control differences in this tract (Gibbard et al., 2013), and provides evidence for the relationship between the white matter microstructural properties and autistic traits across the diagnostic divide. The absence of association in other regions may be due to the inadequate sample size and/or unknown patterns of interaction between age and autistic traits.

194 **142.194** Association of Choline Levels on the Severity of Social Anhedonia in Adults with Autism Spectrum Disorder

*M. Batra[1], **J. P. Giacomantonio**[2], H. Garman[3], A. Mulhall[4], R. A. Vogel[5] and K. Gadow[3], (1)College of Osteopathic Medicine, New York Institute of Technology, Glen Head, NY, (2)Stony Brook University, Stonybrook, NY, (3)Stony Brook University, Stony Brook, NY, (4)Psychiatry, Stony Brook University, Stony Brook, NY, (5)Neurobiology and Behavior, Stony Brook University, Stony Brook, NY*

Background: High functioning adults with autism spectrum disorder (HFA) often experience social anhedonia and depression although their pathogenesis remains poorly understood. Recent studies show increased choline levels in the brains of adults with HFA, as well as in participants diagnosed with major depressive disorder (MDD; Murphy *et al.*, 2002; Riley *et al.*, 2018). Increased concentrations of choline in the anterior cingulate cortex (ACC) are reported to alter brain activity and connectivity between the medial prefrontal cortex (mPFC) and posterior cingulate cortex (PCC) in adults with ASD (Libero *et al.*, 2015). Prior research has linked higher choline levels in the brain to increased depression and length of illness in adults with MDD (Riley *et al*, 2018; Portella *et al.*, 2011).

Objectives: The aim of the present study was to examine the association of brain choline levels with severity of social anhedonia, depression and rumination symptoms among adults with HFA.

Methods: Participants were 16 adults (18-45 years) with ADOS-defined ASD; IQs (≥80). (1)H-MRS data was acquired with a 3T scanner for the metabolite choline, which was performed with one voxel (30×30×20 mm^3) in the ACC using a TR/TE of 2000/68 ms with a spectral bandwidth of 2 kHz and 16 water reference lines. Prior to the scan, participants completed the Hamilton Depression Ration Scale, Social Anhedonia Scale – Revised, Kaufman Brief Intelligence Test Second Edition.

Results: After controlling for ASD severity there was a positive correlation found between choline levels and severity of social anhedonia (r= .548, p= .034), severity of depression (r= .621, p=.018), and rumination (r= .560, p= .037).

Conclusions: These findings provide a tentative support for the notion that brain choline levels may be associated with processes involved in the severity of social anhedonia, depression and rumination among HFA. Moving forward, additional studies with larger samples are necessary to fully understand this possibility.

195 **142.195** Association of the Anterior Cingulate Volume and Emotion Regulation in Girls but Not Boys with Autism Spectrum Disorder

***D. Y. Song**[1], D. Crocetti[1], K. S. Rosch[1,2,3] and S. H. Mostofsky[1,4], (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Department of Neuropsychology, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD, (4)Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD*

Background:
Children with autism spectrum disorder (ASD) have been observed to experience challenges with controlling emotional responses that are often expressed as aggression, self-injurious behavior and mood dysregulation. Previous literature has looked at the amygdala, anterior cingulate

cortex (ACC) and prefrontal cortex (PFC) as essential brain regions involved in emotional regulation (ER). While influences of sex based differences on ER have been well established, there is still a lack of investigation at the brain and behavior level looking at ER in ASD children with the impact of sex.

Objectives:

To examine brain-behavior associations underlying emotion dysregulation in boys and girls with ASD, as compared with their typically developing (TD) peers.

Methods:

104 ASD (16 girls, 88 boys) and 163 TD (32 girls, 132 boys) participants were balanced on age, sex, socioeconomic status and IQ score. The emotion lability (EL) t-score from the Conners parent rating scale was used to assess ER. Volumes of cortical regions (amygdala, ACC, dorsolateral PFC) were derived from high resolution T1-weighted images using FreeSurfer version 6.0. Multiple regression analyses were performed to investigate: 1) the effect of diagnosis, sex, and interaction thereof (diagnosis*sex) on EL scores, and 2) associations of cortical regions with EL t-scores and effects of diagnosis, sex, and diagnosis*sex on the relationship between cortical regions and EL t-scores; significant associations were followed-up with Pearson correlations.

Results:

Multiple regression revealed a statistically significant effect of diagnosis ($F(1,263) = 5.213$, $p = 0.023$), sex ($F(1,263) = 96.457$, $p < 0.001$), and interaction of diagnosis*sex ($F(1,263) = 4.029$, $p=0.046$). Follow up post hoc analyses tests revealed elevated EL t-scores in children with ASD compared to TD children. Significant interactions were found such that both girls and boys with ASD showed higher EL scores compared to TD peers, although it was significantly stronger in girls (M=66.19, SD=14.232) than boys (M=59.39, SD=11.165). Regression analyses of brain-behavior associations revealed that there was a marginal diagnosis*sex interaction ($F(7,259) = 22.266$, $p=0.094$) for the relationship between the left ACC volume and the EL t-score. Specifically, as figure 1 indicates, the left ACC volume showed significant correlations with the EL t-scores in ASD but not TD girls. Lower left ACC volumes were negatively correlated with higher EL t-scores in ASD girls ($r=-.579$, $p=0.019$). No significance was found with the amygdala and PFC regions.

Conclusions:

Findings reveal that children with ASD face difficulty with ER when compared to TD peers but this may be a problem that is more present in girls with ASD. Furthermore, ASD girls show a unique association with the left ACC volume; therefore, the dysfunction of the left ACC may contribute to the emotional challenges experienced by girls with ASD.

196 **142.196** Atypical Cerebral Lateralization in Children with Autism Spectrum Disorder

M. J. Rolison[1] *and D. Scheinost*[2]*, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Radiology & Biomedical Imaging, Yale School of Medicine, New Haven, CT*

Background: Autism Spectrum Disorder (ASD) affects 1 in 59 children, yet relatively little is known about its etiology or development before the emergence of symptoms. Recent research has focused on identifying biomarkers to understand how abnormalities in neural development lead to the ASD phenotype. Prior work has suggested that ASD is characterized by abnormal network connectivity (Wass, 2011). Similarly, previous work has identified abnormal lateralization of functional connectivity at rest in prematurely born individuals—a group at high risk for developmental delay—with greater lateralization associated with poorer language ability (Scheinost et al., 2015). This study utilized resting-state fMRI to investigate cerebral lateralization in children with ASD to elucidate potential mechanisms of aberrant neurodevelopment.
Objectives: Investigate whether children with ASD demonstrate atypical cerebral lateralization.

Methods: Using resting-state fMRI data from the Autism Brain Imaging Data Exchange, we examined connectivity lateralization in children with ASD aged 6-14 years compared to typically-developing (TD) peers. We used cross-hemisphere intrinsic connectivity distribution to correlate each voxel to every other time course in the series in the ipsilateral and contralateral hemispheres independently and then calculated ipsilateral connectivity minus contralateral connectivity. Functional connectivity was performed using linear regression while controlling for sex, age, site, and motion. Analyses included 309 children with ASD and 434 TD peers.Significance was assessed at $p<0.05$, corrected for multiple comparisons.

Results: Children with ASD compared to TD peers exhibited increased connectivity lateralization in right BA-22, right BA-19, and right BA-23/31, and decreased connectivity lateralization in right BA-10. To identify the functional connection most likely responsible for these cross-hemisphere connectivity differences, follow up seed connectivity analysis was performed with these regions as seeds. For children with ASD compared to TD peers, seed connectivity from right BA-22 revealed greater ipsilateral connectivity with right fusiform and middle temporal gyrus and greater contralateral connectivity with left medial prefrontal cortex (mPFC), posterior cingulate cortex (PCC), and inferior frontal gyrus (IFG). Seed connectivity from right BA-19 revealed greater ipsilateral connectivity with right inferior and middle temporal gyrus. Seed connectivity from right BA-23/31 revealed greater contralateral connectivity with the left insula and weaker contralateral connectivity with the left mPFC, PCC, and IFG. Seed connectivity from right BA-10 revealed greater ipsilateral connectivity with right fusiform and angular gyrus, greater contralateral connectivity with the left precuneus, and weaker contralateral connectivity with the left putamen.

Conclusions: Findings suggest that children with ASD demonstrate increased right-hemisphere lateralization in temporal and parietal regions relative to their TD peers. However, children with ASD demonstrated reduced right-hemisphere lateralization in a frontal region relative to peers. This atypical lateralization is associated with multiple resting-state brain networks including the default mode (PCC, mPFC), fronto-parietal (fusiform), ventral-attention (middle temporal gyrus), cingular-oppercular (insula), and subcortical networks (putamen). These findings are consistent with prior work suggesting long-range under-connectivity and short-range over-connectivity in ASD (Lewis et al., 2014)and lend support to the hypothesis that ASD is associated with altered cerebral network development. Future work will investigate plasticity of this lateralization across development and its functional significance.

197 **142.197** Atypical Functional Network Connectivity to Emotional Faces in Adults with ASD

K. Safar[1]*, V. Yuk*[2]*, S. M. Wong*[3]*, R. C. Leung*[4]*, E. Anagnostou*[5] *and M. J. Taylor*[2]*, (1)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)Division of Neurosurgery, Hospital for Sick Children, Toronto, ON, Canada, (4)Hospital for Sick Children, Toronto, ON, Canada, (5)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

Background:

Pronounced socio-emotional impairments, including atypical emotional face processing, are inherent to autism spectrum disorder (ASD). At the neural level, differences in functional networks during face processing in ASD compared to controls have been highlighted recently (Kana et al., 2016), which may be associated with difficulties in social functioning. However, few studies have used magnetoencephalography (MEG) to investigate functional connectivity during affective processing in ASD. MEG is ideally suited to examine functional connectivity - it is a direct measure of neural activity and offers good spatial and excellent temporal resolution.

Objectives:

We investigated whole-brain functional connectivity using MEG in the largest sample to date of adults with ASD 48 (M_{age}= 26.76, *SD*= 5.21) and 60 typical developed age-matched controls (M_{age}= 26.64, *SD*= 5.87) during the implicit presentation of emotional faces.

Methods:

Adults participated in an emotional faces task, in which each trial consisted of a happy or angry face and a scrambled pattern (target stimulus) simultaneously presented for 80ms on either side of a central fixation cross. Participants indicated the location of the target (left or right) as rapidly as possible by pressing a button. Structural MRIs were obtained for MEG co-registration. MEG data were epoched by emotional face type. Time series were estimated from 90 cortical and subcortical sources of the AAL atlas using the LCMV beamformer. The phase-lag index was used to assess phase synchronization of ongoing neural oscillations among sources (Stam, Nolte & Daffertshofer, 2007).

Results:

We found a network of increased beta-band phase synchrony 58-228ms following angry faces in adults with ASD compared to controls (35 edges, 35 nodes; p_{corr}= 0.019). This network involved almost exclusively connections among bilateral frontal, including orbitofrontal areas and the right ACC, and temporal regions, including left superior temporal gyrus. Additionally, reduced phase synchrony in the low-gamma frequency band 85-283ms following angry face onset was found in the adults with ASD (51 edges, 47 nodes; p_{corr}< 0.001). This network was anchored in frontal regions, including orbitofrontal areas and the right ACC, and connecting to occipital, and temporal regions, also including the right amygdala.

Conclusions:

These results indicate atypical patterns of hyper- and hypo-connectivity during angry face processing in the beta and low-gamma frequency bands in adults with ASD compared to typical controls. The current findings may suggest atypical top-down/bottom-up functional connectivity in ASD. In particular, beta-band synchronization is implicated in top-down influences, while gamma-band synchronization is involved in bottom-up influences (Fries, 2015). In the current study, greater beta-band phase synchrony may suggest increased top-down influences from primarily frontal areas in adults with ASD compared to controls, whereas reduced gamma phase synchrony may suggest lower bottom-up influences of regions, including the amygdala, which may contribute to difficulties with selective attention of emotional faces in ASD. Abnormal top-down functional connectivity has recently been proposed in this population (Mamashli et al., 2018). Overall, findings are consistent with previous work reporting abnormal neurodevelopment of functional connectivity to emotional faces in ASD (Mennella et al., 2018; Safar et al., 2018).

198 **142.198** Between Group Differences in Correlation of FA with Performance IQ and Age in Autism Spectrum Disorder. Results from EU-AIMS Diffusion Imaging.

R. A. Dallyn[1,2], *P. A. Luque Laguna*[1,2], *C. E. Davison*[3], *D. G. Murphy*[1,2], *L. G. EU-AIMS*[4], *L. G. UK-AIMS*[4] *and F. Dell`Acqua*[3,5], *(1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)EU-AIMS Organization, London, United Kingdom, (5)Institute of Psychiatry, Psychology and Neuroscience, Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:

European Autism Interventions is a multicentre initiative aiming to stratify biomarkers for Autism Spectrum Disorder (ASD) through acquisition and integration of large datasets from different imaging modalities and behavioural measures. We are investigating Diffusion MRI data acquired as part of EU-AIMS. Previous studies have implicated Fractional Anisotropy (FA) differences in the corpus callosum[1], the uncinate[1,2]and reduced volume in the arcuate[3]with ASD.

Objectives:

We aimed to investigate voxel-wise differences between a large cohort (N=187) of ASD and Typically Developing (TD) subjects imaged at King's College London. We also investigated the relationship between FA and Performance IQ (PIQ) behavioural scores and age between our cohorts.

Methods:

Diffusion Imaging data is taken from the King's College London cohort of EU-AIMS. Following exclusion for anatomical/genetic abnormality, high subject motion[8]and intellectual disability we obtain a cohort of 144 subjects (61 TD 83 ASD; *ages 6-30,mean=18.2 STD=5.8*). Data acquisition parameters were: voxel size 2x2x2 mm, b-value = 1500 s/mm^2, 60 diffusion weighted directions and 6 b0s.

Data was de-noised[4], corrected for Gibb's ringing[5], for motion and eddy-current distortions using exploreDTI[6]and outlier replacement using FSL eddy[7]. PIQ for each subject was evaluated using the Wechsler Abbreviated Scale of Intelligence (WASI), including matrix reasoning and block design. Voxel-wise statistical analysis of Fractional Anisotropywas carried out using TBSS (Tract-Based Spatial Statistics[9]) part of FSL[10]. In this study we present results for group differences in Fractional Anisotropy (FA) while correcting for sex and age, and correlation of FA with PIQ and Age.

Results:

Group comparison (TD vs ASD): We find collections of significant *(p<0.05)*voxels across the Corpus Callosum body, Superior Cerebellar peduncles and Uncinate fasciculus *(fig .1)*. These results replicate previously published results from UK-AIMS[2](males, *age 18-40)*.

Significant correlations were found with performance IQ in ASD but not in the whole cohort (p<.05) in regions consistent with U-shaped fibres connecting medially to Caudal Inferior Parietal Lobule *(fig .2, .3)* in left hemisphere.

Finally, correlation of FA with age produces large areas of highly significant (p<.01) voxels, as expected from our large cohort age ranges (6-30) *(fig*

.4). By creating masks of significant voxels for each cohort and subtracting TD from ASD we find areas in the genu and splenium of the Corpus Callosum which correlate strongly with age in ASD only *(fig .3)*.

Conclusions:

Group differences observed in this preliminary analysis of the EU-AIMS cohort and their replication with previous diffusion results from the UK-AIMS cohort identify the Corpus Callosum, Uncinate Fasciculus and the Cerebellar Peduncles as anatomical targets for further analysis. FA in the Genu and Splenium also emerge as showing more correlation with age in ASD than TD, suggesting that brain development in autism may follow a delayed developmental trajectory[11]within these areas. PIQ measures used feature matrix reasoning and block design tests. Block design tests have been previously implicated in autism in the central coherence account[12]. Correlation of performance on these tasks with a parieto-temporal region only in ASD may be of interest to this view of ASD.

199 **142.199** Brain Activity Underlying Fluid Reasoning in School-Aged Autistic Children

E. Danis[1], *J. Degré-Pelletier*[2], *E. B. Barbeau*[3], *F. Samson*[4] *and I. Soulieres*[5], *(1)University of Quebec in Montreal, Montreal, QC, Canada, (2)Université du Québec à Montréal, Montreal, QC, Canada, (3)Cognitive Neuroscience Unit, Montreal Neurological Institute, McGill University, Montreal, QC, Canada, (4)McGill University, Montreal, QC, Canada, (5)Psychology, University of Quebec in Montreal, Montréal, QC, Canada*

Background: Autistic children perform as well as typically developing (TD) children at visual analogy tests measuring fluid reasoning (Green et al., 2014; 2016; Morsanyi & Holyoak, 2010; Sahyoun et al., 2009). Previous fMRI studies in adults revealed stronger posterior brain activations paired with weaker prefrontal and parietal activations in autistic relative to non-autistic participants during fluid reasoning (Soulières et al., 2009). However, the development of brain mechanisms underlying fluid reasoning has not yet been investigated in young autistic children.
Objectives: To investigate the cerebral activity patterns during a fluid reasoning task in autistic and TD children aged between 8 and 14 years old.

Methods: Sixteen (1 female) autistic and 14 (2 females) TD children (data collection in progress) equivalent in age (M=12.39, SD=1.81), Raven's Progressive Matrices raw scores (M=40.23, SD=8.88) and percentiles (M=53.97, SD=30.14), and laterality were scanned in a 3T MRI scanner while completing a computerized reasoning task containing 168 problems. Problems were 4x4 pictorial matrices with the last entry to be filled with one of 3 response choices. The problems varied in content (either semantic or visuospatial content) and in complexity, implemented as the number of relations to jointly consider in order to solve the problem (0, 1 or 2 relations). SPM12 was used for preprocessing and whole-brain analyses (k=20 voxels, FWE corrected p=.05) of the fMRI data.

Results: Autistic and TD children did not differ in accuracy (p=.65) and response times (p=.93) at the reasoning task. There was a Content X Complexity interaction (p=.02), the 2-relations visuospatial condition being the hardest in both groups. Accuracy also correlated with age in both groups (r=.378). At the cerebral level, a large reasoning network was revealed in both groups, involving mainly occipital, temporal and parietal regions. Autistic children presented stronger activations in the pulvinar, left superior temporal and inferior frontal gyri than TD children, who showed stronger cingular and cerebellar activations. For the semantic problems, there was stronger pulvinar activity in the autistic group. For the visuospatial problems, the precuneus was more active in the TD group. In terms of complexity, there was no significant between-group differences for the 2-relations versus easier problems. In both groups, performance at most complex visuospatial problems was positively correlated with cerebral activity in the occipital lobe and inferior frontal gyrus.

Conclusions: In line with previous findings (Santarnecchi et al., 2017), fluid reasoning was supported by a network of frontal, temporal, parietal and occipital activations in both of our groups. However, even with similar fluid reasoning skills, autistic and TD children presented distinct cerebral activity patterns. In the semantic problems, autistic children seemed to rely on regions involved in visual cognition, such as the pulvinar (Bourne & Morrone, 2017), more so than TD children. During the visuospatial problems, the TD children may have relied more extensively than autistic children on the precuneus (involved in motor and/or visual imagery), a finding we previously reported in adults (Soulières et al, 2009). Thus, cerebral activity would differ between autistic and TD children according to the content of reasoning.

200 **142.200** Brain-Behavior Associations Underlying Praxis Impairments in Girls and Boys with ASD

C. Chen[1], *D. Crocetti*[1], *D. Y. Song*[1], *K. S. Rosch*[2] *and S. H. Mostofsky*[3], *(1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD, (3)Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD*

Background:
Studies have consistently reported that children with autism spectrum disorder (ASD) show impaired performance of skilled motor gestures, consistent with a developmental dyspraxia. Praxis may therefore serve as a biomarker informative to diagnosis and intervention. There is increasing awareness that autism presentation may differ in girls and boys. Despite this, there has been limited investigation of the impact of sex on praxis in autism.

Objectives:

To examine the impact of sex on praxis and its association with morphology of relevant frontal-parietal circuits in children with ASD and typically-developing (TD) peers.

Methods:

Data from 165 participants (55 girls, 42 ASD) balanced on age, socioeconomic status (SES), IQ, and handedness. Praxis was assessed using the Florida Apraxia Battery, modified for children (total percent correct). The volumes of the left and right inferior parietal cortex (IPC) and the premotor cortex (PMC), structures important to praxis, were processed with Free-surfer. Multiple regression analyses was performed to investigate: 1) the effect of diagnosis, sex, and interaction thereof (diagnosis*sex) on praxis performance, and 2) associations of brain volumes with praxis performance and effects of diagnosis, sex, and diagnosis*sex on the relationship between IPC and PMC morphology with praxis performance; significant associations were followed-up with Pearson correlations.

Results:

Multiple regression revealed a significant effect of diagnosis (p=.000). Effect of sex and diagnosis*sex were not significant. Effect sizes were strong for both girls and boys, although somewhat stronger for boys (see Table 1). Regression analyses of brain-behavior associations revealed that for

right hemispheric IPC and PMC there was a significant diagnosis*sex interaction (F(1, 157)=4.5714, p=.0341; F(1, 157)=9.6430, p=.0023 respectively) (see Figure 1). Specifically, for right IPC and PMC volumes, TD girls showed significant positive correlations, such that higher volumes correlated with better praxis score (r(40)=.343, p=.028); whereas, girls with ASD showed significant negative correlations such that higher volumes correlated with worse praxis score (r(13)= -.744, p=.002). No significant correlations were observed for boys or for left hemisphere in girls.

Conclusions:

Girls and boys with ASD both showed impaired praxis performance compared with their TD peers. The findings suggest that performance of skilled motor gestures is broadly impaired in children with autism. Investigation of brain-behavior associations revealed a pattern specific to girls. For girls with ASD, impaired praxis was found to be associated with larger volumes within a frontal-parietal praxis network (in contrast to TD girls who show better praxis with larger volumes). The findings suggest that right hemisphere morphology may uniquely contribute to dyspraxia in girls with autism.

201 **142.201** Can Resting-State fMRI be Used to Inform Differential Diagnosis between ASD and ADHD?

L. Antezana[1] *and J. A. Richey*[2]*, (1)Virginia Polytechnic Institute and State University, Blacksburg, VA, (2)Virginia Tech, Blacksburg, VA*

Background: Autism spectrum disorder (ASD) and attention deficit/hyperactivity disorder (ADHD) are difficult to differentiate in clinical settings (Miodovnik et al., 2015; Smith et al., 2017), as both exhibit atypical patterns of attention and executive functioning (Gioia et al., 2002; Johnson et al., 2014). Further, children with ASD and ADHD have shared and distinctive patterns of long-range functional connectivity in the brain (Di Martino et al., 2013), though such patterns have not yet been used to mechanistically distinguish between these two disorders. Two brain networks have been implicated in these disorders and are of interest: the salience network (SN), which is related to attentional processes for internal and external events, and the FPN, which plays a role in flexible goal-driven behavior (Seeley et al., 2007). Functional connectivity between these two networks may reveal meaningful subgroups for those with ASD vs. ADHD.

Objectives: The aim of this project is to determine whether community detection, a graph-theory algorithm for subtype identification, can differentiate children with ASD from children ADHD using patterns of SN and FPN connectivity.

Methods: Functional and structural Magnetic Resonance Imaging (MRI), and phenotypic data were selected from the Autism Brain Imaging Data Exchange (ABIDE), its follow-up project ABIDE-2, and the ADHD-200 database. All data were used from New York University Langone Medical Center in order to match datasets on scanner protocol. After excluding subjects with high motion the final dataset consisted of 60 children with ASD, 64 children with ADHD, and 65 typically developing (TD) controls. 5mm spherical regions of interest (ROIs) were chosen for the SN and FPN using Neurosynth (Yarkoni et al., 2011). Group Iterative Multiple Model Estimation (GIMME), a graph theory approach (Gates and Molenaar, 2012), was used with scrubbed resting state data from each subject. Subsequently, a community detection algorithm was used to identify subgroups characterized by SN-FPN connectivity patterns.

Results: ASD and ADHD groups did not differ on age, FSIQ, sex, and motion (all *p*s>.21). GIMME identified two subgroups. Subgroup A had 70 cases and was characterized by hyperconnectivity of SN-FPN nodes. Subgroup B had 119 cases and was characterized by hypoconnectivity of SN-FPN nodes. A chi-square test was performed and a relationship was found between diagnostic status (ASD, ADHD, TD) and the frequency of subgroup membership, X^2 (1, N=189)=7.18, p<.05. Of note, 71.7% of the ASD group and 67.7% of the TD group were in subgroup B. The ADHD group demonstrated more heterogeneity in network patterns with 50% in subgroup B.

Conclusions: ASD and ADHD were not characterized by distinct subgroup patterns, though analyses revealed more heterogeneity in ADHD than in ASD. Hyperconnectivity in SN-FPN nodes may reveal specific inattention or executive function difficulties. These results suggest potential for functional connectivity of the SN-FPN in understanding the similarities and differences in ASD vs. ADHD. It will be important for future research to collect phenotypic data in symptom severity and executive function domains in order to best understand what factors impact subgroup membership and play a role in the heterogeneity of brain networks.

202 **142.202** Changes in Brain Functional Connectivity Associated with the Emergence of Reaching and Grasping in Infants at Risk for Autism

Background: Early reaching experiences are associated with outcomes across multiple domains implicated in autism spectrum disorder (ASD), including socially oriented attention and language. While the consequences of the transition to independent reaching have been studied, little is known about the underlying neural systems. Characterizing brain changes involved in this motor milestone may inform our understanding of both typical and atypical developmental trajectories and potentially aid in ASD early identification.

Objectives: To identify brain functional connectivity (fc) changes associated with the emergence of reaching and grasping. We hypothesized that children showing the largest changes in manual motor behavior between 6 and 12 months would show the largest concurrent changes in fc between a subset of brain regions.

Methods:

Participants: The Infant Brain Imaging Study collected behavioral and resting-state fc magnetic resonance imaging (MRI) data from high risk (HR;

with a sibling with ASD) and low risk (LR; with a typically developing sibling but no familial history of ASD) participants. Analyses included 71 IBIS participants (24 LR) with fcMRI and behavioral assessments at both 6 and 12 months. This mixed-risk sample enabled investigation of brain-behavior relationships across a broad continuum relevant to both typical and atypical outcomes.

Imaging: Each participant completed 2-3 fcMRI scans (3T; 130 frames/scan, TR=2.5 s). A framewise displacement (FD) threshold of .2 mm was used to eliminate motion-contaminated data, and 150 clean frames were used for each participant. fcMRI time traces for 230 functionally defined regions of interest (ROIs) were correlated on a pairwise basis to generate whole-brain fc matrices at each age for each participant (Fig.1b). ROIs were sorted into twelve putative functional networks using the Infomap community detection algorithm run on the average fc matrix across all subjects at both ages (Fig.1a). Six-month fc values were subtracted from 12-month fc values to generate an fc change matrix for each subject (Fig.1b).

Measures: Raw fine motor scores and a "reaching and grasping (RG) composite" derived from the Mullen Scales of Early Learning were used to index manual motor ability. Six-month scores were subtracted from 12-month scores to evaluate behavior change (Fig.1c).

Brain-behavior enrichment analysis: Pearson's correlation was calculated between ROI-ROI fc change and motor score change (Fig.2a) and thresholded at $p<.05$ to identify "strong" fc-behavior relationships (Fig.2b). X^2 and hypergeometric tests identified greater-than-chance densities of strong fc-behavior relationships within network pairs for each motor measure, and empirical significance levels were determined using permutation.

Results: Our brain-wide search revealed maturation of functional connections clustered in motor networks and between motor and subcortical/cerebellar regions were important for both measures of manual motor development (Fig.2c,d). For RG, important fc changes also extended to more of the motor system as well as to visual and attention networks (Fig.2e).

Conclusions: This marks the earliest known description of changes in functional brain systems that underlie the emergence of visually guided reaching. As hand-eye coordination may play a role in socially oriented attention during infancy, future work will investigate whether these fc changes are also important for the emergence of early social behaviors.

203 **142.203** Cluster Analysis of Responsivity to Citalopram in Autism Spectrum Conditions: Preliminary Evidence of Neurobiological Sub-Groups.

J. Findon[1], *R. H. Wichers*[2], *J. Horder*[3], *E. Daly*[2], *D. G. Murphy*[4] *and G. M. McAlonan*[5], *(1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, and the Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Institute of Psychiatry, King's College London, London, United Kingdom, (4)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)MRC Centre for Neurodevelopmental Disorders, King's College London, London, United Kingdom*

Background: Alterations in excitatory (E) glutamate and inhibitory (I) GABA systems, have been reported in Autism Spectrum condition (ASC). Modulating E/I balance may therefore be considered a target for pharmacological management of autistic symptoms. E/I can be indirectly modulated by the serotonergic system. However, there are also differences in the serotonin system in some, but not all individuals with ASC, making it unlikely that everyone with ASC will respond in the same way to a serotonergic drug challenge.
Objectives: Therefore, here we tested the hypothesis that there are E-I responsivity differences to selective serotonin reuptake inhibition (SSRI) with citalopram within a group of individuals with ASC and between ASC and neurotypical controls.

Methods: This study used MEGAPRESS proton magnetic resonance spectroscopy ([^{1}H]-MRS) to measure concentrations of GLx (glutamate + glutamine) and GABA in unmedicated adult men with ASD (n=19) and age- and IQ- matched controls (n=20). Individuals were scanned twice, once after oral administration of 20mg of citalopram and once under placebo in a randomised double-blind procedure. Scans were at least 8 days apart to ensure full washout of the drug. Spectra was acquired in the dorsomedial pre-frontal cortex (DMPFC). Responsivity was defined as percentage change (placebo to citalopram) for each metabolite. Two-step cluster analysis was performed in order to identify subgroups based on response.

Results: There was a significant group by drug interaction on Glx levels ($p<0.05$). Overall Citalopram decreased Glx in controls but had no significant impact on Glx in ASD. However, this result masked marked individual variation in response to citalopram in both groups. Cluster analysis revealed a three-cluster solution with 'good' fit (average silhouette = 0.7). Clusters could be characterised as 1) 'responders with decreased Glx after citalopram' (ASD=4, Control=6 average response = -18.30%), 'non-responders' (ASD=10, Control= 13, average response = -0.71%) and 'responders with increased Glx after citalopram' (ASD=6, Control=0, average response = +21.42%). There were no significant interactions or main effects of GABA.

Conclusions: These findings suggest that Glx response to an SSRI is significantly different in ASD compared to controls. The considerable individual variation in pharmacological response which may inform efforts to stratify individuals with ASC into more biological homogeneous subgroups. This may encourage future work to examine whether these responsivity differences are predicative of treatment response.

204 **142.204** Combining Supervised and Unsupervised Learning to Subgroup Autism Spectrum Disorder According to Regional Brain Volumes

R. Chadaram[1], *D. S. Andrews*[2], *L. Libero*[2], *S. Rogers*[2], *C. W. Nordahl*[2], *W. J. Bosl*[1] *and D. G. Amaral*[2], *(1)School of Nursing and Health Professions, University of San Francisco, San Francisco, CA, (2)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA*

Background: Autism Spectrum Disorder (ASD) is a highly heterogenous condition with an unknown number of potentially unique neural phenotypes with distinct etiological causes. One biological factor that may be important in efforts to fractionate the autism spectrum into more homogenous subgroups is brain size. Recently it has been shown that a proportion of individuals with ASD have persistent disproportionate megalencephaly, i.e. brain volume disproportionate to body size (ASD-DM). There is some evidence that individuals with ASD-DM, on average have poorer outcomes. However, it is unknown if certain brain regions in ASD-DM are disproportionately affected and how regional variation in brain volumes in ASD-DM may contribute to the severity of ASD phenotypes.

Objectives: Utilizing both supervised and unsupervised machine learning techniques we aim to 1) identify the most important brain volumes for classifying ASD-DM and individuals with ASD but more typical brain volumes (ASD-N) and 2) use these identified brain regions to cluster individuals into groups with more homogenous volumetric neural phenotypes.

Methods: We acquired structural magnetic resonance imaging (MRI) scans of 147 male preschool aged children with ASD. ASD-DM classification was defined as having a total cerebral volume greater that 1.5 standard deviations from an established sample of age matched typically developing (TD) children, resulting in 16 ASD-DM and 131 ASD-N cases. Volumetric data from 239 brain regions were extracted using an automated T1-segmentation pipeline (https://mricloud.org) and normalized for total brain volume. Regional brain volumes were input as features for classification of ASD-DM and ASD-N using a RandomForest model. Model accuracy (ACC), specificity (SP) and sensitivity (SN) were estimated using a 10-fold cross validation scheme utilizing SMOTE to account for sampling bias as well as within an independent sample of 7 ASD-DM and 36 ASD-N cases. Model significance was assessed via *n*=1000 permutations of the class labels. The most discriminative features were determined according to measures of MeanDecreased accuracy and Out-of-Bag (OOB) error. Hierarchical clustering was then performed on the entire sample utilizing the most discriminative volumetric features in order to identify clusters of individuals with homogenous volumetric neural phenotypes.

Results: RandomForest was able to classify ASD-DM from ASD-N with a cross-validated ACC=89%/SN=74%/SP=90%. Similar results were observed when tested on an independent sample (ACC=86%/SN=75%/SP=87%). Permutation testing showed all classification results to be significant below chance level ($p<0.05$). After ranking features according to mean decreased accuracy it was determined that selecting 28 features resulted in the lowest OOB error, thus the top 28 features which included the superior frontal gyrus, middle temporal gyrus, and posterior cingulate gyrus, were further exported for hierarchical clustering of the entire sample. Cutting the resulting dendrogram at the second level resulted in two clusters containing *n*=4 ASD-DM/110 ASD-N and *n*=12 ASD-DM/21 ASD-N respectively.

Conclusions: Combining supervised and unsupervised machine learning techniques offers a powerful methodological framework for classifying and grouping individuals across the autism spectrum according to more homogenous biologically based subgroups. Such techniques represent a valuable tool in future efforts to identify new ASD subgroups with shared biological features.

205 **142.205** Cortical and Cerebellar Contributions to Pupillary Light Reflex in Individuals with and without Autism Spectrum Disorder

K. O. Anguah[1], *C. Daluwatte*[2], *J. H. Miles*[3], *G. Yao*[4] *and S. E. Christ*[5], *(1)Nutrition and Exercise Physiology, University of Missouri, Columbia, MO, (2)Biological Engineering, University of Missouri, Columbia, MO, (3)Thompson Center at the University of Missouri, Columbia, MO, (4)Bioengineering, University of Missouri, Columbia, MO, (5)Department of Psychological Sciences, University of Missouri, Columbia, MO*

Background: Accumulating evidence suggests that autism spectrum disorder (ASD) has its roots in early development, however diagnosis is not made until at least two years of age. Thus research in this field has mainly focused on the identification of behavioral, cognitive and neurophysiological markers that may serve as indicators for increased risk and also provide more insight into the neurophysiological mechanisms of ASD. Pupillary light reflex (PLR) which represents a stimulus-driven phenomenon whereby the pupil automatically dilates in response to the presentation of a bright luminance change is one such potential marker. Findings from previous studies suggest that PLR may be abnormal in individuals with ASD. Although the basis for ASD-related PLR is unclear, one possibility is that atypical PLR may arise from damage or disruption of other cortical and cerebellar areas not directly associated with modulation of the autonomic nervous system (ANS).
Objectives: We sought to further elucidate the neural basis for atypical PLR in individuals with ASD.

Methods: Twelve adolescents aged 13-18 years (*M* =16.1 yrs) with ASD and comparison sample of 12 neurologically uncompromised individuals without ASD aged 12-19 years (*M* =16.1 yrs) participated. We utilized a MRI-compatible eye monitoring system in concert with functional MRI (fMRI) to evaluate pupillary response and associated neural activity. Participants performed a passive viewing task in which they were shown a series of red-filtered, emotionally-neutral images that changed every 5 s. Every 20s the imperative stimulus (bright, dim, or black intensity levels) was superimposed over the red-filtered background. For each participant, PLR and neural responses were recorded for a total of 96 light stimulus trials (32 per condition). Trials were intermixed and presented over the course of 8 bold runs.

Results: Analysis of the eye tracking data revealed a main effect of condition (dim, bright) for constriction amplitude and time but not for latency. Greater constriction amplitude (18.3 ± 8.1 vs 10.4 ± 5.6) and time (469.4 ± 49.8 vs. 439 ± 49.1) were observed for the bright compared to the dim condition [$F(1, 22) > 6.0$, $p < .05$ in both instances]. There was no main effect of group (ASD, non-ASD) nor interaction effect of group and condition for any of the three PLR parameters. For the fMRI analyses, we found a group-by-PLR condition interaction for several regions including left cerebellum (-46, -64, -22), right ventral PFC (22, 32, -2), and right superior parietal lobule (30, -72, 46). In all cases, the activation contrast (Bright+Dim > Black) was greater for the ASD group as compared to the non-ASD group [$t > 2.6$, $p < .05$ in all instances].

Conclusions: Findings are consistent with previous studies (e.g., Nowinski et al, 2005) that have found that secondary regions such as cerebellum which project to the primary PLR circuitry are compromised in individuals with ASD and may possibly contribute to abnormal PLR.

206 **142.206** Cortical Folding Differences in Autism Spectrum Disorder (ASD) and Attention-Deficit/ Hyperactivity Disorder (ADHD) Relative to Typically Developing Peers (TD): Data from the Pond Network

Anagnostou*[1,8,12,15], *(1)Institute of Medical Science, University of Toronto, Toronto, ON, Canada, (2)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Department of Psychiatry, University of Toronto, Toronto, ON, Canada, (4)Program in Brain and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada, (5)The Margaret and Wallace McCain Centre for Child, Youth, & Family Mental Health, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada, (6)The Hospital for Sick Children, Toronto, ON, Canada, (7)Diagnostic Imaging, The Hospital for Sick Children, Toronto, ON, Canada, (8)Neuroscience & Mental Health Program, The Hospital for Sick Children Research Institute, Toronto, ON, Canada, (9)Department of Medical Imaging, University of Toronto, Toronto, ON, Canada, (10)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada, (11)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (12)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (13)Psychology, The Hospital for Sick Children, Toronto, ON, Canada, (14)Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (15)Department of Pediatrics, University of Toronto, Toronto, ON, Canada*

Background: ASD and ADHD are relatively common neurodevelopmental disorders (NDDs), with onset in early childhood. Due to their high comorbidity and rate of co-occurring symptoms, investigation of both NDDs in a single cohort will add clarity to our understanding of the shared and disorder-specific underlying neurobiological mechanisms that may drive these conditions. Magnetic resonance imaging (MRI) has been used extensively to study atypical brain development in both NDDs, however, cortical folding as a specific measure derived from MRI has received less attention.

The limited number of studies that have investigated cortical folding in ASD and ADHD present contradictory results. To the best of our knowledge, no study has investigated cortical folding across individuals with ASD and ADHD and typically developing controls (TD), and little is known about the relation of this measure to clinical symptoms.

Objectives: We examined cortical folding in children and adolescents with ASD and ADHD relative to TD, and the relation between cortical folding and social, attention, behavioural and adaptive functioning difficulties across disorders.

Methods: T_1-weighted MRI, cognitive and behavioural data of children and adolescents with ASD, ADHD and TD, between 6.1-15.9 years of age, were obtained from the Province of Ontario Neurodevelopmental Disorders (POND) Network dataset, an Ontario Brain Institute-funded multi-site study. FreeSurfer software was used to obtain whole-brain 3-D measures of cortical folding using *l*ocal Gyrification Index (*l*GI), a surface-based measure providing vertex-wise quantification of cortical folding. General linear model (GLM) analyses was conducted, on the module QDEC (Query, Design, Estimate, Contrast) on FreeSurfer to examine *l*GI differences between groups.

Results: 42 ASD (mean age: 12.11, SD: 2.76), 17 ADHD (mean age: 11.97, SD: 2.43) and 76 TD (mean age: 12.79, SD: 3.11) participants with IQ>70 were included in this preliminary study, which revealed significantly reduced cortical folding in individuals with NDDs relative to controls in a left hemisphere cluster located in the superior parietal lobe ($p<0.0001$). No significant difference in cortical folding was found on comparison of ASD versus ADHD groups. Decrease in cortical folding was associated with better adaptive functioning, less hyperactive/impulsive & inattention impairments, but more repetitive behaviours across all children with NDDs. No significant relation was found between cortical folding and social communication deficits. All results were corrected for multiple comparisons using Monte-Carlo simulations.

Conclusions: Findings of cortical folding differences in individuals with ASD and ADHD relative to TD point to an early marker of altered development in these conditions that predates clinical onset and may drive other brain alternations. Findings of no significant differences between ASD and ADHD suggests further similarities between these two NDDs.

207 **142.207** Cortical Activation Patterns during a Joint Cooperation Task in Children with and without Autism Spectrum Disorder (ASD)

M. Culotta[1], *W. C. Su*[1], *D. Tsuzuki*[2] *and A. Bhat*[3], *(1)Physical Therapy, University of Delaware, Newark, DE, (2)Department of Computer Science, Tokyo Metropolitan University, Tokyo, Japan, (3)Department of Physical Therapy, University of Delaware, Newark, DE*

Background:

Children with ASD present with social impairments and comorbidities in sensori-motor control that impairs their ability to adjust their actions to that of others (Bhat et al., 2011). We aimed to examine the underlying cortical mechanisms important for social cooperation, specifically, mirror neuron system (MNS) and sensori-motor activation in the frontal, temporal and parietal cortices as well as executive functions in the prefrontal cortices during a naturalistic social cooperation game of Lincoln logs using functional near-infrared spectroscopy (fNIRS), a cutting-edge neuroimaging tool that allows for study of cortical activity during naturalistic social interactions and turn-taking between people.

Objectives:

To compare social cooperation behaviors and associated prefrontal, frontal, temporal, and parietal cortex activation between children with and without ASD.

Methods:

Fifteen children with ASD and 17 typically developing (TD) children without ASD between ages 6 and 17 years wore an fNIRS cap embedded with a 3x11 probe set covering bilateral middle frontal gyrus (MFG), pre/post-central gyri (PSG), inferior frontal gyrus (IFG), superior temporal sulcus (STS), and inferior parietal lobule (IPL). Both, children and adults sat across a table to complete the building game involving four randomized blocks/conditions: a) *Coincide (C)*: each partner builds their own structure, b) *Lead (L)*: child leads the building and adult partner follows as they build own structures, c) *Follow (F)*: child follows the adult partner in building as they build own structures, and d) *Turn-take (T)*: child and partner alternate turns to build a common structure. The average oxy-hemoglobin response was analyzed to study differences between groups, tasks, hemispheres, and regions.

Results:

Our results are based on a smaller dataset (n=10 per group). Results from the entire dataset will be presented at the conference. In general, the children with ASD had lower cortical activation across multiple building conditions compared to the TD children without ASD across bilateral prefrontal, frontal, superior temporal, and left inferior parietal cortices. However, children with ASD had greater right inferior parietal cortex activation compared to the TD children without ASD. In terms of hemispheric differences, in the TD group, all conditions led to greater left hemispheric activation in the MNS regions except in the joint condition there was more bilateral activation. However, the ASD group showed no hemispheric lateralization or had greater right lateralization in the MNS regions.

Conclusions:

Children with ASD displayed errors during social cooperation as well as lower cortical activation across bilateral prefrontal, frontal, superior temporal, and left inferior parietal cortices compared to age-matched TD peers. There was differential activation across varying contexts with the TD group showing left lateralization in the MNS ROIs for all conditions except the Joint condition. Interestingly, the ASD group rarely showed left lateralization and often showed more right lateralization for the majority of the conditions. During social cooperation, children with ASD showed clear differences in processing of sensori-motor and social information compared to TD peers. Each of the aforementioned contexts affords a different challenge and should be used as therapeutic contexts to facilitate cooperation between children with ASD and their peers.

208 **142.208** Comparing fNIRS-Based Cortical Activation Patterns during Communicative Gestures between Children with and without Autism Spectrum Disorder (ASD)

A. Bhat[1], ***W. C. Su***[2], *M. Culotta*[2] *and D. Tsuzuki*[3], *(1)Department of Physical Therapy, University of Delaware, Newark, DE, (2)Physical Therapy,*

University of Delaware, Newark, DE, (3)Department of Computer Science, Tokyo Metropolitan University, Tokyo, Japan

Background:
Children with Autism Spectrum Disorder (ASD) have difficulty using communicative gestures with others. In this study, we investigated the neural mechanisms underlying this gestural impairment. Specifically, we examined the activation within the Mirror Neuron Systems (MNS) including the inferior frontal gyrus (IFG), superior temporal sulcus (STS), and inferior parietal lobule (IPL). Past studies have used fMRI to study gesture control in relatively unnatural contexts (within a scanner bore facing 2D displays). Functional near-infrared spectroscopy (fNIRS) is a neuroimaging tool that allows for more naturalistic, face to face gestural communication between people.

Objectives:

In this study, we compared MNS activation between children with and without ASD as they observed of performed communicative gestures with an adult partner.

Methods:

Fifteen children with ASD and 16 typically developing children with ASD between the ages of 6 and 17 years wore an fNIRS cap embedded with 3x3 probe sets covering bilateral MNS regions including the inferior parietal, superior temporal and inferior frontal cortical gyri. Each child was seated across from an adult social partner. The gestural task involved 3 conditions completed using a randomized block design: a) *Watch (W)*: child observed adult's gestures, b) *Do (D)*: child performed a gesture on their own c) *Together (T)*: child performed the gesture in synchrony with the adult. 18 trials were collected, 6 per condition using a randomized blocked design. The oxy-hemoglobin response was analyzed to study differences between groups, tasks, hemispheres, and regions.

Results:

In terms of group differences, children with ASD had lower activation in the Left IFG and STS regions than the TD children, mainly for the Do/solo action condition. In contrast, children with ASD showed greater activation in the right IFG and both PI regions compared to the TD children, mainly for the Watch/observe and Together/synchrony conditions. In terms of hemispheric differences, the TD children showed greater cortical activation in the left inferior frontal and superior temporal regions compared to the right homologues for these unilateral tasks. In contrast, children with ASD had symmetrical activation across multiple ROIs even though the tasks were unilateral in nature.

Conclusions:

Children with ASD showed reduced cortical activation in the superior temporal cortices and in contrast showed greater cortical activation in the right inferior frontal and inferior parietal cortices compared to TD children. Children with ASD lack the left lateralized pattern of cortical activation clearly seen in the TD children during unilateral tasks. Multiple neurobiomarkers associated with gestural communication were obtained and seemed atypical in the children with ASD. In the future, we hope to test intervention contexts to facilitate gestural communication and normalize activation patterns in children with ASD.

209 **142.209** How Is fNIRS-Based Cortical Activation Different in Children with Autism Spectrum Disorder (ASD) Compared to Those without ASD during Synchronized Postural Sway.

W. C. Su[1], *M. Culotta*[1], *D. Tsuzuki*[2] *and A. Bhat*[3], *(1)Physical Therapy, University of Delaware, Newark, DE, (2)Department of Computer Science, Tokyo Metropolitan University, Tokyo, Japan, (3)Department of Physical Therapy, University of Delaware, Newark, DE*

Background:
Apart from diagnostic impairments, children with Autism Spectrum Disorder (ASD) present with fundamental motor impairments in motor coordination and balance as well as difficulties with socially-embedded motor skills such as imitation/interpersonal synchrony. These motor impairments may contribute to the fundamental social impairments of children with ASD. Using functional near-infrared spectroscopy (fNIRS), we have reported reduced Mirror Neuron System (MNS) activation in the Inferior Frontal Gyrus (IFG) and Superior Temporal Sulcus (STS) and greater activity in the Inferior Parietal Lobule (IPL) in children with ASD compared to TD peers during a reaching synchrony task. However, the reaching task was limited to arm use and did not involve whole body movements. In the present study, we extend our research to studying cortical activation during synchronized postural sway.

Objectives:

We compared cortical activation and connectivity between prefrontal, frontal, parietal, and temporal cortices between children with and without ASD during synchronized postural sway.

Methods:

Fifteen children with ASD and 18 TD children between 6 to 17 years of age and fifteen TD adults participated. Each participant wore a cap embedded with a 3x11 fNIRS probe set that covered multiple cortical regions including bilateral middle frontal gyrus (MFG), inferior frontal gyrus (IFG), pre- and postcentral gyrus (PSG), superior temporal sulcus (STS), and inferior parietal lobe (IPL). The participants were asked to stand face to face with an adult social partner or to face a computer screen to complete four conditions: a) *Watch*: the participants stood still and watched the social partner swayed; b) *Do*: the participants swayed with a bar showed on a computer screen, c) *Face*: the participants swayed face to face with an adult social partner, and d) *Touch*: the participants swayed face to face with an adult social partner and with their fingertips touching. The oxy-hemoglobin response of the fNIRS signal was analyzed.

Results:

In the TD children and adults, greater activation was found in conditions requiring action execution (Solo, Face, and Touch) compared to the Watch condition. In the left hemisphere, greater activation was found during the Touch compared to the Solo and Face conditions whereas in the right hemisphere greater activation was found in the Solo compared to the Touch and Face conditions. Lastly, while IFG and STS regions were highly active across all conditions, the PSG region showed increased activation during the Solo condition only. We also expect reduced cortical activation in the children with ASD across multiple cortical regions including MNS regions such as IFG and STS compared to those without ASD.

Conclusions:

Our preliminary results show that left MNS regions are important for whole body movement synchrony with social partners. In addition, the primary sensori-motor cortices played a greater role during non-biological, whole body movement synchrony. We also expect more sway errors

and reduced cortical activation in children with ASD as they engage in synchronized postural sway compared to controls. In the future, we will utilize these shared social and motor neurobiomarkers to develop socially-embedded motor interventions that target the neural impairments of children with ASD.

210 **142.210** Differences in fNIRS-Based Cortical Activation Patterns between Children with and without Autism, during Object-Related Gestures.

S. Trost[1], *M. Culotta*[2], *M. Hoffman*[2], *W. C. Su*[2], *D. Tsuzuki*[3] *and A. Bhat*[4], *(1)Rollins School of Public health, Emory University, Atlanta, GA, (2)Physical Therapy, University of Delaware, Newark, DE, (3)Department of Computer Science, Tokyo Metropolitan University, Tokyo, Japan, (4)Department of Physical Therapy, University of Delaware, Newark, DE*

Background:
Children with Autism Spectrum Disorder (ASD) have significant impairments in gestural performance including errors during tool use, pantomime, as well as meaningless actions. Children with ASD have more errors during meaningless gestures compared to tool use or pantomimed actions that involve a clear context (Smith & Bryson, 2007). Gestural impairments could be attributed to poor gesture perception, planning, or execution of motor programs/sequences required for gesture production (Dowell et al., 2009). Mirror Neuron Systems (MNS) in the inferior frontal gyrus (IFG), inferior parietal lobule (IPL), and superior temporal sulci (STS) play a role in the aforementioned processes when performing object-related gestures.

Objectives:

In the current study, we compared cortical activation in the MNS and sensori-motor regions during three naturalistic, object-related gestural tasks - object use, pantomime, meaningless.

Methods:

14 children with ASD and 15 children without ASD between 6 and 16 years were seated at a table with a hammer and pegboard. The task was administered in a randomized, blocked fashion. Participants held a hammer and hit eight pegs on a pegboard in 3 different ways: a) *Holds hammer*: child hits pegs with an actual hammer, b) *Pantomimes*: child pretends to hammer, and c) *Meaningless*: the child taps the air. The oxy-hemoglobin response of the fNIRS signal was further analyzed to study differences in activation patterns between tasks, hemispheres, and the aforementioned regions of interest.

Results:

TD children showed greatest right MNS activation (IFG, STS, and IPL) in the Pantomime and Meaningless condition and both significantly differed from the Hammer condition; which had the lowest level of activation. There were no conditional differences in the left hemisphere. In contrast, children with ASD had fewer condition-based differences except for the right STS region wherein the pantomime condition led to greatest activation compared to both, meaningless and hammer conditions. In terms of group differences, TD children had greater bilateral STS activation whereas the children with ASD had greater right IFG and IPL activation than the TD group. In terms of lateralization, TD children had clear left lateralization in all MNS regions whereas the children with ASD showed bilateral activation except in the IFG in spite of the unilateral nature of the task.

Conclusions:

Children with ASD showed reduced activation in bilateral STS regions; however, compensatory enhanced activation was seen in the right IFG and IPL regions. Pantomime and meaningless conditions led to greatest MNS activation in the TD children. In contrast, only pantomime led to higher activation in the children with ASD. Children with ASD also do not show clear left lateralization during unilateral gestures; which was clearly seen in the TD children. We may have identified neurobiomarkers of object-related gestures that could be used to explain gestural deficits and to develop contexts to facilitate gesture understanding/production in children with ASD.

211 **142.211** Default Mode and Striatal Connectivity in Youth with Co-Occurring Autism Spectrum Disorder and ADHD

R. K. Greene[1], *T. Henry*[1], *E. Walsh*[2], *P. Cernasov*[1] *and G. S. Dichter*[2], *(1)Psychology and Neuroscience, University of North Carolina, Chapel Hill, NC, (2)Psychiatry, University of North Carolina, Chapel Hill, NC*

Background: It is currently estimated that ~70% of youth with autism spectrum disorders (ASD) have at least one co-occurring psychiatric condition, with Attention Deficit Hyperactivity Disorder (ADHD) being one of the most common (Leyfer et al., 2006; Simonoff et al., 2008). These two conditions share various behavioral symptoms including deficits in executive function and social communication, and atypical neural phenotypes have been observed in both ADHD and ASD within default mode network (DMN; Assaf et al., 2010; Lynch, 2013; Uddin, 2008) and corticostriatal networks (Bush et al., 2005; Cao et al., 2009; DiMartino et al., 2011); however, little is known about the shared and distinct neural connectivity patterns of individuals with ASD with co-occurring ADHD.
Objectives: This study aims to parse apart the neural heterogeneity within the DMN and striatal regions of individuals with ASD and co-occurring ADHD (ASD+ADHD) as compared to age-, IQ-, and gender-matched individuals with ASD without ADHD (ASD-), ADHD without ASD (ADHD-), and typically developing controls (TDC). Understanding the common and unique neural signatures across co-occurring psychiatric conditions in ASD may serve to inform diagnosis, as well as guide research by addressing heterogeneity within ASD samples.

Methods: Resting state functional magnetic resonance imaging (rs-fMRI) data from the ABIDE and ADHD-200 initiatives included 33 ASD-, 46 ADHD-, 29 ASD+ADHD and 51 TDC youths (ages 5-14; see Table 1). The present study used Group Iterative Multiple Model Estimation (GIMME), a causal search algorithm that can identify patterns in neural connectivity across individuals and groups. Specifically, the GIMME confirmatory subgrouping algorithm was employed using diagnostic subgroups (group cutoff: 0.65, subgroup cutoff: 0.5) to examine resting state connectivity patterns within the DMN and striatal regions (see Table 2). Participants with maximum head motion >2mm in any direction were excluded, and all volumes with framewise displacement >.3mm were removed.

Results: At the group level (i.e., significant for participants across all groups), there were several significant bilateral connections and connections between anatomically close regions; however, there were few group-level, long-range pathways linking anterior and posterior regions (see Figure 1). Indeed, subgroup-level analyses revealed differences between diagnostic subgroups in connections from parietal to frontal regions (see Figure

1). In addition, both ASD groups showed attenuated striatal connectivity compared to the TDC and ADHD- groups. Neither of the ADHD groups recruited the anterior medial prefrontal cortex. Furthermore, the ASD+ADHD group showed anterior to posterior connections most similar to the ASD- group, and both ASD groups omitted connections between the posterior cingulate cortex and restrosplenial cortex.

Conclusions: The psychiatric subgroups, primarily the ASD subgroups, showed relatively reduced between network (i.e., DMN, striatal) interaction compared to the TDC subgroup. These findings also provide evidence of both distinct and shared neural connectivity patterns across individuals with ASD, ADHD, and ASD+ADHD that may have implications for core symptoms of each disorder.

Table 1. Participant Demographics.

	ASD- (n=33)	ADHD- (n=46)	ASD+ADHD (n=29)	TDC (n=51)
FSIQ	105.48 (15.55)	109.85 (15.51)	110.00 (20.23)	105.48 (15.55)
Age	10.01 (2.78)	10.23 (1.89)	9.57 (2.10)	10.27 (2.60)
% Female	9.09%	21.74%	10.34%	17.65%

212 **143.212** Spinal Deformities Assessment in ASD Subjects: A CROSS Sectional Study

*L. Trentin[1], A. Signori[2], **G. Valagussa**[1,3] and E. Grossi[1], (1)Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy, (2)Department of Health Sciences (DISSAL), Section of Biostatistics, University of Genoa, Genoa, Italy, (3)School of Medicine and Surgery, University of Milan-Bicocca, Milano, Italy*

Background: The term “spinal deformity” includes conditions such as post-traumatic deformities, iper-kyphosis, iper-lordosis and idiopathic adolescence scoliosis. Early identification and effective treatment of mild scoliosis could slow or stop curvature progression before skeletal maturity, thereby improving long-term outcomes in adulthood (US task force JAMA 2018). In a systematic review (PROSPERO registration number CRD 42018100894), we found that spinal deformities appear to be understudied within autism research and that no studies on spinal deformities assessment in ASD subjects exist. Since severe spinal deformities may be associated with adverse long-term health outcomes (e.g. pulmonary disorders, disability, back pain, psychological effects, and reduced quality of life), the value of spinal deformities screening becomes increasingly relevant.

Objectives: Our study aims to assess the applicability of a spinal deformities screening protocol in ASD subjects.

Methods: The screening protocol included two tests: the “Adam Test”, measured with the Bunnell method for assessing the trunk asymmetry on the frontal plane, and the “Sagittal Index” as suggested by Zaina that gives a measure of spinal deformities on a sagittal plane. The Literature indicates that subjects who present “Adam Test” or “Sagittal Index” values above cut-off limits are in need of second level clinical assessment. We also considered the three ASD severity grades and the four intellectual disability (ID) categories (mild, moderate, severe and profound) as suggested by DSM-V.

Results: Sixty-one subjects (mean age 14.03 – SD 4.26; 55 males) were included in the study. Seven out of 61 subjects (11,5%) presented grade 1, 26 (42,6%) grade 2, and 28 (45,9%) grade 3 ASD severity. Three subjects (4,9%) exhibited mild ID, 22 (36,1%) moderate ID, 34 (55,7%) severe ID, and 2 (3,3%) profound ID. Despite the relatively high autism severity of our sample, we found the screening test applicable to 92% of our population. Five subjects were non-testable because of their behavioral difficulties; all of them had high ASD severity grades and moderate to severe ID. Using this protocol screening, we found 11 ASD subjects (18%) presenting abnormal values: three subjects (4,9%) with Adam’s test values over cut-off (>5°), and eight subjects (13,1%) with “Sagittal Index” values over the cut-off (>9,5 cm). Using a chi-square test, we found that subjects over the cut-off limits had higher ASD severity (p=0.039), and ID severity (p=0.002).

Conclusions: The screening protocol for spinal deformity is generally applicable in ASD, also in subjects with high ASD severity and severe ID. About 20% of ASD subjects present spinal deformities, a value in line to what described in the general population (15%-20% over cut off) therefore deserving special attention for eventual adverse long-term health outcomes.

213 **143.213** Spinal Deformities and Autism Spectrum Disorders: A Systematic Review

*L. Trentin[1], **G. Valagussa**[1,2] and E. Grossi[1], (1)Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy, (2)School of Medicine and Surgery, University of Milan-Bicocca, Milano, Italy*

Background: The function of the vertebral column is to support humans in upright positions, mechanically balance the stress of gravity, permit locomotion and assist in purposeful movements. The term “spinal deformity” includes conditions such as post-traumatic deformities, iper-kyphosis, iper-lordosis and idiopathic adolescent scoliosis. Severe spinal curvatures may be associated with adverse long-term health outcomes (e.g. pulmonary disorders, disability, back pain, psychological effects, and reduced quality of life). Early identification and effective treatment of mild scoliosis could slow or stop curvature progression before skeletal maturity, thereby improving long-term outcomes in adulthood. There is scientific evidence to support the value of spinal deformity screening in general population. This is true also for children with Autism Spectrum Disorder (ASD) for which untreated spinal deformity can interplay with impairments in fine and gross motor skills, motor planning, motor coordination and praxis.

Objectives: The aim of this systematic review is to critically describe the current knowledge on spinal deformities in ASD subjects in terms of prevalence, assessment methods and treatment.

Methods: The systematic review protocol was previously registered on the PROSPERO database (registration number CRD 42018100894). We conducted an extensive literature search in PubMed, CINAHL, PsycINFO, The Cochrane Library, and Scopus databases. We also considered grey literature sources such as: Opengray, Penn Libraries and International Society for Autism Research (INSAR) Congress archives. There were no restrictions on the types of study design eligible for inclusion, publication date or language. The main keywords used were: ASD, Autism, Autistic Disorder, Spinal deformities, Scoliosis and Spine.

Results: Following the PRISMA statement study selection process, we screened 2640 records after removing duplicates for eligibility. We found 11 eligible studies (figure 1). All of them were excluded because the main object was not pertinent to our aim. The main topics found were genetics, spinal surgery or surgery outcomes, since ASD is also used in the literature as the acronym for Adult Spine Deformity.

Conclusions: Spinal deformities appear to be an understudied topic within autism research. At present, in all the literature screened, there is no evidence on prevalence, assessment methodology and treatment of spinal deformities in ASD subjects. Since adolescent idiopathic scoliotic curves typically progress most rapidly during adolescent growth and clinical settings reveal it is possible to find developing ASD subjects presenting spinal deformities, it becomes relevant and important to conduct studies that verify the applicability of screening protocols in developing ASD subjects.

214 **144.214** A Comparison between Traditional and Musical Working Memory Assessments and the Associated Cognitive and ASD Behavioural Correlates

G. Philibert-Lignieres[1], *B. Tillmann*[2], *A. Bertone*[1] *and E. M. Quintin*[3], *(1)McGill University, Montreal, QC, Canada, (2)Université Claude-Bernard Lyon1, Lyon, France, (3)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada*

Background: Autism Spectrum Disorder (ASD) is often associated with executive functioning difficulties, which can be exacerbated by autism-related symptoms such as restricted and repetitive behaviours. Individuals with ASD also tend to possess strengths and weaknesses in visual-spatial and verbal skills, respectively. Music perception is considered a strength in ASD, with most studies investigating perception of music-evoked emotions, pitch and melody, and long-term musical memory. One aspect of music-related cognition that has yet to be systematically assessed in ASD is musical working memory, and how it relates to cognition and behaviour.

Objectives: **Aim 1):** Compare the performance on traditional and musical short-term working memory tests to examine whether music could be used as an alternative assessment modality of working memory in ASD. **Aim 2):** Compare the cognitive (i.e., visual-spatial and verbal skills) and behavioural ASD correlates (i.e., restricted and repetitive behaviours) of traditional vs. musical short-term working memory in children with ASD.

Methods: Fifty-nine children with ASD participated in this study (age= 9-16, M=12.37, SD=2.11, male n=51). **Aim 1)**: The Working Memory Index (WMI) subtests (i.e., Digit and Picture Span) of the Weschler Intelligence Scale for Children-Fifth Edition (WISC-V) were used as measures of traditional working memory. To assess musical working memory (MWM), sequences of 3, 4, and 5 pitches were presented in pairs to participants who were asked to identify whether sequence-pairs were similar or different. Total performance (3,4, and 5 pitch sequences combined) on the MWM task was calculated as Hits minus False Alarms (Hit-FAs). **Aim 2)**: The Verbal (VCI) and Visual Spatial (VSI) Indices of the WISC-V (cognitive correlates) as well as the Restricted Interests and Repetitive Behavior (RIRB) sub-scale score (ASD behavioural correlate) of the Social Responsiveness Scale-Second Edition (SRS-2) were correlated with both the MWM task total performance (Hit-FAs Total) and the WMI scores.

Results: **Aim 1)**: Paired sample t-tests (using standardized values) revealed that participants performed significantly better on the MWM task (M=.52, SD=.32) than on the Digit Span (M=.12, SD=1.09, p = .013) and the Picture Span (M=.14, SD=1.02, p = .009) subtests of the WISC-V. **Aim 2)**: Significant correlations were found between MWM task performance and the VSI (p=.001) and the RIRB sub-scale scores (p=.02). MWM task performance was not significantly correlated with the VCI score (p=.46). In comparison, the WMI score was significantly correlated with the VCI (p< .00), the VSI (p<.00), and the RIRB sub-scale scores (p=.05).

Conclusions: Our findings reveal that children with ASD performed better on a MWM task in comparison to traditional working memory tasks. Furthermore, both traditional and musical working memory were associated with visual-spatial skills, a well-documented strength in ASD, and with RIRBs, which are related to executive functioning. Furthermore, in comparison to traditional working memory tasks, musical working memory seems independent of verbal abilities. Results provide preliminary evidence for the use of music as a strength-based modality to assess the working memory abilities of children with ASD, which may be underestimated by traditional cognitive testing relying on verbal skills often impaired for this population.

215 **144.215** Executive Function and Academic Achievement in Autism Spectrum Disorder

A. C. Armour[1], *L. Kenworthy*[1], *A. Verbalis*[1] *and G. L. Wallace*[2], *(1)Children's National Health System, Washington, DC, (2)The George Washington University, Washington, DC*

Background: Executive function (EF) is predictive of academic achievement in the general student population (Ahmed et al., 2018). Children who come to pre-Kindergarten with fewer EF skills have trouble engaging in learning opportunities in the classroom and thus make fewer gains in math and literacy during the school year (Nesbitt et al., 2015). The limited evidence to date suggests associations between EF and academics in Autism Spectrum Disorder (ASD); however, the two existing studies have focused on children in the preschool to early primary school age range (Pellicano et al., 2017, St. John et al., 2018). EF might exert an even greater influence over academic outcomes in older children and adolescents with ASD.

Objectives: To determine whether performance-based EF tasks of working memory, inhibition, and flexibility predict academic performance on mathematical and literacy tasks in children and adolescents with ASD.

Methods: 60 individuals (28 with ASD, 32 neurotypical controls [NT]), ages 8-18 years (M=12.94, SD=2.5) matched on age and gender ratio (see Table 1) completed testing procedures. IQ was estimated with WASI Vocabulary (Voc, M=57.78, SD=10.11) and Block Design (BD, M=54.67, SD=10.81)

T-scores. For all regressions examining EF-academics relations, Model 1 (M1) included diagnostic group, age, gender, Voc and BD as nuisance variables, while Model 2 (M2) added performance-based measures of EF: WISC-V Digit Span (DS) measuring working memory, TEA-Ch Walk Don't Walk measuring inhibition, and DKEFS Switching Accuracy measuring flexibility. Academic performance-dependent variables included WIAT-III Math Fluency, WJ-IV Math Calculation, GORT-V Reading Fluency, and GORT-V Reading Comprehension.

Results: WIAT Math Fluency (N=45): M2 explained a significant proportion of the variance in math fluency, R^2=.45, F(8, 36)=3.62, p<.05. In M2, DS significantly predicted math fluency, b=2.31, t(36)=3.90, p<.001.

WJ Calculation (N=38): M2 explained a significant proportion of the variance in math calculation, R^2=.55, F(8, 29)=4.45, p<.05 (see Figure 1). In M2, DS significantly predicted math calculation, b=2.06, t(29)=2.92, p< .05.

GORT Reading Fluency (N=44): M2 explained a significant proportion of the variance in reading fluency, R^2=.63, F(8, 35)=7.33, p<.001. In M2, there was a significant association between gender, b=1.62, t(35)=2.01, p=.05; Voc, b=0.15, t(35)=3.06, p<.05; DS, b=0.32, t(35)=2.85, p<.05, and reading fluency.

GORT Reading Comprehension (N=43): M2 explained a significant proportion of the variance in reading comprehension, R^2=.72, F(8, 34)=10.85, p<.05. In M2, there was a significant association between gender, b=1.75, t(34)=2.35, p<.05; Voc, b=0.15, t(34)=3.52, p=.001; DS, b=0.34, t(34)=3.31, p<.05; and reading comprehension. For both reading fluency and comprehension, girls have higher mean scores than boys.

Conclusions: Of the EF measures considered, only DS, a measure of working memory, explained a significant proportion of variance in all four measures of math and reading skills. This study suggests that during the school years, EF, specifically working memory, is associated with academic performance in ASD, consistent with studies of younger children with ASD (St. John et al., 2018) and the broader population of school age youth (Ahmed et al., 2018). Further work should consider whether scores from more ecologically-valid measures of EF play a predictive role in academic performance in ASD.

216 **144.216** Neurobehavioral Phenotype of Autism Spectrum Disorder Associated with Germline Heterozygous Mutations in PTEN

*R. M. Busch[1], S. Srivastava[2], O. Hogue[1], **T. W. Frazier**[3], A. Y. Hardan[4], J. A. Martinez-Agosto[5], M. Sahin[6] and C. Eng[7], (1)Cleveland Clinic, Cleveland, OH, (2)Boston Children's Hospital, Boston, MA, (3)Autism Speaks, New York, NY, (4)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA, (5)Departments of Human Genetics, Pediatrics and Psychiatry, University of California, Los Angeles, Los Angeles, CA, (6)Boston Children's Hospital/Harvard Medical School, Boston, MA, (7)Genomic Medicine, Cleveland Clinic, Cleveland, OH*

Background: Mutations in *PTEN*, the gene that encodes phosphatase and tensin homolog, have been identified in up to 20% of children with autism spectrum disorder (ASD) and macrocephaly and are associated with marked abnormalities in the white matter of the brain.
Objectives: This study sought to comprehensively characterize the neurobehavioral phenotype of *PTEN*-ASD.

Methods: Comprehensive neurobehavioral evaluations were conducted in 28 children/adolescents (ages 3 to 21 years) with *PTEN*-ASD and compared to two groups of controls: non-syndromic ASD with macrocephaly (Macro-ASD, n=20) and *PTEN* mutations without ASD (PTEN-no ASD, n=19). ANOVA, ANCOVA, or Kruskal Wallis tests were used to examine group differences on neurobehavioral measures (cognitive, behavioral, sensory, and adaptive functioning) and, for select measures, t-tests were used to compare group performance to healthy control norms.

Results: There is a distinct neuropsychological profile associated with mutations in *PTEN* suggesting primary disruption of frontal lobe systems (i.e., processing speed, motor coordination, attention/working memory, executive functioning). Cognitive deficits in *PTEN*-ASD are more severe than those in *PTEN*-no ASD and extend to other areas of neurobehavioral function (i.e., adaptive behavior and sensory deficits). Interestingly, group differences in IQ were no longer apparent after controlling for processing speed. While core ASD symptoms are similar in *PTEN*-ASD and Macro-ASD, *PTEN*-ASD had lower clinical ratings of autism severity and showed more sensory abnormalities.

Conclusions: *PTEN*-ASD has a distinct neurobehavioral phenotype compared to idiopathic ASD that is likely to warrant special consideration for overall assessment and treatment.

217 **144.217** Salivary Sex Hormone Responses to Intranasal Oxytocin in Autistic and Neurotypical Women

***T. L. Procyshyn**[1], M. V. Lombardo[1,2], M. C. Lai[1,3,4], B. Auyeung[1,5], S. Crockford[1,6], J. B. Deakin[7,8], S. Soubramanian[8,9], A. Sule[8], S. Baron-Cohen[1] and R. A. Bethlehem[1], (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (2)University of Cyprus, Nicosia, Cyprus, (3)The Hospital for Sick Children, Toronto, ON, Canada, (4)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (5)University of Edinburgh, Edinburgh, United Kingdom, (6)University of Cambridge, Cambridge, United Kingdom, (7)Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom, (8)Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (9)Behavioural and Clinical Neuroscience Institute, University of Cambridge, Cambrideg, United Kingdom*

Background: Oxytocin may be of therapeutic use for enhancing social functioning in autism spectrum conditions (ASC). Given recent evidence that (i) response to oxytocin treatment in ASC may depend on baseline hormone levels and (ii) oxytocin treatment may alter short-term production of other socially-relevant hormones, further investigation of the relationships among endogenous hormone levels and oxytocin treatment is warranted.
Objectives: This study aimed to assess baseline levels of estradiol and testosterone in adult women with and without an ASC diagnosis and to test relationships between these sex hormones and psychological variables of relevance to autism. Changes in endogenous estradiol and testosterone levels following single intranasal administration of oxytocin or placebo—and whether such changes were dependent on ASC diagnosis—were also explored.

Methods: As part of a larger fMRI experiment with a cross-over design (Bethlehem et al., 2017), saliva samples were collected from 47 women (age range 18–50) at three timepoints: (1) baseline, (2) after intranasal administration of placebo or 24 IU oxytocin (Syntocinon, Novartis), and (3) at the end of scanning (approximately 2 hours after administration). Participants comprised 16 women with an autism-spectrum condition (ASC group) and 31 neurotypical women (NT group) who completed the Autism-Spectrum Quotient (AQ) and Empathy Quotient (EQ). Salivary estradiol and testosterone were quantified by an independent lab blinded to the research hypotheses using commercially-available enzyme-linked immunosorbent assay kits (Salimetrics). Baseline sex steroid levels were calculated as the mean of the two pre-administration saliva samples per participant. The ratio of baseline estradiol to testosterone was then determined. Post-administration changes in estradiol and testosterone levels were calculated as percent change relative to individual baseline.

Results: Baseline sex steroid levels did not differ between age- and IQ-matched ASC and NT women. Baseline estradiol to testosterone ratio was

negatively correlated with AQ (r = -0.34, p=0.02) and positively correlated with EQ (r=0.35, p=0.02). For the overall population, both estradiol and testosterone levels showed small but significant decreases over time, consistent with diurnal patterns. Percentage change in estradiol and testosterone from time 1 to time 3 differed significantly between the ASC and NT groups (p<0.01). For estradiol, the mean change was +12% for the ASC group and -9.9% for the NT group (Tukey HSD, p = 0.01) for combined drug conditions. For testosterone, the mean change was +7.8% for the ASC group and -14.6% for the NT group (Tukey HSD, p = 0.001). The percentage change testosterone showed an even larger between-group difference under the oxytocin condition (+14.4% for the ASC group vs. -15.5% for the NT group, Tukey HSD, p = 0.013). Interestingly, in the overall population under the oxytocin condition, there was a trend of a positive relationship between AQ score and percent change testosterone (r= 0.36, p = 0.06).

Conclusions: These findings support a relationship between sex steroid levels in women and psychological traits of relevance to autism. Further, they present evidence of a difference in endogenous sex steroid response to intranasal oxytocin between neurotypical women and women with autism or higher levels of autism-spectrum traits.

218 **144.218** Susceptibility to Relative Saliency in Processing Hierarchical Figures Among Adolescents with ASD

A. Baisa[1], *C. Mevorach*[2] *and L. Shalev*[3], *(1)School of Education, Tel-Aviv University, Tel-Aviv, Israel, (2)School of Psychology, University of Birmingham, Birmingham, United Kingdom, (3)School of Education and the Sagol School of Neuroscience, Tel-Aviv University, Tel-Aviv, Israel*

Background: One of the consistent characteristics of individuals with Autism spectrum disorders (ASD) is hypersensitivity to small details in their surroundings. It has been previously claimed that while typically developing (TD) individuals exhibit a perceptual bias towards processing of the 'whole' over the small details, individuals with ASD favor the processing of small/local elements. However, findings from studies that used hierarchical figures (HF) with individuals with ASD are inconsistent. One possible reason for such discrepancies is the differences between the stimuli's physical characteristics that were employed in previous studies which can affect the relative saliency of the global and local levels.
Objectives: The present study aimed at examining the effects of relative saliency of the global/local aspects of HF (by manipulating the size of the local elements of compound figure, with fixed distance between the elements) on local and global perception among adolescents with ASD compared to TD adolescents. We hypothesized that the perceptual bias of participants with ASD will be influenced by relative saliency.

Methods: Participants were 51 adolescents aged 15-20. Twenty-six were high functioning individuals with ASD (22 males, 3 females) and 25 (21 males, 4 females) were TD participants. To assess global and local perception we used hierarchical numerals (i.e., large numeral comprised of small numerals). We manipulated the saliency of each level relative to the other level by changing the visual angle of the stimuli. Three sizes were employed: *small* – the global level was more salient than the local level; *medium* – both levels were equally salient; *large* –the local level was more salient than the global level.

Results: Participants from both groups were influenced by the saliency manipulation as was evidenced by a triple interaction between Level, Size and Congruency. In addition, triple interaction between Group, Level and Size indicated that TD participants showed global precedence with small figures (where global level was more salient than local level), whereas participants with ASD exhibited global precedence with small figures and local precedence with large figures (when local level was more salient than global level). Importantly, with medium figures no Level effects were obtained. Also, an interaction between Group and Congruency revealed that ASD participants exhibited larger congruency effects compared to TD participants.

Conclusions: Participants with ASD were more sensitive to saliency manipulations compared to TD participants. Furthermore, while global bias was demonstrated by TD adolescents, no level preference was recorded among adolescents with ASD. Rather, ASD participants were equally biased towards salient information regardless of level of processing. Moreover, they exhibited increased difficulty in filtering irrelevant information compared to TD adolescents. Taken together, our results do not corroborate the notion of superior local processing among individuals with ASD but instead consistent with the idea that participants with ASD do not develop efficient perceptual organization mechanisms, which may further impair top-down suppression of irrelevant information. The results of the present study may have clinical implications such as developing computerized perceptual and cognitive training programs for improving visual perceptual organization and better cognitive control among individuals with ASD.

219 **144.219** The Local and Global Conceptualization of Autistic Cognitive Processing

S. Lung, *J. Oh and A. Bertone, McGill University, Montreal, QC, Canada*

Background: Rigidity and inflexibility are one of the core diagnostic features of Autism Spectrum Disorder (ASD; APA, 2013). Results from cognitive performance-based tasks such as the Wisconsin Card Sorting Task (WCST) and informant-based measures such as the Behavior Rating Inventory of Executive Function (BRIEF) suggest that autistic individuals demonstrate unique cognitive processing (Leung & Zakzanis, 2014). They tend to persevere on narrow topics and struggle with transitions or seeing novel relationships. At a perceptual level, autistic information processing has been conceptualized in a local and global manner, as suggested by the Weak Central Coherence theory (Happé & Frith, 2006) and Enhanced Perceptual Functioning hypothesis (Mottron et al., 2006). Given the robust use of local and global conceptualization in studying autistic perception, we extend this approach to cognitive processing with a specific focus on cognitive flexibility.
Objectives: This study aims to (i) explore the relationship between measures that are commonly used to define cognitive flexibility in ASD, and (ii) assess the possibility of conceptualizing cognitive flexibility measures in local and global dimensions.

Methods: Twenty-nine adolescents with ASD, M_{age} = 14.82 (1.21), were administered the WCST, Conners Performance Test – 3rd Ed. (CPT-3), and Wechsler Abbreviated Scale of Intelligence – 2nd Ed. (WASI-II). From these tests, T-scores from (i) WCST Perseveration errors, (ii) WCST Correct responses, (iii) CPT-3 Perseveration errors and (iv) WASI-II Matrix Reasoning (MR) subtest were obtained and entered into correlation and factor analyses.

Results: Descriptive statistics of the four scores tended to gather around two clusters: $M_{WCST\text{-}Pers}$ = 68.95 (12.33) & $M_{CPT\text{-}Pers}$ = 69.00 (18.59), and $M_{WCST\text{-}Corr}$ = 38.60 (6.36) & M_{MR} = 34.27 (10.74). Correlation analyses indicated that both WCST-Pers and CPT-Pers were negatively correlated with both WCST-Corr and MR T-scores. Three correlations were also found to be significant; a positive correlation between WCST-Corr and MR (r = .59, p = .02) T-scores, and negative correlations between CPT-Pers and MR (r = -.46, p = .03) T-scores as well as between WCST-Pers and WCST-Corr (r = -.63, p = .003) T-scores. Factor analysis and scree plot identified two factors from the scores. The distribution of means, directionality/significance of

correlations, and the elbow from factor analysis support to two cognitive flexibility clusters.

Conclusions: Our findings demonstrate that cognitive flexibility can be organized into two factors in ASD, with one factor measuring perseverative responses (WCST-Pers and CPT-Pers) and another measuring ability to see relationships (WCST-Corr and MR), which we coin as perseveration and concept formation factors, respectively. The perseveration factor measures persistent and random responses to simple, discrete and narrow information, and hence is more locally-oriented. The concept formation factor measures the ability to integrate characteristics of objects, deduce relationships among them and apply the deduced relationship to solve problem, and hence is more globally-oriented. Overall, this study extends the local and global conceptualization to study cognitive processing in autism. It opens avenues to future research on autistic cognitive processing and urges clinicians to address both aspects of cognitive flexibility in autism assessment.

220 **144.220** Thinking in Pictures in Autism Spectrum Disorder

C. Bled[1], *I. Soulieres*[2] *and L. Bouvet*[1], *(1)Psychology, Université Toulouse - Jean Jaures, Toulouse, France, (2)Psychology, University of Quebec in Montreal, Montréal, QC, Canada*

Background:

Individuals with Autism Spectrum Disorder (ASD) show an important sensory sensitivity (Crane et al., 2009), superior attention to detail (Mottron et al., 2006) and enhanced mental imagery abilities (Soulières et al., 2011). Moreover, some authors hypothesized that the use of mental imagery and visual strategies could partly explain the atypical performances of individuals with ASD (Kunda & Goel, 2011). Furthermore, according to personal reports, individuals with ASD would possess a specific visual cognitive style (Grandin, 2009).

Objectives:

The aim of this study is to assess the presence of a *visual cognitive style* in autistic individuals and to better characterize its manifestations. We also want to verify whether this visual cognitive style is related to the sensory atypicalities present in ASD.

Methods:

Participants: 39 adults with ASD participated in this study (age range 18 to 62, mean = 33.5, SD = 10.6). 104 comparison participants (age range 18 to 69, mean = 37.0, SD = 12.7) were also included. The two groups are matched on age (p = .184), education levels (p = .089) and gender (73.1 % of women in the control group, 71.8 % in the ASD group, p = .878).

Protocol: We used an online questionnaire containing 66 items:

- *Attention to detail*: 6 items from the Autism Spectrum Quotient (AQ; Baron-Cohen et al., 2001).

- *Mental imagery*: 6 items concerning the colors, level of details, duration, level of abstraction, movements and manipulation of mental images.

- *Cognitive styles*: Participants indicated whether they use images only, words only or both images and words in seven different situations: recollection, problem solving, anticipation, decision making, planning, comprehension and memorization. Two open questions were also asked, for example: “Describe what comes to your mind when you hear the name of a city you've already been to”.

- *Adolescent/Adult Sensory Profile* (AASP; Brown & Dunn, 2002): 42 items including sensory sensitivity.

Results:

Attention to detail (p < .001), the use of mental images (versus words) (p = .005) and the sensory sensitivity (p < .001) are significantly more important in participants with ASD than in controls. Moreover, there are correlations between the use of images, sensory sensitivity (rs = .37, p = .020) and attention to detail (rs = .35, p = .028) only in participants with ASD. In addition, mental images appear to be more persistent in participants with ASD than in controls (p = .052). Finally, qualitative analyses indicate that, when describing their experiences, controls tend to use the lexical field of memories, whereas participants with ASD tend to use the lexical field of perception.

Conclusions:

Our results support the existence of a visual cognitive style in ASD individuals with the frequent and persistent use of mental images. This visual cognitive style is related to the sensory atypicalities present in individuals with ASD. These results question the impact of this particular cognitive style on the daily life of these individuals, especially in terms of learning and attention.

221 **145.221** Shift from Scarce Neuropathological Findings to Emerging Pattern of Developmental Encephalopathy in Autism Spectrum Disorders

J. Wegiel[1], *T. Wisniewski*[2], *I. Kuchna*[3], *K. Nowicki*[4], *S. Y. Y. Ma*[5], *W. Kaczmarski*[1] *and J. Wegiel*[1], *(1)NYS IBR, Staten Island, NY, (2)NYU School of Medicine, New York, NY, (3)Developmental Neurobiology, NYS Institute for Basic Research, Staten Island, NY, (4)Developmental Neurobiology, NYS IBR, Staten Island, NY, (5)Department of Developmental Neurobiology, NYS Institute for basic research in developmental disabilities, Staten Island, NY*

Background: Autism is considered a behavioral disorder. Due to scarcity of brains donated for postmortem studies of ASD and limited number of neuropathological studies this functional definition was not questioned for decades. Tissue deficits delayed testing the hypothesis that behavioral changes are associated with a broad spectrum of structural abnormalities corresponding to developmental encephalopathy with brain region and neuronal network specific patterns of structural and functional changes.
Objectives: The overall goal of three groups of researchers from the Mount Sinai School of Medicine, New York State Institute for Basic Research in Developmental Disabilities and University of Maastricht supported by Autism Speaks/Autism Tissue Program was to (a) overcome tissue limitations by examining 14 brain hemispheres of subjects with idiopathic autism and 14 control subjects, (b) examine cases from 4 to 64 years of age to monitor pattern of changes during lifespan, (c) process the entire hemisphere for complex multiregional study which may reveal global and diverse pathology, (d) preserve serial hemispheric sections for qualitative neuropathological studies and unbiased stereological studies of the

number and size of neurons and (f) provide access to these collections of slides for researchers examining dozens of brain structures and their subdivisions.

Methods: Entire hemispheres including cerebellum and brainstem of 14 subjects with idiopathic autism and 14 control subjects were dehydrated, embedded in celloidin, cut into hemispheric 200-µm-thick coronal serial sections and stained with cresyl violet for neuropathological and stereological studies. To compare developmental changes in idiopathic and syndromic autism, the 11 brains of subjects diagnosed with syndromic autism caused by chromosome 15 duplication, 11 diagnosed with idiopathic autism and 11 control subjects were embedded in polyethylene glycol and cut into 50-µm-thick sections for stereological and immunocytochemical studies.

Results: Neuropathological studies revealed in both idiopathic and syndromic autism numerous similarities in type, topography and severity of developmental defects of neuronal migration with ectopias, heterotopias, dysplastic changes and subependymal nodular dysplasia which may contribute to epilepsy. Dysplastic changes of the flocculus might be related to altered gaze control. Reduced size of neuronal soma and nucleus detected in almost all examined cortical and subcortical structures may reflect developmental alterations contributing to autism clinical phenotype. Corpus callosum developmental abnormalities including focal agenesis and diffuse hypoplasia with severe deficit of small, medium size and large axons in all segments connecting prefrontal, premotor, motor, sensory and temporal cortex might be another factor associated with a broad spectrum of autism manifestations.

Conclusions: Studies revealed signs of global developmental encephalopathy in idiopathic and syndromic autism including: (a) abnormal neuronal migration with ectopias and heterotopias, dysplastic changes in the cortex, subcortical structures and cerebellum, (b) reduced size of neurons in almost all examined structures, (c) disruption of long range interhemispheric connectivity with congenital focal CC agenesis and diffuse hypoplasia resulting in a severe deficit of interhemispheric connections in all five CC segments. In general, these studies performed by numerous research groups but on the same material indicate that research driven tissue banking/processing provides powerful alternatives in the study of clinicopathological associations in autism.

222 **146.222** Autistic Traits and Cognitive Abilities Associated with Two Molecular Causes of Silver-Russell Syndrome

C. Lane[1], *M. Freeth*[2] *and L. Robinson*[3], *(1)The University of Sheffield, Sheffield, United Kingdom, (2)Psychology Department, University of Sheffield, Sheffield, United Kingdom, (3)University of Sheffield, Sheffield, United Kingdom*

Background: Silver-Russell syndrome (SRS) is a rare condition associated with restricted growth, estimated prevalence 1 in 30,000. A molecular cause has been identified in approximately 60% of individuals with a clinical diagnosis of SRS. Specifically, 30 – 60% of individuals with SRS have loss of methylation on chromosome 11p15 (SRS 11p15) and 5 – 10% have maternal uniparental disomy for chromosome 7 (SRS mUPD7). Previous research has indicated that autistic traits and intellectual disability may be prevalent in SRS and particularly in SRS mUPD7. However, to date, autistic traits and cognitive abilities associated with the SRS molecular subtypes have not been systematically investigated using standardised assessments.

Objectives: The primary aim of this study was to identify and compare the prevalence of autistic traits associated with two molecular causes of SRS (SRS 11p15 and SRS mUPD7). A secondary aim of this study was to assess cognitive abilities in order to establish and compare the intellectual ability of individuals with SRS 11p15 and individuals with SRS mUPD7.

Methods: The Social Responsiveness Scale, second edition (SRS-2) was used to assess autistic traits via parental report. The parent/caregiver of each participant completed the SRS-2 for 47 individuals with SRS 11p15 (mean age = 8.17 years, SD = 4.24) and 32 individuals with SRS mUPD7 (mean age = 11.63 years, SD = 7.12). The Autism Diagnostic Observation Schedule, second edition (ADOS-2) and the British Ability Scales, third edition (BAS3) were used to assess autistic behaviours and cognitive abilities, respectively. These in-person assessments were completed by a subset of participants: 18 individuals with SRS 11p15 (mean age = 8.63 years, SD = 3.44) and 15 individuals with SRS mUPD7 (mean age = 14.27 years, SD = 6.37).

Results: As assessed by the SRS-2, 45% of participants with SRS 11p15 and 53% of participants with SRS mUPD7 scored above clinical cut-off for ASD (total T-score ≥ 60). In addition, 10% of participants with SRS 11p15 and 38% of participants with SRS mUPD7 scored in the severe clinical range (total T-score ≥ 76). Comparison of SRS-2 mean total T-scores revealed that the SRS mUPD7 group were reported as displaying more autistic traits than the SRS 11p15 group. As assessed by the ADOS-2, 33% of participants with SRS mUPD7 scored in the autism spectrum or autism range, compared to 11% of participants with SRS 11p15. Based on general conceptual ability (GCA) scores, the majority of participants with SRS 11p15 had average intellectual ability (M = 98.56, SD = 19.23), whereas the majority of participants with SRS mUPD7 had borderline intellectual ability (M = 79.86, SD = 8.72). There was no association between SRS-2 total T-scores and GCA or ADOS-2 total scores and GCA for either group.

Conclusions: Overall, the findings demonstrate that individuals with SRS 11p15 and SRS mUPD7 display increased prevalence of autistic traits and these are particularly pronounced in SRS mUPD7. In addition, SRS mUPD7 is associated with increased risk of intellectual disability but autistic traits and intellectual ability are not associated in either of these groups.

223 **146.223** Spontaneous Neural Responses Relate to Behavioural and Psychiatric Traits in 16p11.2 Deletion Carriers: A Joint Analysis of EEG Spectral Power and Multi-Scale Entropy.

R. Al-Jawahiri, *M. Jones and E. Milne, The University of Sheffield, Sheffield, United Kingdom*

Background: Copy number variations (CNV) at the 16p11.2 chromosomal region (~600 kb breakpoints 4–5 (BP4-BP5)) are rare high-risk CNVs associated with myriad clinical features and neurodevelopmental disorders including intellectual disability, developmental delays, and autism spectrum disorder. Previous studies reported atypical event-related neural activity in 16p11.2 deletion carriers in response to auditory (Jenkins *et al.*, 2016), visual (LeBlanc and Nelson, 2016), and social stimuli (Hudac *et al.*, 2015). However, to date, it is not clear if neural responses are related to behavioural and psychiatric traits in 16p11.2 deletion carriers. Here, we investigated resting-state spectral power and entropy in 16p11.2 del carriers and its link to core del symptoms.

Objectives: The aim of this study is to examine the impact of 16p11.2 deletions (del) on neural activity and its relationship to social and communication impairment, autism symptom severity, and other behavioural and psychiatric problems.

Methods: EEG data were previously collected as part of the Simons Variation in Individuals Project (Simons VIP Consortium, 2012). Using spectral power, complexity index (CI), and multi-scale-entropy (MSE) analysis techniques, we analysed whole-brain resting-state EEG data collected from 22 16p11.2 del carriers and 12 typical controls. Given the small sample size, permutation tests were used for investigating group differences in neural responses (i.e., power and entropy levels). Additionally, permutation correlation tests were performed to examine whether del neural responses correlate with scores in the Social Responsiveness Scale (SRS), Autism Diagnostic Observation Schedule Calibrated Severity Score (ADOS-CSS), and Child Behaviour Checklist for ages 1.15-5 (CBCL).

Results: In terms of neural responses, no significant group differences were observed in absolute and relative power within each frequency band (delta, theta, alpha, beta, and gamma) at each of the four examined regions (frontal, occipital, parietal, and temporal). Significant group differences were found, however, in CI and MSE at all brain regions. Specifically, del showed higher levels of CI and MSE than controls at all time-scales (1-20) and regions. In addition, these neural power and entropy responses strongly correlated with most of the CBCL symptoms in deletion carriers. However, no links were found between neural responses and SRS and ADOS-CSS scores.

Conclusions: Atypical neural entropy levels are implicated in 16p11.2 del carriers over all timescales and brain regions. This indicates that local and longer-range information processing were atypical in 16p11.2 del carriers and possibly driving cognitive inflexibility and impairment in CBCL symptoms.

224 **146.224** Links between Autism and the FMR1 Premutation: Insights from Studies of Gaze, Language, and Cognition in Carriers of the FMR1 Premutation

K. Nayar[1], *M. Winston*[1], *A. L. Hogan*[2], *W. S. McKinney*[3,4,5], *G. E. Martin*[6], *J. N. Barstein*[1], *C. G. La Valle*[7] *and M. Losh*[4], *(1)Feinberg School of Medicine, Department of Psychiatry and Behavioral Sciences, Northwestern University, Evanston, IL, (2)Department of Psychology, University of South Carolina, Columbia, SC, (3)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (4)Communication Sciences and Disorders, Northwestern University, Evanston, IL, (5)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, (6)Communication Sciences and Disorders, St. John's University, Staten Island, NY, (7)Department of Psychological and Brain Sciences, Boston University, Boston, MA*

Background: Fragile X syndrome (FXS) is an X-linked, monogenic disorder resulting from a mutation of >200 CGG repeats in the fragile X mental retardation gene (*FMR1*), and is the most common monogenic disorder associated with autism spectrum disorder (ASD). Importantly, individuals with the *FMR1* premutation (PM; 55-200 CGG repeats) have been reported to exhibit features of the broad autism phenotype (BAP), suggesting that the *FMR1* gene may contribute to ASD-related features. This presentation will report findings from two eye-tracking tasks (that previously documented differences in ASD and the BAP), to investigate underlying cognitive processes related to language and social-emotional processing in PM carriers.

Objectives: To examine links between gaze, language, and social cognition in the *FMR1* PM, to determine whether phenotypic similarities exist with ASD and the BAP.

Methods: Forty-eight PM carriers and 56 controls completed two eye-tracking tasks previously used in studies examining ASD and the BAP: 1) A language fluency task (i.e., rapid automatized naming, or RAN), which involved serially naming common symbols and non-symbols. Refixations (the repeated fixations to previously-fixated items) and eye-voice span (i.e., the coordination between gaze and speech; longer EVS indicating greater automaticity) were variables of interest. 2) A passive viewing emotion processing task using faces from the NimStim Face Stimulus Set, during which gaze to the mouth, eyes, and nose were explored. Social cognitive and language abilities were assessed using the Reading the Mind in the Eyes Test and the Pragmatic Rating Scale, respectively. Correlations between gaze, language, and social-cognitive abilities were examined, and *FMR1*-related variation were explored within the PM group.

Results: PM carriers showed atypical gaze patterns in both tasks. During RAN, the PM group made more refixations (p<.05) and had shorter EVS (p<.10), particularly during the latter portion of the RAN sequence when key executive skills are most heavily taxed (ps<.05). Shorter EVS (i.e., less fluent language processing) was related to poorer social language abilities (but not executive functioning) (r =-.38, p<.01). Greater CGG repeats were also associated with shorter EVS (r=.35, p<.05). In the emotion processing task, the PM group fixated more quickly to the mouth, and spent more time looking at the mouth compared to controls (ps<.01). These atypical gaze patterns were surprisingly related to better social cognitive and social language abilities (rs>|.25|; ps<.05), as well as higher CGG repeats (r=.30, p<.10) in the PM group.

Conclusions: Findings revealed atypical gaze patterns in the PM, consistent with patterns previously observed in the BAP, which were observed across tasks targeting different language and social cognitive processes. Atypical gaze patterns in PM carriers may suggest that common neurocognitive processes are impacted in ASD/the BAP and PM carriers. Associations with CGG expansion suggest that the *FMR1* gene may play a role in modulating gaze and cognition. As such, results from this study may elucidate our understanding of the *FMR1* gene and its contributions to ASD-related features in the PM and more broadly.

225 **146.225** Precision Sensorimotor Control and Neurophysiology in Aging FMR1 Premutation Carriers

W. S. McKinney[1,2], *K. E. Unruh*[1,2], *Z. Wang*[3] *and M. W. Mosconi*[1,2], *(1)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (2)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, (3)Department of Occupational Therapy, University of Florida, Gainesville, FL*

Background:
FMR1 premutation carriers are at risk of developing Fragile X-associated Tremor/Ataxia Syndrome (FXTAS), a neurodegenerative condition characterized by significant motor impairments as well as cognitive and psychiatric issues. It is unknown whether sensorimotor issues are present during aging in premutation carriers who are not yet reporting clinical signs of FXTAS. Studies examining sensorimotor control and associated neural processes in aging premutation carriers may provide important insights into degenerative processes associated with FMR1 premutations as well as neurobiological mechanisms associated with FXTAS.

Objectives:

We sought to (1) characterize precision motor behavior and (2) associated brain activation in aging FMR1 premutation carriers during task-based functional MRI (fMRI). We also quantified the relationships between sensorimotor behaviors and FMR1 premutation allele repeat count.

Methods:

27 FMR1 premutation carriers ages 44-77 years and 38 age-, sex-, and handedness-matched controls completed a visually guided precision gripping task. Participants pressed with their thumb and forefinger against two precision load cells while viewing two horizontal bars. Participants pressed to move the lower bar upwards to the height of the static target bar and maintained a constant force for 2- or 8- seconds. The target bar was set at 15%, 45%, or 85% of their maximum voluntary contraction (MVC). Approximate entropy (i.e., force time series complexity, or ApEn), force variability, force accuracy, and peak rate of force increase during initial responses were examined. Sixteen FMR1 premutation carriers and 20 controls repeated the 2-s version of the task during fMRI at 20% and 60% of their MVC.

Results:

Compared to controls, premutation carriers showed reduced MVCs. During the initial phase in which participants increased their force, premutation carriers showed a reduced rate of force increase compared to controls. When trying to maintain a constant level of force, premutation carriers showed reduced ApEn relative to controls, though there was no difference in force accuracy or force variability between groups. For premutation carriers, greater CGG repeat length was associated with reduced ApEn, increased force variability, and reduced force accuracy. During fMRI, premutation carriers demonstrated increased activation of left superior temporal gyrus (STG) and right superior parietal lobule during force relative to controls at 20% MVC only. At 60% MVC, premutation carriers demonstrated reduced force-related BOLD activation relative to controls in orbitofrontal cortex (fMRI FWE corrected $p < .025$).

Conclusions:

Our findings indicate that aging premutation carriers show deficits of precision sensorimotor behaviors that are associated with greater CGG repeat length. In the context of prior studies showing that greater CGG repeat length is associated with increased risk of FXTAS in aging premutation carriers, these findings suggest that reduced control of precision sensorimotor behaviors may provide important biobehavioral risk markers of disease. During fMRI, premutation carriers demonstrated increased activation in visual and multisensory processing cortical circuits, indicating that sensorimotor deficits may reflect deficits in processing sensory feedback information during behavior. Decreased OFC activation during sensorimotor behavior compared to rest may indicate that premutation carriers show a reduced ability to flexibly shift their behavior during rapid (2 sec) sensorimotor tasks.

226 **146.226** A Comparison of Head Circumference Growth Trajectories in the Context of the CHD8 Regulatory Network

B. M. Boyd[1], *A. B. Arnett*[1], *C. M. Hudac*[1], *K. Hoekzema*[2], *T. Turner*[3], *B. J. O'Roak*[4], *E. E. Eichler*[5] *and R. Bernier*[1], *(1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Genome Sciences, University of Washington, Seattle, WA, (3)University of Washington, Seattle, WA, (4)Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, (5)Department of Genome Science, University of Washington, Seattle, WA*

Background: At least 30% of autism spectrum disorder (ASD) diagnoses are attributable to disruptive genetic events (Torre-Ubieta, Won, Stein, & Geschwind, 2016). Although no single genetic event explains the majority of ASD cases, functional genetic networks and shared deficiencies in neural growth pathways have been identified (Huguet, Ey, & Bourgeron, 2013). Research has examined converging regulatory networks, such as genes targeted by *CHD8*, a gene strongly associated with ASD (Cotney et al., 2015). One of the most prominent phenotypes in CHD8 is macrocephaly (Bernier et al., 2014; Barnard, Pomaville, & O'Roak, 2015). Despite the relevance of head size to brain development, growth trajectories have not been examined across functional gene classifications.

Objectives: Compare head circumference growth trajectories across functional genetic and clinical categories among individuals with disruptive genetic events associated with ASD either targeted or not targeted by *CHD8*.

Methods: Seventy-six participants with a disruptive mutation to an ASD-associated gene were included in the analyses (see Table 1). HC measurements were derived from medical record review and medical examination at the research visit. CHD8 target versus non-target functional gene groups were dichotomized based on prior research (Cotney et al., 2015). Participants were characterized as Macrocephalic or Microcephalic if they met criteria at any time point (i.e. +/- 2 population-based z-scores). Random effect, two-level models were tested in Mplus 7.3 with HC and age at the within level, and sex, gene functional category and clinical phenotype at the between level.

Results: Across the full sample, HC increased linearly (B = 2.71, SE = .28, p <.001) and showed quadratic deceleration (B = -.11, SE = .02, p < .001) with age, as shown in Figure 1. Females had smaller mean HC (B = -2.14, SE = .96, p = .026). Both functional gene group and clinical HC characterization moderated growth trajectories. The CHD8 Targets group had steeper linear growth (B = .22, SE = .08, p = .008) than non-Targets. The Macrocephaly group also had greater early linear growth (p < .001) relative to normal and Microcephaly groups. The Microcephaly group did not differ from the Normal group on growth rates (p > .10), indicating small and stable HC. Gene events in the Microcephaly and Macrocephaly groups were largely non-overlapping.

Conclusions: Growth patterns differ significantly within the population of individuals with ASD-associated gene disruptive events, and provide further evidence for discrete macrocephalic and microcephalic groups. Rapid early growth was characteristic of the broader CHD8 Target and Macrocephaly groups, indicating a shared phenotype and post-natal expression of this functional genetic class. In contrast, the Microcephalic group did not show atypical growth post-birth, suggesting related expression of these genes may be constrained to the prenatal period.

Grey matter overgrowth in the first years of life (Courchesne, Campbell, & Solso, 2011) and atypical levels of cerebral fluids (Shen et al., 2013) are common in ASD and may contribute to macro- and microcephalic phenotypes. HC phenotypes associated with genomic subtypes of ASD provide clues to the neurobiological and developmental etiology of neurodevelopmental disorders.

227 **146.227** Altered Striatum Centered Connectivity in SHANK3-Deficient Patients

ABSTRACT WITHDRAWN

Background:
Neuroimaging has been used extensively to dissect the pathophysiology underlying autism spectrum disorder (ASD). However, most studies are

conducted on subjects that etiologies are unknown and expected to be heterogeneous. These may create a challenge for data interpretation and reproducibility. SHANK3 is a master synaptic scaffolding protein enriched at the postsynaptic density (PSD) of excitatory synapses and plays a crucial role for synaptic development and function. Genetic defect of SHANK3 is one of the most frequent causes found in individuals with ASD from recent ASD genomics studies. SHANK3 causing ASD present a unique opportunity to dissect the pathophysiology of ASD by neuroimaging.

Objectives:

To investigate the neuromorphometry and clinical characteristics of Chinese children with *SHANK3* deficiency by neuroimaging and neurobehavioral evaluation.

Methods:

This is a case control study. Subjects were recruited and conducted from Aug 1, 2015 to Aug 31, 2017 in the Neurodevelopment Clinic of Children's Hospital of Fudan University. Among the total of 72 children participating in the study, 14 children have confirmed *SHANK3* genetic mutations, 26 have idiopathic ASD without *SHANK3* and other common genetic defect, and 32 were typically developing children as controls. Genetic tests, comprehensive clinical and neurobehavioral evaluations, as well as brain imaging were conducted for these subjects. Genetic mutations including chromosomal deletions and point mutations of *SHANK3* were identified or confirmed by MLPA, chromosome microarray, WES or Sanger sequencing methods. Comprehensive clinical and neurodevelopment evaluations including diagnostic evaluation of ASD were performed by experienced development pediatrician or certified ADOS and ADI-R administrators. Differences in quantitative grey matter indices were assessed using voxel-based morphometry (VBM) while in white matter were analyzed with tract-based spatial statistics.

Results:

Among 14 subjects with *SHANK3* mutations, 12 have heterozygous deletions including *SHANK3* ranging from 0.1 to 75 Mb size in the chromosome 22q13.3 and two have novel pathogenic point mutations in the *SHANK3* gene. Phenotypically, we described several previously unreported clinical features and manifestations including nostril eversion (100%), sensory stimulus seeking (64%), dental abnormalities (43%), hematological problem (21%) and prominent granulation tissue (7%), as well as common features of *SHANK3*-related ASD and chromosome 22q13.3 deletion (i.e. Phelan-McDermid syndrome, PMS) consisting of hypotonia, global developmental delay, and mild dysmorphic features. For the grey matter, VBM analysis revealed decreased gray matter volume (GMV) in dorsal striatum, amygdala, hippocampus and parahippocampal gyrus ($P < 0.05$, corrected for family-wise error, FWE). For the white matter, tract-based spatial statistics (TBSS) results demonstrated decreased FA in multiple tracts mainly with projection fibers and association fibers, including internal capsule, external capsule, cerebral peduncle, sagittal stratum, and etc. ($P < 0.05$, FWE corrected).

Conclusions:

This was the first major neuroimaging study of *SHANK3* deficiency related ASD. We have found a disrupted striatum centered connectivity associated with *SHANK3* genetic defects. These findings from human are consistent with the reports from the studies of *Shank3*-deficient mouse models. The cross species approach clarify the underlying neuropathological mechanisms of *SHANK3* in the human brain, thus may provide the target areas for the novel therapeutic.

228 **146.228** Characterizing Comorbid Seizures in Rare Genetic Conditions Associated with Autism and Neurodevelopment Disorders in the Simons Searchlight Cohort

***E. Brooks**, L. A. Cartner, L. A. Green Snyder and W. K. Chung, Simons Foundation, New York, NY*

Background:

Simons Searchlight (formerly Simons VIP) is an online registry collecting data on rare genetic conditions associated with autism and other neurodevelopmental disorders and includes over 50 monogenic conditions. Seizures are a frequent comorbidity in these conditions and is of great interest to both families and the research community, but epilepsy has not been well characterized since most have only been described in the last 2-4 years.

Objectives:

To characterize common seizure types, frequency, age of onset, and treatment effectiveness across monogenic conditions associated with seizures in Simons Searchlight.

Methods:

14 of the 16 monogenic conditions with data available in Simons Searchlight are known to have co-occurring seizures in some individuals. 113 participants with a history of seizures and pathogenic or likely pathogenic variants were included in this study. The Medical History Interview (MHI) was administered to families by a licensed genetic counselor and assessed seizure characteristics. An online parent-report seizure was also administered.

Results:

Within the monogenic conditions with seizures as a known comorbidity, 113 (39%) of participants reported one or more seizures. The sample population was evenly divided between females (49%) and males (51%). 35% of the participants have SCN2A mutations. The prevalence of seizures varies from 8% (MED13L) to 63% (SCN2A). The average age at onset across seizure types and gene groups was 22 months, ranging from the neonatal period to 12 years. Average age of seizure onset varied from 7 months (infantile spasms) to 2.8 years (drop attack).

57 participants (50%) reported more than one seizure type. Grand mal seizures were the most frequently reported seizure type (49%), followed by petit mal (42%), complex partial (28%), infantile spasms (24%), and simple partial (22%). Drop attacks were the least common (11%). The mean number of seizure types experienced was 1.8. The highest number of seizure types was reported by SCN2A participants (mean = 2.55).

74% of those participants with simple partial seizures reported achieving seizure control at the time of the most recent medical history interview. In contrast, 95% of those with complex partial seizures had achieved control. In examination of medication treatments, no one medication emerged as most effective in controlling seizures within any one genetic condition.

Conclusions:

Comparisons across rare gene conditions provides insights into seizure phenomenology. Some neurogenetic conditions have higher penetrance of seizures, such as STXBP1, SCN2A, and SYNGAP1. Grand mal seizures are observed in almost all of the groups and is the most frequently reported

seizure type. In contrast, infantile spasms are reported in only 4 genes, and 93% of those with infantile spasms had mutations in SCN2A or STXBP1. This could be evidence of an underlying biological mechanism uniquely predisposing to spasms for certain genes. There also appear to be trends in the age of onset by gene. More data are needed to determine what treatments are most effective for each gene.

229 **146.229** Data Harmonization across Genetic Conditions Associated with Autism

A. Halladay[1,2], *H. Grosman*[3], *J. Acampado*[4] *and J. Tjernagel*[4], *(1)Autism Science Foundation, New York, NY, (2)Rutgers University, Piscataway, NJ, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (4)Simons Foundation, New York, NY*

Background:
Advances in genetic testing have resulted in the discovery of rare variants that increase the risk for autism spectrum disorder (ASD) and related neurodevelopmental disorders. Individuals with these specific mutations have an up to 70% penetrance of ASD. Understanding ASD with a distinct genetic etiology is critical to developing interventions for both syndromic and idiopathic ASD. Families affected by these rare disorders have established Patient Advocacy Groups (PAGs) that have developed and maintained research registries that are crucial to this effort. The registries provide researchers important data, help communicate information to families, and help with participation in research studies. These PAGs have come together to form a consortium to address common issues, including registry-based data, in a group called AGENDA (Alliance for the Genetic Etiologies of Neurodevelopmental Disorders and Autism).

Objectives:

The Autism Science Foundation and the Simons Foundation Variation in Individuals (Simons VIP) project sought to enhance harmonization of data across rare disorder registries and allow for improved access and utilization of these registries to understand commonalities and differences across different forms of autism

Methods:

A total of 8 registries participated in this project and submittedfull data dictionaries. They included data dictionaries from the Autism Treatment Network, Interactive Autism Network, Dup15q Alliance, National Fragile X FORWARD, National Database for Autism Research, Phelan-McDermid Syndrome Foundation, Simons VIP and the Tuberous Sclerosis Alliance. Based on feedback from families, scientists and industry, questions across different domains were organized and categorized. Domains included: demographics, developmental history, pregnancy and birth history, and neurological or seizure history.

Results:

The information was itemized and made publicly available along with data use guidelines for each dataset. The information can be found on a single spreadsheet via the AGENDA website at: https://www.gdaac.org/for-scientists. The comparison highlights questions within each topic that exist in a single registry as well as those that appear similarly in multiples registries. Recommendations for wording and answer coding were made for both existing registries looking to update data formats as well as new registries wishing to design useful data structures at the outset. Within these high priority areas, 90 of the 1277 questions collected were itemized, following a protocol such that additional topic areas can be examined in the future.

Conclusions:

One of the barriers to research across different forms of autism, both syndromic and idiopathic, is the variation in resources and diversity of data collected through research registries. This project sought to decrease these difficulties by highlighting and harmonizing questions within special topics of interest across different registries. Future directions include determining individual governance policies to facilitate a unified data access process. As more rare variants considered causative for autism are identified, ensuring consistent resources to support scientific research is necessary.Increased collaboration between research registries and Patient Advocacy Groups should be encouraged so that standardization of the data can be initiated at earlier stages of clinical research studies, mirroring the approach taken within clinical trial research and the alignment with CDISC (clinical data interchange standards consortium).

230 **146.230** Early Activity Level and Later ASD Symptoms and Attention Problems in Children with FXS

R. E. Coyle[1], *A. L. Hogan*[2] *and J. E. Roberts*[3], *(1)Psychology, USC Neurodevelpomental Disorders Lab, Columbia, SC, (2)Department of Psychology, University of South Carolina, Columbia, SC, (3)Psychology, University of South Carolina, Columbia, SC*

Background: Fragile X syndrome (FXS) is a genetic disorder resulting in physical, behavioral, and intellectual abnormalities. FXS is the leading known genetic cause of autism spectrum disorder (ASD) and is also commonly comorbid with ADHD and attention problems. Activity level, operationally defined as intensity of bodily vigor, early in development has been linked to later attention problems in typically-developing (TD) children. However, no studies have examined bodily vigor in relation to later attention problems and/or ASD symptoms in FXS.
Objectives: The aim of this study was to examine the relation between activity level in infancy and later ASD symptoms and attention problems in children with FXS, controlling for gross motor abilities.

Methods: This study included 22 children with FXS (18 male) assessed at 12 months of age (T1) (*M* = 12.96 months, *SD* = 0.49 months) and again between 4 and 6 years of age (T2) (*M* = 51.18 months, *SD* = 7.08 months). Measures included a five-minute behavioral observation of free play, the Vineland Adaptive Behavior Scales Gross Motor subscale raw score, the Child Behavior Checklist (CBCL) Attention Problems Subscale *T*-score, and the Autism Diagnostic Observation Schedule – Second Edition (ADOS-2) calibrated severity score. The behavioral observation of free play was coded from video for bodily vigor, a weighted composite score was computed, with higher scores indicating more time spent at higher bodily vigor. Partial correlations between bodily vigor at T1 and ASD and inattention symptoms at T2, controlling for T1 gross motor abilities, were run. Linear regression was then used to examine the relation between bodily vigor at T1 and ASD symptoms and attention problems at T2, controlling for gross motor abilities.

Results: Partial correlations between bodily vigor and the CBCL Attention Problems were non-significant *T*-score, $r = .48$, $p = .072$ when controlling for gross motor abilities, with a slight correlation that suggests significance may arise with a larger sample size. The correlation between bodily vigor and ADOS-2 calibrated severity score was non-significant, $r = .26$, $p = .309$. For CBCL Attention Problems *T*-score, the linear regression model

was non-significant, $F(2,17) = 2.77$, $p = .095$, $R^2 = .27$, but suggestive of a significant correlation with a larger sample. Both bodily vigor ($b = 16.15$, $p = .092$) and gross motor abilities ($b = -.58$, $p = .059$) were non-significant predictors with a possibility of significance in a larger sample. For ADOS calibrated severity score, the model was non-significant, $F(2,21) = 1.30$, $p = .295$, $R^2 = .12$. Neither bodily vigor ($b = 2.46$, $p = .225$) nor gross motor abilities ($b = -.10$, $p = .149$) were significant predictors.

Conclusions: Taken together, these findings show that bodily vigor in infancy and gross motor abilities in infancy both may contribute to later attention problems, but not ASD symptoms. Future studies should take into account other variables of activity level and inattention in infancy in larger groups in order to identify the earliest risk factors of ADHD in FXS.

231 **146.231** Early Development and ASD Risk in Neurofibromatosis Type 1

A. Kolesnik[1], *E. J. Jones*[2], *J. Begum Ali*[2], *S. Garg*[3], *T. Charman*[4], *J. Green*[3] *and M. H. Johnson*[5], *(1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom of Great Britain and Northern Ireland, (2)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (3)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom*

Background: Neurofibromatosis Type 1 (NF1) is a monogenic disorder which affects 1 in every 2700 births (Evans et al.,2010), with up to 25% incidence of Autism Spectrum Disorder (ASD;Garg et al.,2013) and up to 45% presenting with ASD symptomatology (Garg et al.,2015). Levels of social impairment remain the main challenge for parents and children with NF1, although very little is understood about their early development. Our initial case series analysis of 10 infants revealed early motor and language delays at 10 months of age (Kolesnik et al.,2017).
Objectives: This project is designed to help identify early behavioural and neurophysiological markers of ASD in NF1, as well as gain a broader understanding of developmental trajectories. It further explores possible common pathways of ASD in children with NF1 and those without genetic disorders to inform construction of individualised intervention protocols.

Methods: We present data from a prospective study of infants with NF1 at 10 (n=10) and 14 (n=10) months. Data collection is ongoing and the final presentation will include data from 30 infants with NF1 recruited into the study. Results from a series of standardised assessments (Mullen,1995; McKinlay et al.,2011) were compared to a cohort of infants with familial risk of ASD including infants with a three-year diagnosis of ASD (HR-ASD:n=34), atypical (HR-Atyp:n=44) and typical development (HR-TD:n=89), as well as low risk controls (LR:n=89), co-varied by age (in days).

Results: Follow-up assessments at 14 months mirrored our initial findings (Fig1), showing reduced motor abilities in NF1 than non-ASD (HR-TD, HR-Atyp, LR) groups [Mullen Gross Motor(GM): ps=.03-.007], but not HR-ASD [p=n.s.]. Fine Motor(FM) and Vineland Adaptive Motor(VAM) scores were significantly lower in NF1 than all other groups [ps<.001]. Additionally, the NF1 group showed significant impairment in *language* ability, including lower Expressive (EL) [p=.033, η^2=.07], Receptive Language(RL) [p=.022, η^2=.044] and Adaptive Communication(VAC) scores [p<.001,η^2=.11], with significant differences between NF1 and LR groups only. Age comparisons (10 vs.14m) revealed age *x* outcome interaction for EL [p=.03, η^2=.023], RL [p=.02, η^2=.024], and VAC[p=.008, η^2=.01] scores, with comparable low scores in NF1 and HR-ASD groups, and lowest overall EL scores in NF1 group [ps ≤.001].

Conclusions: There are notable developmental difficulties in infants with NF1 in motor and language domains, which are similar to infants with later ASD diagnosis. Social skills are reported to be less affected at both time-points, which is unexpected relative to difficulties reported in later life. Based on our findings of pervasive language impairment in NF1 cohort, we will further discuss EEG data from an auditory habituation task (analysis ongoing), which was reported to show sensitivity to early variation in language growth (Kolesnik et al.,in review; Benasich et al.,2002). We hope to explore the relationship between neural markers of auditory processing and language difficulties observed in infants with NF1 and those with a later diagnosis of ASD. Using a prospective design will further help identify the time-window where these early impairments may be addressed.

232 **146.232** Effects of Age, Gender, and Genotype on Auditory Processing in Phelan-Mcdermid Syndrome

M. Reese[1], *E. Berry-Kravis*[2], *A. Thaliath*[3], *E. Isenstein*[4], *A. R. Durkin*[5], *J. Foss-Feig*[6], *P. M. Siper*[6], *C. A. Nelson*[7], *L. M. Baczewski*[8], *A. R. Levin*[9], *C. M. Powell*[10], *S. P. White*[11], *M. W. Mosconi*[12], *A. Kolevzon*[6] *and L. E. Ethridge*[13], *(1)Psychology, University of Oklahoma, Norman, OK, (2)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (3)Rush University Medical Center, Chicago, IL, (4)University of Rochester, Rochester, NY, (5)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (6)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (7)Boston Children's Hospital, Boston, MA, (8)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA, (9)Neurology, Boston Children's Hospital, Boston, MA, (10)Neurobiology, UAB School of Medicine, Birmingham, AL, (11)Department of Pediatrics, Emory University, Atlanta, GA, (12)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, (13)Pediatrics, University of Oklahoma Health Science Center, Norman, OK*

Background: Phelan-McDermid Syndrome (PMS) is a rare genetic condition characterized by deletion or mutation of region 22q13.3, which includes the *SHANK3* gene. Approximately 84% of individuals with PMS have autistic-like traits, which include abnormal reactivity to sensory stimuli.
Objectives: This study uses a standard auditory gating task that measures attenuation of neural activity to repetitive auditory responses in PMS and typically-developing (TD) controls, with a focus on age, genotype, and deletion-size effects in PMS. Auditory gating deficits are commonly associated with abnormal sensory responsiveness and speech processing; understanding variations contributing to auditory gating abnormalities may provide insight into observed variations in clinical phenotype.

Methods: Thirty-seven PMS (age range 46-216 months, 20 females) and 14 TD participants (age range 76-178 months, 6 females) completed 150 trials of a two-stimulus auditory gating task while undergoing dense-array EEG. Gating, amplitude, and latency measures of the P50, N1, and P2 were compared using ANCOVA, examining spatial topography, gender, and genotype (TD, deletion, mutation) for adolescent and adult PMS (n=20 out of 37) matched to TD (n=13 out of 14). Additional analyses included within-PMS comparisons for the full available age range and deletion size.

Results: **Gating.** PMS showed a significantly decreased p50 gating response compared to TD. TD showed stronger gender effects on the N1 gating response than PMS. When variations in topography were examined using global field power, mutations (n=6) could also be differentiated as showing gating deficits intermediate between TD and deletions. Within PMS, an age by deletion size interaction for the N1 gating response indicated there were fewer age differences in gating with small deletion sizes, but as deletion size increased, younger individuals tended toward poorer gating. **Amplitude.** A significant effect of deletion size for PMS indicated that as deletion size increased, P50 and N1 amplitudes decreased.

Latency. Within PMS, there was a gender by deletion size interaction for the P2 response latency to the repeated stimulus. Males and females with small deletion sizes did not differ, but males had longer latencies than females as deletion sizes increased.

Conclusions: Here we demonstrate differences in age, gender and genotype findings between and within PMS and TD. The most notable differences between PMS and TD were in genotype, where PMS showed worse gating than TD for P50. Within PMS, larger deletion sizes were associated with increased auditory processing abnormalities, especially in younger individuals, suggesting the possibility for developmentally-regulated involvement of additional genes in this region. Auditory gating deficits are commonly associated with deficits filtering irrelevant sensory information and can lead to difficulty with sensory responsiveness and speech development. Results suggest that PMS exhibit auditory processing abnormalities that show complex variation by deletion-size, gender and age, which may provide valuable insight into clinical characterization of sensory and speech behaviors in future studies.

233 **146.233** Electrophysiological Biomarkers of Sensory Processing Alterations in Idiopathic and Single-Gene Causes of ASD

M. A. Rowe[1], *J. George-Jones*[2], *E. Isenstein*[3], *H. Grosman*[1], *S. Guillory*[1], *Y. Zhang*[1], *S. M. Lurie*[4], *C. McLaughlin*[1], *L. Tang*[1], *I. Giserman-Kiss*[1], *J. Foss-Feig*[1] *and P. M. Siper*[1], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Psychology, University of Texas at Austin, Austin, TX, (3)University of Rochester, Rochester, NY, (4)Psychology, Ferkauf Graduate School of Psychology, Yeshiva University, Bronx, NY*

Background: Studying syndromic ASD (sASD) represents a unique opportunity to uncover gene-specific neural response patterns and examine the extent of overlap with idiopathic ASD (iASD). Sensory symptoms are prominent features in patients with both sASD and iASD. Electroencephalography (EEG) represents one method to objectively examine sensory processing, and, more specifically, excitatory (glutamatergic) and inhibitory (GABAergic) neurotransmission.

Objectives: This study aims to characterize neural response patterns in iASD, ADNP syndrome, Phelan-McDermid syndrome (PMS), and FOXP1 syndrome with typically developing (TD) controls. We investigate whether sensory abnormalities observed behaviorally in iASD and sASD are also detectable using electrophysiological (EEG) measures.

Methods: EEG data were obtained from 19 individuals with Phelan-McDermid syndrome, 4 with FOXP1 syndrome, 3 with ADNP syndrome, 69 with iASD, and 26 TD controls between the ages of 4 and 16. Clinical genetic diagnoses were confirmed using chromosomal microarray or targeted sequencing. Transient visual evoked potentials (VEPs) were elicited using a contrast-reversing checkerboard stimulus. VEPs were extracted from ongoing EEG by signal averaging. Amplitudes for P60-N75 (reflecting excitatory activity) and N75-P100 (reflecting inhibitory activity) were calculated by measuring waveforms peak-to-trough. The magnitude squared coherence (MSC) statistic was used to calculate responses in four previously defined frequency bands: alpha (6-10 Hz), beta (12-28 Hz), low gamma (30-36 Hz), mid gamma (38-48 Hz). Auditory evoked potentials (AEP) during a four-tone habituation paradigm were also obtained from a subset of each group.

Results: The iASD group displayed significant attenuation compared to controls at P60-N75 ($p<.001$) and N75-P100 ($p=.01$) with no difference in latencies. The PMS group also displayed significantly attenuated amplitudes compared to controls at P60-N75 ($p<.001$) with no difference in latencies. The iASD group also displayed significant attenuation compared to controls at P60-N75 ($p<.001$) as well as N75-P100 ($p=.01$) with no difference in latencies. The ADNP group showed a similar pattern at P60-N75 ($p=.027$) and N75-P100 ($p=.006$), and significantly delayed latency at P100 ($p=.048$). There was significant individual variability in the FOXP1 group, corresponding to clinical phenotype. In the frequency domain, the iASD and PMS groups displayed significant differences in beta and both gamma bands (p values=.001 to .042 and <.001 to .012, respectively). The ADNP and FOXP1 groups also showed weaker responses in beta ($p=.034$; $p=.032$) and low gamma ($p=.041$; $p=.016$) bands. Preliminary results from AEPs demonstrate group specific differences in magnitude of response to initial tones and degree of habituation of response to subsequent tones.

Conclusions: Time-domain analyses revealed syndrome-specific phenotypes with excitatory deficits observed in iASD, PMS, and ADNP syndrome groups based on deficits in early negative VEP components (P60-N75). Greater variability in response amplitudes was observed in the FOXP1 syndrome group, although on average, longer latencies were observed in both ADNP syndrome and FOXP1 syndrome groups at P100. Frequency-domain analyses demonstrated differences in beta and low-gamma activity present across iASD and sASD groups. Future directions include collecting additional AEP data to determine whether brain-based sensory abnormalities exist across sensory modalities. This information could potentially be used to inform treatment approaches for individuals with both syndromic and idiopathic ASD.

234 **146.234** Evaluating Properties of Electrophysiological Biomarkers in Duplications of Chromosome 15q11.2-13.1(Dup15q syndrome)

V. Saravanapandian[1], *J. Frohlich*[1], *D. Nadkarni*[2] *and S. Jeste*[3], *(1)University of California Los Angeles, Los Angeles, CA, (2)Pediatrics and Neurology, UCLA, Los Angeles, CA, (3)University of California, Los Angeles, Los Angeles, CA*

Background:

Dup15q syndrome is highly penetrant for autism, intellectual disability, hypotonia, and epilepsy. The 15q region harbors genes critical for brain development and synaptic function, particularly the UBE3A and $GABA_A$receptor genes. In a recent study we found that individuals with Dup15q syndrome show an electrophysiological biomarker characterized by excessive beta oscillations (12-30Hz) (Frohlich, 2016). This pattern resembles EEG changes induced by allosteric modulation of $GABA_A$Rs, and the frequency at which we see the highest peak in the beta band (peak beta frequency), is modulated by $GABA_A$R kinetics. Given the overexpression of $GABA_A$R genes and UBE3A, which modulates synaptic GABA release, beta power and peak frequency may reflect abnormal GABA neurotransmission in Dup15q syndrome. Therefore, we sought to examine properties of these biomarkers, namely relation to phenotype and stability across states, that might inform its use in future clinical trials of pharmacological agents that modulate GABA neurotransmission.

Objectives:

To determine whether beta power and peak beta frequency 1) correlate with cognition, 2) differ between children with and without epilepsy, and 3) differ between awake and sleep states.

Methods:

Spontaneous resting awake EEG were collected at UCLA and two Dup15q family meetings, from 46 individuals, ages 9months-16years. To analyze

sleep, we accessed clinical overnight EEG from 8 individuals with Dup15q syndrome, ages 2-11 years. Participants under medications known to pharmacologically elicit beta oscillations were excluded. EEG data were processed offline using MATLAB-EEGLAB software. Data were filtered, artifact reduced using both manual and independent component analysis, and physiological artifacts removed. Data were average referenced, and spectral power and peak frequency computed. Clinical measures tested included verbal(VDQ) and nonverbal cognition(NVDQ) based on the Mullen Scales of Early Learning, and adaptive function based on the Vineland Adaptive Behavior Scales. Simple and multiple linear regression models were implemented to model the effects of clinical features.

Results:

Beta power did not correlate with cognition (VDQ: R^2=0.0052, p=0.6756; NVDQ: R^2=0.0002, p=0.9354) and did not significantly differ based on epilepsy status (R^2=0.0003, p=0.9002). Peak beta frequency did not correlate with cognition (VDQ: R^2=0.0489, p=0.1947; NVDQ: R^2=0.0547, p=0.1695). Peak beta frequency was significantly lower in children with epilepsy compared to those without an epilepsy diagnosis at the time of EEG recording (R^2=0.1055, p=0.0383). Analysis of sleep EEG demonstrated persistent beta oscillations in sleep. Additionally, we found evidence of remarkably abnormal sleep characterized by attenuated slow wave sleep, presence of alpha-delta and beta-delta patterns. Particularly in participants with epilepsy, frequent spikes, and reduced spindle density were found.

Conclusions:

Peak beta frequency stratifies children with Dup15q syndrome based on epilepsy status. Sleep EEG revealed presence of excessive beta oscillations. Persistent beta oscillations and other abnormal electrophysiological patterns may compromise healthy sleep physiology and therefore disrupt sleep-dependent cognition. While this needs further investigation, stability of the biomarker across brain states underscores our hypothesis that the Dup15q EEG signature reflects the underlying genetic variation. Such genetically informed brain-based biomarkers can inform and improve clinical trials by serving as measures of target engagement or as outcome measures that precede behavioral responses to pharmacological treatment.

235 **146.235** Exploring Social Profiles of Individuals with 16p11.2 Deletion and Duplication

S. Trinh *and R. Bernier, Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background: Copy number variation (CNV) of the 16p11.2 chromosomal region has been associated with a wide range of neurodevelopmental outcomes. Approximately 19% of pediatric duplication carriers and 26% of pediatric deletion carriers meet criteria for a diagnosis of autism spectrum disorder, and a majority of carriers exhibit some autistic features (Green Snyder et al., 2016; Hanson et al., 2015). Few studies have investigated specific patterns of social strengths and challenges in 16p11.2 CNV carriers. Mouse model studies of 16p11.2 deletion have reported a pattern of intact social approach with atypical social interactions (Yang et al., 2015). Recently, clinical phenotyping of a 16p11.2 duplication cohort has similarly revealed a possible social profile of intact social motivation in the presence of impacted social cognition (Green Snyder et al., 2016). Further investigation of social behaviors in a large cohort of 16p11.2 duplication and deletion carriers may further validate this social profile. Objectives: To explore social profiles of individuals with 16p11.2 deletions and duplications.

Methods: Participant data from 223 children with 16p11.2 deletions and 100 children with 16p11.2 duplications were extracted from the Simons VIP Phase 2 data (Simons VIP Consortium, 2012). A repeated measures ANOVA was used to test whether mean *T*-scores differed on theoretically derived subscales of the Social Responsiveness Scale, Second Edition (SRS-2; Constantino & Gruber, 2012) within the 16p11.2 duplication and deletion groups.

Results: For the 16p11.2 duplication group, results showed a significant main effect of SRS-2 subscale on subscale mean *T*-score, *Greenhouse-Geisser Adjusted* $F(3.25, 321.62) = 28.65$, $p < 0.001$, *partial* $\omega^2 = 0.22$. Follow-up paired *t*-tests among SRS-2 subscales using Dunn-Sidak adjustment revealed that the Social Motivation subscale had a lower mean *T*-score, suggestive of better developed social motivation abilities, compared to Social Awareness ($t(99) = -6.08$, adjusted $p < 0.001$, $d = -0.56$), Social Cognition ($t(99) = -7.21$, adjusted $p < 0.001$, $d = -0.73$), Social Communication ($t(99) = -5.42$, adjusted $p < 0.001$, $d = -0.54$), and Restrict Interests and Repetitive Behaviors (RRB; $t(99) = -8.18$, adjusted $p < 0.001$, $d = -0.82$) subscales. Similarly, for the 16p11.2 deletion group, results showed a significant main effect of SRS-2 subscale on subscale mean *T*-score, *Greenhouse-Geisser Adjusted* $F(3.06, 680.29) = 10.66$, $p < 0.001$, *partial* $\omega^2 = 0.04$. Follow-up paired *t*-tests among SRS-2 subscales using Dunn-Sidak adjustment revealed that the Social Motivation subscale had a lower mean *T*-score compared to Social Cognition ($t(222) = -4.14$, adjusted $p < 0.001$, $d = -0.28$), Social Communication ($t(222) = -6.37$, adjusted $p < 0.001$, $d = -0.43$), and RRB ($t(222) = -2.92$, adjusted $p < 0.05$, $d = -0.23$) subscales.

Conclusions: The social profile of 16p11.2 CNV carriers was quantified in a large sample using standardized caregiver report. Evidence suggests that social motivation represents a relative social strength for both 16p11.2 duplication and deletion carriers. Further investigations should explore social motivation in other standardized measures along with the developmental trajectory of social motivation in individuals with 16p11.2 CNV.

236 **146.236** Genotype-Phenotype Correlations in Phelan-Mcdermid Syndrome

A. Ricciardello[1]*, F. Cucinotta*[1]*, L. Turriziani*[1]*, M. Briguglio*[1]*, M. Boncoddo*[1]*, F. Bellomo*[1]*, G. Turturo*[1]*, P. Tomaiuolo*[2]*, M. Baccarin*[2]*, C. Picinelli*[2]*, P. Castronovo*[2]*, C. Lintas*[3]*, R. Sacco*[3] *and A. M. Persico*[1,2]*, (1)Interdepartmental Program "Autism 0-90", "G. Martino" University Hospital, University of Messina, Messina, Italy, (2)Mafalda Luce Center for Pervasive Developmental Disorders, Milan, Italy, (3)Service for Neurodevelopmental Disorders & Laboratory of Molecular Psychiatry and Neurogenetics, University "Campus Bio-Medico", Rome, Italy*

Background: Phelan-McDermid syndrome (PMS, OMIM# 606232) is characterized by intellectual disability, muscle hypotonia, delayed or absent speech and autism spectrum disorder (ASD). PMS is due to heterozygous chr. 22q13.3 terminal deletions or, more rarely, point mutations involving the SHANK3 gene, crucial to the formation and plasticity of excitatory synapses. Disruption of SHANK3 causes approximately 0.5% of ASD cases, with higher rates reported in ASD co-morbid with ID. Patients with PMS may undergo behavioral regression, with two incidence peaks around 6 years of age and in adolescence.

Objectives: This study aims to assess genotype-phenotype correlations in PMS.

Methods: Fifty PMS patients (2-42 y.o., M:F=1:1) were recruited at the Interdepartmental Program "Autism 0-90" of the "G. Martino" University Hospital (Messina, Italy). All patients underwent medical history collection, neurological examination, behavioral observation, medical work-up and psychodiagnostic testing, including ADOS-2, ADI-R, Leiter-3 or GDMS, VABS-II, VAS, CGI, CBCL, SCQ, SSP, WHOQOL, QOL-A, ABC and RBS-R. Genetic diagnosis was confirmed by array-CGH (400K Kit, Agilent) or by targeted Sanger sequencing in 46 patients, by FISH in 1 case and by

karyotype in 3 cases.

Results: All patients received a DSM-5 diagnosis of Intellectual Disability and/or global development delay; 15/50 (30.0%) also satisfied DSM-5 and ADOS criteria for ASD. Moreover, all patients share deficits in gross and fine motor skills, as well as in alternating movement, visuo-motor and bimanual coordination. Deletion size ranges from 25 Kb to 9 Mb, spanning up to 7 autosomal dominant disease genes (SHANK3, SCO2, PLXNB2, UPK3A, SAMM50, PNPLA3, TCF20). Large deletions (>5 Mb), spanning from SHANK3 to UPK3A and beyond, are significantly associated with: (a) female sex (P<0.05), (b) more severe clinical phenotypes and greater developmental delay (P<0.05 for delay in walking and sphincter control, P<0.01 for deficits in receptive language); (c) presence of multiple brain MRI abnormalities (P<0.01). The largest deletions involving also TCF20 always yield a very severe phenotype with extreme muscle weakness, hypotonia, difficult weaning, reduced spontaneous activity and lack of autonomous walking. On the other hand, deletion sizes >0.42 Mb, spanning from SHANK3 to PLXNB2 and beyond, tend to be associated more frequently with renal malformations, but these are occasionally observed also with smaller deletions. Clinical regression occurred in 12/50 (24.0%) patients and may be more frequent in carriers of small deletions encompassing only SHANK3 (P=0.14). In general, large phenotypic variability is observed among carriers of identical or similar deletions.

Conclusions: Interindividual differences in PMS severity may stem from at least three sources: (a) deletion size involving other functional genes in addition to SHANK3, especially PLXNB2 and TCF20; (b) additional mutations, microdeletions or epigenetic influences in the non-deleted allele; (c) greater penetrance of familial genetic loading for neuro-behavioral disturbances in the presence of a SHANK3 synaptopathy. Larger deletions may be rarely compatible with life in male offspring. The medical work-up for PMS should be broad, structured, and consistent, and should not be driven by deletion size, although dominant and recessive genes located in the deleted segment can point toward specific vulnerabilities.

237 **146.237** Language and Motor Development in Children with Adnp Syndrome

L. Tang[1], *I. Giserman-Kiss*[1], *M. Mulhern*[1], *D. Halpern*[1], *J. Zweifach*[1], *J. Foss-Feig*[1], *H. Voulgarakis*[1], *M. A. Rowe*[1], *A. R. Durkin*[1], *J. Buxbaum*[2], *A. Kolevzon*[1], *S. De Rubeis*[3] *and P. M. Siper*[1], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (3)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY*

Background:

Activity-Dependent Neuroprotector Homeobox Protein (*ADNP*) is a transcription factor-encoding gene located on chromosome 20. ADNP Syndrome is a rare neurodevelopmental disorder caused by mutations and deletions in the *ADNP* gene and has been identified as one of the more common single-gene causes of autism spectrum disorder (ASD). ADNP syndrome has also been associated with intellectual disability and global developmental delay encompassing both language and motor domains.

Objectives:

To comprehensively characterize language and motor development in children with ADNP syndrome.

Methods:

Ten children with ADNP syndrome (4 female, ages 3-12 years) were evaluated using standardized assessments including the Mullen Scales of Early Learning, the Expressive Vocabulary Test, Second Edition (EVT-2), the Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4), and the Vineland Adaptive Behavior Scales, Second or Third Edition, Survey Interview Form. Language and motor milestones were collected using the Autism Diagnostic Interview-Revised (ADI-R).

Results:

Language and motor milestones were delayed in all participants. In the language domain, average age of first word and phrase speech were 31 and 60 months, respectively. At the time of evaluation, six participants were nonverbal or minimally verbal, two children used phrase speech, and two children used fluent speech. Seventy-one percent of participants (5/7) who completed the Mullen had higher age equivalents on the receptive language scale (M=22.29, SD=11.66) compared to the expressive language scale (M=19.14, SD=10.24). Of participants able to complete the PPVT-4 and EVT-2 (n=6), 67% scored higher on tasks of receptive language (M=60.57, SD=12.54) compared to tasks of expressive language (M=54, SD=14.25). On the Vineland, 70% of caregivers reported their child's expressive language skills (M=25, SD=14.19) were better developed than receptive language skills (M=22, SD=10.15).

In the motor domain, nine of 10 participants were able to walk unaided. Average age of first crawling and walking was 16 and 25 months, respectively. Of the seven participants who completed the Mullen, 71% (5/7) of participants had higher age equivalents on the Mullen for gross motor (M=25, SD=8.02) than for fine motor development (M=20.86, SD=5.40). Similarly, 71% (5/7) of participants had higher age equivalents on the Vineland for gross motor subdomain (M=26.71, SD=16.77) compared to the fine motor subdomain (M=24.86, SD=16.47).

Conclusions:

Delays in achieving language and motor milestones were reported in all participants. Current scores from standardized clinician-administered assessments indicated better developed receptive language abilities compared to expressive language abilities, despite caregiver report of an opposite profile. Results indicate that children with ADNP syndrome may understand more than they are able to express, which has important implications for behavioral and educational interventions. Both clinician-administered and caregiver interviews revealed better developed gross motor abilities relative to fine motor abilities. Results suggest intensive speech therapy, occupational therapy, and physical therapy are critical for individuals with ADNP syndrome and should be initiated early on.

238 **146.238** Medical Issues in Ehlers-Danlos Syndrome/Hypermobility Spectrum Disorders, Autism Spectrum Disorder, and Unaffected Controls

E. L. Casanova[1], *J. L. Sharp*[2], *S. M. Edelson*[3], *D. P. Kelly*[4], *E. M. Sokhadze*[5] *and M. Casanova*[6], *(1)University of South Carolina, School of Medicine, Greenville, SC, (2)Colorado State University, Fort Collins, CO, (3)Autism Research Institute, San Diego, CA, (4)University of South Carolina School of Medicine Greenville, Greenville, SC, (5)University of Louisville, Louisville, KY, (6)University of South Carolina School of Medicine, Greenville, SC*

Background: Ehlers-Danlos syndrome (EDS)/hypermobility spectrum disorders (HSD) are believed to be largely collagen-related disorders, which are often accompanied by neurodevelopmental and neuropsychiatric conditions (Baeza-Velasco et al., 2015). In particular, a growing body of literature suggests overlap between EDS/HSD and some cases of autism spectrum disorder (ASD), although to date this relationship is poorly delineated (Casanova et al., 2018; Baeza-Velasco et al., 2015). The possibility that a subset of autism cases are in fact connective tissue disorders is intriguing and it is therefore important to determine to what extent connective tissue impairment (clinical or subclinical) occurs within the autism spectrum.
Objectives: To study clinical similarities between adults with EDS/HSD, ASD, and controls across key symptom areas to determine the extent of phenotypic overlap across these groups.

Methods: We surveyed 702 adults aged 25 years or older with or without EDS/HSD and/or ASD diagnoses on a variety of EDS/HSD-related health topics, including immune, autonomic, and endocrine symptomology; diagnostic clustering within affected families; hypermobility and occurrences of dislocations/subluxations of joints; skin abnormalities (e.g., bruising, scarring, bleeding); and chronic pain and fatigue.

Results: Compared to controls, the autism group reported similar though less severe symptomology than the EDS/HSD group, especially in areas of immune, autonomic, and endocrine dysregulation; skin abnormalities; and chronic pain. The ASD group did not significantly differ from controls in reported rates of generalized hypermobility unless already diagnosed with EDS/HSD. Interestingly, EDS/HSD mothers with autistic children reported more immune symptoms than EDS/HSD mothers without (p = 0.0119). The same trend was found in EDS/HSD mothers with EDS/HSD children (p = 0.0145), suggesting the maternal immune system may play an important role in both these conditions' etiologies.

Conclusions: These data suggest that EDS/HSD and autism share some clinical, and perhaps etiological, overlap that should be further studied. This work also indicates that mild connective tissue impairment and chronic pain could be under-recognized issues in ASD that warrant further attention.

239 **146.239** Motor Trajectories and Language Outcomes in a Genetic Model of ASD: Early Development in Fragile X with and without ASD

E. A. Will, *K. D. Smith and J. E. Roberts, Psychology, University of South Carolina, Columbia, SC*

Background: Fragile X syndrome (FXS) is the most prevalent genetic subgroup of autism, with a comorbidity rate of 50-70%[1,2]. With substantial phenotypic overlap and high ASD comorbidity, FXS offers a particularly useful ASD model for characterizing the longitudinal implications of early developmental impairments. Motor is one particular area of early impairment in FXS[3] that is more significant in those with comorbid FXS and ASD[4,5]. Motor has been established as an important foundation language development in children with non-syndromic ASD[6]. However, the implications of delayed motor development on language outcomes in FXS and those with FXS and ASD has yet to be examined.
Objectives: To determine whether early foundations and rate of change in fine and gross motor development predict receptive and expressive language outcomes in children with FXS-only and FXS+ASD.

Methods: Participants were from a larger prospective longitudinal study and included 43 children with FXS. According to clinical best estimate procedures 24 of the 43 participants were confirmed to have comorbid ASD (FXS+ASD). Participants were tested at regular intervals between 6 and 60 months old and groups were age-matched across assessments (p=.50; FXS M=23.86; FXS+ASD M=24.78). Study measures included the Mullen Scales of Early Learning[7] the Vineland Adaptive Behavior Scales 2nd Edition[8] at each assessment. MSEL fine and gross motor raw scores were used as predictors and VABS-II receptive and expressive raw scores were used as outcome variables. We used growth models in a multilevel framework to determine level (intercept) and rate of change (slope) in fine and gross motor development over time in each group separately. Intercepts (with age centered at 9-months) and slopes were extracted and then modeled as predictors of receptive and expressive language outcomes at approximately 5-years-old in each group.

Results: Model results indicated that early gross motor (intercept) but not rate of change (slope) predicted receptive language for FXS (b=1.30; p=0.003), and FXS+ASD (b=0.88; p=0.037). This pattern was consistent between gross motor trajectories and expressive language outcomes for FXS (intercept b=5.49; p<.001); however, neither early gross motor nor rate of change predicted expressive outcomes in FXS+ASD. Early fine motor (intercepts) predicted receptive language outcomes for FXS (b=1.85; p<0.001) and FXS+ASD (b=2.54; p=0.02), whereas rate change predicted receptive outcomes only for the FXS (b=25.56; p=0.04). Early fine motor (b=6.26; p<0.001), but not rate of change, predicted expressive outcomes for FXS. Neither early fine motor, nor rate of change in fine motor predicted expressive language outcomes for FXS+ASD.

Conclusions: Study findings suggest that fine and gross motor development plays a significant role in receptive and expressive language outcomes for children with FXS. However, different patterns of influence emerged for children with FXS-only and those with FXS+ASD. Early motor foundations were a more salient predictor of both receptive and expressive outcomes for both groups. Rate of motor skill acquisition only emerged as a salient factor fine motor predicting receptive language in FXS without ASD. Decelerated motor development in FXS+ASD[5] may account for these patterns and collective findings underscore the necessity of targeted motor intervention.

240 **146.240** Neurophysiological Outcomes in a Preclinical Model of Ube3a Overexpression and Dup15q Syndrome

N. A. Copping[1] and ***J. L. Silverman***[2]*, (1)UC Davis, Sacramento, CA, (2)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis School of Medicine, Sacramento, CA*

Background:
Copy number variants (CNV) are among the most common genetic causes of autism spectrum disorders (ASD), with 10-20% of cases resulting from one or more CNVs. Maternally derived duplications or triplications of 15q11.2-q13 (Dup15q syndrome) are the most penetrant CNV observed in ASD, accounting for up to ~3% of ASD cases (Glessner et al., 2009; Pinto et al., 2010). Dup15q syndrome, as a genetically defined subtype of ASD, also shares the core transcriptomic signature observed in idiopathic ASD (Ohta et al., 2015). Characteristic features of Dup15q syndrome are moderate to severe intellectual disability, seizures, hypotonia, speech impairments, anxiety, impaired motor coordination, and ASD (Cook et al., 1997; Bolton et al., 2001; Hogart et al., 2010; Urraca et al., 2013; Conant et al., 2014; Finucane BM et al., 2016). We and others postulate that overexpression of the E3 ubiquitin ligase gene (*UBE3A*), a critical gene in this region, contributes to the Dup15q syndrome phenotype.

Objectives:

To examine neurophysiology by electroencephalographic (EEG) for spiking events in our *Ube3a*overexpression model system.

To investigate EEG characteristics such as epileptiform activity, total spectral power, and spectral power by band width frequency that are translationally relevant and observed in the Dup15q clinical population (e.g., high beta power measured in children with Dup15q).

Methods:

Wildtype and Ube3a overexpression mouse EEG was recorded over a24-48hr acquisition period (N=8-10/per genotype/per sex). EEG data were collected using the DSI telemetry system. Subjects were implanted with F20-EET telemeters bearing two channels to measure EEG and EMG. EEG leads were attached to surgical screws in the skull (anterior to the ICV coordinates), and EMG leads were placed in the trapezius muscles. Relative to bregma, EEG leads were located 1.0mm, 0.5mm for the positive channel and -1.0mm, -0.7mm for the negative counterpart. Animals were given one week to recover from surgery prior to data acquisition. Data were analyzed by DSI Neuroscore software and customized Matlab algorithms.

Results:

Previously, we discovered that neuronal specific overexpression of Ube3a isoform 2 is sufficient to cause seizures, behavioral and anatomical phenotypes (Copping et al., 2017). We extended our initial seizure data herein by reporting subthreshold seizure activity and an approximate 2-3 fold increase in spike train activity (0.5 s minimum duration and a minimum of 4 spiking events). Interestingly, we also observed increased beta spectral power without increased total power.

Conclusions:

Ube3a overexpression mice exhibited higher beta spectral power compared to their WT littermate controls, recapitulating the increased beta power signature seen in the clinical population and highlighting the use of spectral power as a biomarker for therapeutic efficacy. Seizures and epileptiform signatures in EEG can be similarly measured in both rodents and humans, and thus EEG phenotypes, such as those described herein, have realistic translational relevance (Featherstone et al., 2015; Modi and Sahin, 2017; Dickinson et al., 2018).

241 **146.241** Neuropsychiatric Phenotypes in 3q29 Deletion Syndrome and Novel Features of ASD: Results from the 3q29 Registry

R. M. Pollak[1], *M. M. Murphy*[2], *M. P. Epstein*[2], *M. E. Zwick*[2,3], *C. Klaiman*[3,4], *C. A. Saulnier*[3,5] *and J. G. Mulle*[2,6], *(1)Genetics and Molecular Biology, Laney Graduate School, Emory University, Atlanta, GA, (2)Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, (3)Department of Pediatrics, Emory University School of Medicine, Atlanta, GA, (4)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (5)Neurodevelopmental Assessment & Consulting Services, Decatur, GA, (6)Department of Epidemiology, Emory University Rollins School of Public Health, Atlanta, GA*

Background: 3q29 deletion syndrome (3q29Del) is a rare (~1:30,000) genomic disorder characterized by a 1.6 Mb heterozygous deletion on chromosome 3. It is associated with a wide range of neurodevelopmental and neuropsychiatric disorders, as well as growth deficits, feeding problems, and congenital heart defects. Notably, the 3q29 deletion confers a 30-fold increased risk for Autism Spectrum Disorder (ASD), a 40-fold increased risk for schizophrenia, and a significantly increased risk for intellectual disability and generalized anxiety disorder.
Objectives: The aim of this study is to describe the spectrum of ASD-related features in the largest 3q29Del patient cohort ever assembled.

Methods: We used Emory University's 3q29Del registry (3q29deletion.org) to obtain self-report data on 3q29Del patients and typically developing controls, including a custom medical and demographic questionnaire (n=94 3q29Del, 58.5% male, mean age=12.7 years; n=64 control, 51.6% male, mean age=10.6 years); Achenbach Behavior Checklists (CBCL/ABCL, n=48 3q29Del, 57 control); Social Responsiveness Scale (SRS, n=48 3q29Del, 59 control); and the Social Communication Questionnaire (SCQ, n=33 3q29Del, 46 control). Statistical testing and data visualization were performed in R.

Results: Self-reported ASD diagnosis in 3q29Del participants was significantly inflated versus the general population (30.7% vs. 1.47%, p<2.2e-16). The male:female ratio of self-reported ASD diagnosis in 3q29Del is 1.8:1, strikingly different from the 4:1 ratio. Additionally, some participants that do not report an ASD diagnosis scored in the clinical range on all self-report scales, and mean scores for all participants were elevated (mean SRS T-score=71.75; mean SCQ score=13.88; mean CBCL/ABCL T-score=62.5), indicating substantial behavioral impairment in the absence of a clinical diagnosis. Finally, 3q29Del individuals showed a novel constellation of ASD features on the SRS, with elevated mean scores on 5 of the 6 subscales (Social Awareness, Social Cognition, Social Communication, Social Communication and Interaction, and Restricted Interests and Repetitive Behaviors). The mean score for Social Motivation, however, was in the mild range (Figure 1), which is dramatically different from the profile observed in idiopathic ASD.

Conclusions: These results showed that the 3q29Del population is significantly enriched for ASD diagnosis and ASD features measured via standardized ASD surveys; however, several individuals scored in the clinical range on all scales, despite reporting no diagnosis of ASD. This implies that either ASD is underdiagnosed or not adequately assessed in 3q29Del patients, or additional psychopathology is present that may be independently elevating scores. Additionally, we find that potential confounders such as self-reported ID diagnosis are not driving the increase in scores for 3q29Del participants, indicating that the 3q29 deletion itself is the major risk factor for this impaired behavioral profile. Moreover, a unique pattern of ASD symptomatology was observed, with social motivation being relatively less impaired than other areas of social functioning; this profile is qualitatively different from what is observed in idiopathic ASD. These findings have implications for standard of care recommendations for individuals diagnosed with 3q29Del; they also suggest that 3q29Del could serve as an investigative inroad to a novel subtype of ASD.

242 **146.242** Predictors of Psychotic Symptoms Among 16p11.2 Copy Number Variant Carriers

A. Jutla[1], *J. Veenstra-Vander Weele*[2] *and W. K. Chung*[3], *(1)1051 Riverside Drive, New York State Psychiatric Institute / Columbia University, New York, NY, (2)Psychiatry, New York State Psychiatric Institute / Columbia University, New York, NY, (3)Pediatrics, Columbia University, New York, NY*

Background: Autism spectrum disorder (ASD) and psychotic disorders such as schizophrenia co-occur more frequently than chance would suggest. This relationship may in some cases be mediated by obsessive-compulsive disorder (OCD)-like symptoms, which are common in ASD and related to psychosis in the general population. However, psychosis in ASD is difficult to diagnosis, with little known about its predictors, correlates and outcomes. 16p11.2 copy number variation (CNV) is a promising model of the relationships between these pathologies. Both 16p11.2 deletion and duplication are associated with ASD, but only the duplication has been reported in schizophrenia. A comparison of psychotic symptoms

among deletion carriers, duplication carriers, and non-carriers could yield insights relevant to the broader ASD population.
Objectives: We sought to identify predictors of psychosis among 16p11.2 CNV carriers and their non-carrier siblings in the Simons Variation in Individuals Project (VIP) cohort, which represents a range of ages (23 ± 17 years). We hypothesized that: 1) psychosis would be most common in duplication carriers followed by deletion carriers and non-carriers, 2) ASD diagnosis would predict psychosis among carriers, and 3) OCD symptoms would predict psychosis among carriers and non-carriers.

Methods: To identify psychotic symptoms, an index was derived from items across existing measures. As psychosis and ASD can both involve social impairment, we focused on items measuring hallucinations, delusions, and disordered thought. The index incorporated Adult/Child Behavior Checklist (ABCL/CBCL) scores and item responses from the Scale of Prodromal Symptoms (SOPS), Diagnostic Interview Schedule for Children (DISC-Youth), and Simons VIP medication questionnaire (which asks about medications taken specifically for psychosis). The index yielded a binary psychosis variable considered positive if both an elevated ABCL/CBCL t-score and a positive DISC, SOPS or medication questionnaire response were present. Logistic regressions were conducted against this variable using carrier status, age, IQ, clinical ASD diagnosis, OCD symptoms (measured by DISC), and gender as *a priori* predictors. Generalized estimating equations were used to control for intra-family correlations.

Results: In the whole cohort (n = 544), psychosis (n = 27) was predicted by duplication carrier status (OR 4.3, 95% CI 1.1 - 16.4, p = 0.03) and OCD symptoms (OR 6.9, 95% CI 2.4 - 19.7, p = 0.0003). Among deletion carriers (n = 130), psychosis (n = 9) was predicted by OCD (OR 11.4, 95% CI 2.2 - 58.3, p = 0.003). Among duplication carriers (n = 108), psychosis (n = 12) had no significant predictors. Among noncarriers (n = 306), psychosis (n = 6) was predicted by OCD (OR 28.9, 95% CI 2.2 - 372, p = .01). No noncarriers with ASD had psychotic symptoms.

Conclusions: Our findings indicate an association between 16p11 duplication and psychosis that is independent of ASD diagnosis or OCD symptoms. In people without the duplication, OCD symptoms and psychosis were robustly associated. The lack of association between ASD and psychosis is surprising in light of previous work suggesting a relationship, albeit in much larger samples. Additional analyses will assess whether ASD symptoms, rather than categorical diagnosis, may show a relationship with psychosis.

243 **146.243** Restricted Repetitive Behaviors of Individuals with Comorbid Tuberous Sclerosis Complex and Autism Spectrum Disorder

H. K. Root[1], *S. E. O'Kelley*[1], *M. Bebin*[1], *H. Northrup*[2], *J. Wu*[3], *D. A. Krueger*[4] *and M. Sahin*[5], *(1)University of Alabama at Birmingham, Birmingham, AL, (2)McGovern Medical School, Univ. TX Health Sci Cntr-Houston, Houston, TX, (3)University of California Los Angeles, Los Angeles, CA, (4)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background: While atypical language development is the most common area of first concern for children with ASD, restricted repetitive behaviors (RRBs) may be some of the first manifestations of ASD, often presenting prior to language development (Wolff et al., 2014). Children with ASD of varying cognitive and adaptive abilities have significantly greater frequency and severity of RRBs compared to typically developing children (Ozonoff et al.,2008; Wolff et al.,2014). In infancy, children with ASD are likely to display repetitive motor movements including rocking, hand flapping, and unusual posturing (Wolff et al.,2014; Harrop et al.,2014; Ozonoff et al.,2008; Richler et al.,2010). By age 3 years, children with ASD also display unusual sensory preoccupations or interests.
There has been increasing interest in examining ASD within genetic disorders (Moss et al.,2012) such as tuberous sclerosis complex (TSC; McDonald et al.,2017; Jeste et al.,2014; Sundberg & Sahin,2015). However, caregivers and clinicians frequently do not recognize the proper diagnosis as being ASD in individuals with TSC (Capal et al.,2017), as RRBs are not well characterized within the TSC population. Better understanding of RRBs in individuals with TSC, as well as those with comorbid TSC and ASD, may inform earlier diagnosis of ASD, promoting optimal outcomes.

Objectives: The current study aims to examine and define the presence of RRBs in individuals with TSC and ASD.

Methods: Participants included 129 children with TSC participating in a multisite longitudinal study through the TSC Autism Center of Excellence Network. Within this sample, 26 individuals received an ASD diagnosis and 103 did not have ASD. Cognitive ability was assessed via the Mullen Scales of Early Learning, adaptive functioning via the Vineland Adaptive Behavior Scales-Second Edition, and RRBs via the Autism Diagnostic Interview-Revised (ADI-R).

Results: Groups did not significantly differ on age or gender($p's>0.05$). The ASD group had significantly lower cognitive ($t(26.5)=-3.14, p<.001$) and adaptive scores ($t(93)=-4.65, p<.001$). Overall, the ASD group had significantly higher scores on ADI-R Total Restricted, Repetitive, and Stereotyped Patterns of Behaviors($p<0.05$). Further, the ASD group showed significantly higher scores on C1-Encompassing Preoccupations or Circumscribed Patterns of Interest, C3-Stereotyped and Repetitive Motor Mannerisms, and C4-Preoccupation with Parts of Objects or Nonfunctional Elements of Materials ($p's<0.05$). At the item level, the ASD group showed significantly higher scores on Unusual Preoccupations, Hand and Finger Mannerisms, Other Complex Mannerisms or Stereotyped Body Movements, Repetitive Use of Objects, and Unusual Sensory Interests ($p's<0.05$). Groups did not differ on Circumscribed Interests, Verbal Rituals, or Compulsions/Rituals.

Conclusions: Results suggest that individuals with TSC and ASD have overall increased amounts and severity of RRBs, specifically increased unusual preoccupations, hand/finger and other complex mannerisms, repetitive use of objects, and unusual sensory interests. This suggests that children with TSC and ASD have a similar RRB profile to children with ASD only at 3 years of age (Wolff et al.,2014; Harrop et al.,2014; Ozonoff et al.,2008; Richler et al.,2010). As such, this profile may aid in detecting individuals with ASD within the TSC population at an earlier age, allowing for better detection of affected individuals.

244 **146.244** The Effectiveness and Feasibility of the PEERS® School-Based Social Skills Intervention in a Transdiagnostic Group of Adolescents

C. Leonczyk[1], *S. E. O'Kelley*[2], *A. Wainer*[3] *and S. Mrug*[4], *(1)AARTS Center, Rush University Medical Center, Chicago, IL, (2)University of Alabama at Birmingham, Birmingham, AL, (3)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (4)University of Alabama, Birmingham, AL*

Background: Social skills difficulties are common in adolescents with a range of neurodevelopmental (NDD) and mental health disorders (MHD). There are few evidence-based social skills interventions for adolescents, and access to these programs is limited. Social skills interventions are generally evaluated in tightly-controlled research settings, which differ substantially from community settings in ways that may limit the generalizability of program effectiveness. For example, social skills programs are generally studied within a single diagnostic group, while in community settings youth with a variety of NDDs/MHDs may be included together. School-based social skills interventions have potential to

overcome barriers to care. Given the limited research on these interventions in school settings, considerations of social validity and feasibility are warranted.

Objectives: The present study evaluated the feasibility, acceptability, and initial effectiveness of the PEERS® social skills intervention for a transdiagnostic group of adolescents with social difficulties in the public high school setting.

Methods: Twenty-four high school students were assigned to the PEERS® intervention or a waitlist control group (WLC). The majority of students (71%) had IEPs. Twenty-nine percent had ASD, 29% had other diagnoses, and 42% had no diagnoses. We assessed variables related to feasibility including attendance, dropout, and scheduling obstacles. We also assessed parents' and adolescents' ratings of program acceptability. We evaluated the impact of the PEERS® program on participants' social skills, ASD symptom severity, social anxiety, and explicit knowledge of social skills, as rated by parents, teachers, and the adolescents themselves. Further, we directly evaluated participants' conversational abilities with the Contextual Assessment of Social Skills (CASS).

Results: Both parents and adolescents rated the intervention acceptable overall. Drop out was low, and the remaining students attended most sessions, although scheduling difficulties arose. Results of ANCOVA indicated adolescents in the intervention group displayed significantly improved social skills knowledge on a measure of skills taught in the program (Cohen's d = 3.26) and overall involvement in conversation on the CASS (Cohen's d = 1.00) compared to adolescents in the WLC. There were small-to-large effect sizes favoring the intervention group for most other intervention outcome measures, although these differences did not reach statistical significance. Reliable change indices revealed that almost half of adolescents (46%) in the intervention group displayed reliable improvement in at least one conversational skill domain that was observable to an independent rater blinded to treatment status and time point, compared to 18% of adolescents in the WLC.

Conclusions: Our findings provide preliminary support for the effectiveness of the PEERS® intervention in transdiagnostic groups. They also highlight the importance of continued research into factors that facilitate implementation of interventions in community-based settings. Future research should evaluate moderators of treatment response to provide guidance for which students are most likely to benefit from the intervention and identify modifications or alternative treatments for those who are less likely to benefit. As this work progresses it is also critical to consider factors that increase the reach and sustainability of interventions, such as training school-based providers and integrating programs into the structure of existing services.

245 **146.245** The Neurocognitive Profile of Individuals with Phelan Mcdermid Syndrome (PMS): Comparison with Autism Spectrum Disorder (ASD) and Individual Differences.

J. Cooke[1], *A. San Jose Caceres*[1], *L. Mason*[2], *E. J. Jones*[2], *D. V. Crawley*[1], *H. L. Hayward*[3], *B. Oakley*[1], *J. Ahmad*[1], *C. L. Ellis*[4], *M. Nunez*[1], *D. G. Murphy*[5] *and E. Loth*[1], *(1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, King's College London, London, United Kingdom, (4)Social, Genetic and Developmental Psychiatry Centre, Kings College London, London, United Kingdom, (5)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:

Phelan-McDermid Syndrome (PMS) is a rare neurodevelopmental condition caused by a chromosome 22q13.3 deletion. Individuals have mild to profound learning disabilities and 70-80% also have autism spectrum disorder (ASD). Little is known about the shared cognition of PMS and ASD or individual differences within PMS.

Objectives:

To investigate three early processes often disrupted in ASD; spontaneous social attention, biological motion, and visual attention shifting. First, we examined mean group differences and individual variability. Second, we used hierarchical clustering to identify subgroups based on performance profiles across domains. Third, we investigated the relationship between neurocognitive performances, ASD symptoms, and developmental delay.

Methods:

22 PMS (2-19 years), 27 ASD (2-19 years) and 28 typically developing (TD) individuals (1.6-6 years) completed a series of eye-tracking (ET) and behavioural tasks. Spontaneous social attention was measured with a face pop-out ET task and a social orienting behavioural task. Biomotion was measured using a point-light display ET task, and visual attention shifting (disengagement time) with the Gap Overlap (ET) task. Autistic symptoms were assessed in PMS and ASD using the ADOS and ADI-R, and level of adaptive function for all using the Vineland Adaptive Behaviour Scale. Non-verbal mental age (NVMA) was estimated using developmentally appropriate tests. Developmental delay was calculated as chronological age/NVMA.

Results:

Social orienting differed by group ($F_{(2,66)}$ = 7.298, p = .001), with a higher percentage of orienting to social versus object sounds in TD (p = .001) and ASD (p = .001) versus PMS. 59% of PMS participants showed preference for social orienting, 12% for object orienting, 18% had no preference, and 12% did not orient to either stimuli. Social orienting was positively related to social adaptive functioning ($r_{(63)}$ = .438, p < .001) across groups, and negatively to ASD symptom severity in PMS ($r_{(17)}$ = -.620, p = .008). Face pop-out effect (i.e., first look to face in >50% of trials) (45% in PMS, 43% in ASD, and 55% TD) and preference for Biomotion (PMS and ASD 53%, TD 57%) did not differ between groups, but 88% (6/7) of PMS had longer disengagement times than the average ASD or TD individual.

Hierarchical clustering applied to 40 participants with data across all tasks revealed 3 clusters (stability of >.75 after 1,000 bootstraps). Cluster 1 (3 PMS, 3 ASD, and 4 TD) contained the longest disengagement times on average, cluster 2 (1 PMS, 8 ASD, and 5 TD) the highest social attention/orienting preference, and cluster 3 (1 PMS, 2 ASD and 13 TD) the fastest disengagement and lowest social attention. Cluster 1 had on average the lowest NVMA, highest ASD symptom severity and lowest social adaptive functioning. Cluster 2 had the most developmental delay and cluster 3 had the least developmental delay and highest social adaptive functioning.

Conclusions:

PMS individuals performed similarly to ASD on ET tasks of social attention but had lower rates of social orienting relating to ASD symptom severity, and longer disengagement times. No performance profile distinguished ASD and PMS groups as individual performance varied within

both groups.

246 **146.246** Understanding the Landscape of Behavioral Interventions for Individuals with Phelan-Mcdermid Syndrome

A. Wainer[1], *M. Printen*[2], *C. Leonczyk*[3], *E. Berry-Kravis*[4], *J. Buxbaum*[5], *G. Bliss*[6] *and L. Soorya*[1], *(1)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (2)Child and Adolescent Psychiatry; Autism Assessment Research and Treatment Center, Rush University Medical Center, Chicago, IL, (3)AARTS Center, Rush University Medical Center, Chicago, IL, (4)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (5)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (6)Phelan-McDermid Syndrome Foundation, Venice, FL*

Background: The essence of developmental synaptopathies (DS) such as Phelan-McDermid Syndrome (PMS), PTEN, and Tuberous Sclerosis Complex (TSC) suggest a need for interventions addressing nontraditional treatment targets – namely learning and cognition. The presence of cognitive and physical delays in DS suggests an increased risk for failing to respond to behavioral intervention as a stand-alone treatment, in part due to impairments in learning, motivational, and motor abilities. Developing effective interventions for DS requires paradigms with potential to address complex processes like learning, as well as procedures for enhancing generalization and maintenance of new skills. Any novel behavioral intervention used with this population must be acceptable, compatible, and feasible at a minimum to ensure effectiveness and sustainability. Particularly important is parents' perception that proposed intervention approaches are reasonable, appropriate and relevant for the unique needs of their children.

Objectives: The ultimate aim of this program of work is to identify an acceptable, effective, and safe therapeutic approach to enhance learning processes leading to sustainable improvements in individuals with DS. As a first step in this process, we examined the landscape of behavioral interventions for individuals with Phelan-McDermid Syndrome (PMS) by developing a better understanding of the acceptability of existing behavioral interventions and identifying barriers that may limit the impact and sustainability of these interventions.

Methods: This study used a research-community partnership framework, which emphasizes collaboration with community stakeholders to address a variety of shared goals. An online survey for parents of individuals with PMS was developed to gather quantitative and qualitative about perceptions of and experiences with behavioral interventions. Participants were asked about the nature and acceptability of prior experiences with behavioral intervention. They were also asked to suggest modifications to improve the fit of these programs with the unique needs of their child and family. Descriptive statistics were used to analyze the survey data.

Results: Applied Behavior Analysis (ABA) was the most commonly endorsed behavioral intervention, followed by developmental interventions, and naturalistic developmental behavioral interventions (NDBIs). Parents rated early social communication skills (e.g., turn taking) and expressive language as the most important intervention targets, indicated the importance of delivering behavioral intervention across settings (e.g., home and school), and expressed a desire for a stronger parent/caregiver training component to these services. Suggested modifications to existing models include more flexibility in terms of scheduling appointments and better training for clinicians around the PMS profile and appropriate intervention targets for this population.

Conclusions: There was a wide range of variability in terms of the nature, intensity and acceptability of interventions received by individuals with PMS in the community. Importantly, parents reported many limitations that are consistent with those reported in previous studies of individuals with neurodevelopmental disabilities, including some that appear more PMS-specific. Data from this survey study will be used to inform the next phase of this work seeking to develop and investigate a novel multi-modal therapy utilizing a high quality behavioral intervention plus targeted pharmacotherapy to improve early social learning and communication in individuals with PMS.

247 **146.247** Utilizing the SRS-P to Examine ASD Symptoms in a Sample of High-Risk Toddlers with Neurogenetic Syndromes

T. Halligan*, W. S. Neo, L. R. Hamrick and B. Tonnsen, Psychological Sciences, Purdue University, West Lafayette, IN*

Background: Elevated rates of psychopathology such as autism spectrum disorders (ASD) are common in individuals with neurogenetic syndromes (NGS), including Angelman (AS; 63%), Prader-Willi (PWS; 23%), and Williams (WS; 50%) syndromes. ASD prevalence in these populations is highly elevated compared to 2% in the general population and 20% in siblings of a child with ASD (Baio et al., 2018; Betancur & Coleman, 2013; Ozonoff et al., 2011). Comparing early social responsivity across multiple NGS at increased risk for ASD may elucidate potential pathways of ASD by informing which phenotypic features differentially map on to each NGS, as the genetic mechanisms underlying each NGS are relatively well understood. Some reports suggest differences in social cognition and the underlying processes within NGS (Morel & Demily, 2017), however, very little is known about the early phenotypic profiles of ASD symptomatology in toddlers who are likely most naïve to interventions.

Objectives: To examine differences in early ASD symptomology in toddlers at increased genetic risk for ASD.

Methods: 98 caregivers of toddlers with AS (*n*=23), PWS (*n*=18), WS (*n*=31), and low-risk controls (LRC; *n*=26) completed the *Social Responsiveness Scale Preschool Age, 2nd Edition* (SRS-P) as part of an online, longitudinal study of early development. The 65-item SRS-P is rated from 1 (not true) to 4 (almost always) and identifies social impairment associated with ASD. *T*-scores are generated for Overall Social Deficits and five subscales: social awareness (SA), social cognition (COG), social communication (COM), social motivation (MOT), and restricted interests and repetitive behavior (RRB). We used Kruskal-Wallis tests to test omnibus group differences for SRS scores and Dunn's *post-hoc* procedure with Bonferroni correction to probe pairwise comparisons.

Results: Age (*M*=36.33 months, *SD*=5.11, Kruskal-Wallis $X^2(3)=1.12$, $p=.773$) and sex (47% female, $X^2(3)=4.50$, $p=.212$) did not differ across groups. The distributions of each SRS score significantly differed across groups (*p*s<.01). Post-hoc analyses revealed that relative to LRC, NGS groups demonstrated significantly higher *t*-scores on Overall Social Deficits and SA, COM, and RRB subscales (*p*s<.01), but NGS groups did not differ from one another. However, this pattern differed for COG and MOT subscales. On the COG subscale, AS and WS (medians [*Mdn*s]=64, *p*s<.001) were significantly higher than LRC (*Mdn*=42), but PWS (*Mdn*=51) did not differ from LRC (*p*=.057). Additionally, on the COG subscale, PWS was significantly lower than both AS and WS (*p*s=.007). On the MOT subscale, AS (*Mdn*=51) was significantly higher than LRC (*Mdn*=45, *p*=.023), with no other differences between groups (*p*s>.05).

Conclusions: Results suggest that although toddlers with NGS consistently exhibit atypical social responsiveness symptoms compared to LRC, more nuanced patterns present across NGS groups, particularly in relation to social cognition and social motivation. These findings provide preliminary evidence that although multiple NGS exhibit heightened risk for ASD, the genetic mechanisms and associated profiles related to these

risks may vary. Continuing to probe these differences in an expanded longitudinal cohort may further inform how and why different NGS are more highly impacted by ASD, as well as potential models of differential detection and intervention.

147 - Sensory, Motor, and Repetitive Behaviors and Interests
5:30 PM - 7:00 PM - Room: 710

248 **147.248** Developmental Changes in Neural Responses to an Interoception Task: Implications for Autism Symptoms.

M. D. Failla[1], *L. K. Bryant*[2], *B. H. Heflin*[3], *L. E. Mash*[4,5], *K. Schauder*[6], *S. L. Davis*[7], *A. S. Weitlauf*[8], *B. P. Rogers*[9] *and C. J. Cascio*[10], *(1)Psychiatry, Vanderbilt University, Nashville, TN, (2)Vanderbilt University, Nashville, TN, (3)Florida International University, Miami, FL, (4)Brain Development Imaging Laboratories, Department of Psychology, San Diego State University, San Diego, CA, (5)Joint Doctoral Program in Clinical Psychology, SDSU / UC San Diego, San Diego, CA, (6)Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY, (7)Vanderbilt University Medical Center, Nashville, TN, (8)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (9)Radiology and Radiological Sciences, Vanderbilt University, Nashville, TN, (10)Vanderbilt University School of Medicine, Nashville, TN*

Background: Given the developmental nature of autism spectrum disorder (ASD), it is important to understand how core features of ASD, like aberrant sensory reactivity, change across the lifespan. While most research has focused on external sensory reactivity, we also receive copious sensory information from within our own bodies, which is invaluable to monitoring body state and interpreting emotions. These internally-generated sensations, known as interoception, may be altered in ASD. Neural networks for interoception include insula, cingulate, and somatomotor cortex.
Objectives: We asked whether neural responses to an interoception task (heartbeat counting, compared to a visual counting control task) differed in ASD relative to a typically developing comparison (TC) group.
Methods: Participants included 46 individuals with ASD (age 8 to 54, mean= 20.84±10.11 years) and 55 individuals in a TC group (age 8 to 53, mean= 19.85±11.14 years). Data were processed using FSL, with age added as a covariate in the model given the wide age-range. Group maps investigated responses in the interoceptive task>visual task. A cluster threshold of z=2.3 and an FWE-corrected p-value=0.05 was used and then randomise was applied for non-parametric permutation testing (5000 iterations).
Results: The ASD group showed unilateral insula and secondary somatosensory (S2) responses, and bilateral response in the visual cortex and cerebellum, while the TC group showed bilateral insula and S2 responses. In this model, there was a positive age association with response in the bilateral insula and S2. Given this significant age finding, we then examined group results in children and adults separately. In children (age 8-17), both groups had significant clusters in the visual cortex, while the TC group also had a small cluster in S2. Additionally, there was a significant positive effect of age in the entire interoceptive network (insula, S2, caudate, putamen, thalamus). In adults, the ASD group had a much more widespread significant clusters in interoceptive regions compared to the TC group. There were no significant age findings in adults. Furthermore, percent signal change in the bilateral subdivisions of the insula all showed an inverted curvilinear relationship to age; neural responses in insula increased with age until they peaked in early adulthood and declined slightly in later adulthood. In adults, percent signal change in the insula was also associated with higher scores on the Social Responsiveness Scale.
Conclusions: This work highlights a potential developmental trajectory in interoception processing that could be relevant for ASD. Interestingly, once neural networks for interoception are refined in adulthood, there is still a wider distribution in ASD, suggesting more heterogenous interoceptive processing. Consistently greater recruitment of visual regions in the ASD relative to the TC group suggests the ASD group may rely more heavily on visual strategies to perform the interoception task. These data suggest that aberrant neural response to sensory cues in ASD is not limited to external cues, but also extends to interoception. Future work will need to understand how and when this developmental interoceptive trajectory may be altered in ASD and what impact it might have on behaviors in ASD.

249 **147.249** Preliminary Results of the Sensory Project in Infant Siblings: Early Sensory Responsiveness Is Linked with Communication Development in Infants at Risk for Autism

N. A. Broderick[1], *C. J. Cascio*[2], *J. I. Feldman*[3], *S. Raj*[3], *A. Augustine*[3], *S. Bowman*[3], *C. M. Daly*[3], *K. Dunham*[3], *A. Golden*[3], *P. Santapuram*[3], *E. Suzman*[4], *A. V. Kirby*[5], *B. Keceli-Kaysili*[6] *and T. Woynaroski*[7], *(1)Pediatrics, Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (2)Vanderbilt University School of Medicine, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Vanderbilt University, nashville, TN, (5)University of Utah College of Health, Salt Lake City, UT, (6)Vanderbilt University Medical Center, Nashville, TN, (7)Hearing & Speech Sciences, Vanderbilt University Medical Center, Nashville, TN*

Background:
Children with autism spectrum disorder (ASD) show a broad range of differences in their patterns of responding to sensory stimuli (i.e., sensory responsiveness). It has been proposed that differences in sensory responsiveness, especially in infancy, may produce cascading effects on communication/language development in children with ASD. This theory proves arduous to evaluate given the challenge of reliably diagnosing ASD in infancy and toddlerhood. The **S**ensory **P**roject in **I**nfant **S**iblings (Project SPIS) is prospectively following infants at heightened risk for ASD (infant siblings of children with ASD; Sibs-ASD) to test the "cascading effects" theory.

Objectives:

NIDCD-funded Project SPIS aims to evaluate (a) whether sensory responsiveness differs in Sibs-ASD versus infants at relatively lower, general population-level risk for ASD (infant siblings of typically developing children; Sibs-TD), (b) whether early sensory responsiveness is associated with communication and language skill, and (c) whether associations between sensory responsiveness and communication/language skill vary according to risk group.

Methods:

Preliminary analyses were conducted on 28 infants 11-18 months of age (11 Sibs-ASD, 17 Sibs-TD) for whom Project SPIS data has been collected and scored/coded to date. Sensory responsiveness was measured with two previously developed and validated measures of early sensory responsiveness – the Sensory Experiences Questionnaire (SEQ) and Sensory Processing Assessment (SPA). Parents reported on infants' concurrent

communication and language skill via the Vineland Adaptive Behavior Scales (VABS) and MacArthur-Bates Communicative Development Inventories: Words and Gestures (MCDI) checklist. Infants' prelinguistic skill was additionally assessed using the Communication and Symbolic Behavior Scales (CSBS). A partial interval coding system was utilized to code CSBS samples for presence/absence of communication acts, vocalizations including canonical syllables, and selected consonants. Two metrics of prelinguistic vocal complexity were derived: (a) canonical syllabic communication and (b) consonant inventory.

Results:

Preliminary results indicate that Sibs-ASD do not significantly differ from Sibs-TD in sensory responsiveness between 11-18 months of age: sensory seeking (d = 0.42, *t* = 1.07, *p* = 0.30), hyporesponsiveness (d = 0.11, *t* = 0.28, *p* = 0.78) and hyperresponsiveness (d = −0.34, *t* = 0.88, *p* = 0.39). Effect sizes for between-group differences are small in magnitude. However, individual differences in sensory responsiveness are associated with indices of communication and language ability across risk groups. For example, more hyporesponsive symptoms were associated with decreased communication skill (e.g., zero-order correlation = −0.45), decreased vocabulary size (zero-order correlations with expressive and receptive vocabulary = −0.40 and −0.36, respectively), and decreased canonical syllabic communication and consonant inventory (−0.44 and −0.35, respectively). These associations do not vary according to group. Final analyses, including results from observational measures of sensory responsiveness, will be presented at INSAR.

Conclusions:

Findings suggest that individual differences in early sensory responsiveness are linked with communication and language development across infants at high and low risk for ASD, providing increased support for the cascading effects theory. Infants are being followed longitudinally to assess the extent to which early sensory responsiveness may be useful for predicting future language and communication skill and to evaluate putative mechanisms by which sensory responsiveness may influence development.

250 **147.250** Parent Responsiveness Mediates the Association between Child Hypo-Reactivity and Later Communication

L. R. Watson[1], *R. Grzadzinski*[2], *E. Crais*[1], *G. Baranek*[3], *L. Turner-Brown*[4] *and S. W. Nowell*[5], *(1)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (3)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (4)UNC TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)University of North Carolina - Chapel Hill, Chapel Hill, NC*

Background:

Infants and toddlers who are at high-risk (HR) for developing Autism Spectrum Disorder (ASD) often display hypo-reactivity to sensory stimuli. Research indicates that child hypo-reactivity to sensory stimuli is related to 1) lower child language and communication abilities (Watson et al., 2011; Patten, Ausderau, Watson, & Baranek, 2013) and 2) lower parent responsiveness (Kinard et al., 2017). Studies also suggest that higher parent responsiveness is related to increased child communication and language abilities (Siller & Sigman, 2008; Watson et al., 2017). Many parent-mediated interventions have resulted in increased parent responsiveness over the course of treatment (Green et al., 2015; Siller et al., 2013; Watson et al., 2017). Yet, whether parent responsiveness mediates the relationship between child hypo-reactivity and later communication outcomes remains unexplored.

Objectives:

To evaluate whether parent responsiveness mediates the relationship between child hypo-reactivity to sensory stimuli at one year and child communication at two years.

Methods:

This study includes 83 HR children (56 boys) identified at 12 months based on community screenings with the *First Year Inventory 2.0* (Baranek et al., 2003). Children were seen at 14 months old (+/- 0.77; Time 1) and completed the Sensory Processing Assessment (SPA; Baranek, 1999) while parents completed the Sensory Experiences Questionnaire (SEQ; Baranek, 1999). Children were seen again 9 months later (mean age 23 months +/- 0.90; Time 2); parents completed the Vineland Adaptive Behavior Scales (VABS; Sparrow, Cicchetti, & Balla, 2005) at Time 2. Parent Verbal Responsiveness (PVR) was coded at Time 1 and Time 2 from 10-minute video samples using a coding system adapted from Yoder et al. (2015). An average of PVR (AvgPVR) was calculated [(PVR Time 1 + PVR Time 2)/2]. 50% (n=45) of the children were randomly assigned to an experimental intervention. A series of mediation analyses, controlling for intervention group, were conducted using Process v3.1 (http://www.afhayes.com) in SPSS.

Results:

Mediation analyses revealed that the relationship between SPA Hypo-reactivity at Time 1 and VABS Communication at Time 2 was mediated by AvgPVR (See Figure 1). Additional mediation analyses indicated that, when using SPA, this mediation effect was specific to the VABS Communication domain. Mediation analyses were also conducted using the Hypo-reactivity domain of the SEQ. Consistent with SPA results, the relationship between SEQ Hypo-reactivity at Time 1 and VABS Communication domain at Time 2 was mediated by AvgPVR (See Figure 2). When using the SEQ, AvgPVR also mediated the relationship between Hypo-reactivity and later VABS Social domain.

Conclusions:

Child hypo-reactivity negatively impacts later child language outcomes, though this work suggests that parent verbal responsiveness may attenuate this negative impact. Based on these results, parent-mediated interventions may want to focus on parent responsiveness given the subsequent effect this transactional behavior has on child language development. In addition, this work also indicates that parent responsiveness may have an impact on later child socialization skills.

251 **147.251** A Dynamic Approach to Measuring Temporal Binding Windows in Adults with Autism Spectrum Disorder: Differences with the Commonly Used Synchrony Judgement Task

M. Ferland[1], *M. Segers*[2] *and J. M. Bebko*[2], *(1)York University, Toronto, ON, CANADA, (2)York University, Toronto, ON, Canada*

Background: Being able to integrate information from multiple sensory modalities, such as hearing and sight, is essential for everyday functioning. Individuals with autism spectrum disorder (ASD) have difficulties in audiovisual integration (e.g., Bahrick, 2010; Bebko et al., 2006). These difficulties likely contribute to their social-communicative deficits (Wallace & Stevenson, 2014) and therefore, a better understanding of audiovisual integration in ASD could hold valuable information for interventions.
A way of measuring audiovisual integration is through the temporal binding window (TBW); a window of time in which separate sensory information are perceived as one, synchronous event, despite some degree of asynchrony (Dixon & Spitz, 1980). A common way to measure the TBW is the synchrony judgment (SJ) task (Exner, 1875), where participants decide whether audio and visual components of a stimulus are synchronous or not. The SJ task could be considered *"static"* as it does not enable a *dynamic* manipulation of the TBW size. In the current study a method developed by Segers & Bebko (2013) allowing active manipulation of the auditory timing was used to more precisely measure the audiovisual TBW.

Objectives: To build on previously-presented work at INSAR by Segers & Bebko (2013), by using a more refined version of the new "*dynamic*" method. Specific objectives include: a) how does the TBW of ASD adults compare to non-ASD adults across the new *dynamic* task and the commonly used *static* SJ task, and b) determining what can influence TBW size in ASD.

Methods: Data from 21 TD and 11 ASD adults have been collected and analyzed, with additional ASD participants nearing completion. Participants performed two types of audiovisual integration tasks: a) the dynamic task, where participants manually adjusted the soundtrack of a video by 50ms increments until a point of perceived synchrony with the visual information, and b) the SJ task. Two stimulus types were used: social-linguistic (SL: someone reading a story), and non-social-non-linguistic (NSNL: e.g., a hand playing the piano). Participants also completed questionnaires on sensory information and autism-like traits.

Results: A 2-way-repeated-measures ANOVA yielded significant main effects of task, $F(1,25) = 19.85$, $p < 0.01$, and stimulus type, $F(1,25) = 28.05$, $p < 0.01$. When using the dynamic task, participants produced significantly smaller TBWs (M = 377ms) than when using the SJ task (M =522ms). Furthermore, smaller TBWs were produced for SL stimuli (M =405ms) compare to NSNL stimuli (M = 493ms). In contrast to previous studies, there was no significant difference in the TBW size between ASD and TD participants across the tasks ($p > .10$).

Conclusions: Giving participants the ability to control the soundtrack appears to produce smaller TBWs in both ASD and TD participants and may lead to more precise measurement of the TBWs than more passive, static tasks. It is possible that helping to focus the participants' attention to the task by requesting them to actively manipulate the audio file was sufficient to help ASD participants overcome underlying audiovisual integration issues. This nonverbal dynamic procedure offers considerable promise for research into perceptual systems in ASD.

252 **147.252** A Family Study of Sensory Processing in Autism Spectrum Disorder

J. N. Barstein[1], *S. P. Patel*[2], *K. Nayar*[1], *G. E. Martin*[3], *C. J. Cascio*[4] *and M. Losh*[2], *(1)Feinberg School of Medicine, Department of Psychiatry and Behavioral Sciences, Northwestern University, Evanston, IL, (2)Communication Sciences and Disorders, Northwestern University, Evanston, IL, (3)Communication Sciences and Disorders, St. John's University, Staten Island, NY, (4)Vanderbilt University School of Medicine, Nashville, TN*

Background: Sensory processing atypicalities are now conceptualized as a core symptom of autism spectrum disorder (ASD), with evidence of impairments across individual sensory modalities and in the integration of multiple sensory systems. Recent studies have also documented atypicalities in self-reported behavioral responses to sensory stimuli in first-degree relatives of individuals with ASD. However, no studies have investigated objective measures of sensory processing (including sensory integration) or examined relationships with the broad autism phenotype (BAP; or, subclinical features that correspond to the defining features of ASD). Investigation of traits among unaffected first-degree relatives has been critical in understanding core features linked to genetic liability. Moreover, investigating relationships between sensory processing and clinical-behavioral correlates impacted in ASD and the BAP may lend insight into the causal pathways of co-occurring symptoms of ASD.
Objectives: To examine sensory processing in individuals with ASD and their parents, and explore relationships with clinical behaviors impacted in ASD and the BAP.

Methods: Twenty-four individuals with ASD, 18 proband controls, 50 parents of individuals with ASD, and 29 parent controls completed three measures of sensory processing – a self- and parent-report measure of sensory processing styles, an objective measure of tactile detection, and a measure of visuotactile-proprioceptive integration ("rubber hand illusion"). In the rubber hand illusion task, participants observed a rubber hand being stroked simultaneous to their own hand, which was obscured from their view. Typically, this results in a subjective feeling of embodiment of the rubber hand and estimates of one's real hand as having drifted towards the direction of the rubber hand (i.e., proprioceptive drift). The brushing was administered in two separate three-minute blocks per condition and proprioceptive drift was measured by subtracting the average estimate of hand location at baseline from the average estimate at each block. Participants also completed measures investigating clinical behaviors impacted in ASD and the BAP (e.g., social communication, social cognition).

Results: Individuals with ASD demonstrated atypicalities across all measures of sensory processing, including greater self- and parent-reports of atypical sensory processing styles, a higher tactile detection threshold, as well as a delayed effect of the rubber hand illusion as indicated by an increase in proprioceptive drift following the second block of brushing. On the contrary, parents of individuals with ASD did not differ from controls across objective measures of sensory processing or sensory integration and self-reported few differences in sensory processing styles. In individuals with ASD and their parents, lower proprioceptive drift was related to greater social communication violations.

Conclusions: Findings contribute to a growing body of literature documenting atypical sensory processing and *inefficient*, rather than deficient, integration of visual-tactile-proprioceptive stimuli in ASD. Notably, the lack of differences observed in parents suggest that sensory processing does not to relate to the BAP or genetic liability observed in relatives. While few relationships were observed between measures of sensory processing and clinical features of ASD, findings do suggest that atypicalities in visuotactile-proprioceptive integration in ASD relate to higher-order impairments in social communication.

253 **147.253** Abnormal GABA Concentration in Brain Motor Areas Are Related with Gross Motor Impairments in Individuals with Autism Spectrum Disorder

Y. Umesawa[1], *K. Matsushima*[2], *T. Atsumi*[1], *T. Kato*[2], *R. Fukatsu*[1], *M. Wada*[1] *and M. Ide*[1], *(1)Department of Rehabilitation for Brain Functions, Research Institute of National Rehabilitation Center for Persons with Disabilities, Tokorozawa, Saitama, Japan, (2)Department of Human Health Science,*

Graduate School of Medicine and Faculty of Medicine, Kyoto University, Kyoto, Japan

Background: Various motor difficulties are commonly observed in individuals with autism spectrum disorder (ASD). Previous studies have demonstrated that impaired motor performance may be explained by a lower concentration of gamma-aminobutyric acid (GABA) in the primary motor area (M1) in individuals with ASD. However, lower GABA concentrations in M1 have been linked to strong neural activity in the corresponding region and strong muscle constriction in neurotypical individuals; thus, it seems paradoxical that many individuals with ASD have motor skill impairments.

Objectives: We investigated the types of motor skill that are associated with GABA levels in brain motor area. Motor skills were evaluated using the clinically accepted Bruininks-Oseretsky Test of motor proficiency, second edition (BOT-2).

Methods: The BOT-2 measures various motor performances which includes both fine and gross motor skills. The fine motor skills assessed include precise bodily control that requires finger and hand movement (1. fine manual control) and bimanual/arm-hand coordination (2. manual coordination). The gross motor skills include sequential and simultaneous bodily coordination (3. body coordination) and strength of trunk, upper and lower body (4. strength and agility). Total score is summation of the scores for four motor skills. GABA concentration in brain motor area were measured using ^{1}H-magnetic resonance spectroscopy (^{1}H-MRS). We measured GABA in left M1 and the supplementary motor area (SMA). In addition, we evaluated degree of the autistic traits by the autism spectrum quotient (AQ) score.

Results: Eight individuals with ASD and ten typically developing (TD) controls participated in the experiments. We found that significant negative correlation between GABA concentration in M1 and total score in the BOT-2 (see figure.1), especially for gross motor skills (3. body coordination, 4. strength and agility) in all participants. ASD participants who had a lower concentration of GABA in SMA tended to exhibit lower levels of motor performance (see figure.2) especially for the skills of whole body coordination (3. body coordination). Furthermore, higher GABA levels in M1 were associated with stronger autistic traits evaluated by the AQ score. M1 receives information from higher-order motor related areas and outputs signals to control muscles via the brainstem and spinal cord. We assumed that excessively high GABA concentration in M1 would suppress strong neural activity, resulting weak neural signal to muscle and degraded muscle contraction necessary for gross motions. Reduced GABA in SMA may induce asynchronized neural oscillations across the left and right hemispheres since GABA is required for synchronising neural oscillations. These atypical conditions of GABA concentration in motor related areas were implied to be an underlying basis of other aspects of autism (e.g., difficulties in social communication).

Conclusions: Abnormal GABA levels in M1 and SMA contributes to motor impairments (i.e., gross motor skills and body coordination, respectively) in ASD. The present findings would contribute to the development of objective evaluations for several motor impairments, and accompanied difficulties derived from autistic features.

254 **147.254** Abnormal Walking Patterns in Children with Autism Spectrum Disorder Associated with Social Impairments

L. Gong[1], *Y. Liu*[1], *L. Yi*[2] *and K. Wei*[1], *(1)School of Psychological and Cognitive Sciences, Peking University, Beijing, China, (2)School of Psychological and Cognitive Sciences and Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China*

Background: Children with autism spectrum disorder (ASD) have various degrees of motor impairments. Researchers have been striving to establish the association between their atypical motor patterns (e.g., motor coordination) in early development with their social function, and to use motor deficits as early behavioral markers of ASD. Previous studies have found that ASD children tend to walk with gait abnormalities, but the evidence are inconsistent. For example, retrospective video analyses showed asymmetry in arm movement in infants, but movements of lower limbs measured by motion capture system and force plate failed to identify similar asymmetry. Furthermore, gait abnormality, demonstrated by reduced stride length, increased stride width and reduced range of motion of ankle and knee angles, failed to correlate with social impairments. We postulate that kinematic measures of lower limb movement during walking vary widely across individuals and idiosyncrasy might mask ASD-related changes in gait.

Objectives: We aimed to find gait abnormity and its association with social impairments might be revealed by examining foot pressures during foot-ground contact.

Methods: Twenty-five low-functioning autism (LF, age: 5.28±0.84 yrs, IQ: 84.12±18.41), 33 high-functioning autism (HF, age: 5.50±0.61 yrs, IQ:113.36±12.03) and 29 age- and IQ-matched TD children (age: 5.69±0.62 yrs, IQ: 109.69±10.96, n.s. from HF) were recruited. Children were instructed to walk naturally, self-paced and looking straight ahead, for 5 meters for 10 trials. A high-density, high-frequency pressure mat (RSScan, Inc) was placed in the middle of the walkway to collect the pressure distribution of foot contacts (Fig1). The parents completed Chinese version of the Autism Spectrum Quotient: Children's Version (AQ) and the Social Responsiveness Scale (SRS) before the experiment.

Results: We found no evidence of tendency to toe walk in ASD groups since majority of trials involved heel contact (Table1). The frequency of initial foot-contact in the toe and fore-foot regions were similar between three groups. However, during the foot roll-off, the center of pressure (CoP) started more anteriorly on the foot (initial contact of CoP) and traveled less (distance of CoP), even after removing the individual difference in foot length (Fig1). This indicates that they walk with less foot roll-off. Their stride-to-stride variability was higher as shown by the standard deviation of these two CoP measures. We also found more left-right asymmetry among ASD children, shown by significantly smaller correlation between left and right-foot CoP movements. Examining the force profiles of the metatarsal region, the predominant region for force production during foot contact, revealed a similar reduction in left-right correlation. These converging evidences indicate that ASD children have larger left-right asymmetry in foot function. Importantly, most gait variables were significantly correlated to social function (SRS and AQ scores) but not to IQ. The more abnormal the gait deficit the more severe the social impairment.

Conclusions: In conclusion, we find that foot pressure is a sensitive measurement for quantifying autism-related motor deficits and its correlation with social impairments support the proposition that motor impairments might contribute to the development of core symptoms of ASD.

255 **147.255** Adaptation to the Running Speed of Biological Motion in Autistic Children/Adolescents

R. Arrighi[1], ***T. Karaminis***[2], *G. Forth*[3], *D. C. Burr*[4] *and E. Pellicano*[5], *(1)University of Florence, Florence, Italy, (2)Department of Psychology, Edge Hill University, Ormskirk, United Kingdom, (3)Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Department of Neuroscience, Psychology, Pharmacology and Child Health, University of Florence, Florence, Italy, (5)Macquarie University, Sydney, Australia*

Background:
Adaptation is a ubiquitous property of perception, a form of experience-dependent plasticity in which our current sensory experience is intimately affected by how we viewed the world only moments before. Previous research has demonstrated that autistic individuals often present reduced adaptation to a range of social and non-social sensory stimuli, relative to non-autistic individuals. Here, we examined adaptation to the processing of biological motion – a higher-level visual attribute important for a range of social competences, such as inferring other people's emotions, mood, and intentions.

Objectives:

We sought to compare adaptation to the speed of biological motion in autistic and typical children and adolescents.

Methods:

We tested 19 autistic children and adolescents (6 girls) aged between 8;8 and 19;5 years and 19 typically children of similar age and verbal and non-verbal reasoning abilities. Each participant received a child-friendly dual-task paradigm adapted from an existing study (Arrighi, Orsi & Burr, 2010) and based on point-light-display (PLD) representations of running silhouettes. The paradigm included a primary speed-discrimination task, which provided a measure of precision in the discrimination of running speed and a measure of adaptation to the running speed. We also included a secondary change-detection task, which motivated participants to attend to centre-screen and provided an implicit measure of attention (accuracy in change-detection). Reaction times and eye-movement data were also collected.

Results:

Unexpectedly, analyses showed that autistic and typical participants performed similarly in both tasks – both in terms of their precision in the speed-discrimination task and their adaptation to speed. Autistic and typical participants also showed similar patterns of attention during the task – as indexed by similarly high performance in the change-detection task and the scatter of fixation preferences around a centrally-located fixation point.

A secondary correlational analysis revealed no systematic relationship between the magnitude of adaptation and age, cognitive ability or autistic symptomatology. Interestingly, adaptation was less pronounced in participants (autistic *and* non-autistic) who presented more scattered fixations around the centrally-located fixation point.

Conclusions:

Contrary to our prediction, we found that adaptation to the speed of biological motion was comparable in our autistic and typical children/participants. This finding could not be attributed to group differences in attention or fixation patterns. Our results suggest that limitations in adaptive coding are not pervasive in autistic perception. More nuanced accounts of adaptation in autism are warranted, which would also consider the role of attention and looking preferences.

256 **147.256** Associations between Repetitive Behaviors and Play Diversity in Toddlers with Autism Spectrum Disorder

L. Hughart[1], *C. Harrop*[2], *J. R. Williams*[3] *and C. Kasari*[1], *(1)University of California, Los Angeles, Los Angeles, CA, (2)University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Biostatistics, UCLA, Los Angeles, CA*

Background: Research investigating the relationship between repetitive behaviors and play skills in children with autism spectrum disorder is limited. Restricted and repetitive behaviors (RRBs) are a core symptom of ASD. RRBs encompass a broad range of heterogeneous behaviors, including repetitive motor mannerisms, overriding preoccupations with object parts, preoccupation with restricted patterns of interests, and adherence to nonfunctional routines (Richter et al. 2007). Currently, it is unclear how RRBs relate to other core areas of ASD. For example, children with ASD demonstrate less frequent, diverse, elaborate, and integrated symbolic and non-symbolic functional play than their typically-developing peers (Kasari et al., 2005; Jarrold, Boucher, & Smith, 1996; Williams, Reddy, & Costell, 2001). Research indicates that frequency of play acts is inversely related to the frequency of RRBs (Honey et al., 2006). However, this research relied upon caregiver report through questionnaires. Thus, the purpose of this study is to determine how behaviorally-coded RRBs within the context of a free play session associate with play acts within a standardized assessment of play.
Objectives: This study aims to examine the relationship between the frequency of behaviorally-coded repetitive behaviors during a free play session and the diversity of play acts demonstrated by toddlers with ASD.

Methods: 85 toddlers (69 male: 16 female; mean age = 31 months, SD = 3 months) with a diagnosis of ASD were included in the study. The ADOS-2 and ADI-R were completed by independent research-reliable testers to confirm the diagnoses of ASD. Child RRBs were coded from the 10-minute caregiver-child free play session. Observational coding focusing on lower-order RRBs was based on the coding scheme developed by Harrop et al. (2014). Higher-order RRBs were excluded for the purpose of this study to account for the young population age and time-limited observation. RRBs were coded into four categories: (a) motor/body behaviors, (b) visual behaviors, (c) repetitive object use, and (d) repetitive vocalizations/language. The frequency, type, and level of spontaneous play behaviors were coded from a 15-minute structured play assessment (SPA; Ungerer & Sigman, 1981). Children were presented with a variety of related toy sets to assess play skills.

Results: Two children who didn't display any RRBs during the interaction were excluded from the analysis. On average, toddlers had 10.8 instances of RRBs during the 10-minute interaction (SD = 7.10), and had an average of 17.5 total types of play (SD = 10.4). Repetitive object use constituted the majority of repetitive behavior displayed (55%). There was a significant negative correlation between the number of RRBs and total play diversity (r = -0.26, p-value = 0.02).

Conclusions: These results suggest that the presence of repetitive behaviors is associated with impairments in the diversity of play demonstrated by toddlers with ASD. This highlights the pervasive effects of repetitive behaviors and suggests that the extent of their intrusiveness may preclude a child's ability to play. Our results suggest that improving play within intervention may yield *spillover* effects in reducing the frequency of observed RRBs, emphasizing the need for targeted early interventions that specifically address repetitive behaviors.

257 **147.257** Atypical Auditory Perception in Autism Spectrum Disorder: A Synthetic Approach to Evaluate the Perceptual Patterns and Environmental Causes

J. J. Hsieh[1], *Y. Nagai*[2], *S. Kumagaya*[3], *S. Ayaya*[3] *and M. Asada*[1], *(1)Graduate School of Engineering, Osaka University, Osaka, Japan, (2)Center for Information and Neural Networks, National Institute of Information and Communications Technology, Osaka, Japan, (3)Research Center for*

Advanced Science and Technology, The University of Tokyo, Tokyo, Japan

Background: Atypical perception was reported as a potential cause of social difficulties in autism spectrum disorder (ASD). The subjective reports from people with ASD indicated that the atypical perception varies depending on the environmental context. However, it is not easy for everyone to describe their perceptual experiences. Further, the traditional subjective reports are insufficient for quantitative analysis. Therefore, the previous reports could not clarify the detailed patterns of the perception and the influence of environmental factors. In order to solve the problem, a previous study [Nagai et al., 2015] has proposed a synthetic approach to investigate atypical visual perception in ASD. Nevertheless, the understanding of atypical perception in other modalities is still insufficient.

Objectives: According to the previous reports from people with ASD, we assume atypical perception would be affected by environmental stimuli. This study aims at investigating the patterns and environmental causes of atypical auditory perception in ASD. We employed a synthetic approach to lead the participants to systematically report their auditory perception, and then quantitatively analyzed the reports.

Methods: Twenty-two adults with ASD (12 males; age: mean = 30.7, SD = 10.0) were recruited in this study. We presented 30 videos with different scenes and 7 auditory filters (amplify, noise, sine wave, band-reject, echo, flanger, and water effect), which were designed to simulate potential patterns of atypical auditory perception, to the participants. The participant can adjust the strength of the filters to change the sound. The task was using the filters to make the sound similar to his/her auditory perception. We conducted principal component regression on the strength values of the filters and the audiovisual features of the videos.

Results: We found significant regressions on the perception of amplify ($F = 2.892$, $p = 0.002$), echo ($F = 2.298$, $p = 0.012$), and noise ($F = 2.014$, $p = 0.030$). There was a marginally significant regression on the perception of band-reject ($F = 1.841$, $p = 0.051$). We checked the audiovisual features which correspond to the significant principal components. The results showed a negative correlation between the perception of amplify and the intensity of video sound. The perception of echo was positively correlated with the mean and the change of both video sound intensity and object movement in the scene. The perception of noise was positively correlated with the mean and the change of sound intensity. There was no clear correlation between the perception of band-reject and audiovisual features. However, the participants reported that the perception of band-reject has occurred due to the sound of human speech.

Conclusions: This study revealed the patterns and the potential environmental causes of atypical auditory perception in ASD. We found there are similar patterns between our results and the atypical visual perception in the previous study, e.g. visual perception of enhanced brightness and the perception of amplify are both sensory enhancements, and snow-like noise in visual perception may be related to the auditory perception of noise. It implies that there exist common neural mechanisms for the atypical perception of seeing and hearing.

258 **147.258** Auditory Event-Related Spectral Perturbations in Children with and without ASD

C. Harrop[1], *A. Campbell*[2], *L. J. Idichandy*[2], *Y. J. Chen*[3], *G. Baranek*[3] *and A. Belger*[4], *(1)University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)UNC Chapel Hill, Chapel Hill, NC, (3)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (4)University of North Carolina, Chapel Hill, NC*

Background:

Sensory atypicalities are well established in ASD and represent core diagnostic criteria (APA, 2013). Although the neurobiological underpinnings of these features are not well defined, there is consensus that they show bidirectional influences on perceptual systems throughout development.

Previous studies have explored the associations between EEG activity and sensory response patterns in ASD. The electrophysiological signatures of sensory processes are observed in both the alpha (8-12Hz) and gamma (30-60Hz) bands. Gamma activity has been reported during a variety of early sensory responses and facilitates sensory processing (Skinner et al., 2000; Singer & Gray, 1995). Increased gamma power in ASD was associated with lower P50 suppression, suggesting ineffective inhibitory control (Orekhova et al., 2008). Alpha activity had been implicated in sensory gating (Klimesh et al., 2007). In High-Risk infants, reversed alpha asymmetry was associated with increased sensory seeking (Damiano-Goodwin et al., 2018).

Objectives:

(1) Examine between group (ASD vs. TYP) differences in EEG event related spectral perturbations (ESRP) during an auditory mismatch negativity paradigm; (2) Explore associations between parent-reported sensory response patterns and ESRP activity in children with ASD.

Methods:

We present findings from 31 children (16 ASD) ages 5-11. A larger sample (N = 60) is anticipated by Spring 2019. Parents completed the Sensory Experiences Questionnaire (Baranek, 2006). Participants watched a silent video while standard and novel sounds (7%) played in the background. EEG was recorded via a 12-channel Electro Cap at 500Hz with Neuroscan and band-pass filtered (0.15Hz – 70HZ) online. Offline EEG processing used EEGLAB (Delorme & Makeig, 2004). ESRP from -200-500ms around novel sounds at electrode Cz was measured, based on previous research (Donkers et al., 2013). We explored the association between SEQ patterns and ESRP in the gamma range and examined other spectral bands.

Results:

Low gamma activity was enhanced from baseline (150-300ms) in ASD compared to controls. Theta activity (4-8Hz) was reduced (0-400ms) in ASD compared to TD controls (Figure 1). There were no associations between ERSP and SEQ patterns, though peak theta and peak *low* gamma were negatively correlated ($r = -.63$, $p = .03$).

Conclusions:

Our preliminary findings suggest that processing of auditory stimuli differ between children with and without ASD. Children with ASD had elevated gamma-related responses, suggesting enhanced sensory processing and gating. Children without ASD showed more evaluative processing (Donkers et al., 2015) with greater theta activity post stimulus. Theta is commonly studied in relation to working memory processing and enhanced theta in TD controls may reflect greater cognitive evaluation to the novel stimulus across the course of the MMN task. Further work is required to characterize the neurophysiological signatures of sensory processing in ASD and relate them to sensory processing atypicalities. Further analysis of gamma and theta power, including the timing of peaks (Isler et al., 2010) could inform about the biological underpinning of sensory atypicalities in ASD.

259 **147.259** Auditory Processing in Autism Spectrum Disorder: Probing Individual Differences with Behavioral, Audiological, and

Neurophysiological Measures

B. K. Lau[1]*, A. Estes*[2]*, S. R. Dager*[2] *and A. K. Lee*[1]*, (1)Speech and Hearing Sciences, University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA*

Background:

Auditory processing differences including hyper- or hyposensitivity to sounds as well as aversions or unusual interests in sounds are commonly reported by individuals with autism spectrum disorder (ASD). Furthermore, past studies of auditory perception have revealed difficulty listening under noisy conditions, reduced responsiveness to speech, impaired prosody and voice emotion perception, and enhanced pitch perception in individuals with ASD. Atypical physiological responses have also been documented, including otoacoustic emissions (OAE), auditory brainstem responses (ABR), as well as cortical event-related potentials. However, the findings reported are variable across studies and are dependent on the stimuli presented and the age of participants. Thus, the etiology of auditory processing differences in ASD is currently not well understood. One likely contributor to these inconsistent past findings is the heterogeneity of ASD itself.

Objectives:

This pilot study investigates individual differences in auditory processing by combining behavioral, audiological, and neurophysiological measures to create Auditory Processing Profiles for each participant. We hypothesize that this assay of auditory function, in contrast to previous measures of a single neurophysiological response, will reveal replicable patterns of neurophysiological differences across individuals with ASD.

Methods:

Twenty-four participants age 21-22 years (ASD n=12; TD n=12) were recruited from a larger longitudinal study conducted at the University of Washington Autism Center and the community. Speech perception, otoacoustic emissions, electrophysiological responses, and standardized assessments of cognition, language, and adaptive function were conducted. The Autism Diagnostic Observation Scale was administered to confirm diagnosis. Speech perception was assessed by estimating target-to-masker ratios at 50% correct for speech targets (0° azimuth) presented with two spatially separated (±45° azimuth) simultaneous speech maskers. The electrophysiological battery used to characterize the transmission and representation of sound included: (1) a click-evoked supra-threshold auditory brainstem response, (2) an envelope following response (EFR) recorded to a 400-ms-long 4 kHz pure tone carrier amplitude modulated at 100 Hz at two modulations depths (0 and -6 dB) and (3) a binaural evoked interaural phase difference (IPD) threshold.

Results:

Preliminary analyses revealed that as a group, ASD participants demonstrated difficulty with speech perception in a multi-talker situation with poorer thresholds than controls. However, individuals with ASD did not show the same deficits on electrophysiological measures. Some individuals with ASD showed reduced EFRs and poorer IPD thresholds while other individuals showed EFRs and IPD thresholds comparable to controls.

Conclusions:

Preliminary analyses suggest that although overall, individuals with ASD in this study showed decreased speech perception under complex conditions, we also found distinct patterns of neurophysiological differences that may underlie this deficit. Some individuals showed differences in temporal representation (i.e., reduced EFRs) or binaural integration (i.e., poor IPD thresholds) while others did not. Together, these measures provide a robust and promising assay of auditory function with the potential to further our understanding of the mechanisms underlying auditory abnormalities in individuals with ASD by leveraging individual differences.

260 **147.260** Autistic Children's Responses in a Multi-Sensory Environment: The Effect of Having Control over Sensory Changes on Behaviour, Mood and Physiological Arousal.

K. L. Unwin*, G. Powell and C. R. Jones, Wales Autism Research Centre, Cardiff University, Cardiff, United Kingdom*

Background:

Multi-Sensory Environments (MSEs; also called sensory or Snoezelen rooms) are common in special needs schools and contain equipment that change the sensory environment for educational or therapeutic benefit. They are widely used with autistic pupils yet there is little research in this area. Previous work within our lab has found that practitioners who use MSEs with autistic children believe them to be beneficial for improving behaviour. The practitioners also suggested that the child being in control was necessary for maximum benefit. To date, no study has empirically investigated the effect of being in control of sensory changes within the MSE on autistic children's behaviours.

Objectives:

To assess whether having control of the sensory changes in an MSE, versus not having control, influences autistic children's behaviours, mood and physiological arousal.

Methods:

Forty-one autistic children (8 female) aged 4-12 years (*M*=8 years, *SD*=2.05 years), used the MSE twice. In the 'sensory control' condition they changed equipment themselves using an iPad or interactive board. In the 'no sensory control' condition, the equipment changed without their input. The order of conditions was counterbalanced. During each condition the child sequentially engaged with five pieces of MSE equipment including a bubble tube, touch sound and light panel, fibre optic lights, mirror ball, and immersive room lighting. Each piece of equipment was engaged with for three minutes in a randomised order. The sessions were video recorded and behaviours later coded. The outcome measures were selected based on findings from a previous study of practitioner experiences and included: social communication, repetitive motor behaviours (RMBs), sensory behaviours, anxiety, attention, enjoyment, and rapport. Physiological arousal was measured using heart rate variability.

Results:

Behavioural coding achieved good to excellent inter-rater reliability. Findings showed that when the child did not have control of their sensory environment they produced more RMBs and sensory behaviours, and paid less attention. However, there was no difference in social communicative behaviours or levels of enjoyment and anxiety. Rapport with the experimenter was also unaffected by condition. Analyses are ongoing, including the effect of condition on speech and heart rate variability.

Conclusions:

These preliminary findings suggest that having control over sensory changes in the MSE reduces RMBs and sensory behaviours and leads to better levels of attention. This might be because control of the MSE enables an individual's sensory needs to be met. Alternatively, better prediction of the sensory changes may create a less stressful environment. However, it is also notable that having control did not impact on other behaviours, including levels of enjoyment, anxiety or rapport with the experimenter. These finding have implications for how MSEs could be used for maximum benefit in schools.

261 **147.261** Autonomic Orienting and Adaptation Patterns to Repeated Sensory Stimuli in ASD

J. M. Keith[1], *L. Bennetto*[1], *P. Allen*[2] *and J. P. Jamieson*[1], *(1)Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY, (2)University of Rochester Medical Center, Rochester, NY*

Background: Prevalence estimates of sensory processing differences in individuals with autism spectrum disorder (ASD) range as high as 96%. Furthermore, this difficulty perceiving and integrating sensory stimuli is frequently reported by parents and individuals with ASD as one of the largest barriers to functioning in day-to-day life. One method that is used to objectively examine sensory differences in ASD is measuring autonomic reactivity and regulation to sensory stimuli. The Sensory Challenge Protocol (SCP) is a paradigm that measures autonomic reactivity to a series of highly-standardized sensory stimuli from several domains. Results from past SCP studies in ASD have varied, finding both hyperresponsivity and hyporesponsivity to individual stimuli. However, existing studies have not examined within-domain autonomic responses across trials, which would provide important information about orientation and adaptation patterns to sensory stimuli.
Objectives: The current study measured sympathetic and parasympathetic responses to sensory stimuli using the SCP. Analyses specifically focused on reactivity patterns across trials within each sensory modality to better understand how individuals with ASD react to novel and repeated sensory stimuli.

Methods: Twenty-two adolescents with ASD (12-16 yrs) and 24 typically developing adolescents matched on age, gender, and IQ completed this study. Diagnoses were confirmed/ruled out using the Autism Diagnostic Observation Schedule and cognitive abilities were evaluated using the age-appropriate Wechsler assessment. Each participant completed the SCP, where their heart rate, respiration rate, and electrodermal activity were continuously collected during a standardized presentation of the following stimuli: an 84 dB pure tone, strobe light flashed at 10kHz, 80dB siren, wintergreen oil presented under the nose, and feather drawn across the jawline.

Results: Group x trial repeated measures analyses of variance were performed to examine overall cardiac reactivity and orienting responses. There was a significant group x trial interaction when considering all trials (p<.001), suggesting that individuals with ASD are overall less reactive to stimuli across trials. A separate analysis considering only baseline and the first two sensory trials in each domain also revealed a group x trial interaction (p<.001), suggesting a decreased or absent cardiac orienting response to novel stimuli in ASD. *A priori* analyses were repeated within each domain, as is commonly done in the SCP literature. These revealed significant group x trial interactions for responding across all trials on Tone, Wintergreen, and Feather (p's <.05) and for orienting responses to initial stimuli for Tone, Wintergreen, and Siren (p's <.05; Fig 1).

Conclusions: These results support autonomic hyporesponsivity to several sensory modalities in ASD. Specifically, the reduced cardiac orienting response found in the current study suggests that individuals with ASD may attend less readily to neutral sensory stimuli. This may impact information gleaned from their environment and may contribute to both a lower registration of sensory stimuli and, potentially, a defensive response to more aversive sensory stimuli. This study is the first to examine autonomic orienting responses in adolescents with ASD to several, carefully-presented sensory stimuli. The results help to clarify sensory dysregulation and perception in individuals with ASD, including how sensory differences may impact attentional processes.

262 **147.262** Circumscribed Interests and Unusual Preoccupations in Autism Spectrum Disorder: Patterns across Age and Gender

C. Jorgenson[1], *K. Nowell*[2], *S. M. Kanne*[2] *and C. Brown*[3], *(1)University of Missouri - Columbia, Columbia, MO, (2)Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO, (3)University of Missouri, Columbia, MO*

Background: Circumscribed interests and unusual preoccupations (CIs) are characterized by an intense interest in specific objects or topics (Turner-Brown et al., 2011). CIs are one of the diagnostic criteria for autism spectrum disorder (ASD), and are related to both negative and positive consequences. For example, while CIs may impede social interactions in some situations, individuals on the autism spectrum note that CIs often facilitate social interactions with others with similar interests (Muller et al., 2008). CIs have also been shown to be negatively correlated with depression, and adults on the autism spectrum report using CIs to manage anxiety (Stratis and Lecavalier 2013; Trembath et al. 2012). Better characterizing CIs could improve clinician understanding of how they impact everyday functioning.
Objectives: The aim of this pilot study was to examine the prevalence and types of CIs for children and adolescents on the autism spectrum using a newly developed survey. The following research questions were addressed: What types of CIs do parents most frequently endorse? How many categories of CIs do parents report? What is the impact of CIs on their child's functioning? Are there differences in type of CI across age and gender?

Methods: Parents of children (N=1922, 79.5% male, M *age* = 9.1 years) diagnosed with ASD within the SPARK database completed an online survey regarding their child's CIs. The survey was based on the *Interests Scale* (Bodfish, 2003), but modified to include additional categories and incorporate findings based on recent research (e.g., gender differences). The survey solicited additional information (e.g., age of onset, duration, impact on functioning) and included parent ratings (measured on a Likert scale 1-5) on the uniqueness of the CI and how much it interfered with functioning.

Results: The most commonly reported CIs were in the categories of "television" (81%), "objects" (72%), and "music" (67%). The least commonly reported CIs included "psychology" (3.7%), "politics" (6.2%), and "physics" (6.8%). Age of onset of CI varied across type, with transportation having the youngest age of onset (3 years, 11 months) and politics having the oldest age of onset (10 years, 9 months). Caregivers reported that CIs that interfered the most with functioning were related to collecting, people, things, schedules, television, and objects. The least amount of interference was associated with astronomy, plants, religions, sports, geology, and measurement. Males and females were similarly interested in the majority of the categories. Significant differences emerged in the proportion of males and females interested in "collecting," (χ_2= [1, N=1908] = 4.76 p = 0.029) "people," (χ_2= [1, N=1903] = 4.29 p = 0.038) and "objects." (χ_2= [1, N=1922] = 5.79 p = 0.016)

Conclusions: Participants endorsed CIs across a wide range of categories, though some CI categories were more common than others. The age of onset of CIs varied across categories, as did the impact on daily functioning. Finally, few differences were found in types of interests by gender. The CIs that females were more likely to endorse were three of the six found to have the greatest impact on functioning.

263 **147.263** Does Leading Modality Influence Multisensory Integration in Children with Autism?

***K. Ainsworth**, S. Scholes and A. Bertone, McGill University, Montreal, QC, Canada*

Background: Atypical sensory processing is a key component of Autism Spectrum Disorder (ASD) diagnostic criteria (APA, 2013). The process of multisensory integration (MSI) - the ability to efficiently integrate stimuli from multiple sensory modalities - is necessary to experience the world as a coherent whole. Research suggests that disrupted MSI may partially underlie atypical sensory behaviours in ASD (Wallace and Stevenson, 2014). There has, however, been mixed evidence as to whether MSI is altered in individuals with ASD, especially in stimuli void of social content (e.g. Bao et al., 2017). It has been suggested that MSI, in particular tolerance of asynchrony, is largely influenced by leading stimulus modality in typical adults (Cecere et al., 2016). Although this phenomenon has been studied in relation to autistic traits (Stevenson et al., 2017), this has yet to be explored in individuals with ASD or at different periods of development.
Objectives: Assess the contribution of leading modality on tolerance of asynchrony in children with ASD vs typical children at different periods of development.

Methods: Eighty-six participants were separated into ASD child (n=17; age <12), ASD adolescent (n=13; age > 12), TD child (n=30; age <12) and TD adolescent (n=26; age > 12) groups. Participants evaluated the simultaneity of audiovisual stimulus pairs at seven varying stimulus onset asynchronies (SOAs: 50ms, 100ms, 150ms, 200ms, 250ms, 500ms, 750ms) with 7 SOAs presented audio-leading (A-L), 7 SOAs visual-leading (V-L), and one synced (Powers et al., 2009). Participants were asked to respond whether the auditory stimuli (10ms, 1800 Hz pure tone) and visual stimuli (white annulus subtending 9 visual degrees) were presented at the 'same' or 'different' time.

Results: Proportion of 'same' responses were calculated for each participant. A 3-way mixed ANOVA (4 groups x 2 leading modalities x 7 SOAs) revealed an overall significant effect of leading modality ($p < 0.001$), with V-L trials being indicated as synchronous more often than A-L trials, suggesting a greater tolerance for asynchrony for visual-leading stimulus pairs. No significant overall effect of group was found. However, a significant modality by group interaction was found ($p < 0.001$). This effect is explained by a shift in modality sensitivity across age, mediated by group. Whereas only small changes in proportion of 'same' responses occurred across age for the ASD group (children; $M_{A\text{-}L}$ =62.43 vs $M_{V\text{-}L}$ =68.25 | adolescents; $M_{A\text{-}L}$ =51.65 vs $M_{V\text{-}L}$ =60.71). Meanwhile, a larger difference in audio- vs visual-leading trial performance was found for the TD group (adolescents; $M_{A\text{-}L}$ =53.00 vs $M_{V\text{-}L}$ =67.45 | children; $M_{A\text{-}L}$ =54.68; $M_{V\text{-}L}$ =61.23).

Conclusions: Asynchrony was tolerated to a greater extent in V-L stimuli for all groups. However, performance was mediated by age group, with a larger developmental jump in visual- vs auditory-leading performance in TD groups compared to ASD groups. Our results provide evidence for atypical development of MSI in individuals with ASD, as defined by tolerance to asynchrony, and provide a platform for further investigation of the developmental trajectory of MSI in this population.

264 **147.264** Early Expressive Communication Skills Associated with Development of Lower-Order Rrb in Children with ASD

***E. E. Condy**, C. Farmer and A. Thurm, National Institute of Mental Health, Bethesda, MD*

Background: Restricted repetitive behaviors (RRBs) are a core symptom criterion for an autism spectrum disorder (ASD) diagnosis. RRBs are heterogeneous, as evidenced by research that has psychometrically parsed this symptom domain. One common distinction is between 'lower-order' RRBs, such as restricted stereotyped behavior (RSB) and self-injurious behavior (SIB), and 'higher-order' RRBs, such as compulsive ritualistic sameness behaviors (CRSB). The validity of this distinction is supported by findings showing differential association with phenotypic characteristics; for example, lower-order RRBs are more common among those with lower IQ. Here, we expand on these findings by examining the interplay between the development of expressive communication skills and the development of subdomains of RRBs.
Objectives: We tested the hypothesis that trajectories of higher-order RRBs are positively related to the development of expressive communication in children with ASD, whereas lower-order RRBs are negatively related.

Methods: The sample consisted of 105 children with an ASD diagnosis enrolled in a longitudinal natural history study. The analyses included data from visits that occurred at approximately 1-year intervals between 3–7 years of age, with a minimum of three visits within this period. Each child's parent/caregiver completed the Repetitive Behavior Scale-Revised (RBS-R) at each visit, as well as the Vineland Adaptive Behavior Scale (VABS, second edition). RBS-R subscores were calculated using the three-factor solution (Mirenda et al., 2010): CRSB, RSB, and SIB. To model expressive language skills, the VABS Expressive Communication Age Equivalent (Exp-AE) at each visit was used. Bivariate latent growth models of RBS-R subscore and Exp-AE were run simultaneously for each RRB subscore.

Results: On average, lower-order RRB scores (e.g., RSB and SIB) did not change across 3-7 years of age. Individually, RSB trajectory was negatively related to the intercept of Exp-AE (β=-3.526, p=0.026), such that children with better expressive language at age 3 exhibited a slower increase in RSB from 3-7 years old. Relatedly, Exp-AE trajectory was negatively related to the intercept of SIB (β=-2.090, p=0.032), such that children with more severe SIB at age 3 exhibited a slower increase in Exp-AE between the ages of 3-7 years.

CRSB (the higher-order behaviors) also showed a stable trajectory on average. Neither the intercepts nor slopes of CRSB were significantly related to the intercept or slope of Exp-AE. However, a trend for a positive correlation between Exp-AE and CRSB intercepts was observed (p=.066), such that children with higher expressive language at age 3 had more severe CRSB scores.

Conclusions: Consistent with the literature, the mean trajectory of RRB subscores remained stable from 3-7 years old in this sample of children with ASD. At the individual level, a marginally significant positive correlation was observed between early higher-order RRBs and early expressive language. However, early expressive language skills were negatively related to the slope of RSM development, and early SIB were negatively related to the slope of expressive language development. While consistent with reports that lower-order RRBs are associated with lower cognitive ability, the present findings suggest that the nature of this relationship may vary across lower-order subdomains.

265 **147.265** Eating Behavior Is ASD Child According to Mothers Narratives.

M. P. Ponde *and C. P. Lázaro, BAHIANA School of Medicine and Public Health, Salvador, Brazil*

Background: Several studies indicated that individuals with ASD are resistant to change and have a narrow range of interests that may affect even the food they eat. The most common problems found in those studies were: limited food intake; refusal to eat certain foods or selectivity related to the texture, smell and taste of food; inflexibility regarding the use of utensils, brands and packaging; and behavioral and nutritional problems All the above-mentioned studies dealt with eating problems in patients with ASD from the perspective of the healthcare professional/ physician, with no information on the perceptions and concerns of parents in relation to the eating habits of individuals with ASD.
Objectives: This study aims to investigate the eating behavior of autism spectrum disorder (ASD) individuals through their mothers' narratives.

Methods: The chosen methodological approach was the study of narratives, as we sought the reporting of narrator's experiences. Data on the eating habits of individuals with autism spectrum disorder were collected during semi-structured interviews held individually with the parents/guardians. The interviews were recorded, transcribed and codified using the NVivo software program.

Results: Eighteen mothers of boys with ASD participated in the study. Analysis of the interviews yielded three major categories: eating patterns, the family's attitudes in relation to the child's eating habits, and food-related behavior. The results show that factors related to autism spectrum disorder may affect the child's food choices. Environmental factors, particularly the parents' behavior, may also play a decisive role, both in reinforcing the child's food choices and in encouraging a healthier and more diversified diet.

Conclusions: Professionals should be attentive and instruct parents regarding their decisive role in reinforcing or discouraging inappropriate mealtime behavior in children with autism spectrum disorder.

266 **147.266** Effects of Coloured Lighting on Behaviour of Children with and without Autism Spectrum Disorder

D. R. Simmons[1], *T. Marinova*[2], *M. H. Laurie*[3], *A. Giannadou*[4], *A. J. Wilkins*[5], *P. Allen*[6], *A. Franklin*[7] *and A. Ludlow*[8], *(1)School of Psychology, University of Glasgow, Glasgow, United Kingdom of Great Britain and Northern Ireland, (2)School of Psychology, University of Glasgow, Glasgow, United Kingdom, (3)Patrick Wild Centre, University of Edinburgh, Edinburgh, United Kingdom, (4)University of Sheffield, Sheffield, United Kingdom, (5)Department of Psychology, University of Essex, Colchester, United Kingdom, (6)Department of Vision & Hearing Sciences, Anglia Ruskin University, Cambridge, United Kingdom, (7)School of Psychology, University of Sussex, Falmer, Brighton, United Kingdom, (8)Department of Psychology and Sports Sciences, University of Hertfordshire, Hatfield, United Kingdom*

Background: "Visual stress," an adverse reaction to bright lighting and high-contrast visual patterns, is common in ASD (e.g. Robertson & Simmons, 2015; Ludlow & Wilkins, 2016). An established, if controversial, treatment is to use individually chosen coloured filters, lenses or lighting, thought to reduce neural hyper-responsivity (Wilkins, 1995; 2003), a concomitant of sensory hyper-responsivity (Takarae and Sweeney, 2017).
Objectives: To determine whether coloured lighting influences the observed behaviour of children with ASD.

Methods: A cross-over, double-masked, placebo-controlled study involved 11 children with ASD and 11 controls (aged 6-14 years) matched on verbal (BPVS) and non-verbal (Ravens) IQ measures. An optimal coloured light was individually selected for each child using the "Intuitive Colorimeter" process (Wilkins et al, 2002). A placebo colour was selected using an algorithm so as to differ by 0.091 in CIE UCS chromaticity. The lighting was matched for illuminance. One month after colorimetry all children were videoed performing the "Description of a picture" tasks from the ADOS, under both test and placebo lighting. The videos were rendered in monochrome and behavioural observation coding was used to assess social interaction and autism-like behaviours in the two different lighting conditions. The two raters were both ADOS trained and blind to both diagnosis and lighting condition. They rated eye-contact, social conversation, non-verbal communication, joint attention, atypical social conversation, autistic features (e.g. hand flapping, covering eyes) and other notable behaviours. They also each scored the child's behaviour on an ADOS-like questionnaire and gave their "general impression" of whether the child was autistic on a scale from 0-100.

Results: Observable autistic features decreased significantly under optimal coloured lighting relative to placebo (β= -0.887; SE=0.225, z= -4.34, p=0.001). Post-hoc pairwise comparisons on the significant condition-by-group interaction, (β=1.538; SE=0.419, z=2.756, p=0.006) revealed a significant difference between conditions only in the ASD group (Z = -3.23, p = 0.007). Thus, under optimal coloured lighting, observable autistic features decreased to a greater extent in autistic children than in controls. Both groups of children were rated as significantly less likely to be autistic in the optimal colour condition (WTS(1) = 7.765; p = 0.016). However, there was no evidence that the optimized lighting altered conversational engagement, non-verbal communication, eye contact or joint attention in the ASD group.

Conclusions: Results suggest overall positive effects of optimal coloured lighting both for autistic and typical children and particularly on the non-social signs of ASD. Together with recent related data showing improvements in other areas of difficulty faced by autistic children (Ludlow et al, 2018), they encourage future research on the potential of coloured lighting and lenses as a beneficial adaptation of the sensory environment.

267 **147.267** Examining the Relationship between Early Sensory Reactivity and Later Autism Severity

R. Grzadzinski[1], *K. Donovan*[2], *K. Truong*[2], *S. Nowell*[3], *H. Lee*[4], *J. Sideris*[4], *L. Turner-Brown*[5], *G. Baranek*[4] *and L. R. Watson*[6], *(1)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (2)Gillings School of Global Public Health, University of North Carolina, Chapel Hill, NC, (3)University of North Carolina at Chapel Hill, Carrboro, NC, (4)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (5)UNC TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, (6)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background: Infants at high-risk (HR) for developing Autism Spectrum Disorder (ASD) often display atypical patterns of sensory reactivity, including hypo-reactivity, hyper-reactivity, and sensory seeking behaviors. Sensory seeking behaviors often increase over the second year of life in children later diagnosed with ASD (Baranek et al., 2018) and hypo-reactivity to sensory stimuli at 24 months has also been linked to later ASD diagnoses (Germani et al., 2014). Extending this work to younger samples and evaluating how sensory reactivity changes over the first years of life has implications for early identification and treatment planning.
Objectives: To examine the relationship between sensory reactivity at 12 and 24 months and later ASD severity.

Methods: This study includes 87 HR children (60 boys) identified at 12 months based on community screenings with the *First Year Inventory 2.0* (Baranek et al., 2003). Children completed the Sensory Processing Assessment (SPA; Baranek, 1999) at 14 months (+/- 0.77; Time 1) and 23 months (n=83; +/- 0.86; Time 2). 50% (n=45) of the children were randomly assigned to an intervention trial. A subsample (n=45) returned between ages 3 and 5 years (mean= 4.5 years +/- 0.92; Time 3) for follow-up diagnostic assessments and received the Autism Diagnostic Observation Schedule

(ADOS-2; Lord, Luyster, Gotham, & Guthrie), yielding calibrated severity scores: overall score (CSS), CSS social affect (CSS SA), and CSS restricted, repetitive behaviors (CSS RRB). To account for missing data, multiple imputation was carried out using Multivariate Imputation by Chained Equations (see MICE package in R). Linear regression models were fit to the imputed datasets with each SPA score at Time 1 and the change in each SPA score from Time 1 to Time 2 (covariates: treatment group and age at Time 3). Effect sizes were calculated (the parameter estimate divided by the standard error).

Results: SPA hypo-reactivity at Time 1 was significantly related to CSS [95% CI (0.35, 3.43); effect size = 2.49] and CSS SA [95% CI (0.33, 3.32); effect size = 2.48]. Increases in SPA Hypo-reactivity from Time 1 to Time 2 was significantly related to CSS [95% CI (0.41, 2.78); effect size = 2.73], CSS SA [95% CI (0.30, 2.61); effect size = 2.57], and CSS RRB [95% CI (0.05, 3.03); effect size = 2.11]. Increases in SPA Hyper-reactivity from Time 1 to Time 2 was significantly related to CSS [95% CI (0.45, 4.79); effect size = 2.46], but not CSS SA or CSS RRB. Sensory Seeking behaviors at Time 1 and changes from Time 1 to T2 were not significantly related to later ASD severity.

Conclusions: Child hypo-reactivity at 12 months may be particularly helpful in predicting ASD severity during the preschool years. In addition, increases in hypo- and hyper-reactivity from 12 to 24 months may provide new information about the emergence of ASD symptoms prior to a diagnosis. These results indicate that early sensory reactivity may be a useful precursor to an ASD diagnosis and may provide a new target for early interventions.

268 **147.268** Exploring the Relationship between Sensory Reactivity and Mental Health: A Comparison of ASD and Neurotypical Youths.

T. Rossow[1], *K. MacLennan*[2], *M. R. Gerdes*[3], *E. J. Marco*[3] *and T. Tavassoli*[4], *(1)University or Reading, Reading, United Kingdom, (2)University of Reading, Reading, United Kingdom, (3)Neurology, University of California San Francisco, San Francisco, CA, (4)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom*

Background: Research shows that sensory reactivity symptoms are often present in individuals with a diagnosis of an autism spectrum condition (ASC), irrespective of level of functioning. The literature also asserts that autistic individuals are at a significantly higher risk of developing mental health conditions than their neurotypical peers. Whilst some research has investigated individual sensory reactivity constructs within specific diagnoses, particularly with hyper-responsivity/sensory sensitivity and anxiety, little research has been conducted more broadly into the relationship between other sensory reactivity constructs (poor registration/hyporesponsivity and sensation seeking) and the development of other mental health disorders. The current study explores the correlational relationship between sensory reactivity and mental health constructs across a sample of ASC and neurotypical youths.

Objectives: To examine whether there are relationships between sensory reactivity and mental health, and explore any differences in sensory processing and mental health across groups of ASC and neurotypical youths.

Methods: This study analysed standardised parent-report measures of sensory difficulties and mental health. Measures were completed for 29 children diagnosed with ASC (ages 7 to 11) and 43 children without a diagnosis (ages 8 to 12). The Sensory Profile - Parent (SP) was used as the measure of sensory reactivity, and the Child Symptom Inventory (CSI) for mental health constructs. The SP provided symptom scores for auditory, visual, vestibular, touch, multisensory and oral processing, and total scores for sensory seeking, poor registration and sensory sensitivity. The CSI provided symptom scores for inattention, hyperactivity, Attention Deficit Hyperactivity Disorder (ADHD), Oppositional Defiant Disorder (ODD), Conduct Disorder (CD), Generalized Anxiety Disorder (GAD), specific phobia, obsessions, compulsions, Post-Traumatic Stress Disorder (PTSD), depression, social phobia and separation anxiety. Cross-tabulation analyses were used to understand sensory reactivity symptoms across groups, and bivariate correlational analyses were used to assess sensory reactivity and mental health.

Results: Cross-tabulation analysis found that autistic participants had greater sensory processing difficulties compared with their neurotypical peers ($p < .01$), and that autistic participants had higher scores on poor registration than sensory seeking or sensory sensitivity ($p < .01$). Significant correlations were also found between sensory sensitivity constructs and mental health in autistic participants, including in sensory seeking and hyperactivity ($r = -.67$, $p < .01$) and generalised anxiety ($r = -.60$, $p < .01$), and in total sensory processing and generalised anxiety ($r = -.59$, $p < .01$) and depression ($r = -.56$, $p < .01$). Significant correlations were also found for individual sensory modalities and mental health in autistic participants ($p < .05$).

Conclusions: Our results suggest that there is a relationship between sensory reactivity and mental health, both at a total construct level and at an individual modality level. The results also suggest that there may be a potential for diagnosis-specific profiles of sensory reactivity and mental health. Further, poor registration may be an under-assessed variable. Future directions include understanding the causal relationship between sensory reactivity and mental health, and developing a more robust understanding of across-group profiles.

269 **147.269** Exploring the Relationship between Stereotypy, Sensory-Driven Behaviors, and Self-Injury in Children with Autism Spectrum Disorder

C. E. Finn[1], *J. Straus*[1], *H. V. Medeiros*[1] *and E. Hanson*[2], *(1)Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background: The DSM-V categorizes stereotyped movements and hyper- or hypo-reactivity to sensory input as subtypes of restricted and repetitive behaviors (RRBs), a defining characteristic of Autism Spectrum Disorder (ASD) (American Psychiatric Association, 2013). Self-injurious behaviors (SIBs) are also seen at high rates in this population and can cause significant impairment (Minshawi et al., 2014). SIBs have been theorized by some to be an extreme form of RRBs (Eynat, Dyck, & Passmore, 2009; Mace et al., 1994). While there is research examining factors that influence SIBs, no study has examined the relationship between stereotypy and sensory-driven behaviors and SIBs in the ASD population. Objectives: The study aims were to 1) examine the relationship between stereotypy and SIBs, 2) examine the relationship between sensory-driven behaviors and SIBs, and 3) determine predictors of SIBs.

Methods: Data from 220 children with ASD ages 2.5–16.9 years enrolled in a previous research through Boston Children's Hospital and the Boston Autism Consortium was used. All children met diagnostic cutoff on the Autism Diagnostic Observation Schedule (ADOS, Lord et al., 2003). The Behavior and Sensory Interest Questionnaire (BSIQ, Hanson et al., 2016) measures type and severity of 74 RRBs with codes ranging from 0-3. Using the averages of BSIQ questions related to stereotypy and sensory RRBs, four groups were developed: 1) stereotyped movements (SM) (Items B1.a-B4.f), 2) unusual sensory interests (SI) (Items B5.a-k), 3) sensory aversions (SA) (Items B6.a-d), and 4) SIBs (Items E1.a-g). The first three groups

were then divided into three levels of severity: Low severity=scores below the 25th percentile, Moderate severity=scores ranging from the 25th to 75th percentile, and High severity=scores above the 75th percentile. Analysis was conducted by first using Spearman rank order correlations to identify relationships between SM, SI, SA and SIBs. Next, a Kruskal-Wallis test was used to determine if there was a significant difference in SIBs for low, moderate, and high levels of SM, SI, and SA. Lastly, a linear regression model was run to determine any predictors of SIBs controlling for nonverbal IQ (NVIQ), age, and gender.

Results: All groups were positively correlated with SIBs (SM, SI, SA; p<.001). There was also a significant difference in SIBs between the different severity groups. Post hoc testing showed that SM high (p=.002), SI high (p<.001) and SA high (p=.029) were significantly correlated with SIBs. There was no significance for SM, SI, SA moderate or low severity and SIBs. SA was the only significant predictor of increased SIBs (r =.102, p<.001).

Conclusions: The results indicate that high severity levels of increased stereotypy, sensory-seeking behavior, and sensory aversion are all associated with SIBs. This could support the hypothesis by Eynat et al., 2009 that these behaviors are related. In addition, SA was a predictor of SIBs. Individuals who experience distress and aversions to specific sensory stimuli (BSIQ Items B6.a-d), could potentially show this by engaging in SIBs. In the future, more research will be critical to understand the causes and relationships of these behaviors and how best to design intervention approaches.

270 **147.270** Family Experiences of Auditory Hypersensitivity in ASD

S. Hussein[1], *B. Bahmei*[1], *K. Gustafson*[2], *R. Fisher*[3], *G. Iarocci*[4], *S. Arzanpour*[1] *and E. Birmingham*[2], *(1)Mechatronic Systems Engineering, Simon Fraser University, Surrey, BC, Canada, (2)Faculty of Education, Simon Fraser University, Burnaby, BC, Canada, (3)Psychology, Simon Fraser University, Burnaby, BC, Canada, (4)Simon Fraser University, Burnaby, BC, Canada*

Background: Auditory hypersensitivity is a common sensory issue for individuals with autism spectrum disorder (ASD). Previous research suggests that auditory sensitivity negatively impacts family life and limits participation in everyday activities.
Objectives: To provide insight into the experiences and behaviors of individuals with ASD and auditory sensitivity, and better understand their needs and concerns and those of their families.

Methods: Parents of individuals with ASD (n=90) were recruited to participate in a 54-item survey, adapted from the Auditory Sensitivity and Child Safety Questionnaire (Law et al., 2016). The survey probed the individual's past and current levels of auditory sensitivity and how this issue affects the individual's behavior and family life. A follow-up focus group interview was conducted with a subset of parents (n=7). The focus group discussed the nature of challenging sounds and situations, behaviors, negative effects on family activities and loss of opportunities, safety issues and effectiveness of current solutions.

Results: Child characteristics: Gender (77% male); Ethnicity (63% white; 14% Asian; 23% other/mixed ethnicity); Age (Median = 10.5 years, Range: 3-30 Years).

86% of the respondents reported that their child experienced negative reactions during the last 6 months. 51% of parents reported that their child reacts negatively to both very specific and general sounds; 40% indicated that their child reacts only to specific sounds; 6% of parents reported that their child reacts only to general noises; 3% of parents were unsure. When asked to indicate all of the types of problematic sounds, 83% of parents indicated loud noises, 61% indicated sudden noises, and 53% indicated high-pitched noises.

Commonly reported emotional states in response to aversive sounds included stressed (80%), irritable (62%) and scared (51%). Common responses included ear covering (86%), screaming (50%), and trying to stop the sound (34%). When the sound sensitivity was at its worst point, many respondents reported a negative reaction daily/multiple times a day (68%), or weekly/several times a month (18%). When asked whether sound sensitivity has an impact on daily life and social opportunities, the most common response was that sound sensitivity *at least sometimes* limits participation in family (67%), school (69%), and community (70%) activities. Several parents (39%) considered auditory sensitivity moderately or extremely difficult to manage in their child; 43% of parents found that it led to unsafe behavior in their children.

The focus group provided valuable and nuanced insights into changes and variability in sound sensitivity for individuals over time and across contexts. Data is being analyzed using content analysis. Parents indicated that emotional states and motivation to participate in activities often had an important effect on their child's tolerance to aversive sounds. They indicated some success with existing therapies and technologies, but also expressed a need for further improvements that could more effectively address the complexity of sound sensitivity issues.

Conclusions: Sound sensitivity is an important and still poorly understood aspect of the ASD profile. It is an issue that affects the lives of individuals and families, and warrants greater focus in the areas of research and development.

271 **147.271** Food Addictive and Selective Eating Traits in Autism and Their Health and Behavioral Consequences

M. V. Nadeau, *E. Richard, A. J. Wolff and G. L. Wallace, The George Washington University, Washington, DC*

Background:
Obesity is a prevalent issue in those with Autism Spectrum Disorder ([ASD]; Curtin et al., 2014). People with ASD are more likely to develop high blood pressure, diabetes, cardiovascular disease/stroke, etc. when compared to the general population (Croen et al., 2015). The mechanisms driving these adverse health outcomes are unclear. There is some evidence for increased overeating in individuals with ASD (Hess, Matson, & Dixon, 2010); however, this evidence is limited. Food addiction [FA] is a set of traits used to explain the drive to eat due to the rewarding nature of food, despite the potential accompanying negative health consequences. To date, neither FA traits, nor their health-related correlates have been examined in individuals with ASD. Furthermore, the overlap between FA traits and food selectivity has yet to be examined and may be associated with further negative health outcomes.

Objectives:

Characterize food addictive and selective eating traits in children with ASD and their associations with body mass index [BMI].

Methods:

Participants consisted of parents of children with ASD (n=153;M age=8.9,109 males) and parents of typically developing [TD] children (n=78;M age=8.3,36 males) who completed psychometrically sound and well-established questionnaires assessing FA traits and picky eating behavior. FA was assessed using The Yale Food Addiction Scale for Children (Gearhardt et al., 2013; Burrows et al., 2017). Food selectivity (i.e., picky eating) was

assessed using a portion of the Eating Habits Survey (Wilde et al., 2012). Lastly, parents were asked to report their child's biological sex, chronological age, height, and weight in order to calculate BMI and categorize overweight/obesity status using Center for Disease Control norms.

Results:

Children with ASD were more likely to be rated as picky eaters than TD children(ASD:55.6%,TD:29.5%;$\chi 2$ =14.1,p<.001). Additionally, parents rated children with ASD as having more FA traits than TD children(t=4.15,p<.001), and significantly more children with ASD than TD children surpassed the threshold for elevated FA traits(ASD:23.8%,TD:8.5%;$\chi 2$=7.40,p<.01). Of the children with ASD surpassing the threshold for elevated FA traits, 68.6% were also rated as being picky in their eating, which was significantly higher than among the non-picky eaters(50.9%,p<.05). Finally, among the children with ASD, BMI was found to be lower for picky eaters compared to non-picky eaters(t=3.84,p<.001), but positively correlated with FA traits(r=.20,p<.05). Furthermore, those who have elevated FA traits alone and those who exhibit both elevated FA traits and picky eating have higher BMI than those who are picky eaters only(F=18.05,p<.001).

Conclusions:

This study indicates that not only food avoidant behaviors, but also FA traits, are overrepresented in children with ASD. Moreover, there appears to be an overlap between selective eating and FA traits in ASD, suggestive of a 'selective overeating' phenotype. Finally, picky eating (lower) and FA (higher) exert opposing influences on BMI in the context of ASD. This study informs our understanding of appetitive traits and eating behaviors in ASD that could serve as behavioral risk factors for overweight/obesity. In turn, these behaviors might represent viable intervention targets, around which to design effective treatments to optimize health outcomes in individuals with ASD.

272 **147.272** Functional Brain Mechanisms of Sensorimotor Deficits in Individuals with Autism Spectrum Disorder

K. E. Unruh[1], *L. Martin*[2], *G. Magnon*[3], *D. E. Vaillancourt*[4], *J. A. Sweeney*[5] *and M. W. Mosconi*[1], *(1)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (2)Hoglund Brain Imaging Center, University of Kansas Medical Center, Kansas City, KS, (3)University of Pittsburgh Medical Center, Pittsburgh, PA, (4)Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (5)Division of Developmental Behavioral and Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH*

Background: Abnormalities in sensorimotor behavior are present in the majority of individuals with ASD and are associated with core symptoms. Cortico-cerebellar networks that control sensorimotor behavior have been implicated in ASD, but little is known about their function during sensorimotor actions.

Objectives: The purpose of this fMRI study was to examine cortical-cerebellar function during feedback-guided motor behavior in ASD.

Methods: Individuals with ASD (11-30 years; N = 18) and age-matched controls (N = 15) completed a visuomotor task of feedback-guided precision gripping during fMRI. Participants pressed with their right thumb and forefinger on a force transducer while viewing a green FORCE bar on a screen that moved upwards with increased force toward a fixed white TARGET bar. Individuals were instructed to maintain the FORCE bar at the level of the TARGET bar for 24 seconds. Target force levels were set at 20% and 60% of each participant's maximum voluntary contraction (MVC). Force variability was characterized as the coefficient of variation (i.e., standard deviation of the force time series / mean force output; CoV).

Results: Mean force did not differ between groups indicating participants were able to follow task demands. Participants with ASD showed increased force variability ($F_{(1,30)}$= 5.214, p= 0.03) at both 20% (d= .45) and 60% (d= .77) MVC compared to controls. Compared to controls, individuals with ASD showed decreased activation in left angular gyrus during the visuomotor task compared to rest (AG; maximum t= 4.31). Individuals with ASD also showed greater visuomotor activation compared to controls in ipsilateral ventral M1, extending anteriorly into posterior ventral pre-motor cortex (PMv; maximum t= -4.06, cluster size = 38 voxels). This difference reflected the finding that control participants showed a selective deactivation of ipsilateral M1/PMv during visuomotor behavior, whereas individuals with ASD did not show this pattern. A significant group x force interaction was observed for contralateral Crus I activation (maximum t= -2.42) that was driven by an increase in activity during 60% compared to 20% MVC in control participants, while individuals with ASD showed no significant change in Crus I activation between force levels.

Conclusions: Increased force variability in individuals with ASD suggests impaired processing of sensory feedback to guide precision motor behaviors. Individuals with ASD did not show deactivation of right motor cortex during visuomotor behavior relative to rest, suggesting reduced ability to selectively modulate motor cortical output. Reduced activation in left AG may reflect an inability to integrate visual, haptic, and proprioceptive inputs to reactively adjust ongoing motor output. Failure to show force-dependent scaling of Crus I in ASD suggests lateral cerebellar circuits do not adapt sensory prediction and error processes to maintain precision motor output during more demanding conditions. Together, our results demonstrate multiple cortical-cerebellar mechanisms associated with sensorimotor imprecision in ASD.

273 **147.273** Gender Differences in Parent-Reported Restricted Interests in Children with and without ASD

T. Boucher*, H. Aime, N. M. Kauppi, N. E. Scheerer and G. Iarocci, Simon Fraser University, Burnaby, BC, Canada*

Background: Restricted interests (RIs), a diagnostic criterion of ASD, are pursuits that are circumscribed and intense, causing interference in daily activities (Lord et al., 1993). Clinician assessments of RIs indicate a greater prevalence in boys than in age- and IQ-matched girls both with and without ASD (Anthony et al., 2013). However, the assessment of RIs may be biased towards identification in boys, particularly as the topic of girls' interests may appear 'typical', despite causing significant impairment in everyday contexts (Duvekot et al., 2017; Hiller et al., 2014).

Objectives: The objectives of the current study were to: (1) identify the number of parent-reported RIs in a sample of IQ-matched children with and without ASD and (2) examine group and gender differences in interest topics and whether they cause interference in the child's life.

Methods: A total of 125 age- and IQ-matched children (age 6-12, IQ>80) and their caregivers participated in this study (55 ASD, 41 boys; 70 typically developing [TD], 43 boys). Children were administered the Wechsler Abbreviated Scales of Intelligence 2nd Edition (Wechsler, 2011) while their parents completed the Yale Special Interests Survey (Klin & Volkmar, 1996), a qualitative questionnaire eliciting information on the presence of intense interests and activities relating to the interest. Interference of interest was assessed as a sum of questions on a 4-point scale reporting the percentage of time spent engaging in the interest within contexts of daily living (i.e., alone, with family, with peers).

Results: Seventy-seven children were identified as possessing RIs (ASD: 34 boys, 11 girls; TD: 22 boys, 11 girls). A majority of youth with ASD were identified as having a RI (83% of boys, 79% of girls) compared to 51% and 41% of TD boys and girls, respectively. Independent samples t-tests identified that IQ was not significantly different between diagnostic groups (t(123)=1.64, p=.09) or between those with and without RIs (t(123)= -.561,

p=.58). Eight of 11 ASD girls shared a similar interest to ASD boys, primarily video games and Pokémon (50%); 73% of all girls shared similar interests (animals, cartoon characters, drawing, and reading). However, despite similarities in content, the RI of girls with ASD caused significantly more interference in daily living compared to TD girls (*t*(19)= -2.71, *p*=.01, *d*=1.17). 58% of all boys shared similar interests; however, 43% were an obsessive interest in video games. Parent ratings of interference did not significantly differ between boys and girls with ASD (*t*(42)= -.78, *p*=.44).

Conclusions: Consistent with previous research, our results indicate that the RI topics of girls with ASD were similar to those of TD girls. However, parent-ratings of interference were significantly higher in ASD girls than TD girls, while not significantly different from those of boys with ASD. These findings suggest that interference in daily activities may be a key distinguishing feature of RI between children with and without ASD more so than the topic of interest itself. Assessment of the interference parents attribute to a RI may be a possible avenue to improving diagnostic accuracy in ASD, particularly among girls.

274 **147.274** Gross Motor Features during Balance Training Distinguish Youth with Autism Spectrum Disorder Compared to Youth with Typical Development

*B. G. Travers[1], O. J. Surgent[1], **A. Ardalan**[2] and A. Assadi[3], (1)University of Wisconsin - Madison, Madison, WI, (2)Computer Sciences, University of Wisconsin-Madison, Madison, WI, (3)University of Wisconsin-Madison, Madison, WI*

Background: Motor challenges are commonly reported in individuals with ASD (Fournier et al., 2013), and fine motor skills during tablet play were shown to reliably distinguish between children with autism spectrum disorder (ASD) and children with typical development (Anzulewicz et al., 2016). However, it is unclear whether gross motor movements would similarly distinguish youth with ASD and youth with typical development. Understanding markers of gross motor function that are more common in ASD would help clarify the nature of motor challenges in this population.

Objectives: (1) Use machine learning to determine whether whole body movement and postural stability during balance tasks can reliably distinguish between youth with ASD and youth with typical development. (2) Investigate whether the results of our machine learning classification corresponded to performance on a standardized motor task. (3) Explore which features of whole-body movement are most informative in the classification algorithm.

Methods: Kinematic and postural sway data were collected in 46 youth with ASD and 18 age-matched youth with TD (ages 7.0-17.9 years), as part of a biofeedback-based videogame training to enhance balance in youth with ASD (Travers et al., 2018). Kinematic data from one-hour sessions were recorded with a Microsoft Kinect Camera, and postural sway data were recorded with a Wii Balance Board. Given the heterogeneity within the ASD profile, a 3:1 ratio of ASD to TD was selected, to allow the motor data to be representative of the diversity within the autism spectrum. Training sessions 2-4 (of 18) were used in these analyses to characterize motor skills before the majority of the training (sessions 5-18) but after the initial intake assessment (session 1). These data were cleaned, informative features were extracted, and an ensemble of random forests were trained. The intake session included confirmation of an ASD diagnosis (providing training labels) and a standardized measure of overall motor function (Bruininks & Bruininks, 2005).

Results: The machine learning algorithm demonstrated average sensitivity of .90, average precision of .84, and average F1 score of .86, using 5-fold cross-validation. The machine learning results were highly correlated with the standardized motor scores, $r = -.50$, $p < .001$, suggesting that the machine learning results aligned with an outside measure of motor ability. Postural sway movement was the feature that most robustly distinguished between the two groups, followed by movement in the right shoulder, left foot, right hand, right foot, left hand, right wrist, neck, and right elbow.

Conclusions: Gross motor features during a balance-training task were able to distinguish between the youth with ASD and the youth with typical development with a high degree of sensitivity and precision. Further, the metrics rendered from the machine learning were highly related to overall motor skill, suggesting that our data and machine learning results were representative of participant motor function (and not other potential sources of noise in the data). The results further suggest postural sway data (both left-to-right and forward-to-back movement) may be a distinctive feature for individuals with ASD and a key skill to target in therapy.

275 **147.275** How Do Adults with ASD Respond to Volatile Stimuli? Behavioral and Neural Evidence

***V. Parma**[1], M. Furlan[2], D. N. Top[3], K. G. Stephenson[4] and M. South[5], (1)William James Center for Research, ISPA - Instituto Universitário, Lisbon, Portugal, (2)International School for Advanced Studies, Trieste, Italy, (3)Brigham Young University, Provo, UT, (4)Nationwide Children's Hospital, Columbus, OH, (5)Psychology & Neuroscience, Brigham Young University, Provo, UT*

Background: Adults with autism spectrum disorder overestimate the volatility of their sensory environment (Lawson et al., 2017), which should theoretically correspond to longer reaction times and reduced accuracy in discrimination tasks. The neural mechanism underlying this overestimation may be grounded in brain areas known to preferentially encode features (e.g., quality) and sensitive to repeated exposures (Li et al., 2008).

Objectives: We investigated these hypotheses in a sample of adults with autism (ASD group, n=20, 8F) and neurotypical controls (TD group, n=14, 8F) by presenting olfactory stimuli which are naturally volatile and dynamic, and whose perception is generally not consciously rehearsed.

Methods: Participants were presented with subjective ratings during a behavioral olfactory discrimination task and a cross-adaptation task performed during fMRI. Four odorants followed a 2x2 design of two qualities (minty vs. floral) and two chemical groups (ketone vs. alcohol); for instance, one odor had a minty quality which came from a molecule containing either a ketone or an alcohol group. Participants sniffed twice in succession and smelled pairs of odorants that could share perceptual quality (e.g., they were both minty) or the chemical group (e.g., they were both ketones). Participants smelled 40 pairs of odorants (cued by the words 'sniff now') in a pseudo-randomized order 4.25s apart with trials separated by 24s of clean air to minimize sensory habituation. Participants had to decide whether the two odorants were the same or different.

Results: For the odor-quality (i.e., minty vs floral) discrimination task, the ASD group does not show the same reaction time benefit for “same” odor pairs as the TD group, and the interaction of condition (same vs. different odor) and group (ASD vs TD) is statistically significant. The same interaction pattern is significant for accuracy rates. Subjective ratings of familiarity changed significantly in the ASD group over the course of the task, increasing from 42/100 to 58/100 on the visual analog scale; the TD group started at the same level where the ASD group ended (60/100) and did not change with time. In the TD group, the “mintiness” rating seems to be is driven by the ketone odor, whereas the “floralness” rating is

driven by the alcohol odor; in the ASD group, ratings of odor quality were not tied to chemical group. Analyses of fMRI data are ongoing. Preliminary data suggest suppression of activity following the presentation of two stimuli sharing one feature in the TD but not in the ASD group (Rosen et al., 1998) and the same pattern (TD not ASD) of odor-evoked activity in posterior piriform cortex (PPC) which significantly decreased (cross-adapted) in response to qualitatively similar, but not to chemically similar, odorant pairs.

Conclusions: In line with the hypothesis of overestimated volatility, the ASD group takes longer, with decreased accuracy, to discriminate pairs of odorants even for perceptually-similar olfactory stimuli. We discuss implications for treatment of uncertainty and anxiety and in everyday life.

276 **147.276** Identifying Interests Related to Literacy in Preschool Autistic Children: Results of the New Autism Toddler Strengths and Interests Questionnaire

V. Larose[1,2], *V. Langlois*[1,2], *L. Mottron, M.D.*[2] *and C. Jacques*[1,2], *(1)University of Quebec in Outaouais, Gatineau, QC, Canada, (2)University of Montreal Center of Excellence for Pervasive Developmental Disorders (CETEDUM), Montreal, QC, Canada*

Background: Klin, Danovitch, Merz and Volkmar (2007) showed that 75% of young autistic children (age 2 to 6) with typical intelligence present intense interests. However, few studies and instruments have documented intense interests in autistic children at age of diagnosis. Moreover, diagnostic instruments give little information on the nature of autistic interests, despite documenting their restriction and intensity. In contrast, an abundant literature based on questionnaires or interviews indicates that intense interests are valued by parents of typical children and may be used for motivational and learning ends (Hume, Lonigan et McQueen, 2015).
Objectives: To compare parental reports of young autistic children's interests to those of typical children using the recently developed Autism Toddler Strengths and Interests Questionnaire (ATSIQ).

Methods: The ATSIQ, is composed of 19 close- and open-ended questions, documenting the child's interests and how the parents perceive these interests. 20 parents of autistic children (mean age = 60.75 months SD= 8.27) and 20 parents of typical children (mean age = 53.40 months SD= 15.17; p=.067) participated in a semi-structured phone interview using the ATSIQ. Non-parametric tests (U Mann-Whitney) were performed to compare groups on 1-the frequency of each topic of interest and 2- the parental perception of the child's interests.

Results: Four topics of interest were significantly more frequent in autistic children: Letters, Numbers, Electronics (computers/tablets /smartphones) (all *p*'s<.05) and Logos (*p*<.01). These were also considered more intense by the parents (*p*<.05) compared to interests in typical children. Seven topics of interest were significantly more frequent in the typical group: Play with friends (*p*<.001), Stuffed animals (*p*<.01), Books, Symbolic play, Legos, Cars, and Insects (all *p*'s<.05). Parents' perception of their child's interests was less favorable in the autistic group (*p*<.001).

Conclusions: The present study indicates a higher frequency of interests related to literacy in preschool autistic children compared to typical children. Literacy skills emergence in young autistic children is associated to the strength profile seen in this population's development trajectory (Ostrolenk et al. 2017; Westerveld et al. 2016; Mottron et al. 2013). However, the results suggest a less favorable parental perception of interests in autism. The next step of the present study is to perform a qualitative analysis that will provide more information about the nature of the child's principal interest and its context of emergence. Since parental attitude toward their child's interests tends to favor learning in typical development (Lukie, Skwarchuk, LeFevre et Sowinski, 2014), the ATSIQ could be useful in informing parents about the nature and value of their child's interests.

277 **147.277** Impaired Olfactory Detection and Identification in Children and Young Adults with ASD

L. Bennetto[1], *J. M. Keith*[1], *P. Allen*[2], *C. J. Zampella*[3], *K. Schauder*[1], *L. S. Cubit*[1] *and C. Stodgell*[4], *(1)Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY, (2)University of Rochester Medical Center, Rochester, NY, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)University of Rochester School of Medicine & Dentistry, Rochester, NY*

Background: Individuals with autism spectrum disorder (ASD) often experience significant sensory processing differences, including atypical chemosensory (i.e., taste and smell) functioning. Carefully characterizing olfactory differences in ASD is important given the functional impact they may have on the significant feeding challenges in this population, as well as shared neural circuitry between olfactory and social regions. Extant olfactory findings in ASD have varied, with some studies finding lower detection and/or identification in individuals with ASD and others finding no differences. Further research is needed to reconcile these findings, including controlling for other factors affecting performance, and to examine whether olfactory differences are specific to ASD or present in the broader phenotype.
Objectives: This study aimed to clarify and extend the ASD olfaction literature by examining detection and identification abilities in a large, well-characterized sample of children and young adults with ASD, while also assessing other factors that might influence performance (e.g., exposure, receptive language). To examine shared genetic and environmental factors, participants with ASD were compared to both unaffected siblings and typically developing (TD) controls.

Methods: Participants were 85 children and young adults with well-characterized ASD, 49 unaffected siblings of the participants with ASD, and 66 unrelated TD controls. Ages ranged from 10-24 years, and groups did not differ by age. IQs were > 70. Receptive language was also measured with the PPVT-4, which has a similar response format to the identification task.

Olfactory detection thresholds were determined using the Smell Threshold Test, in which varying concentrations of phenyl ethyl alcohol were presented bilaterally in a two-interval forced-choice adaptive paradigm. Odor identification was assessed using the University of Pennsylvania Smell Identification Test (UPSIT), in which participants identified a target odor amongst four choices (presented with photographs in this study to decrease verbal demands). Finally, each participant's prior exposure to UPSIT target odors was assessed via parent-report questionnaire.

Results: Kruskal-Wallis analysis of variance (ANOVA) revealed an overall group difference in olfactory detection, X^2 (2)=19.65, *p*<.001. Follow-up comparisons indicated that individuals with ASD had higher (worse) thresholds than siblings (*p*<.001) and TD controls (*p*=.001), who did not differ. Olfactory identification, analyzed via ANOVA, also revealed an overall group difference, *F*(2,195)=16.65, *p*<.001. The ASD group showed worse identification compared to siblings (*p*<.001) and controls (*p*<.001), who did not differ. To account for differences in exposure, we calculated adjusted scores based only on target odors each participant had previously experienced. After adjusting for exposure history, the ASD group remained significantly worse than both siblings (p<.001) and controls (p=.02). A similar pattern of results emerged after controlling for age, gender, receptive language, and olfactory detection abilities.

Conclusions: These results support reduced olfactory detection and identification abilities in children and young adults with ASD, even after

controlling for other factors influencing task performance. Furthermore, unaffected siblings demonstrated intact olfactory abilities, which were statistically comparable to TD controls, suggesting a unique olfactory phenotype in individuals with ASD, which does not extend to full siblings without the diagnosis.

278 **147.278** Inhibitory Control of Prepotent Eye Movements in ASD

S. E. Kelly[1], *L. M. Schmitt*[2], *J. A. Sweeney*[3] *and M. W. Mosconi*[4], *(1)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, Kansas Center for Autism Research and Training (KCART), University of Kansas, Lawrence, KS, (2)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Division of Developmental Behavioral and Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS*

Background: Impairments in inhibitory control (IC), or the ability to suppress a dominant behavioral response, are common in individuals with autism spectrum disorder (ASD). Multiple psychological and neurophysiological processes contribute to successful IC, though the extent to which these distinct processes are affected in ASD is not known. We previously have documented that individuals with ASD show a reduced ability to proactively delay response onset during a manual motor stop-signal task which contributes to failures inhibiting contextually inappropriate responses. Relative to manual motor behaviors, eye movements are highly automated, more difficult to inhibit, and more closely linked to discrete neurophysiological processes. Characterizing IC of eye movements in ASD may provide key insights into spared and affected psychological and neurophysiological processes.

Objectives: To characterize oculomotor inhibitory control impairments in individuals with ASD.

Methods: Sixty individuals with ASD aged 5-29 years and 65 age- and gender-matched typically developing controls completed an oculomotor stop-signal task (i.e., countermanding). During this task, the majority of trials were GO trials, on which participants made rapid eye movements (i.e., saccades) toward peripheral targets (12 degrees to the left or right of center). The remaining trials were STOP trials, on which a stop signal appeared at variable intervals following the peripheral target (i.e., stop signal delays) to cue the participant to inhibit the saccade. Stopping accuracy (i.e., the percent of STOP trials successfully inhibited), estimated reaction time of the stopping process (SSRT), and reaction time slowing on GO trials (RT slowing) compared to a baseline RT task were examined.

Results: Individuals with ASD exhibited reduced stopping accuracy compared to controls, especially for rightward targets. Compared to controls, individuals with ASD also showed reduced RT slowing that was more severe for rightward targets. SSRT did not differ between groups. Across both groups, increased age was associated with higher stopping accuracy and RT slowing, and these effects did not differ as a function of group membership.

Conclusions: The results indicate that inhibitory control deficits in ASD reflect a reduced ability to strategically delay behavioral responses as evidenced by reduced RT slowing. These findings suggest that fronto-striatal pathways necessary for top-down proactive inhibitory control are compromised in ASD. Additionally, these impairments were found to be more severe when inhibiting rightward eye movements. Because rightward eye movements are controlled primarily by the left hemisphere, our findings suggest a lateralized deficit in communication between higher-level cognitive systems and motor control processes in individuals with ASD. Alternatively, as prior brain activation findings indicate that inhibitory control processes are right hemisphere dominant, our findings also may indicate inter-hemispheric communication impairments in ASD.

279 **147.279** Kinematic Performance during a Human-Robot Imitative Gesturing Task Differentiates Autism Spectrum Disorder (ASD) from Typical Development and Correlates with Clinical Assessments of Motor Skills

G. M. Sherrod[1], *D. Blankenship*[2], *I. Wijayasinghe*[3], *E. Walsh*[2], *R. Patterson*[2], *D. Popa*[3], *N. L. Bugnariu*[2] *and H. L. Miller*[2], *(1)University of Alabama - Birmingham, Birmingham, AL, (2)University of North Texas Health Science Center, Fort Worth, TX, (3)University of Louisville, Louisville, KY*

Background: Individuals with Autism Spectrum Disorder (ASD) may have difficulty imitating social-communicative gestures, perhaps in part due to significant challenges in areas of motor control including postural stability and coordination. Currently, assessment of a person's ability to appropriately use gestures relies on subjective observation and parent-report. While useful clinically, these approaches do not identify kinematic signatures of ASD and typical development (TD) that may enhance our understanding of the underlying mechanisms driving imitative gesturing differences. Technologies such as motion-capture and robotics may help to quantify motor problems in ASD.

Objectives: We aimed to quantify differences in imitative gesturing between ASD and TD using motion capture during human-robot interaction. We also aimed to determine whether scores on common clinical measures of motor function and symptom severity capture the full scope of imitation difficulties in ASD.

Methods: Thirty-two participants with ASD (n = 18) and TD (n = 14) imitated unilateral and bilateral social gestures of an interactive robot (e.g., wave). Participants and the robot were instrumented with reflective markers on corresponding head and body locations. Body position during imitation was tracked by an infrared motion-capture system. We used Dynamic Time Warping (DTW) to quantify the degree to which the participant's and robot's movement were aligned across the movement cycle. Participants also completed a battery of social, motor, cognitive, and behavioral assessments.

Results: We used repeated-measures ANOVA to test main and interaction effects of gesture type (fist bump, give, hug, wave, ask, celebrate) and group (ASD, TD) on imitation accuracy (DTW cost), including age as a covariate in the model. The main effect of gesture type was significant (F(5, 145) = 37.92, p < .001) with all gestures differing significantly from one another (ps < 0.005) except for "celebrate" and "wave". The main effect of the covariate, age, was significant (F(1, 29) = 5.27, p = 0.29,η_p^2 = 0.15), but its interaction with gesture was not (p > 0.05). The main effect of group was nonsignificant (F(1, 29) = 2.11, p = 0.16), with low observed power (0.29). The interaction of gesture and group was significant (F(5, 145)= 2.56, p = 0.03, η_p^2 = 0.08), with the ASD group demonstrating significantly lower accuracy for the "fist bump" and "celebrate" gesture types than the TD group. Imitation accuracy was correlated with MABC-2 aiming & catching, balance, and total scores for both the "fist bump" and "celebrate" gestures (ps < 0.05), but not ADOS-2 scores.

Conclusions: Preliminary results revealed kinematic differences between ASD and TD in imitative accuracy, which related to clinical motor assessments. Future analyses will include examination of positional matching for specific joint angles (e.g., elbow flexion/extension), as well as correlational analyses for additional clinical tests. Imitative gesturing is a building block to later development of social-communication skills; difficulty with reproduction and functional use of gestures may negatively impact social engagement, and in turn, learning opportunities. It is

important to understand the underlying motor control and sensorimotor integration mechanisms that support imitative gesturing in ASD in order to identify appropriate intervention targets.

280 **147.280** The Relation between Preference for Predictability and Autistic Traits

J. Goris[1], *M. Brass*[1], *J. R. Wiersema*[2] *and S. Braem*[3], *(1)Department of Experimental Psychology, Ghent University, Ghent, Belgium, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (3)Department of Psychology, Vrije Universiteit Brussel, Brussels, Belgium*

Background: A common idea about individuals with autism spectrum disorder (ASD) is that they have an above average preference for predictability and sameness. In fact, this idea is central to recent predictive coding accounts of ASD, that propose that a deficit in dealing with unexpected information could be the single impairment accounting for all ASD symptoms. However, the precise mechanisms underlying these preferences received surprisingly little attention in research.
Objectives: In the current study, we investigated whether we could observe this common symptom of ASD under controlled experimental conditions using three different paradigms. We used a dimensional approach in order to estimate the correlation between autistic traits and preference for predictability.

Methods: A large sample of participants (*n* = 164) was presented with three tasks that each measured preference for predictability in a different way, including both explicit and implicit measures. The first task assessed aesthetic preferences for sequences of tones that varied in their predictability. In the second task, we measured preference for perceptual fluency. The third task consisted of choosing between decks of cards with reward outcomes varying in predictability. Autistic traits were measured by using the Autism Spectrum Quotient (AQ) and Social Responsiveness Scale (SRS).

Results: We observed a significant positive correlation between autistic traits and preferences for both predictable sequences of tones and perceptual fluency. However, there was no correlation between behavior in the cards task and autistic traits.

Conclusions: These results show that there is a relation between autistic traits and preference for predictability in a standardized lab environment, but that this is restricted to specific situations. Our findings might indicate that the correlation is only apparent when preferences are explicitly measured as compared to implicitly investigated, and that transferring preferences from one context to another might be disturbed in ASD. However, as these studies are only a first step towards a better understanding of insistence on sameness, more research is necessary. Overall, we hope that these studies might inspire future systematic investigations into this key symptom of ASD.

281 **147.281** Problems with Sensory Information Processing in Sexual Offenders with an Autism Spectrum Disorder Who Are Treated in a Forensic Psychiatric Clinic. a Qualitative, Exploratory Study.

W. Radius[1], *S. Lammers*[2], *R. Bosch*[3] *and J. W. Hummelen*[4,5], *(1)Forensic Psychiatry, GGNet FPA 'de Boog', Warnsveld, Netherlands, (2)Clinical Psychology, Nijmegen University, NIjmegen, Netherlands, (3)forensic psychiatry, GGNet FPA 'de Boog', Warnsveld, Netherlands, (4)Criminal Law, Rijksuniversiteit Groningen, Groningen, Netherlands, (5)University of Groningen, Groningen, Netherlands*

Background:
In recent years abnormalities in sensory functioning have been increasingly regarded as an important, even a central characteristic of autism spectrum disorder (ASD). Yet these abnormalities are still a neglected area in the forensic diagnosis and treatment of offenders with an ASD.

The current study was conducted in a (medium risk) forensic psychiatric clinic and out- patient clinic in the Netherlands, specialized in the treatment of (high functioning) sexual offenders with an ASD.

Research shows that the diagnosis ASD, on a group level, does not imply an increased risk for sexual offending. With regard to people with ASD who did commit sexual crimes, theorists have hypothesized that almost every characteristic of the autistic phenotype could potentially contribute to the likelihood of committing such an the offence. Abnormal sensory information processing however, is a neglected area in this respect.

Objectives:

The objective of this study was to explore the role of abnormal sensory information processing in the lives of forensic ASD patients who committed sexual offences. The research questions were:

- Do these patients in effect experience abnormalities in their processing of sensory stimuli?

- Do these abnormalities pose problems for them in their everyday lives and, if so, how do they cope with these difficulties?

- Do they perceive a relationship between these problems and their criminal sexual behaviour?

Methods:

Eight adult male patients participated after informed consent. Research design: 'thematic analysis', a qualitative method for identification and analysis of patterns in a qualitative dataset. Specialized software (Atlas.ti) was used to facilitate analysis. The data were acquired with a semi-structured interview. The interviews were taped and transcribed. A set of codes covering all aspects of the phenomena under investigation was carefully constructed. The interviews were subsequently coded and the analysis was conducted on the resulting data.

Results:

All respondents experienced several types of abnormal sensory information processing. Visual, tactile and auditory oversensitivity were the most prevalent. Five patients had problems with the filtering of multiple sensory stimuli or with the integration thereof. Seven out of the eight respondents experienced severe problems as a result of their abnormal sensory processing. Problems that affected their social relationships in a negative way were most mentioned. Coping strategies that patients used were overwhelmingly the avoidance of situations involving problematic sensory stimuli. In the majority of cases this resulted in social isolation. Four out of eight patients described a relation between these sensory problems and their sexual offences.

Conclusions:

Although this exploratory study has its limitations, the results indicate that abnormal sensory processing may pose real problems for many forensic patients with ASD who committed sexual offences and may be a risk factor for offending. Careful assessment of, and attendance to, these

problems may improve treatment quality and contribute to the reduction of recidivism.

Poster Session
148 - Social Cognition and Social Behavior
5:30 PM - 7:00 PM - Room: 710

282 **148.282** Conjoint Effects of ASD Status and ADHD Symptom Severity on Inflated Social Self-Perception in Youth

T. M. Abu-Ramadan[1], *A. H. Gerber*[1], *E. J. Libsack*[1], *F. Noor*[1] *and M. D. Lerner*[2], *(1)Stony Brook University, Stony Brook, NY, (2)Psychology, Stony Brook University, Stony Brook, NY*

Background:
Inflated self-perception, or positive illusory bias (PIB) is a common phenomenon in youth (Barry, 2011), particularly among those with ADHD (Owens et al., 2007; Emeh et al., 2014). PIB is associated with negative outcomes in individuals with ADHD including aggressive behavior, poor social functioning, and poor treatment response (Hoza et al., 2010; Mikami et al., 2010). Recent research suggests that PIB may also be evident in individuals with ASD (Lerner et al., 2012). Crucially, ADHD is highly comorbid with ASD, with up to 80% of individuals with ASD meeting criteria for ADHD (Rommelse et al., 2010). Due to the high rate of comorbidity, it is plausible that PIB in individuals with ASD is an artifact of their ADHD symptoms, rather than a unique phenomenon in ASD, or that ASD and ADHD confer additive influences. To date, no study has investigated this conjoint influence in PIB.

Objectives:

To investigate the relative contributions of ASD status and ADHD symptom severity on PIB in a large sample of youth with and without ASD.

Methods:

Parents completed a developmental history questionnaire on 142 youth (102 male) ages 7-17 (M_{age} = 12.51, SD_{age} = 2.46) which included information on diagnoses. Adolescents and their parents completed the Social Skills Improvement System (SSIS; Gresham & Elliot, 2008), a measure of social skills. ADHD symptom severity was measured using the parent-reported ADHD Combined-type severity score from the Child & Adolescent Symptom Inventory (CASI-5; Gadow & Sprafkin, 2013; Table 1). Effects were also examined for Hyperactive- and Inattentive-type ADHD. PIB was measured using difference scores on the SSIS (see Table 1). Hierarchical multiple regression was used to predict PIB based on ASD status (to ascertain the relationship of ASD diagnosis to PIB), ADHD severity (to determine its relative influence on PIB), and their interaction (to determine if any ADHD severity effect is unique to those with ASD), controlling for ADHD status (to isolate symptom severity and clinical diagnosis effects).

Results:

ASD status predicted PIB (Table 2). After controlling for ASD status, ADHD severity predicted PIB, and ASD status no longer predicted PIB (Table 2). This effect held after controlling for ADHD status and the ASD status x ADHD severity interaction. Effects did not differ by ADHD symptom type.

Conclusions:

This is the first study to examine the conjoint effect of ASD status and ADHD symptom severity on PIB. While ASD status predicted PIB, this effect was reduced when ADHD severity (itself a predictor of PIB) was modeled. This was neither attributable to ADHD diagnosis, nor specific to youth with ASD. Thus, results suggest that, in a sample of youth with and without ASD and ADHD, while ASD does confer elevated PIB, this effect is partially accounted for by ADHD symptom severity regardless of ASD status. This suggests the presence of shared additive (but not multiplicative) influence of ASD status and ADHD symptom severity on social self-perception. Given the high rate of ADHD symptoms in ASD populations, this helps explain how and when PIB manifests in youth with ASD.

283 **148.283** Coordinating Attention to Faces Relates to Response to Joint Attention in the First Year of Life

I. Stallworthy[1] *and J. T. Elison*[2], *(1)Institute of Child Development, University of Minnesota, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN*

Background:
Responding to joint attention (RJA), or the ability to share attention to an object with another, emerges in the first year of life and is a pivotal skill, foundational for later language and social development. The relative roles of social understanding and features of objects in the environment for early RJA have long been debated (Moore & Dunham, 1995), and are central to understanding the emergence and developmental significance of RJA, and RJA-related deficits in autism spectrum disorder (ASD).

Bakeman and Adamson' (1984) characterized two interactive infant-caregiver play states. During *passive joint engagement*, infants focus primarily on a shared object in the presence of another. *Coordinated joint engagement* involves infants' active coordination of attention between another person and an object, increases from 6 to 18 months, predicts language outcomes, and exhibits deficits in toddlers with ASD (Adamson et al., 2009).

Objectives:

This study takes a micro-analytic approach to quantifying passive and coordinated joint engagement states in the context of RJA. This study examined whether where infants look directly after responding to an RJA bid was associated with response sophistication. We hypothesized that the amount of social gaze directly after RJA would increase with age, and positively relate to RJA sophistication, while the amount of non-social gaze directly following RJA would decrease with age and not relate to RJA sophistication.

Methods:

We measured RJA using the Dimensional Joint Attention Assessment (*DJAA;* Elison et al., 2013). This measure characterizes individual differences in infants' RJA abilities using 4 series of hierarchically ordered joint attention bids varying in cue redundancy. Higher DJAA scores (range 0-4) reflect the ability to respond to subtler, less redundant bids (i.e., gaze shift and head turn cues, vs. gaze shift, head turn, *and* verbal cue) for joint attention. The DJAA was administered during naturalistic play at 125 assessments of 90 typically developing infants aged 8 to 16 months

(mean=11.4).

The targets of infants' gaze directly after responding to each RJA bid were coded offline and categorized as *social* (i.e., looking to the face of the experimenter or caregiver) or *non-social* (i.e., looking to a toy, object, or anywhere). The proportion of infants' social and non-social post-RJA looks were calculated for each DJAA assessment. Analyses employed linear mixed models with sex as a covariate.

Results:

Results indicate that age did not predict the proportion of social (t(95)=0.14, p=0.89) or non-social looks (t(121)= 1.52, p=0.13) directly following RJA. However, over and above age-related increases in mean DJAA scores (t(56)=5.43, p<0.01), the proportion of social looking directly after RJA positively predicted mean DJAA scores (t(56)=2.16, p=0.034). Conversely, the proportion of such non-social looks did not predict mean DJAA scores (t(64)=0.96, p=0.34).

Conclusions:

Findings suggest that infants of all ages who reference those around them after responding to an RJA bid exhibit more sophisticated abilities to respond to others' joint attention cues. Despite the central role of objects in joint attention contexts, the ability to coordinate attention with others after following gaze may play an important role in the emergence of RJA sophistication early in life.

284 **148.284** Diagnosis or Not: Dimensional Autism Symptoms Are Related to Adaptive Social Skills across Adults with and without an Autism Diagnosis

J. R. Bertollo *and A. Scarpa, Virginia Polytechnic Institute & State University, Blacksburg, VA*

Background: Adaptive social functioning is often impaired in individuals with Autism Spectrum Disorder (ASD) relative to their typically developing peers and is a well-established measure of functional outcomes for these individuals. This discrepancy cannot be explained entirely by intellectual functioning and seems to widen over the lifespan, as research suggests an increase in adaptive functioning deficits in ASD with age. However, less is known about the relationship between subclinical ASD symptoms (i.e., in those individuals who do not meet for a diagnosis but present with symptoms of ASD) and adaptive social skills, which may reveal important, unique needs of individuals who do not currently qualify for services by diagnostic standards. The current study seeks to fill this gap. We hypothesized that dimensional autism symptoms would explain variance in adaptive social skills, above and beyond an individual's intellectual functioning, age, and ASD diagnosis, particularly for adults.

Objectives: To explore the relationship between a dimensional report of autism symptoms and adaptive social skills across individuals with and without autism, controlling for diagnosis.

Methods: A total of 74 participants with and without ASD were included in this study. This included 35 adults (40% Male; 60% ASD) and 39 children (85% Male; 64% ASD) who completed the Adaptive Behavior Assessment System, Second or Third Edition (ABAS) and Autism Spectrum Quotient (AQ). Analyses of adults and children were conducted separately to account for differences in raters and assessment versions. A series of hierarchical regressions were conducted for each age group with ABAS Social Domain standard score as the dependent variable. We first controlled for IQ, age, and ASD diagnosis, and then added the AQ total raw score in the subsequent model. Results of the model comparisons are reported.

Results: For adults, the covariates of IQ, age, and ASD diagnosis accounted for 30.6% of variance in adaptive social skills, although diagnosis was not statistically significant. Autism symptoms on the AQ accounted for an additional 14.7% of variance in adaptive social skills ($\Delta F_{1,30} = 8.06$, associated $p < 0.01$), indicating that greater ASD symptoms were associated with lower adaptive skills. There was no significant relationship between ABAS Social score and AQ total for children. See Table 1 for complete regression results.

Conclusions: This study suggests an association between dimensional autism symptoms and adaptive social skills for adults with and without ASD, even after controlling for ASD diagnosis. We did not find similar results for children, which may be a factor of age-related increases in adaptive skill deficits often seen in ASD. Our study is, however, limited by a small sample size. Future work should evaluate similar relationships with a focus on individuals without an ASD diagnosis, or below the "clinical cutoff" on the AQ, to confirm whether similar results are found within a purely sub-clinical population. In conclusion, this study sets the stage for future research to identify individuals who do not meet for a diagnosis of ASD but nonetheless display adaptive social skill deficits in their daily lives and may benefit from access to similar interventions.

285 **148.285** Differing Anxiety Levels in Youth with Autism Spectrum Disorder, Attention-Deficit Hyperactivity Disorder, and Both Diagnoses

D. Kumar[1]*, L. A. Santore*[1]*, E. Kang*[1]*, N. N. Capriola*[2] *and M. D. Lerner*[3]*, (1)Stony Brook University, Stony Brook, NY, (2)Psychology, The University of Alabama, Tuscaloosa, AL, (3)Psychology, Stony Brook University, Stony Brook, NY*

Background: Attention-Deficit/Hyperactivity Disorder (ADHD) is a common co-occurring neurodevelopmental disorder among youth with autism spectrum disorder (ASD; Lanes et al. 2016). Both children with ADHD or ASD individually, and those with comorbid ADHD and ASD, experience higher rates of total anxiety compared to typically developing (TD) peers (Bauermeister et al. 2007; White et al 2009; Wood & Gadow 2010), which impacts treatment response (Antshel et al., 2011; March et al., 2000). ASD youth often experience separation anxiety (van Steensel et al., 2011), social anxiety and generalized anxiety symptoms, while ADHD youth typically report heightened separation and generalized anxiety (Tsang et al., 2012). Therefore, there is reason to believe that ADHD and ASD may confer differential and conjoint risk for specific anxiety symptoms in youth. No study to date has examined the relative impact of having comorbid ASD and ADHD on specific anxiety symptoms in youth.

Objectives: This study investigates relationships between anxiety, ADHD, and ASD in order to determine if this co-morbidity can affect the presentation of anxiety. It was hypothesized that youth with comorbid ADHD and ASD would experience higher levels of overall anxiety, specifically separation, generalized, and social anxiety symptoms, compared to TD youth and youth with only one of the two disorders.

Methods: 86 participants (M_{age} = 13.71, SD_{age} = 1.83, 63 male) were divided into one of four diagnostic groups (Table 1). The ASD group met the criteria on the ADOS-2 (Lord et al., 2012). Youth who met criteria for ADHD exceeded the ADHD combined-type clinical cutoff on the parent-reported CASI-5 (Gadow & Sprafkin, 2013). Participants and their parents completed a measure of anxiety (MASC-2; March, 2013). One-way ANOVA was used to compare mean anxiety across groups.

Results: ASD+ADHD (*M*=60.13) and ASD only (*M*=59.17) groups had higher total parent-reported overall anxiety than the TD group (*M*=51.41; *p*=.050; see Figure 1). Both the ASD (*M*=58.70) and ADHD (*M*=66.50) groups self-reported greater overall anxiety than the TD group (*M*=51.66; *p*=.04). Regarding specific anxiety symptoms, parent-reported separation anxiety was higher in the ASD+ADHD group (*M*=60.04) than the ASD (*M*=53.03) and TD (*M*=51.31) groups, and in the ADHD group (*M*=64.50) than the TD group (*p*=.03). Self-reported separation anxiety was higher in the ADHD group (*M*=73.00) than the ASD+ADHD (*M*=59.22) and ASD groups (*M*=57.90), all of which were higher than TD (*M*=50.45) youth (*p*<.001). Neither parent- nor self-reported generalized anxiety or social anxiety symptoms differed significantly between groups (all *p*>.15).

Conclusions: Parents reported higher separation anxiety symptoms in the ASD+ADHD group relative to all other groups, while youth with ADHD reported themselves to experience higher levels of separation anxiety in comparison to other groups. When comparing individuals with ASD and ADHD separately, ADHD was particularly associated with co-occurring separation anxiety. Overall, ASD and ADHD both confer risk for anxiety in youth, but those with ADHD may be more likely to develop separation anxiety over other types of anxiety. Our results have implications for the nosology, taxonomy, and etiopathology of these common complex comorbidities in youth.

286 **148.286** Discrepancies between Parent- and Self-Reported Social Skills in Autism Spectrum Disorder: Magnitude and Treatment Effects

K. M. Normansell[1], *K. M. Hauschild*[1], *E. Kang*[2] *and M. D. Lerner*[1], *(1)Psychology, Stony Brook University, Stony Brook, NY, (2)Stony Brook University, Stony Brook, NY*

Background:

While most people usually rate themselves as "above average" on objective measures of performance (e.g., test performance; Kreuger & Dunning, 1999), for certain populations the discrepancy between self- and other-report ratings is particularly pronounced (i.e., the positive illusory bias; Hoza et al., 2000; Gresham et. al., 2000). This bias is particularly pronounced among those with developmental disorders. For instance, youth with ADHD persistently over-estimate their own skills relative to others' reports of their skills (Owens et al., 2007). A growing body of literature suggests that youth with autism spectrum disorder (ASD) exhibit a similar – perhaps even greater – discrepancy (Lerner et. al., 2012; Vickerstaff et. al., 2007; Kalyva, 2010). While social skills interventions have been shown to affect parent- and self-reported social skills independently (Gates et. al., 2017; Lerner et. al., 2011), the impact they may have on this informant discrepancy remains unknown. Similarly, it is unclear what role common treatment moderators (e.g., age, sex, comorbidity) may play in this relationship.

Objectives:

To investigate the impact of a social skills intervention program on the discrepancy between parent- and child-rated social skills in adolescents with ASD.

Methods:

Adolescents and their parents (Table 1) completed the Social Skills Rating System (Gresham & Elliot, 1990) before and after participating in an empirically-supported intervention (McMahon et al., 2013) known to increase both self- and parent-reported social skills for youth with ASD (Lerner, Mikami, & Levine, 2011). These activities provided the participants with additional opportunities to practice social skills in an engaging and reinforcing group environment (Lerner, Mikami, & Levine, 2011).

Results:

Adolescents rated their own social skills higher than their parents rated them both pre-intervention ($t(44) = 7.84$, $p < .001$) and post-intervention ($t(44) = 6.53$, $p < .001$). However, the discrepancy between child- and parent-reports was significantly smaller post-intervention than pre-intervention ($t(44) = 2.16$, $p = .04$); this effect was driven by an increase in parent-reported scores rather than a reduction in child reported scores. Hierarchical multiple regression analyses revealed that older adolescents experienced a relatively greater reduction in discrepancy than their younger peers (Table 2).

Conclusions:

This is the first study to assess the impact of a social skills intervention program on the discrepancy between parent- and child-rated social skills for adolescents with ASD. Results indicated that while adolescents with ASD overestimate their abilities relative to parent-report even after undergoing social skills treatment, the magnitude of discrepancy reduces following a social skills intervention program. This indicates two potential explanations for our findings: either the adolescents are showing real improvements and their ratings that reflect increased skill and awareness of the skills, or we are observing parents' tendency to report changes due to expectancy effects that are common within intervention research (Jones et al., 2017). In order to tease this apart and discover the cause of the discrepancy decrease, further research should employ the use of peer-report and observational data of social skills. This will help us to understand if social skills interventions are truly increasing social skills and/or self-awareness.

287 **148.287** Effect of Diagnostic Disclosure on First Impressions of Autistic Adults Made By Autistic and Neurotypical Observers

K. M. DeBrabander[1], *K. E. Morrison*[1], *D. R. Jones*[1], *D. Faso*[2], *M. Chmielewski*[3] *and N. J. Sasson*[1], *(1)University of Texas at Dallas, Richardson, TX, (2)nonPareil Institute, Plano, TX, (3)Southern Methodist University, Dallas, TX*

Background: Although adults on the autism spectrum (ASD) receive unfavorable first impressions from typically-developing (TD) adults, impressions improve when TD adults are made aware of their diagnosis (Sasson & Morrison, 2017). It is unclear, however, whether these patterns extend to autistic adults evaluating other autistic adults. Some work suggests autistic adults evaluate other autistic adults similarly to TD controls (Grossman et al., 2018), yet other evidence indicates autistic adults perceive autistic adults differently than TD peers (Milton, 2012).
Objectives: This study compared the first impressions of ASD and TD adults made by ASD and TD raters and examined how diagnostic disclosure affected those impressions.

Methods: ASD (*n* = 32) and TD raters (*n* = 62) adults served as rater participants. Each viewed 10 second videos of ASD (n =20) and TD (n = 20) stimulus participants introducing themselves (Sasson et al., 2017). Each video was presented with either an accurate diagnostic label (e.g. ASD adults as "this person has autism" and TD adults as "this person has no diagnosis"), or no label. Raters were then asked to give their first impression of the stimulus participant, rating six traits (e.g., awkwardness) and four behavioral intentions (e.g., desire to live near; Sasson et al.,

2017).

Results: TD stimulus participants were rated more favorably than ASD stimulus participants on awkwardness, attractiveness, and dominance, and received stronger interest in hanging out with, sitting near, and having a conversation with from all raters (*p*s<.002). Compared to ASD raters, TD raters evaluated stimulus participants as less attractive but were more willing to hang out with them (*p*s<.02). ASD raters were more willing than TD raters to live near TD and ASD stimulus participants (*p*s<.03), but TD raters were more comfortable sitting near TD stimulus participants than they were ASD raters (*p*=.03).

Including an accurate diagnostic label was related to more favorable ratings on likeability and trustworthiness, and greater willingness to hang out with and start a conversation with stimulus participants (*p*s<.02), relative to when a diagnosis was withheld.

TD raters gave more favorable ratings to ASD stimulus participants when an accurate diagnostic label was provided compared to no label on awkwardness, likeability, comfort living near, and willingness to start a conversation with (*p*s<.01). In contrast, these patterns did not extend to ASD raters, whose ratings for ASD stimulus participants did not improve with a diagnostic label, and actually worsened for awkwardness ratings (*p*=.04).

Conclusions: Results suggest similarities and differences in how autistic adults are evaluated by TD and ASD adults. Overall, ASD participants were rated less favorably than TD participants by both groups. ASD raters expressed lower interest in hanging out with participants regardless of their diagnosis, and reduced comfort sitting next to TD participants. Further, only TD raters improved their ratings of ASD participants when a diagnosis was provided. ASD raters even evaluated ASD participants as *more* awkward when their diagnosis was known. Diagnostic disclosure therefore appears to improve first impressions of autistic adults made by TD but not by ASD raters.

288 **148.288** Effect of Intranasal Oxytocin on Visual Processing and Salience of Human Faces

L. Westberg[1], *D. Hovey*[2], *S. Leknes*[3], *B. Laeng*[3] *and L. Martens*[3], *(1)University of Gothenburg, Gothenburg, Sweden, (2)Department of Pharmacology, University of Gothenburg, Gothenburg, Sweden, (3)Department of Psychology, University of Oslo, Oslo, Norway*

Background: There is still no pharmacological treatment available for improving the core symptoms of autism. Promise has emerged from studies showing that treatment with the neuropeptide oxytocin promotes attention to social cues, and alleviates autism symptoms in patients. However, the underlying mechanisms of oxytocin's actions remain undetermined. Social salience hypothesis suggest that oxytocin increases the salience of social cues, which in turn can modulate the influence of context and inter-individual factors on social behavior. Salience of cues can be manipulated through binocular rivalry, a visual phenomenon that has been extensively used to study visual perception. In a binocular rivalry paradigm the eyes are presented with two discordant images, that compete for visual awareness – i.e. each eye is continuously exposed to only one of two images, but the image that the viewer subjectively perceives is one or the other ("dominant" percept), or a mix of the two ("piecemeal" percept).

Objectives: This study investigates if oxytocin treatment may affect binocular rivalry, a measure of visual perception and interplay of excitation and inhibition in the cortex. Binocular rivalry has been previously shown to be deficient in individuals with autism.

Methods: We recruited 50 male volunteers, and carried out a randomized, double-blinded, cross-over study of the effects of intranasal oxytocin on binocular rivalry. The participants viewed images of social stimuli (faces with different emotional expressions) and non-social stimuli (houses and Gabor patches) as salience of social cues was quantified using duration of dominance for social and non-social stimuli.

Results: We demonstrate a robust effect that intranasal oxytocin increases the salience of human faces in binocular rivalry, such that dominance durations of faces are longer – this effect is not modulated by the facial expression. We tentatively also show that oxytocin treatment increases dominance durations for non-social stimuli.

Conclusions: Our results lend support to the social salience hypothesis of oxytocin, and in addition offer provisional support for the role of oxytocin in influencing excitation-inhibition balance in the brain.

289 **148.289** Efficacy Study of a Social-Communication and Self-Regulation Intervention for School-Aged Children with Autism Spectrum Disorder: A Randomized Controlled Trial

S. W. Nowell[1], *L. R. Watson*[2], *B. A. Boyd*[3] *and L. G. Klinger*[4], *(1)University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Juniper Gardens Children's Project, University of Kansas, Kansas City, KS, (4)TEACCH Autism Program; Psychiatry, University of North Carolina, Chapel Hill, NC*

Background:

The Growing, Learning, and Living with Autism (GoriLLA) group intervention is a blend of two widely used approaches: Structured TEACCHing (Klinger et al., 2006) and Social Thinking (Hendrix et al., 2013; Winner & Crooke, 2009). This intervention is designed to increase social-communication and self-regulation skills in children with ASD, and is parent-assisted to promote generalization of skills. Components of Social Thinking are commonly used for children with ASD, but lack an established evidence-base. In fact, very few RCTs have been conducted with this type of social-cognitive intervention package for young children and even fewer examining the role of parents.

Objectives:

This study aimed to examine the initial efficacy of the GoriLLA group intervention

Methods:

Participants were 17 1st and 2nd grade children with ASD (ages 6 to 9 years), and their parents. A randomized delayed treatment control group (DT) design was used with pre- and post-intervention assessments of parent and child intervention strategy knowledge and generalization of strategies as observed during a parent-child play interaction. Fidelity was monitored at each session. Two follow-up assessments were completed at 3 and 6 months post-intervention, corresponding to pretreatment and posttreatment assessments for the DT group.

Measures

The Child Observation Protocol (COP) is a semi-structured observational measure of child knowledge learned in the intervention. Internal consistency of the COP was fair to good (Cronbach's alpha at pretest = .76; at posttest = .81). ICC for the total score was .97.

The Parent Report of Group Outcomes (PROGO) consists of 12 multiple choice questions tapping parent knowledge related to intervention

concepts. Cronbach's alpha at Time 1= .55, Time 2= .66.

The 3 Box Task (Brady-Smith et al., 1999; NICHD, 1999; Vandell, 1979) is a semi-structured parent-child play observation of social interaction skills. This task served as a measure of the generalization of strategies practiced in the groups to parent-child interactions.

Results:

Intervention fidelity was strong based on measures of attendance, adherence, clinician quality, and behavior management. Repeated measures ANOVAs revealed significant overall time by group effects for the PROGO, $F(1,15) = 7.06$, $p \leq .02$, $\eta 2 = .32$ and COP, $F(1,15) = 6.90$, $p \leq .02$, $\eta 2 = .32$, favoring the intervention group over the DT group. The effects of the intervention did not extend to parent-child interactions. All effect sizes were promising despite the small sample size (see Table 1). ANOVAs from the 3 to the 6 month follow-up assessments showed significant gains in the intervention group $F(1,6) = 10.46$, $p < .02$, but not the DT group $F(1, 8) = 4.10$, $p < .10$, although there was a trend toward replication of the effects of the GoriLLA Group intervention on the COP for the DT group (see Figure 1).

Conclusions:

Overall, the results of this study indicate that the GoriLLA Group intervention package is effective in teaching social-communication and self-regulation concept knowledge to children with ASD and their parents. Both parents and children demonstrated an increase in social-communication and self-regulation knowledge after participating in the intervention as compared to a control group.

290 **148.290** Emotion Dysregulation and Empathic Behavior Among Adolescents with ASD: A Pilot Study

E. Zadok[1], *R. Navon*[1], *I. Gordon*[1,2] *and O. Golan*[1], *(1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Gonda Brain Research Center, Bar-Ilan University, Ramat Gan, Israel*

Background: Empathy is a key component of socio-emotional interaction. Empathy research suggests that individuals with ASD have specific impairments in cognitive empathy (seeking and interpreting socio-emotional cues) whereas their affective empathy (emotional contagion) is intact. However, findings are contradictory, and there may be a gap between the abilities individuals with ASD display in mentalizing tasks and the use of these abilities in real-life situations, due to higher complexity of the latter, thus calling for a use of more ecologically valid paradigms.
Objectives: To explore the mechanisms underlying empathy deficits among adolescents with ASD, using a behavioral paradigm and eye tracking.

Methods: Six adolescent males with ASD (clinically diagnosed and verified using ADOS-2) with no intellectual impairment, and eight typically developing (TD) male controls, matched on age and cognitive abilities, were video-recorded while undertaking the Prosocial Empathic Behavioral Assessment (PEBA) - an ecological paradigm that involves 3 minutes of a friendly interaction with an unfamiliar peer, one minute of a response to the peer's sudden distress (following a disturbing text message), and one minute of a return to friendly interaction. Participants wore eye tracking glasses (SMI model 2WA). Socio-emotional behaviors during the last three minutes of the interaction (friendly-distress-back to friendly, each one minute long) were coded minute by minute by trained blind raters.

Results: Behaviorally, in the *friendly* phase the groups displayed similar levels of appropriate affect, whereas in the *distress* phase adolescents with ASD displayed lower levels of appropriate affect, compared to the TD group. This difference persisted in the *return to friendly* phase. Levels of vocal synchrony differed between groups significantly only in the *distress* phase, due to a decrease in the ASD group. In contrast, levels of facial expression synchrony were significantly lower in the ASD group compared to controls in the *friendly* and *return to friendly* phases only. Eye tracking has shown that whereas in the *friendly* phase fixation time on the peer's upper face was similar in both groups, in the *distress* phase adolescents with ASD fixated less than controls on the upper face, a trend that persisted in the *return to friendly* phase.

Conclusions: These preliminary results demonstrate an altered empathic response in adolescents with ASD, which was characterized by a reduced display of appropriate affect and vocal synchrony and diminished eye gaze to the peer's eye region. The latter may reflect an attempt of participants with ASD to down-regulate their own arousal.

The inappropriate affect and diverted eye gaze persisted when the peer allegedly overcame her distress and restored friendly interaction. Furthermore, when the peer *returned to a friendly* conversation, TD adolescents regained facial expression synchrony, while adolescents with ASD did not. These findings may indicate a difficulty among adolescents with ASD to regulate their own emotions and to adjust them to the partner's changing mental state. Future research could include psychophysiological measurement in order to further clarify the role of emotion regulation in adolescents' empathic behavior.

291 **148.291** Emotion Regulation Skills Predicts Friendship Quality in Children with Autism

H. J. Nuske[1], *W. I. Shih*[2], *N. Sparapani*[3], *Z. L. Atkinson-Diaz*[4], *E. Fischer*[5], *D. S. Mandell*[1], *C. Kasari*[2] *and .. AIRB-1 team*[6], *(1)Center for Mental Health, University of Pennsylvania, Philadelphia, PA, (2)University of California, Los Angeles, Los Angeles, CA, (3)School of Education, University of California, Davis, Davis, CA, (4)University of Pennsylvania, Philadelphia, PA, (5)Developmental and Behavioral Pediatrics, University of Rochester Medical Center, Rochester, NY, (6)University of California Los Angeles, Los Angeles, CA*

Background: Emotion regulation is associated with a host of positive outcomes in children with and without autism, including increased mental health, academic achievement, and the deduction of problematic behavior. Less is known regarding whether, and how, emotion regulation and dysregulation relate to social outcomes, such as friendship quality and feelings of loneliness.
Objectives: To examine the impact of emotion regulation and symptoms related to emotion dysregulation (externalizing and internalizing behavior) on friendship and loneliness in school-age children with ASD.

Methods: Across four sites, parents and teachers of 106 children with autism aged 5–12 (*M* = 8 years, *SD* =1.5 years) reported on children's emotional regulation skills as well as externalizing and internalizing symptoms, based on the frequency of these behaviors in home and school environments. Four-to-five months later, children reported on the quality of their friendship with their best friend (companionship, conflict, helpfulness, sense of relationship security, closeness) and their feelings of loneliness. Linear regression models were run to examine longitudinal emotion-regulation related predictors of friendship quality and loneliness in the children.

Results: Across time, fewer reported behavior problems and less emotion dysregulation predicted stronger companionship, increased aggressive behavior predicted more conflict, and more frequent externalizing and depressive symptoms predicted greater feelings of loneliness. Girls with autism had stronger companionship, security, and closeness with their best friend and rated their best friend as more helpful than did boys with

autism. Autism symptoms, IQ, and age were not associated with any aspects of friendship quality or loneliness (Table 1).

Conclusions: Results highlight the importance of targeting emotion regulation and mental health in interventions for school-aged children with ASD to help support friendship development and prevent loneliness. Findings also suggest that interventions targeting autism symptoms and IQ may not facilitate friendship development directly and confirm that girls have a protective advantage in friendship development.

292 **148.292** Examining Associations between Self-Report Measures of the Broader Autism Phenotype and Observed Theory of Mind, Auditory Processing and Effectiveness Communicating during a Collaborative Game

D. Bublitz[1], *V. Lee*[2], *J. Bishop*[3], *P. Y. Choudhury*[4] *and K. Gillespie-Lynch*[5], *(1)Dr., NY, NY, (2)Psychology, College of Staten Island, CUNY, Staten Island, NY, (3)English, City University of New York, Staten Island, NY, (4)CUNY, NY, NY, (5)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY*

Background:

Autism is increasingly conceptualized as the extreme end of a distribution of autistic traits that extends into the general population, known as the Broader Autism Phenotype (BAP; Sucksmith et al., 2011). Although difficulties with perspective taking are commonly observed early in development in autism (Baron-Cohen et al., 1985), evidence that reduced ToM is an aspect of the BAP in adulthood remains conflicted (Yang & Baillargeon, 2013; Sasson et al., 2013). However, strong evidence supports sensory differences as a core aspect of the BAP (Mayer, 2017; Robertson & Simmons, 2013). The current research investigates associations between self-report measures of the BAP and observed ToM, sensory differences (specifically auditory processing), and *in situ* communication among non-autistic college students.

Objectives:

1. Investigate associations between autistic traits, ToM and auditory processing

2. Evaluate if autistic traits, ToM and/or auditory processing contribute to success playing a collaborative language-based game

Methods:

College students without autism (*N* = 103; Age range = 18-28, 65 females) completed BAP assessments (the BAPQ and communication subscale of the AQ-Adult), ToM (Reading the Mind in the Eyes [RMET] test, The Awareness of Social Inference Test [TASIT]), an advanced test of ToM assessing sarcasm and lie detection using audiovisual stimuli), measures of speech and non-speech pitch sensitivity, and interactive computer-based games (the Columbia Games) requiring verbal communication to reach a joint goal of matching an object to a location described by one's partner (we focus here on accuracy and efficiency).

Results:

After conducting a square root transformation to correct skew in AQ communication, we ran correlations (Table 1). AQ communication and the pragmatic language subscale of the BAPQ were associated with each other and with RMET. The full BAPQ was *not* associated with RMET. The TASIT was only associated with RMET but demonstrated limited reliability; its subscales were not correlated. Heightened communication difficulties on the AQ were associated with *reduced* speech pitch detection while heightened pragmatic language difficulties on the BAPQ were associated with *greater* ability to detect pitch in non-speech stimuli. Only pragmatic language was associated with communicative success playing the game.

Conclusions:

Findings align with prior research conducted with family members of autistic people indicating that different aspects of the BAP represent separable phenotypes (Losh et al., 2008). By highlighting a specific relationship between the pragmatic language aspect of the BAPQ and ToM that was *not* apparent when relating ToM to the *entire* BAPQ, findings suggest that conflicted findings concerning associations between the BAP and ToM among adults may arise because of differences in the BAP and ToM measures used. Although each BAP communication subscale was associated with a different measure of pitch, the pattern of findings suggests that longitudinal research examining if early detection of non-speech relative to speech pitch leads to later communicative difficulties associated with the BAP might be fruitful. Given that the pragmatic language subscale of the BAPQ was the *only* predictor of successful in-person communication, ecologically valid strategies for promoting effective pragmatic language skills may be beneficial for college students with and without heightened autistic traits.

293 **148.293** Explaining Variance in Social Competence in School-Aged Children with Autism Spectrum Disorder

D. Alkire[1,2], *K. R. Warnell*[3], *L. A. Kirby*[4], *D. Moraczewski*[1,2] *and E. Redcay*[1,2], *(1)Neuroscience and Cognitive Science Program, University of Maryland, College Park, MD, (2)Department of Psychology, University of Maryland, College Park, MD, (3)Department of Psychology, Texas State University, San Marcos, TX, (4)Yale Child Study Center, New Haven, CT*

Background: Social competence likely depends on multiple social-cognitive and social-affective processes, yet few studies have assessed the relative importance of a range of constructs across these domains, and fewer still have done so in children with autism spectrum disorder (ASD). Deficits in theory of mind (ToM) are often hypothesized to substantially impair social functioning, yet evidence for this link is mixed. Empathy is also considered essential for social competence, and an important distinction may exist between cognitive empathy (recognizing or understanding others' emotions) and affective empathy (experiencing others' emotions in oneself).

Objectives: The present study is the first to our knowledge to directly compare relations between social competence and a range of social factors potentially affected in ASD: ToM, empathy, biological motion perception (BMP), social reward, and social anxiety.

Methods: In school-aged children with ASD (n=51, mean age: 11.48 ± 2.11 years, range: 7.11-14.87), we administered standard ToM tasks (Strange Stories and Reading the Mind in the Eyes), a BMP task featuring walking point-light figures embedded in noise, and the Social Reward Questionnaire (SRQ), from which we selected two subscales for the current analysis: Admiration and Prosocial Interactions. Parents reported on their children's ToM abilities (Theory of Mind Inventory (ToMI): Early, Basic, and Advanced subscales), empathy (Griffith Empathy Measure: cognitive and affective subscales), and social anxiety (Screen for Child Anxiety Related Disorders). Social competence was assessed using the Social Affect domain of the Autism Diagnostic Observation Schedule (ADOS).

Due to high collinearity between the ToMI subscales and between cognitive empathy and ToMI Early, we created a composite of these measures representing parent-reported ToM. Similarly, we created a composite of the two highly correlated SRQ subscales. Predictors also included verbal IQ, nonverbal IQ, and age.

To determine the subset of variables that best explain social competence, we performed Bayesian model selection, which quantified evidence (Bayes Factors; BF) for adding each predictor to the null (intercept-only) model. Then, to determine the relative importance of each predictor, we performed a dominance analysis, which calculates the change in R^2 when each variable is added to the model.

Results: Model selection indicated moderate evidence in favor of affective empathy predicting social competence (BF=3.6) but inconclusive evidence for the other predictors. The dominance analysis provided converging evidence, as affective empathy explained the most variance in social competence (11%), followed by verbal IQ (6%) and BMP (4%). The remaining predictors each accounted for 1% or less of the variance.

Conclusions: These findings suggest that for some individuals with ASD, social deficits are partly explained by a lack of emotional resonance with one's social partner. Our results do not support the hypothesized link between ToM and social functioning in ASD. However, we do not conclude that ToM and the other social domains represented in this study have no relevance for social functioning in ASD. Instead, our results could indicate the limitations of several commonly used behavioral measures, which may not capture the cognitive and affective processes most relevant to real-world social functioning.

294 **148.294** Exploring the Relationship between Visual Evoked Potentials and Visual Search in ASD: Results from the ABC-CT Interim Analysis

M. Kim[1], *A. Naples*[2], *F. Shic*[3,4], *S. J. Webb*[5], *M. Murias*[6], *C. Sugar*[7], *J. Dziura*[8], *C. Brandt*[8], *R. Bernier*[5], *G. Dawson*[9], *S. Jeste*[7], *C. A. Nelson*[10] *and J. McPartland*[2], *(1)Seattle Children's Research Institute, Seattle, WA, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (4)Pediatrics, University of Washington School of Medicine, Seattle, WA, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (6)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)University of California, Los Angeles, Los Angeles, CA, (8)Yale University, New Haven, CT, (9)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (10)Boston Children's Hospital, Boston, MA*

Background: Visual Evoked Potentials (VEP) are electrophysiological signals extracted from the visual cortex that are activated when visual pattern changes occur quickly (Odom et al., 2009). Research suggest that adolescent and adults with Autism Spectrum Disorder (ASD) exhibit lower P100 amplitudes in their VEPs compared to the Typically Developing (TD) individuals (Kovarski et al., 2016). It remains unknown how, or if these differences in brain activity are associated with corresponding higher order mechanisms of visual sampling. Visual pathways carry information to areas of the brainstem that organize and effect eye movements. Thus, the timing and organization of early sensory response may affect the planning and organization of eye-movements at a more cognitive level. Consequently, atypical low-level visual processing may be reflected in atypical Visual Search (VS) behavior, as exemplified by eye-tracking literature that has shown less exploratory eye scanning in children with ASD (Sasson et al., 2008).

Objectives: To explore the relationship between low level perceptual visual processing as measured by VEP and potentially higher-level visual search behavior as measured by the proportion of time spent in fixations in a VS paradigm in children with and without ASD.

Methods: 6-11 year olds with ASD (*n*=126) and TD (*n*=55) watched videos of flickering checkerboards (VEP) and viewed static image arrays, with each array composed of five social and nonsocial images (VS). Low-level visual processing was measured through P100 amplitudes during VEP. Higher-level visual processing was measured by fixation ratios (total fixation duration/valid looking time). Fixations were calculated by Li et al. (2016) with 1° spatial threshold and 100ms minimum fixation time. Correlations and ANCOVAS examined the relationships between the variables.

Results: TD showed higher VS fixation ratios (p=.009), suggesting that TD children spent more time extracting information from the scene than the ASD group, and controlling for IQ did not alter this relationship. Consistently, in the ASD group, higher VS fixation ratios were associated with less social impairment (higher ADOS Social Affect severity scores) (r=.19, p=.037). There were no between-group differences in P100 amplitude (p>.05), but within the TD group lower P100 amplitudes were associated with greater social impairment (r=-.15, p=.046). There were no relationships between P100 amplitude and fixation ratios within any of the groups or when the groups were combined even when controlling for age, ADOS, and/or IQ scores.

Conclusions: P100 amplitudes and eye tracking fixation measures were not found to be related in this study. However the VS results suggest that higher-order visual information processing may be impaired in ASD, with reduced visual sampling being associated with more autism symptomatology. The VEP results suggest that, while between-group differences were not observed, it is capturing some aspect of the continuum of social function across the TD population. The lack of relationship between the VEP and VS variables might be due to task differences between the EEG and ET paradigms, but could also signal a fundamental disconnect between neural and neurobehavioral markers. Lower-level visual perception may not prominently influence the higher-order visual exploratory deficits evident in children with ASD.

295 **148.295** Factors That Affect Performance in Children with ASD on the VEP Task: Results from the ABC-CT Interim Analysis

M. Santhosh[1], *S. J. Webb*[2], *C. Sugar*[3], *M. Sabatos-DeVito*[4], *M. Murias*[5], *G. Dawson*[6], *T. Howell*[7], *R. Bernier*[2], *C. Brandt*[8], *K. Chawarska*[9], *J. Dziura*[8], *S. Faja*[10], *S. Jeste*[3], *A. Naples*[9], *F. Shic*[11,12] *and J. McPartland*[9], *(1)Seattle Children's Research Institute, Seattle, WA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)University of California, Los Angeles, Los Angeles, CA, (4)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (5)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (6)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (7)Psychology and Neuroscience, University of North Carolina at Chapel Hill, Chapel Hill, NC, (8)Yale University, New Haven, CT, (9)Child Study Center, Yale University School of Medicine, New Haven, CT, (10)Boston Children's Hospital, Boston, MA, (11)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (12)Pediatrics, University of Washington School of Medicine, Seattle, WA*

Background: Autism Biomarkers Consortium for Clinical Trials (ABC-CT) aims to identify biomarkers to reliably measure treatment effects in autism spectrum disorder (ASD). This study focuses on analyses of Visual Evoked Potential (VEP) data collected during the EEG at two time points (baseline and 6 weeks). In the protocol, T2 visits were to occur 28-56 days after the T1 visit. Given that test retest reliability of the VEP (using ICC and presented at INSAR 2018) was .80 for the NT group and .68 for the ASD group, we examined the time between visits as a potential moderator of T1 and T2 response.

Objectives: To evaluate factors that impact data acquisition and the effect of the time of day and days between visits of T1 and T2 visits on the VEP EEG biomarker in participants with ASD.

Methods: Participants were 225 6- to 12-years-old children (TD: *n*=64; ASD: *n*=161) at 5 different sites who viewed videos of flickering checkerboards with central red fixation point while EEG was collected. Some of the outcome variables included total number of good trials, and P1 and N1 amplitude at Occipital Midline ROI.

Results: 79.5% children with ASD and 86% in the NT group provided valid data at T1 (χ^2= 1.249, p = .26). At T2, 83.9% children with ASD and 86% NT children provided data (χ^2= 3.883, p = .05). Time of day was coded as 1: A.M/2: P.M and was similar across both groups points (T1: χ^2=.579, p=.447; T2: χ^2 =3.33, p =.19).

Time between T1 and T2 visits and in whether the participant with ASD has valid T2 data collected (p=0.69) was not statistically significant. 10% children were excluded at T1 when tested at A.M, compared to 19% excluded at P.M, χ^2 = 3.732, p = .053. At T2, 7.8% children were excluded when tested at A.M; compared to 12.2% excluded P.M (χ^2 = .831, p = .36). Mean time between T1 and T2 did not differ for those children with and without T2 data. (p = .14)

Regression analysis showed that T2 performance was significantly predicted by both P1 and N1 amplitude in the ASD group at T1 (F=99.8, p < .001; F=135, p<.001). No effect of time between T1 and T2 or P1 variability was noted in T2 performance (t=-.041, p =.97); however, number of trials viewed at T2 did explain additional variability in the N1 amplitude (t=-1.921, p=.06).

Conclusions: Data loss was similar at T1 for both groups, however more ASD children provided data at T2, suggesting exposure to the protocol improved acquisition in ASD children. Testing time of visit time did not impact acquisition success consistently; however, T1 performance significantly predicted T2 performance in P1 and N1 amplitude. Overall, these analyses provide guidance on use of VEP in longitudinal clinical trials, specifically that children with ASD may perform better (higher acquisition rates) when given multiple times to attempt the EEG experiment; but that the distance between time-points (within a specified time frame) did not alter performance.

296 **148.296** From Bias to Behavior: Predicting Prejudice Towards Autistic Individuals

***J. Lipson**, C. Taylor, C. L. Dickter and J. Burk, College of William and Mary, Williamsburg, VA*

Background:

An increasing number of young people with an Autism Spectrum Disorder (ASD) diagnosis are entering the university population, but little research has examined bias that these individuals may experience in the university setting. The existing literature on bias towards individuals with ASD has typically focused on children and offers mixed results. Also, no study has attempted to investigate the connection between bias and behavior in the context of a peer interaction.

Objectives:

This study assessed bias against ASD individuals, by examining whether interacting with an individual they believed to be autistic would influence university students' judgments of and behaviors toward the individual. We also measured both explicit and implicit bias, as well as the relationship between bias and interaction behavior.

Methods:

The participants were 112 undergraduate students from a medium-sized Southeastern university. In Part 1 of the study, participants completed the Societal Attitudes Towards Autism Scale (SATA), an explicit measure of attitudes towards individuals with ASD. Next, participants completed an implicit association test (IAT) to measure implicit biases against individuals with ASD. During Part 2 of the study, participants completed an interaction task in which they spent 3 minutes discussing a neutral prompt with a trained confederate who displayed behaviors consistent with or inconsistent with ASD. A 2 x 2 factorial design was employed, in which the confederate portrayed either an ASD or neurotypical individual, and the participant was led to believe that the confederate belonged to a fictitious ASD Club, or not (non-ASD Club). Non-verbal behavior indicating implicit discomfort in the interaction was subsequently coded by research assistants.

Results:

A total of 56 participants completed all testing sessions and were included in the final data analyses (24 male; M_{age} = 19.00, *SD* = 1.11). Scores on the IAT were significantly higher than 0, p < .001, suggesting an overall implicit bias against ASD individuals. The mean score on the SATA, however, suggested an overall positive explicit attitude towards ASD individuals. Regression analyses revealed a significant IAT x Club interaction, β = .44, p = .015. For the ASD Club condition, there was a significant negative relationship between IAT and non-verbal behavior such that greater implicit bias was associated with more positive non-verbal behavior. For the non-ASD Club condition, there was a significant positive relationship between the two variables such that greater bias was associated with more negative non-verbal behavior. Finally, SATA was associated with more positive non-verbal behavior.

Conclusions:

We found an overall negative implicit bias against ASD individuals but overall positive explicit attitudes towards ASD individuals. Furthermore, more positive attitudes were associated with more positive non-verbal behavior. Implicit attitudes were also associated with non-verbal behavior, but this relationship differed as a function of whether participants thought they were interacting with an ASD individual or not. This work has implications for the experience of college students on the Autism Spectrum. Future research could help establish whether this is a product of social desirability bias.

297 **148.297** Gendered Play Behaviours in Children with and without Autism: A Population-Based Cohort Study

***L. Hull**[1], H. Heuvelman[2], J. Golding[2], A. Reichenberg[3], W. Mandy[1] and D. Rai[4], (1)University College London, London, United Kingdom of Great Britain and Northern Ireland, (2)University of Bristol, Bristol, United Kingdom of Great Britain and Northern Ireland, (3)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (4)Population Health Sciences, Bristol Medical School, Centre for Academic Mental Health, Bristol, United Kingdom*

Background:

Observation that males are more vulnerable than females to autism has led to several theories regarding the relationship between sex, gender and autism. One such theory is the fetal testosterone hypothesis, which proposes commonalities between a typical male cognitive trait profile and autism. This theory suggests that autism represents The Extreme Male Brain (EMB). However, opposing ideas exist, including Gender Identity

Defiance (GID) theory. This proposes that autism is characterised not by a typical male profile, but rather by a presentation that is at variance with sex/gender-typical characteristics.

Objectives:

To test contrasting predictions of the Extreme Male Brain and Gender Identity Defiance theories, via examining gendered play of autistic and non-autistic children.

Methods:

In a longitudinal population-based cohort (N = 10,750) we compared gendered play behaviours in children with and without autism on 3 occasions in early childhood. Gendered play behaviours were ascertained using the Pre-School Activities Inventory administered to parents at ages 2.5, 3.5, and 4.75 years. The Child Activities Inventory was also administered to children at age 8 years. Children with a diagnosis of autism were identified using multiple sources.

Results:

There was no evidence of a difference in gendered play behaviours between children with or without autism at ages 2.5 or 3.5 years. At age 4.75, the play of autistic boys appeared less masculine than that of non-autistic boys (β=-2.5, 95% CI -5.0 to -0.1). The play of autistic girls appeared less feminine as they became older, although these estimates suffered low statistical power (β =+3.4, 95% CI -1.7 to +8.5). Differences in self-reported play at age 8 were broadly consistent with earlier parent-reported differences, continuing the pattern of greater gender typicality for non-autistic children than for autistic children.

Conclusions:

Our results do not support the EMB theory, and are more consistent with GID theory: autism is characterised by sex/gender-variant play, not male-typical play. Importantly, differences appeared to arise through a lack of typical gender development in children with autism. Our findings highlight the importance of examining these differences in a developmental context.

298 **148.298** Hot and Cool Executive Function Have Different Mediating Effects on Theory of Mind in High-Functioning Children with Autism Spectrum Disorder

Y. T. Yu[1,2], *H. J. Li*[3], *C. H. Tsai*[4], *C. H. Lin*[5], *C. L. Hsieh*[1] *and K. L. Chen*[2], *(1)School of Occupational Therapy, College of Medicine, National Taiwan University, Taipei, Taiwan, (2)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (3)Department of Child and Adolescent Psychiatry, Kaohsiung Municipal Kai-Syuan Psychiatric Hospital, Kaohsiung, Taiwan, (4)Department of Child & Adolescent Psychiatry, Kaohsiung Municipal Kai-Syuan Psychiatric Hospital, Kaohsiung, Taiwan, (5)Department of Psychiatry, Chi Mei Medical Center, Tainan, Taiwan*

Background:

Children with autism spectrum disorder (ASD) often show difficulties in executive function (EF) and theory of mind (ToM). The relationship between EF and ToM has been greatly debated due to their developmental coexistence. Previous studies have mainly focused on the association between the cognitive aspect of EF (i.e., cool EF) and ToM in children with ASD, so understanding of the influence of the affective aspect of EF (i.e., hot EF) on ToM is limited, not to mention the separate influences of cool and hot EF on ToM. Separating EF into cool and hot aspects to understand the linkage between EF and ToM could extend current understanding of the cognitive difficulties of children with ASD and be useful in assessment and intervention in clinical practice.

Objectives:

This study examined the mediating effects of cool and hot EF on ToM to elaborate the link between EF and ToM in high-functioning children with ASD.

Methods:

Children with high-functioning ASD aged from 4 to 12 years old were recruited from hospitals, clinics, and developmental centers in Taiwan between January 2015 and June 2018. Children's ToM, cool EF, and hot EF were respectively measured with the Theory of Mind Task Battery, computerized Dimensional Change Card Sort (DCCS) task, and Children's Gambling Task. The DCCS generates four cool EF variables. Mediation analysis was applied to assess whether cool/hot EF mediated the effect of hot/cool EF on ToM. A complete mediator would have an insignificant direct effect (X→Y) and a significant indirect effect (X→M→Y); a partial mediator would have both a significant direct effect and an indirect effect.

Results:

A total of 118 high-functioning children with ASD (104 boys) participated in this study. On average, they had severe ASD symptoms and average verbal comprehension respectively, as determined by the Social Responsiveness Scale, Second Edition (mean = 78.9, SD = 10.2) and the Verbal Comprehension Index (mean = 106.9, SD = 16.4). The mediation analysis showed that cool EF was a complete mediator of the effect of hot EF on ToM (indirect effect: 0.01 [95%CI: 0.00–0.04] and direct effect: 0.05 [95%CI: -0.00–0.11]), whereas hot EF was a partial mediator of the effect of cool EF on ToM (indirect effect: 0.99 [95%CI: 0.05–2.55] and direct effect: 4.87 [95%CI: 0.48–9.26]).

Conclusions:

Both cool and hot EF were correlated with ToM in high-functioning children with ASD. Interestingly, the influence of hot EF on ToM could occur simply through cool EF, while the influence of cool EF on ToM could happen partially through hot EF. Our findings highlight the necessity of considering the distinction of hot and cool EF in clinical assessment and intervention for children with high-functioning ASD.

299 **148.299** I Just Want to be Loved: Autistic People's Experience of Relationships

M. A. Stokes[1], *M. Hooley*[2] *and G. Sala*[2], *(1)Deakin University, Burwood, Australia, (2)Psychology, Deakin University, Burwood, VIC, Australia*

Background:

Autistic peoples' sexuality and functioning in intimate romantic relationships has often been characterised by discourses of asexuality, deficits, need for sexual education, and reifying the purported difference in sexuality (Bertilsdotter Rosqvist, 2013). Although autistic people have difficulties with typical expressions of social-emotional reciprocity, it should not be assumed that they don't have the same need for belonging,

social connection and desire for intimate romantic relationships as neurotypical people, or that they have different, but reasonable needs for these qualities.

Objectives:

The current study is situated within the broader literature of sexual education, while aiming to prioritise the voices of autistic people in sharing their perspectives and experiences of sexuality and intimate romantic relationships. The study is qualitative and exploratory, posing no initial hypotheses. The interpersonal process model of intimacy (IPMI; Reis & Patrick, 1996; Reis & Shaver, 1988) was used to frame research questions, and both autistic and neurotypical individuals were recruited to observe differences and consistencies in experience.

Methods:

Twenty-eight autistic adults and 22 neurotypical adults completed an online qualitative survey. Thematic analysis was employed to identify themes within the data (Braun & Clarke, 2006). The researchers employed a descriptive phenomenological approach within the analysis, focusing on what was explicitly said by participants, prioritising meaning and experience.

Results:

Autistic people described intimacy with romantic partners as a process of mutual support, sharing and the ability to be vulnerable. In terms of maintaining relationships, key themes identified related to emotion regulation and open, direct communication in talking through problems with a partner. Physical intimacy was perceived as an expression of emotional intimacy and important maintaining factor in closeness, however notions of its meaning were variable. Barriers in initiating and maintaining romantic relationships included difficulty expressing needs or emotions, reading and projecting subtle signals (flirting and differentiating between friends and love interests), and feelings of mistrust and negative self-perception.

Likewise, neurotypical people emphasized the importance of open communication and sharing within intimacy. Neurotypical people emphasized the importance of physical intimacy more strongly and maintaining factors in relationships involved learning from the past, intuiting partners' needs, maintaining independence and spending time with friends and others to support oneself through challenges. Both groups demonstrated an understanding of trust as a process that develops over time through an individual's demonstration of character.

Conclusions:

Although autistic people have difficulty with typical expressions of social-emotional communication, the current study demonstrated that mutual support, physical intimacy and open communication are considered important factors in maintaining intimate romantic relationships by most people. Subtle aspects of intimacy, such as interpreting flirting and signs of interest may be a focus for future sexual education for autistic people interested in finding partners.

300 **148.300** Increasing Parent-Child Social Interactions in Preschoolers with and without ASD through Song Books

T. Liu[1], *D. Dai*[1], *B. G. Schultz*[2], *C. Liu*[1] *and M. D. Lense*[1], *(1)Vanderbilt University Medical Center, Nashville, TN, (2)Faculty of Psychology & Neuroscience, Maastricht University, Maastricht, Netherlands*

Background: Providing natural opportunities that scaffold interpersonal engagement is important for supporting social interactions for children with ASD. Shared musical activities may be an effective way to foster such interactions. For example, children with ASD showed increased eye gaze and turn-taking with a therapist when engaged in music therapy versus play therapy (Kim et al., 2008). However, less is known about whether musical contexts support parent-child interactions. Beyond focusing only on children, musical activities may be helpful in supporting parents' behavior during parent-child interactions because music is a natural, familiar, and predictable activity. We use a dyadic book sharing activity to examine the impact of music and song on parents' and children's interpersonal engagement.

Objectives: Examine interpersonal engagement (visual attention and movement coordination) in parent-child dyads during picture book versus song book interactions.

Methods: Nine children with ASD (7 male, M=3.56 years) and twelve typically developing (TD) children (8 male, M=2.92 years) were video recorded during a 5-minute picture book and a 5-minute song book activity with their parents. Parents' and children's visual attention were manually coded using a five-second partial interval coding schema (Klimenko, 2007) that assessed attention to the book and/or gaze toward the partner. Wilcoxon paired sign-rank tests compared child and parent mean visual attention scores during the picture book and song book activities. Movement profiles were extracted from one-minute video clips of the same activities using a frame-difference-method. Granger causality analyses were used to examine interpersonal coordination.

Results: Across all dyads, children demonstrated greater sustained attention to the song books than to the picture books (W=27, p=0.007). Children with ASD showed marginally greater sustained attention during the song books (W=5, p=.08), while TD children demonstrated significantly greater sustained attention to song books (W=9, p=0.037), though the magnitude of the effect was small. Overall, parents showed greater gaze toward their child during the song books than during the picture books (W=12, p=0.0001), which was also evident in parents of only the TD children (W=5, p=0.005) and ASD children (W=2, p=.02). Movement analyses indicated that children Granger-caused parent movement activity more during the song books than the picture books (p<.05), suggesting greater parent responsiveness during the song books.

Conclusions: Song books, as compared to picture books, appeared to create a context that scaffolded parent-child engagement. Children increased sustained attention to the books and parents increased eye gaze toward their children during song book versus picture book activities. The parents' increased gaze to their child during the song book activity may have impacted their movement coordination with their child, as parents' movements were more responsive to their children's movements in this context. Song activities may be an accessible activity that support parent-child engagement due to their familiarity and predictability. Further analyses with an expanded sample size will compare behavior before and after participation in a ten-week parent-child music class involving music-based parent training for social engagement.

301 **148.301** Individuals with Higher Levels of Autistic Traits Are Less Susceptible to Social Conformity on a Perceptual Decision-Making Task

E. P. McKernan, ***J. Kopec****, E. A. Kaplan, E. L. Koelmel, E. C. Masters and N. Russo, Psychology, Syracuse University, Syracuse, NY*

Background:
Previous research on social influence processes in typically developing individuals has suggested that subjective social norms can influence individuals' perceptual judgments, with group influence exerting an effect on judgments. The opinions of others seem to change an individual's perceptual judgment, which is thought to be an effect of conformity.

Key diagnostic criteria of autism spectrum disorder (ASD) include social impairment, such as reduced sharing of interests, emotions, or affect. Individuals with ASD also often have difficulty with theory of mind, including the ability to take on another's perspective. Consequently, individuals with ASD may be expected to conform less than typically developing individuals due to the social difficulties inherent to ASD.

Objectives:

The current study seeks to examine susceptibility to social influence (i.e., conformity) in the context of a perceptual decision-making task in adults with high and low levels of autistic traits.

Methods:

Participants included 40 undergraduate students with normal or corrected-to-normal vision. Participants were asked to indicate the dominant color of squares consisting of 128 x 128 orange and blue pixels. Stimuli ranged from 40 percent to 60 percent orange pixels (e.g., 40% orange/60% blue to 60% orange/40% blue).

Participants first completed 40 trials in which they responded with no social pressure (Block 1). Participants then completed 102 trials (Block 2) in which the alleged responses of other participants were presented before stimulus onset on each trial. Responses were presented consecutively and separated by random delays between 1000 and 2000 ms. The responses of other participants were manipulated such that the majority response was correct for 80 percent of trials to induce social pressure.

Participants completed the Autism-Spectrum Quotient (AQ) following the computer task.

Results:

Overall accuracy was higher in Block 2 compared to Block 1, suggesting that the manipulation of social pressure was effective. For Block 2, preliminary analyses indicate a significant negative correlation between Total AQ scores and accuracy on hard-to-detect trials (with an orange/blue contrast of 49% / 51%) such that individuals with higher AQ scores (i.e., higher levels of autistic traits) performed less accurately (r = -.368, p= .019). There were no correlations between AQ scores and accuracy on easy-to-detect trials, when perhaps relying on either social information or perceptual abilities alone may have led to accurate responses.

Conclusions:

These results suggest that adults with higher levels of autistic traits utilize social information to a lesser extent and are perhaps less susceptible to social conformity, resulting in lower accuracy on very difficult trials of a visual perception task. Future work will explore this relationship in individuals on the autism spectrum in a similar experimental task.

302 **148.302** Interpersonal Movement Coordination in Adults with Autism Spectrum Disorder (ASD): A Potential Tool for Addressing 'Female Camouflage'?

N. Latif[1], *C. Di Francesco*[1] *and A. Nadig*[2], *(1)Psychology, McGill University, Montreal, QC, Canada, (2)School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada*

Background: When individuals engage in social interactions, they coordinate their nonverbal movements such as facial expressions and gestures. This movement coordination is associated with increased rapport and social connection between partners (Miles et al., 2009). Emerging research in ASD has suggested atypical movement coordination in the population (Zampella & Bennetto, 2018), but individual differences are yet to be examined. Interestingly, recent work demonstrates that females with ASD present more typical socio-communicative behaviours (e.g., gestures) relative to males. This strength in females with ASD may 'camouflage' other diagnostic features, resulting in under-diagnosis (Rynkiewicz et al., 2016). Here, we used a novel movement analysis method to explore whether interpersonal movement coordination, a hallmark of successful communication, may differ between males and females with ASD.
Objectives: 1) To utilize a novel, optic-flow methodology to determine whether movement coordination during interaction differs between males and females with ASD, and 2) evaluate how this compares to potential sex differences in movement coordination in neurotypical (NT) adults

Methods: Thirteen adults (3 females; Age: 18-24 years) with ASD without intellectual disability participated. Twenty-six participants will be recruited as NT controls. Participants completed the ADOS-2, Module 4 with a research-reliable administrator while being video-recorded. Semi-structured interview sections of the ADOS (e.g., questions about social interactions difficulties) were selected for analysis. The control sample will be asked the same semi-structured interview questions. Movement coordination was analyzed using Correlation Map Analysis (CMA; Barbosa et al., 2012). CMA uses a standardized optical flow method to assess movement within regions based on changes in pixels across video frames. A moving-window is used to calculate instantaneous correlation between regions. A higher correlation value corresponds to greater coordination. Whole-body regions were identified around the participant and the experimenter to assess movement coordination.

Results: Females with ASD demonstrated greater movement coordination within a much smaller range (Range=.75-.82) than the males (Range=.35-.84; Figure 1). This difference is striking because males and females were similar with respect to age, verbal and non-verbal IQ. Moreover, females exhibited greater coordination despite having higher symptom severity than males (ADOS median calibrated severity score female=9, male=7; Figure 2). Movement coordination between the ASD group and the NT group will be compared. Based on previous work (e.g., Zampella & Bennetto, 2018), we expect that ASD participants will present lower movement coordination compared to NT participants. We also predict a main effect of gender, based on prior results using other methodologies (Hermans et al., 2009). Given that females with ASD present more typical socio-communicative behaviour, we expect a GenderXGroup interaction, such that the difference in coordination between ASD and NT males will be greater than the difference between ASD and NT females.

Conclusions: These preliminary results suggest that there may be intriguing differences in interpersonal movement coordination between males and females with ASD, which need to be investigated in larger samples. Given that females with ASD often 'camouflage' other diagnostic features with their relatively typical socio-communicative behaviours, investigating movement coordination during interaction may provide a tool for better understanding gender differences in ASD.

303 **148.303** Judging Intentionality of Ambiguous Action in an Adult ASD Sample

***A. Eisenkoeck**, Department of Psychology, Goldsmiths College, Univesity of London, London, United Kingdom*

Background: Discerning intentional from unintentional actions is a key aspect of social cognition. Mental state attribution literature has consistently shown that people with autism spectrum conditions tend to be less accurate in discerning an agent's intention when there is clearly a right answer. However, little is known about how autistic people attribute intentions when making judgements about ambiguous actions. Understanding 'intention attribution style' in this population will help us gain an insight into everyday mental state processing whereby intentions may be frequently ambiguous.

Objectives: The aim of this study was to determine whether individuals on the autism spectrum differ in their interpretation of ambiguous actions compared to neurotypical controls.

Methods: Participants included 20 adults with a diagnosis of an autism spectrum condition (7 females) and 20 neurotypical controls (11 females). Verbal and perceptual reasoning ability was measured using the Wechsler Abbreviated Scale of Intelligence II. All participants were asked to complete a modified version of Rosset's (2008) Ambiguous Sentences paradigm which measures the proportion of intentional versus unintentional judgements of ambiguous actions.

Results: There were no significant differences in verbal ability or perceptual reasoning ability between groups. The Strange Stories Film task (SSFt; Murray et al., 2017) which measures advanced theory of mind (ToM) revealed a significant difference in ToM abilities between the autistic group and controls. One statistically significant outlier in the ASD group was excluded from analysis of the Ambiguous Sentence paradigm scores. Participants with autism showed a higher intentionality endorsement percentage for ambiguous sentences (M=18.42.91, SD=13.18) than controls (M=13.18, SD=8.59; t(37)=2.04, p=.048). ToM scores did not correlate with intentionality endorsement percentage scores in either group therefore group differences could not be explained by ToM ability.

Conclusions: Our results suggest that high functioning adults with an autism spectrum condition are more likely to perceive ambiguous behavior to be intentional rather than accidental compared to neurotypical controls. This is a noteworthy result in a small sample and suggests group differences in intention attribution style. Over-attributing intentions when interpreting ambiguous behaviour may be a contributing factor to the social difficulties experienced by autistic individuals. As ToM deficits could not explain the increased tendency to perceive ambiguous but prototypically accidental behavior to be intentional, a follow-up study investigating the relation between executive functioning skills and intention attribution style in autism is planned.

304 **148.304** Metacognitive Executive Functioning and Its Relationship to Social Functioning in Children with Autism Spectrum Disorder

***C. M. Perez**[1], R. N. Larkin[2] and L. A. Oakes[3], (1)Developmental and Behavioral Pediatrics, University of Rochester Medical Center, Rochester, NY, (2)Developmental and Behavioral Pediatrics, University of Rochester, Medical Center, Rochester, NY, (3)University of Rochester Medical Center, Rochester, NY*

Background:

Previous research indicates there is a negative relationship between both executive function and social communication skills (Joseph & Tager-Flusberg, 2004), as they relate to autism spectrum disorder (ASD) symptoms. As such, understanding the relationship among executive function and social communication processes may provide important information for informing intervention strategies in ASD. However, there is limited research examining the relationship between specific processes of executive function (i.e., metacognition, behavioral/emotional regulation) and other social skills.

There is recent interest in this topic. One study found that both difficulties in behavioral regulation and metacognitive executive functioning predicted deficits in social communication in children with ASD while only the relationship between behavioral regulation and social communication was significant in typically developing children. This suggests that there may be a unique link between metacognitive processes and social functioning in children with ASD (Leung, Vogan, Powell, Anagnostou, & Taylor, 2016). Another study compared metacognition to behavior regulation and found that metacognitive processes were the more important factor in accounting for social function in children with ASD (Torske, Nærland, Øie, Stenberg, & Andreassen, 2018).

This previous research on the relationships among executive functioning skills and social functioning has centered on the use of the Social Responsiveness Scale, 2nd Edition (SRS-2), a commonly used screening tool that identifies social communication difficulties relevant to autism symptomology. There is little research exploring this relationship with more comprehensive measures of social functioning, especially ones that are indicative of every day social skills. To address this, the social skills improvement system-rating scale (SSIS-RS) was selected for this study as it gathers a more global assessment of social functioning with the addition of providing guidance for intervention.

Objectives:

The aim of this study was to explore the relationship between social functioning as measured by the Social Skills Improvement System Rating Scales (SSIS-RS) and executive functioning as measured by the Behavior Rating Inventory of Executive Functioning (BRIEF). We predict that, based on emerging research, metacognition will have a stronger relationship with social skills than behavioral regulation.

Methods:

Fifty-three children with ASD, ages 6-12, with full scale IQ scores above 50, were assessed on parent reported measures of executive functioning (BRIEF) and social skills (SSIS-RS). A linear regression was conducted to examine the relationship between the Metacognitive and Behavioral Regulation Indexes of the BRIEF and the social skills index of the SSIS-RS.

Results:

Consistent with our hypothesis, metacognition predicted social skills (β = -0.32, p = 0.03), with greater difficulties in metacognition indicating lower social abilities. The relationship between behavior regulation and social skills was not significant (β = -0.22, p = 0.15, *ns*).

Conclusions:

Results support previous research suggesting that metacognition plays a larger predictive role in every day social functioning than behavioral regulation. Metacognition involves skills such as working memory, activity initiation, planning/organization, and self-monitoring, which may be improved through direct teaching. These results have implications for developing metacognitive-based interventions that could assist in the

development or improvement of every day social skills in children with ASD.

305 **148.305** Modelling the Percentage Looking Time to Social Scenes – Results from a Large Cohort with Autism Spectrum Disorder

T. Del Bianco[1], *L. Mason*[2], *E. J. Jones*[1], *H. L. Hayward*[3], *A. San Jose Caceres*[4], *E. Loth*[4] *and M. H. Johnson*[1,5], *(1)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, King's College London, London, United Kingdom, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Department of Psychology, University of Cambridge, Cambridge, United Kingdom*

Background: The social motivation account of Autism Spectrum Disorder (ASD) stresses the role of decreased social interest as an antecedent of socio-cognitive abnormalities in ASD (Chevallier, Kohls, Troiani et al., 2012). One strong candidate to possibly explain this account is reduced spontaneous social attention (e.g. to the human face and social-communicative cues). A number of studies report reduced attention to faces in children and adults with ASD, but others fail to replicate (Frazier, Strauss, Klingemier et al., 2017). Nonetheless, very few studies utilise large samples and a broad age range, and therefore unable to investigate socialattention at particular developmental stages, or the effects of varying degrees of social content in the stimulus.

Objectives: We report on the developmental profile of social attention and its sensitivity to context from childhood to adulthood in a large European cohort of individuals with ASD and controls.

Methods: We used eye-tracking data from the The EU-AIMS Longitudinal European Autism Project (Loth et al., 2017), which included 366 participants with ASD; 268 with TD; age range 6-30. Participants with ASD had an average IQ of 98.69 (SD = 19.48). Participants watched 6 static photographs depicting social interactions (Figure 1c). Trials with a percentage looking time (PLT) to the screen < 25% were excluded from analysis. Group differences in PLT were explored through 3 linear mixed models including the interaction between Areas of Interest (AOIs) 1) head, body and background people 2) face and hair 3) upper and lower face, group (ASD, TD), and age class (child, adolescent, adult), varying intercept per participant, and IQ as a covariate. We tested the linear contrasts of interest by subtracting the estimate of the TD group from the estimate of the ASD group within each age class.

Results: The groups significantly differed in terms of PLT to the head (difference = -2%, p = .01, d = 0.27) and to the face (difference = -2%, p = .01, d = 0.22) in the adolescent age class, and to the head (difference = -4%, p < .001, d = 0.57), the body (difference = 2%, p = .03, d = 0.26), the face (difference = -5%, p < .001, d = 0.55), and the upper face (difference = -4%, p < .001, d = 0.34) in the adult class - with participants with ASD looking on average less to the head/face and more to the body (Figure 1a). Examination of individual stimuli indicated differential sensitivity to group differences (Figure 1b). Analysis of temporal profiles of attention is ongoing.

Conclusions: We observed a tendency in the TD group to increased social attention with age. The ASD group, in contrast, maintained a flat profile. This suggests that reduced social attention is not an invariable feature of the ASD phenotype in childhood. On the other hand, social attention clearly deviates from typical development at later stages of development: the characterization of social attention indexed in this data may represent the consequences of living a life with ASD, with important consequences for intervention.

306 **148.306** Not so Automatic Imitation: Expectation of Incongruence Reduces Interference in Both Autism Spectrum Disorder and Typical Development

A. J. Gordon[1], *J. P. Hogeveen*[2], *R. M. Geddert*[3], *M. K. Krug*[4] *and M. Solomon*[4], *(1)Psychiatry & Behavioral Sciences, University of California, Davis, M.I.N.D. Institute, Sacramento, CA, (2)Department of Psychology, University of New Mexico, Albuquerque, NM, (3)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (4)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA*

Background:

Individuals with autism spectrum disorder (ASD) exhibit deficits in social functioning. One prominent view is that such impairments are the result of a diminished capacity for imitation; however the underlying mechanisms remain unclear. One recent theory suggests that ASD may be characterized by an aberrant mirror neuron system (MNS), the neural system underlying imitation. Imitative response tendencies can be probed in the laboratory through automatic imitation (AI)–the degree to which observed actions modulate action execution. However, the largest study to date found evidence that AI is intact in ASD, challenging this hypothesis (Sowden et al., 2016). An alternative account suggests that social deficits may instead stem from differences in the ability to exert top-down control of imitation in those with ASD versus those with typical development (TD). Although previous research has suggested that AI is not affected by top-down control in TD (Hogeveen & Obhi, 2013), no research has examined this process in ASD.

Objectives:

To provide further evidence for or against the MNS hypothesis by examining potential differences between ASD and TD in the degree of AI (H^1), and for the control of imitation theory by examining participants' ability to exert top-down control of imitation (H^2).

Methods:

Participants completed two blocks of a paradigm that included both AI and non-imitative control trials (effector priming, EP). Across blocks the congruent/incongruent trial ratio was manipulated such that one block consisted of mostly congruent trials (MC) while the other was mostly incongruent trials (MI). The dependent variables (DVs) were accuracy, reaction times (RT), and drift rate (v) – a combination of accuracy and RT quantifying participants' rate of information processing. Data collection is ongoing for the current study, and at present we examined the control of imitation in ASD (N=27) and an FSIQ case-controlled TD sample (N=27).

Results:

Scores for our three DV's were collapsed across block and submitted to a 2 (stimulus type: imitation vs. effector) x 2 (congruence: congruent vs. incongruent) x 2 (diagnosis group: TD vs. ASD) ANOVA (fig.1). In contrast to the theory of a broken MNS, the degree of AI was equivalent between groups for all three variables (all Fs < 1, BF_{01} > 2), consistent with the notion that the MNS is intact in ASD. Turning to our second hypothesis, interference scores were calculated for each DV and submitted to a 2 (stimulus type: imitation vs. effector) x 2 (block: MC vs. MI) x 2 (diagnosis group: TD vs. ASD) ANOVA (fig.2). For both groups, AI and EP interference effects decreased when the ratio of incongruent-to-congruent trials

increased (MI < MC; *F*s > 13, BF_{10} > 13). The top-down control of imitation was also matched between groups across all variables (*F*s < 1, BF_{01} > 8).

Conclusions:

In agreement with previous work our results demonstrate that AI is unimpaired in ASD and cast further doubt upon the broken MNS theory. Furthermore, we demonstrated that control over AI is similarly unimpaired in ASD, suggesting that for both groups AI is not as automatic as previously theorized.

307 **148.307** Overall Health, Social Functioning, and Motor Functioning of Individuals with High Functioning and Low Functioning Autism Spectrum Disorder

B. K. Redquest[1], *P. C. Fletcher*[2], *P. J. Bryden*[2] *and S. Stewart*[3], *(1)Centre for Addiction and Mental Health, Toronto, ON, Canada, (2)Kinesiology and Physical Education, Wilfrid Laurier University, Waterloo, ON, Canada, (3)Faculty of Education, Western University, London, ON, Canada*

Background: Individuals with autism spectrum disorder (ASD) experience a myriad of challenges. For example, it has been documented that individuals with ASD have compromised health, social, and motor impairments. Multiple risk factors play a role in their challenges experienced, as well as the severity of these challenges. One of the main risk factors is the level of functioning of individuals. However, there is a lack of research comparing the differences in overall health, social, and motor impairments individuals with low functioning (LF) and high functioning (HF) ASD experience.
Objectives: For this reason, the current study compared overall health, social functioning, and motor functioning among individuals diagnosed with ASD through the analysis of the interRAI Child and Youth Mental Health – Developmental Disabilities (ChYMH-DD) and the interRAI Child and Youth Mental Health (ChYMH) assessments.

Methods: Participants were divided into two groups, high functioning (HF) and low functioning (LF). Two hundred and seventy-two were HF (IQ<70) (60 females, 212 males) with a mean age of 12.77 years (SD=3.16). One hundred and six were LF individuals (IQ>70) (25 females, 81 males) with a mean age of 11.8 years (SD=3.29). Within both groups, more than half of the individuals were 12 years or older. Chi-square tests were conducted to detect differences between groups.

Results: The findings revealed minimal differences between LF and HF individuals with regards to their overall health and motor functioning. However, significant differences pertaining to social functioning were revealed. In addition to discussing the differences pertaining to the social functioning of HF and LF individuals, the study highlights implications arising from this research as well as opportunities for future research.

Conclusions: ASD is a highly variable disorder, in that children with the diagnosis exhibit many different characteristics and deficits. As such, it is important research continues to identify differences across LF and HF individuals allowing for the development of effective spectrum specific interventions and in turn improve quality of life among individuals with ASD. It is anticipated reducing the challenges experienced by individuals with ASD, will in turn reduce stress on their caregivers and family members.

308 **148.308** Parental Responsiveness during Musical and Non-Musical Play for Preschoolers with ASD

O. Boorom[1], *M. Watson*[1], *R. Xin*[2], *V. Munoz*[1] *and M. D. Lense*[1], *(1)Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt University, Nashville, TN*

Background: Although a growing body of research is examining connections between music and social development in children with autism spectrum disorder (ASD), there is limited research investigating musical play in parent-child interactions. Parent-child play interactions offer an important avenue for supporting children's social development. Shared engagement and parent responsiveness to children's focus during play are associated with children's social and language development (Gulsrud et al., 2016). Musical play may support interactions because it is familiar, reinforcing, and predictable, which may help children attend to activities and provide parents with an accessible way to be responsive (Lense & Camarata, 2018). However, musical play may also impede interactions due to its sensory and repetitive components.
Objectives: Examine whether use of musical play/toys during parent-child play is related to children's attention and parental responsiveness.

Methods: 8 parent-child dyads of preschoolers with ASD were video recorded for ten minute play sessions that included both musical and non-musical toys (5 male children; M=35.88 months). Videos were coded using a 5-second partial interval schema for engagement in musical play, as well as use of musical toys apart from musical play (e.g., building with drums). Additionally, children's attentional leads and corresponding parental physical toy play or verbal responses were identified. Wilcoxon Signed Rank tests compared differences between children's leads and parental responsiveness during musical and non-musical activities.

Results: Children with ASD spent 35.8%±12% of time engaged in musical play and an additional 22.1%±11% of time engaged with musical toys apart from musical play. Children provided similar numbers of attentional leads when engaged with musical play/toys and non-musical play/toys (W= 9, p = 0.25). Parents showed somewhat greater responsiveness to children's musical play/toy leads (62.1%±16.2%) versus non-musical leads (46.8%±17.0%) (W=5, p = 0.078) but this differed depending on type of responses. Parents provided significantly more physical play responses to musical vs. non-musical leads (p=0.039) but there was no difference in verbal responsiveness (p=0.15). Follow-up analyses restricted only to children's active musical play leads (e.g., playing xylophone, singing) suggested continued parent physical play responsiveness but somewhat reduced parental verbal responsiveness during active music making (p=.078) vs. non-musical play.

Conclusions: While there are substantial individual differences in ASD children's use of musical toys and play during a parent-child free play, engagement with musical play/toys impacted parental responsiveness. Parents provided more physical play responses when their child engaged with musical play/toys potentially due to the familiarity and accessibility of musical activities. Parental verbal responses was not impacted by use

of musical toys alone but may be reduced during active musical play perhaps due to the competing auditory stimuli. Results have implications for incorporation of music into therapy including using musical activities to support parents in following their children's leads and providing responsive input. Follow-up analyses with an expanded sample size will further address different types of play leads and responses.

309 **148.309** Personality Traits Mediate the Relationship between SRS-2 and BASC Composites in Children with HFASD

***S. L. Brennan**, J. D. Rodgers, J. Lodi-Smith, A. J. Booth, C. Lopata, M. Thomeer, C. J. Rajnisz and B. Reilly, Institute for Autism Research, Canisius College, Buffalo, NY*

Background: Meta-analytic findings indicate that lower levels of Big Five personality traits are associated with ASD and ASD characteristics (Lodi-Smith et al., in press). These traits are related to both internalizing and externalizing behaviors in children with ASD (De Pauw et al., 2011; Schriber et al., 2014) and mediate the relationship between ASD characteristics and positive outcomes in a community sample (Rodgers et al., 2018). These studies suggest that higher Big Five personality traits may be adaptive in ASD, just as they are in individuals with non-ASD diagnoses and the general population.

Objectives: The current analyses replicate and extend this work by testing the relationship among Big Five personality traits, ASD symptoms, and behavioral outcomes with the hypothesis that Big Five personality traits will mediate the relationship between ASD symptoms and behavioral outcomes.

Methods: The relationship among personality traits, ASD symptoms, and behavioral outcomes is tested in 46 children with high-functioning ASD recruited for a larger intervention studies targeted at training social skills (see, Lopata et al., 2012; Thomeer et al., 2012 for inclusion criteria and screening procedures). At intake, parents and children reported on child Big Five personality traits using the Big Five Inventory-2 (BFI-2; Soto & John, 2017). Parents also completed the Social Responsiveness Scale – Second Edition (SRS-2; Constantino & Gruber, 2012) and the Behavior Assessment System for Children (BASC-2, Reynolds & Kamphaus, 2004; BASC-3, Reynolds & Kamphaus, 2015). Children were an average of 9.14 years (*SD* = 1.82, range = 6 – 12), were primarily male (*n* = 46, 95.8%), and White and not of Hispanic or Latino descent (*n* = 40, 83.3%). All analyses were conducted in *R* and *SPSS*.

Results: Parent reports of child conscientiousness, agreeableness, emotional stability, and extraversion were negatively associated with SRS-2 total scores, social communication scores, and restricted and repetitive behavior scores as well as BASC scores of internalizing and externalizing problems, and behavioral symptoms. Parent reports on each of these traits were also positively correlated with BASC adaptive skills. The only significant correlations for child reports were negative correlations between emotional stability and BASC externalizing problems and behavioral symptoms. Neither parent or child reports of openness to experience were significantly correlated with SRS-2 or BASC scores. Multiple mediation analyses indicate that parent reports of conscientiousness, agreeableness, and emotional stability mediate the relationship between SRS-2 and BASC scores.

Conclusions: Effects for parent reports replicate meta-analytic findings on the relationship of personality traits to ASD and extend this work to the domain of ASD symptoms. Further, these results replicate prior work suggesting that higher levels of certain personality traits may be a buffer against behavioral challenges within ASD and in children with non-ASD mental health diagnoses. Paired with the robust evidence that personality traits can and do change across the lifespan and are predictive of positive outcomes across multiple domains in clinical and non-clinical populations, these findings add to the growing body of literature that suggests personality traits may be a productive potential target for future interventions in this population.

310 **148.310** Predictive Gaze Shifts during the Observation of Actions in Toddlers and Preschoolers with and without Autism Spectrum Disorders

***M. A. Krol**, I. F. Roth, J. Leano, D. Plesa-Skwerer and H. Tager-Flusberg, Psychological and Brain Sciences, Boston University, Boston, MA*

Background:

The large variety in autism phenotypes complicates the search for understanding underlying mechanisms. A few years ago a new theory was proposed, which suggests that a broad range of autistic symptoms may be manifestations of an underlying impairment in predictive abilities (Van de Cruys et al., 2014; Pellicano & Burr, 2012; Sinha et al., 2014). While there is some initial empirical support for this theory, exactly how impairments in prediction are linked to autism severity and the onset of autism spectrum disorders (ASD) remain unclear. An important ability in social situations is to predict what someone else is going to do, which can be assessed by measuring predictive gaze shifts, eye movements towards the outcome of an observed action before the action is completed.

Objectives:

The current study aimed to compare predictive gaze shifts in typically developing (TD) young children and young children with ASD prior to the onset of goal-directed actions. The second aim was to explore whether the ability to predict others' actions is related to the severity of autism symptoms.

Methods:

Data has been processed for 18 TD children (ages 25-59 months; M = 44.6, SD = 2.5) and 14 children with ASD (ages 27-58 months; M = 39.9, SD = 3.1). ASD diagnosis was confirmed by administrating the Autism Diagnostic Observation Schedule (ADOS-2 Toddler module, Module 1 or 2). Participants observed 30 video clips in which an actor performed a grasping and placing action or pointing action (Figure 1). They were able to predict that the actor would first move towards the toy before moving toward the container, since the sequence was the same in all videos and the participants were first familiarized with the sequence. During the observation of the videos, eye movements were recorded using a Tobii Pro X2-60 eye-tracking monitor. Predictive gaze shifts were defined as eye movements toward the toy before action onset.

Results:

There was a significant difference in predictive gaze shifts between the two groups, $F(1, 30) = 5.83$, $p = .02$, $\eta_p^2 = .16$ (Figure 2). The TD children look more towards the toy prior to the onset of the action (M = .33, SD = .10) compared to the group with ASD (M = .22, SD = .16). In the group with ASD, there was a negative correlation between the total score on the ADOS, indicating the severity of autism symptoms, and the proportion of looking at the toy prior to action onset relative to looking anywhere else on the screen, $r(14) = -.68$, $p = .01$.

Conclusions:

Our findings suggest that prior to the onset of an observed action, young children that are typically developing predict what another person is going to do, while young children with ASD make these predictions less frequently. Especially, children with more severe autism symptoms showed fewer predictive gaze shifts, supporting a link between autism symptoms and impairments in prediction abilities. Therefore, the current study provides new evidence for the theory that individuals with ASD have impairments in predictive abilities.

311 **148.311** Predictors of School Refusal Due to Bullying: The Role of ASD + ADHD Co-Occurrence

***H. E. Morton**, A. J. McClemont, J. Gillis and R. G. Romanczyk, Binghamton University, Binghamton, NY*

Background: Children with Autism Spectrum Disorder (ASD) experience bullying victimization more frequently than children without ASD (Maïano et al., 2016). This disparity is concerning as victimization is related to physiological distress, internalizing symptoms, and school refusal (Bitsika & Sharpley, 2014; Havik et al., 2014, 2015; Tipton-Fisler et al., 2018). Predictors of victimization vulnerability include: externalizing/conduct behaviors, older age, non-Caucasian race, co-occurring diagnosis of Attention-Deficit/Hyperactivity Disorder (ADHD), and public school/general education classroom placement (Fink et al., 2018; Sreckovic et al., 2014). However, the relation of victimization predictors and negative outcomes is unknown. Understanding predictors of negative responses to bullying may elucidate characteristics of particularly vulnerable children.
Objectives: Identify predictors of school refusal due to bullying.

Methods: Participants were 97 parents of 154 children (4-16 years old). Children were diagnosed with ASD (*n*=36), ADHD (*n*=16), ASD + ADHD (*n*=31), other diagnoses (*n*=15), or no diagnosis (*n*=56). Parents were asked if their child had ever resisted going to school due to being bullied and how frequently this resistance had occurred (i.e., at least once per month, past school year, in the past but not this school year, never). Parents of children with ASD also completed the Autism Spectrum Quotient: Children's Version (AQ-Child; Auyeung et al., 2008) as a measure of ASD symptom severity. Study participation occurred online.

Results: Parents reported 35% of children had resisted attending school due to bullying. Of these, 63% had resisted within the past school year. Binary logistic regression was conducted to determine the impact of hypothesized predictors (i.e., age, gender, race, diagnosis, attending public school, general education placement, having a behavior plan) on school refusal likelihood. This model was significant, $\chi2(10) = 35.44$, $p < .001$; it explained 28.4% of variance in school refusal and correctly classified 73.2% of cases. Greater likelihood of school refusal was predicted for children with co-occurring diagnoses of ASD + ADHD (Odds Ratio (OR) 6.6, 95% CI 2.1 to 20.6, $p < .01$) and children of older age (OR 1.16, 95% CI 1.0 to 1.3, $p < .01$; see Table 1). Within ASD, symptom severity (AQ-Child) did not predict school refusal (OR 0.97, 95% CI 0.90 to 1.04, *ns*).

Variables that predicted school refusal with at least trend-level significance were analyzed using ordinal logistic regression for school refusal frequency. The model with these predictors was a significant improvement over the intercept-only model ($\chi2(8) = 33.51$, $p<.001$). Compared to ASD, diagnoses of ADHD or co-occurring ASD + ADHD predicted more frequent school refusal (OR 4.53 and 5.45, respectively). Older child age and having a behavior plan also predicted more frequent school refusal (see Table 2).

Conclusions: Older children with ASD + ADHD and behavior difficulties may have particular difficulty managing victimization and should be targeted for bullying intervention efforts. In contrast to research on victimization predictors, environmental factors (public school, general education placement) did not predict school refusal. Future research should characterize children with ASD who are bullied and display less severe negative outcomes. These children may possess skills that should be intervention targets.

312 **148.312** Pretend Play As a Predictor of Reciprocal Social Behaviors in Children with Autism Spectrum Disorder: A Two-Year Follow-up Study

***T. T. Yu**[1], H. M. Chiu[2], H. J. Li[3], C. H. Tsai[3], C. H. Lin[4] and K. L. Chen[1], (1)Department of Occupational Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan, (2)Department of Rehabilitation, Chung Shan Medical University Hospital, Taichung, Taiwan, (3)Department of Child and Adolescent Psychiatry, Kaohsiung Municipal Kai-Syuan Psychiatric Hospital, Kaohsiung, Taiwan, (4)Department of Psychiatry, Chi Mei Medical Center, Tainan, Taiwan*

Background: Children with autism spectrum disorder (ASD) have been found to have difficulties in both social interaction and pretend play. Social interaction is a back-and-forth process of reciprocal social behaviors. Pretend play is a form of playful behavior that involves nonliteral correspondence to reality. Preschool-age children practice reciprocal social behaviors in the social situations they create during pretend play and later transfer these behaviors into real life. However, previous studies on the relationship of pretend play to social interaction in preschool children with ASD have only focused on the cross-sectional relationship. The elaborateness of pretend play and reciprocity have not been examined.

Objectives: The purpose of this two-year follow-up study was to examine whether the pretend play of preschool children with ASD could predict their reciprocal social behaviors at school age by using elaborated assessments of pretend play and reciprocal social behaviors.

Methods: Children with ASD aged 3 to 12 years were invited to participate in two evaluations at an interval of two years. At the first evaluation, the Child-Initiated Pretend Play Assessment (ChIPPA) was used to assess children's pretend play in sessions of conventional imaginative play and symbolic play. The ChIPPA has three types of scores were percentage of elaborate pretend play (PEPA), number of object substitutions (NOS) and number of imitative actions (NIA). At the second evaluation, the Reciprocal Social Behavior Observation (RSBO), verbal comprehension index (VCI) of the Wechsler preschool and primary scale of intelligence, fourth edition (WPPSI-IV), and Childhood Autism Rating Scale (CARS) were respectively used to assess children's reciprocal social behaviors, language ability and severity of symptoms. Nine linear regression models were used to analyze the prediction of early pretend play to reciprocal social behaviors while considering the covariates of language ability and severity of symptoms.

Results: A total of 64 children with ASD aged 41 to 84 months (SD: 11.75) were recruited at first evaluation. Participants had moderate severity of symptoms and normal language ability, respectively indicated by the CARS total scores (mean = 32.28, SD: 4.67) and VCI (mean = 95.11, SD: 23.29). After controlling for children's CARS total scores and VCI, three early PEPA scores (i.e., conventional imaginative play, symbolic play, and total scores) and two early NOS scores (i.e., symbolic play and total scores) ($p < .05$) significantly predicted the RSBO total scores, respectively. However, no significant predictors of the RSBO total scores were found in other models after controlling for the children's CARS total scores and VCI.

Conclusions: The quality and quantity of pretend play were predictors of reciprocal social behaviors in children with ASD at two-year follow up,

with language ability and severity of symptoms controlled for. This study provides evidence that improving pretend play in preschool children with ASD may lead to better reciprocal social behaviors when they reach school age.

313 **148.313** Quantifying the Active Ingredients of Music Therapy: An Analysis of Movement Dynamics between Therapist and Children with Autism

A. Nadig[1,2], *N. Latif*[3], *C. Di Francesco*[3], *M. Sharda*[4] *and K. L. Hyde*[4], *(1)School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada, (2)Centre for Research on Brain, Language and Music, Montreal, QC, Canada, (3)Psychology, McGill University, Montreal, QC, Canada, (4)International Laboratory of Brain, Music and Sound Research (BRAMS), University of Montreal, Montreal, QC, Canada*

Background: In a randomized controlled trial, we recently showed that 8-12 weeks of music intervention can improve auditory-motor brain connectivity and parent-reported social communication in school-age children with ASD (Sharda et al., 2018). This suggest that collaborative music-making can enhance communication. It has been argued that music is unique in engaging both sensory and motor systems while synchronizing with another person, and that this bears positive effects across domains (Srinivasan & Bhat, 2013, Janzen et al., 2018). Yet we know little about the mechanisms that lead to these effects. Prior work has shown that interpersonal synchrony (coded subjectively) increases in children with ASD over the course of a rhythm intervention (Srinivasan et al., 2015), possibly through enhanced movement coordination. Here we applied a novel, optical flow analysis method to video of therapy sessions from Sharda et al. (2018) to examine dynamic movement amplitude and coordination between child and therapist.

Objectives: 1) To apply a novel, optical flow-based methodology to quantify movement amplitude and coordination between therapist and child; 2) Examine how movement amplitude and coordination may evolve over time; 3) Compare therapist-child movement coordination patterns across music-based intervention and a control play-based intervention.

Methods: Data is available from 51 children with ASD aged 6-12; 26 participated in music-based intervention (MI) and 25 participated in a control play-based intervention (PI), all one-on-one with the same therapist. A preliminary analysis of 10 MI participants is described, with the rest of the sample underway. The duration of therapy was one weekly session (comprising 4 activities) over 8-12 weeks. Specific activities were rotated and reoccurred over the course of intervention. For each participant we selected 1 minute video clips of the same activity (e.g., handheld percussion) occurring in the first third (T1) or last third (T2) of therapy sessions. Movement patterns between child and therapist were analyzed using Correlation Map Analysis (CMA) software. Non-overlapping whole-body plus instrument regions of interest were identified for the child versus therapist. CMA uses a standardized optical flow to assess movement within a given region based on changes in video pixels across video frames. A moving-window filter is applied to calculate an instantaneous correlation between regions across the length of the video (Barbosa et al., 2012).

Results: Average amplitude of motion was calculated for both the child and therapist at each time point. Some dyads exhibited more similar or matched motion amplitude over time (Figure 1). Figure 2 shows that this effect was observed across activities; the mean difference in child-therapist motion amplitude significantly decreased from 3.47 at T1 to .72 at T2 ($p = .018$).

Conclusions: This novel method provides numerous insights into the movement dynamics of a dyad during intervention. Preliminary results demonstrate increased movement matching over the course of music intervention. We are examining individual differences in this effect in our full sample relative to communication and brain connectivity outcomes. Comparisons of movement dynamics between music-based and play-based therapy may elucidate an active ingredient of music intervention: increased interpersonal motion matching.

314 **148.314** Beyond the Lorna Wing Typologies: Personality Profiles in Autism Spectrum Disorder Reconsidered

M. Solomon[1], *A. J. Gordon*[2], *M. K. Krug*[1], *A. Cho*[3] *and J. J. Wood*[3], *(1)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA, (2)Psychiatry & Behavioral Sciences, University of California, Davis, M.I.N.D. Institute, Sacramento, CA, (3)Human Development & Psychology, University of California, Los Angeles, Los Angeles, CA*

Background:

Recent research has highlighted the substantial association between personality traits as assessed by the Five-Factor Model (FFM) and autism spectrum disorder (ASD) characteristics (Lodi-Smith et al., 2018). Notably, FFM personality domain scores appear to differ across the typically-developing and ASD populations and are correlated to some extent with measures of core ASD features. Despite these findings, there is a great deal of variability in personality profiles of individuals with ASD (Schwartzman et al., 2016). This heterogeneity of personality trait expression in the ASD population reflects the notion of "multiple autisms" found in the ASD genetics and neuroscience literatures. By observing ASD symptomatology through a personality lens, it may be possible to better identify ASD subtypes, and to understand variability in symptom profiles. Establishing these links and subtypes could ultimately contribute to efforts to understand developmental pathways and moderators of these pathways for people with ASD.

Objectives:

The current study aimed to extend previous findings on differences in personality traits between typically-developing and ASD populations, determine the extent to which personality traits predict autism symptom expression, and identify common personality profiles that may be representative of autism subtypes in the ASD population.

Methods:

Personality and ASD symptom expression data were collected in a sample consisting of both typically-developing individuals and individuals with ASD ages 12 to 22 (N=176). Youth with ASD (cASD; n=47; M_{age}=14.49 years) were compared with typically-developing youth (cTYP; n=49; M_{age}=14.47 years) and adults with ASD (aASD; n=41; M_{age}=19.88 years) were compared with typically-developing adults (aTYP; n=39; M_{age}=19.95 years) on each Big Five Inventory (BFI) domain (Extraversion, Agreeableness, Conscientiousness, Negative Emotionality, Open-Mindedness) and on secondary personality facets. Regression models were used to calculate the amount of variance accounted for by BFI domains and facets in Social Responsive Scale (SRS) scores. A K-means cluster analysis was used to examine the score patterns to identify common profiles within the ASD subsample (n=81).

Results:

T-tests revealed significant differences (p<.05) across three personality domains (Extraversion, Conscientiousness, Negative Emotionality) between

the cTYP and cASD groups; significant differences (p<.05) were also found across all five domains between the aTYP and aASD groups. Personality facets accounted for 30% and 37% of variance in autism core symptom expression in the youth and adult subgroups, respectively. Three distinct personality profiles were identified in the ASD subsample (37%, 35%, and 28% of the sample, respectively). The clusters differed markedly on Extraversion, Agreeableness, Conscientiousness, and Negative Emotionality. These groups had unique associations with other clinical characteristics such as SRS scores.

Conclusions:

The present results converge with previous findings, suggesting a significant association between personality traits and ASD characteristics. The three identified cluster subgroups present distinct personality profiles that are indicative of notably heterogeneous ASD phenotypes. Future research should use the FFM framework to better understand the substantial heterogeneity within ASD and investigate the degree to which personality may moderate or mediate the relationship between core neurocognitive processes and ASD symptom expression as individuals develop.

Poster Session
149 - Technological approaches
5:30 PM - 7:00 PM - Room: 710

315 **149.315** A Community-Based Randomized Comparison of Speech Generating Devices and the Picture Exchange Communication System for Children with Autism

S. Gilroy[1], *G. Leader*[2] *and J. McCleery*[3], *(1)Psychology, Louisiana State University, Baton Rouge, LA, (2)National University of Ireland, Galway, Ireland, (3)The Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Extensive research has established the Picture Exchange Communication System (PECS) as evidence-based practice for establishing functional communication in nonverbal and minimally verbal children with autism. However, despite strong preference of both families and users to utilize high-tech augmentative and alternative communication systems, such as tablet-based speech-generating devices (SGDs), definitive evidence on the relative effectiveness of SGDs versus PECS for communication training is lacking.
Objectives: To determine the relative effectiveness of SGD versus PECS based communication intervention in a community-based intervention setting, we conducted a randomized controlled trial directly comparing the impacts of SGDs and PECS to an Education As Usual (EAU) comparison control in specialist schools for children with autism in Ireland.

Methods: Nonverbal and minimally verbal students diagnosed with Autism Spectrum Disorder were randomized at the classroom level to receive 2 months of communication intervention via SGD (n=15) or via PECS (n=13), versus EAU (n=13). Experimental change measures were scored from a live interaction previously developed to index unprompted communicative functions, including mands, intraverbals, and tacts, which was administered to all participants at both pre- and post-training.

Results: The groups did not differ on either chronological age or levels of communication at intake. Statistical analyses further indicated significant increases in rates of total communication in both the SGD and PECS groups, each compared with the EAU condition, which was driven by significant increases in overall communication from pre-training to post-training in both conditions. Further analyses indicated that neither total communication nor manding differed for the SGD versus PECS conditions.

Conclusions: The results of this study provide experimental evidence indicating that school-based implementation of communication intervention via SGD and via PECS are each effective for establishing basic functional communication skills, with each modality providing significant improvements above and beyond education as usual. Critically, these effects were driven by significant increases in rates of manding in both conditions, and communication improvements did not differ between the high-tech and low-tech intervention conditions. Taken together, these results provide further support for both high-tech and low-tech augmentative and alternative communication intervention strategies as evidence-based practice for establishing basic functional communication skills for children with autism.

316 **149.316** Leveraging Reward Mechanisms in ASD Behavioral Treatment: A Computer Game Intervention

L. Cordero[1], *C. Sides*[2], *M. Farber*[2] *and J. D. Herrington*[3], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphi, PA, (2)BioStream Technologies, LLC, Philadelphia, PA, (3)Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA*

Background: Consensus is growing that differences in motivation and reward mechanisms are central to the etiology of ASD. These differences not only affect the development of social skills in ASD, but also diminish the effectiveness of behavioral treatments (which typically rely on reward to influence behavior). There is significant untapped potential in using computer game platforms to facilitate social skill enhancement in ASD, as children with ASD (and neurotypicals) generally find these platforms highly rewarding.
Objectives: This presentation focuses on the development and testing of an eye gaze-controlled space adventure game designed to enhance social abilities in ASD. Initial piloting focuses on 1) user experience data, 2) within-game metrics of social skill changes, and 3) the development of naturalistic eye contact assessments for a subsequent clinical trial.

Methods: This National Science Foundation-supported initiative represents a partnership between the Children's Hospital of Philadelphia, University of Pennsylvania, and BioStream Technologies, LLC. This team has developed an immersive, interactive space adventure game that uses consumer-grade eye tracking technology to teach children to make and hold eye contact with game characters. To date, the game has been administered to 99 children with and without ASD (ages 4 to 16), across a total of 269 game sessions, including 52 children with ASD across a total of 172 game sessions.

Results: User experience data suggest a high level of engagement and favorable responses to the game. Preliminary analyses on a subset of data (N = 18) indicate that within-game metrics are useful indicators of social skill, with ASD individuals showing diminished eye contact during initial, incidental interactions with game characters. Preliminary data also indicate that the game's facial expression exercises yield increased emotion recognition scores after 4 or 5 gameplay sessions ($p < .001$, n=24). Analysis of mutual eye gaze data (during a live social interaction) are ongoing,

and involve computer vision and machine learning analyses of video data.

Conclusions: BioStream's game has proven to be safe and well tolerated by all participants to date. The vast majority of participants liked the game, which is essential to assuring that it can be played for a sufficient duration to facilitate behavior changes. Preliminary results suggest that the game provides social skill metrics that have significant potential as change measures (as well as cross-sectional assessment). Next steps in this line of research include the analysis of novel outcome data, and the implementation of a Phase II clinical trial.

317 **149.317** Novel in-Vivo Approach Using Smartphone Reporting to Map Real-World Social Interactions in ASD

A. H. Gerber[1]*, J. M. Girard*[2] *and M. D. Lerner*[3]*, (1)Stony Brook University, Stony Brook, NY, (2)Language Technologies Institute, Carnegie Mellon University, Pittsburgh, PA, (3)Psychology, Stony Brook University, Stony Brook, NY*

Background: While considerable research demonstrates deficits in the quality of social interactions of adults with ASD, little work has examined the quantity and temporal patterning of such interactions. Prior work suggests that adults with ASD engage in few social interactions (Orsmond et al., 2004), however, these studies have almost exclusively utilized caregiver reports, which are subject to recall biases (Shiffman et al, 2008). Ecological momentary assessment (EMA) is designed to address these limitations by facilitating in-vivo data collection, providing a more accurate estimate of social behavior. This is particularly important for individuals with ASD who may have limited insight upon reflection (Damiano et al., 2014). Only one study has utilized an EMA approach to examine social interactions of adults with ASD, finding lower levels of social interaction relative to other activities (Chen et al, 2017). However, this study used beep-contingent reporting, restricting inferences about quantity and patterning of interactions. Finally, prior work has indicated that symptoms of alexithymia (an impairment recognizing and understanding emotion), not ASD, may account for some of the social deficits in ASD (Bird & Cook, 2013). The current study represents a novel EMA approach to quantifying in-vivo patterns of social interaction in adults with ASD and the first examination of temporal patterns and psychosocial correlates of real-world social interaction.

Objectives: Based on previous research, we hypothesized that, controlling for demographic variables, adults with ASD would exhibit fewer social interactions and a daily cycle of social interaction with a lower peak than TD adults. We also hypothesized that symptoms of alexithymia, above and beyond the effects of ASD, would be related to fewer social interactions, and an attenuated peak in daily cycle of social interactions.

Methods: Adults with and without ASD (N_{ASD} = 23, N_{TD} = 52), aged 18 to 47 years (M=22.15 years, SD=5.53; 33 males) reported their social interactions in-vivo via smartphone over one week. Participants completed measures of IQ, ASD symptom severity and alexithymia symptom severity. Cyclical multilevel models were used to account for dependency of observations within person.

Results: Results demonstrated a daily cyclical pattern of social interaction that was robust to symptoms of ASD and alexithymia (Figure 1). Adults with ASD did not report fewer social interactions than TD peers; however, alexithymia symptom severity was negatively related to social interactions regardless of ASD status (Table 1).

Conclusions: This is the first study to use an EMA approach to map quantities and patterns of real-life social interactions. Results suggest a temporal pattern of social interaction, comparable across groups, that could not otherwise be identified. Our findings are the first to link alexithymia to reduced social interactions and suggest that these symptoms, not ASD severity, may drive social isolation for adults with ASD. This implicates a unique subset of individuals with ASD who struggle with social interactions and suggests an avenue for improving personalized intervention. In conclusion, results highlight the utility of a smartphone-based EMA approach for capturing subtle details of daily life in ASD with potential to provide a novel real-world outcome measure.

318 **149.318** A Comparison of Different Technological Interfaces and Activities on Autistic Children's Social Play

M. H. Laurie[1]*, A. Manches*[2] *and S. Fletcher-Watson*[3]*, (1)Patrick Wild Centre, University of Edinburgh, Edinburgh, United Kingdom, (2)Moray House School of Education, University of Edinburgh, Edinburgh, United Kingdom, (3)University of Edinburgh, Edinburgh, United Kingdom*

Background: Technology is widely used by autistic children and is increasingly used to develop skills in the social domain. However, there are ongoing concerns that technology is socially isolating and prohibits real-world interaction. Many of these concerns are directed towards touch-screen devices, however, we won't know whether (and how) different technologies create opportunity for different types of social interaction. Understanding the influence of different technologies has applications to better address community concerns and evaluate uses of new technologies to support autistic children.

Objectives: To compare autistic children's social play whilst using different types of technological devices and software

Methods: Four autistic children were video-recorded in their classroom playing with three different technological interfaces: (a) iPads(tm) with various recreational and educational apps and games, (b) Osmo(tm), a tangible system (physical-digital hybrid) with various educational apps, and (c) Code-A-Pillar(tm), a musical-construction robotic toy. Children's profiles were characterised using the teacher versions of the Social Responsiveness Scale 2 (*mean total t* = 78), Vineland Adaptive Behaviour Scales 3 (*mean ABC* = 58.75), and Wing's Subgroups Questionnaire. A total of 51 five-minute video clips (*mean* = 13 clips per child) were sampled (2 hours 5 minutes footage analysed, comprising 19% of full dataset collected over 4 weeks) and categorical coding of interactive social play applied using Howes' Peer Play Scale. The scale includes 7 categories of social play (in hierarchical order): non-play interaction with adults, non-play, solitary play, parallel-play, parallel-aware play, simple social play (SS), and complementary & reciprocal play (CR). For each observation, the child's play partner (staff or peer) was also coded, as well as interface and app (e.g. Osmo Numbers, iPad Reactickles).

Results: For each interface, patterns of observed play type are reported. Of all observations of SS with peers, 61.2% was observed whilst children played with iPads, 22.4% was observed while children played with Osmo, and 16.4% while children played with Code-A-Pillar. Of all observations of CR with peers, 87.5% was observed on the iPad, 12.5% observed on the Code-A-Pillar, and none observed with Osmo. Of all observations of SS with adults, 47.9% was observed whilst children played with Osmo, 26% observed on iPad, and 26% observed on Code-A-Pillar. Of all observations of CR with adults, 50% observed with iPads, 35% observed with Code-A-Pillar, and 15% observed with Osmo. Between the first two sessions (2 weeks) and the last two sessions (8 weeks), an increase was observed in observations of SS (mean at 2 weeks = 7, mean at 8 weeks = 21.5), but not CR (mean at 2 weeks = 3, mean at 8 weeks = 4).

Conclusions: This study compared autistic children's social interactions whilst using different types of technology, including tablets, tangibles and robotics. The highest rates of social play were observed whilst children used iPads, and more complementary types of play were observed whilst

children used Code-A-Pillar compared to Osmo. These results provide important insights into the differences between different types of technology that can be used to support autistic children in education and therapeutic contexts.

319 **149.319** A Physiologically-Mediated Virtual Reality Experience for Children with Autism Spectrum Disorder

M. Malihi[1]*, J. Nguyen*[2] *and A. Kushki*[3]*, (1)University of Toronto, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Bloorview Research Institute, Toronto, ON, Canada*

Background: Many children with autism spectrum disorder (ASD) have difficulty with transitions to new situations and settings, and this can lead to increased anxiety and missed opportunities for education and meaningful participation. Virtual Reality (VR) systems have highly desirable features to help children cope with such transitions. In particular, they can offer high levels of authenticity and realism, allowing children to explore new and anxiety-provoking settings in safe, controlled, and personalized settings prior to the actual experience. Although many VR systems are commercially available, very little is known about the safety and usability of these systems for children with ASD.
Objectives: The objective of this study was to evaluate the safety and usability of an immersive head mounted display (HMD) VR system for children with ASD.

Methods: Thirty-five children with a diagnosis of ASD participated in the study (age=13.0±2.6 years; 10 females; IQ>=70). During a two-hour session, participants watched two 5-minute, 360º video of a school bus, presented in two ways: a video on a computer monitor (video) and an immersive VR experience on an HMD (VR; Oculus Rift). Each task was separated by a baseline video clip from the Blue Planet series. The order of presentation (video/VR) was randomized. After each task, the participants completed questionnaires probing self-reports of anxiety (State-Trait Anxiety Inventory), sense of presence (ITC-SOPI), and usability (custom questionnaire).

Results: Of the 35 participants, 33 completed the study. The reasons for early drop-out were previous negative experiences on the school bus, sensitivity to the video content (whistling), and difficulty with heart monitoring electrodes. There was no significant difference in self-report of anxiety level pre/post the video and VR conditions. None of the participants reported side effects (e.g., cybersickness, nausea) on the ITC-SOPI for either condition. No significant differences were found between video and VR conditions on the ITC scales of spatial presence, engagement, ecological validity, or negative effects. Based on responses to the usability questionnaire, there were no significant differences between the VR and video condition in self-reports of levels of fatigue, enjoyment, task understanding, ease of navigation, and helpfulness in future school bus experiences. However, 29 of 33 participants indicated that they preferred VR to video. On a follow-up call a month after the study, no side effects were reported. Three of the 35 participants indicated that the study had helped them with school bus anxiety in real life.

Conclusions: The results of this study provide preliminary evidence to support safety and usability of virtual reality for children with ASD.

320 **149.320** An Evaluation of Practitioner Attitudes on Touch Screen Use in Children with an Autism Spectrum Disorder

ABSTRACT WITHDRAWN

Background: The prevalence for Autism Spectrum Disorder's (ASD's) in Australia has increased by 42.1% from 2012 to 2015 (Australian Bureau of Statistics, 2015). This rapid increase in prevalence has also been reported in the United States, UK and Europe (Kuehn, 2012; Baird, Simonoff, Pickles, Chandler, Loucas, Meldrum & Charman, 2006; Hughes, 2011). This escalation in prevalence has subsequently increased the demand for therapeutic services. Touch screen applications (apps) have the potential to alleviate the demand on therapeutic interventions or supplement them because of the way in which they deliver information. For instance, touch screen apps can meet a child with ASD's need for repetition or minimise the reliance on social communication. Furthermore, apps might provide a cost effective solution for families who require intervention while on a waiting list or as an adjunct to therapy. There is limited information on practitioners' experiences with touch screens as a tool for learning and therapeutic outcomes. These data would inform future practice of the efficacy of interventions delivered by touch screens for children with ASDs.
Objectives: This research has set out to explore whether practitioners working with children with ASD's (2-17 years) are using touch screens and ASD specific apps as part of their therapy. An understanding of *how* touch screens are used (e.g. as an AAC, reward, video modelling) could indicate what practitioners are finding most useful for children's therapy and might help educate other practitioners and parents on suitable uses of touch screen apps. This research aims to further understand whether children with ASD's are learning as effectively, or better from touch screens, compared with non-technological methods.

Methods:

Practitioners (*n*=69) were recruited from the health sector (*n*=51) and education sector (*n*=18). The majority of practitioners were psychologists and primary school teachers.

Participants views were accessed using an online survey. The survey was developed for the purpose of this study. Questions were informed by own practice, and parent and practitioner comments on their views of touch screen use as a therapeutic tool. The survey was shared on the University website, and shared amongst practitioners.

Results: Psychologists used ASD apps more often in their sessions (72%) than educators (38.9%). A chi square test indicated the difference between groups was significant p = 012. Quantitative and qualitative analyses informed that practitioners in both groups reported more positive behavioural effects as a consequence of using touch screens (e.g. calming, more engaged and attentive), compared to negative effects (tantrums, challenging behaviour observed). Practitioners in the health sector indicated children's learning from a touch screen was more effective than non-technological methods (58.3%). Practitioners in both groups described children with ASD as less anxious when learning from touch screens, compared to other methods (health: 61.1%, educational: 80%).

Conclusions: This research demonstrates touch screens are being used by practitioners as a tool for engagement with therapy and children, and adolescents with ASD's are benefitting from such platforms. These data might encourage other practitioners to use touch screens in their therapy and furthermore help shape future therapeutic practice for this population.

321 **149.321** An Open-Source, Computing Platform-Agnostic, Calibration-Free Preferential Gaze Detection Approach for Social Preference Assessment

R. Bishain[1], *S. Chandran*[1], *I. Dubey*[2], *J. Dasgupta*[3], *M. Belmonte*[4], *T. Gliga*[5], *D. Mukherjee*[6], *S. Bhavnani*[6], *G. Estrin*[5], *M. H. Johnson*[7], *V. Patel*[8], *S. Gulati*[9], *G. Divan*[10] *and B. Chakrabarti*[2], *(1)Computer Science and Engineering, Indian Institute of Technology, Bombay, India, (2)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (3)Sangath, Delhi, India, (4)Com DEALL Trust, Bangalore, India, (5)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (6)Centre for Chronic Conditions and Injuries, Public Health Foundation of India, Gurgaon, India, (7)Department of Psychology, University of Cambridge, Cambridge, United Kingdom, (8)London School Of Hygiene and Tropical Medicine, London, United Kingdom, (9)Child Neurology Division Department of Pediatrics, All India Institute of Medical Sciences, Delhi, India, (10)Sangath, Bardez, Goa, India*

Background: Social preference assessment, using contrasting video or image pairs, has been commonly used in autism screening. Such assessments tend to be conducted in the presence of experts in a controlled laboratory environment, primarily because most gaze-tracking apparatus are not portable. Further, the solutions employed are proprietary, and platform-dependent, inhibiting the wide acceptance of this important method across researchers. Recent advancements in machine-learning based gaze-tracking techniques, combined with the proliferation of low-cost hand-held devices, have challenged this paradigm. We present an open-source eye-tracking pipeline which enables casual, on-field preferential gaze understanding that can be carried out cost-effectively under minimal supervision in a typical home environment.

Objectives: To develop a portable, fast, open-source preferential gaze tracking pipeline for visual-stimuli guided social preference assessments.

Methods: The proposed gaze-tracking pipeline was deployed on data sourced from the 'preferential-looking' task of START ("Screening Tool for Autism Risk using Technology)", a tablet-based app usable by non-specialists in home settings. The task was administered to a group of 127 children aged 2-7 years at their homes in India. The preferential looking task presents the child with simultaneous social and nonsocial videos on the tablet screen. The tablet camera records the child's face during the task. This recording is analyzed asynchronously by our gaze tracking algorithm to predict the child's visual preference in each frame. The algorithm implemented in python is deployed offline on a desktop system, and processes the data for multiple children in a batch mode. The average processing time for the algorithm is 90ms per frame. The algorithm pipeline, consisting of existing open-source modules,
(a) extracts (using OpenCV[1] library calls) regions corresponding to the face and the eyes,
(b) obtains gaze coordinates[2] in pixels based on the device used (no reference needed for the subject or the camera parameters), and
(c) transforms, with temporal smoothing by a median filter, raw pixel coordinates to higher level preference prediction, enabling social preference assessment.
Results: The algorithm achieved 91% accuracy (percentage of frames with correct classification of gaze preference) on a manually annotated dataset with 5000 frames. The frame-drop rate (failure to detect faces due to poor lighting, occlusions, multiple faces, etc.) is observed to be no more than 5% for more than 73.2% of the on-field dataset, and it exhibits a decreasing trend in this range (Figure 1).
Conclusions: Our computer program (available freely[3]) works on video frames, and can, therefore, be used in any system as long as video frames are provided. The video can be captured by non-specialists in casual environments regardless of the hardware employed, making the system cost-effective for a screening measure. The approach is calibration-free, and can be executed asynchronously on video inputs.

322 **149.322** Are Avatars Just like Humans? Comparing Autism Spectrum Disorder Individuals' Emotion Recognition of Virtual Avatar and Human Faces

E. Amico[1], ***A. Swanson***[2], *J. W. Wade*[3], *A. S. Weitlauf*[1] *and Z. Warren*[4], *(1)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (2)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, NASHVILLE, TN, (3)Vanderbilt University, Nashville, TN, (4)Vanderbilt University Medical Center, Nashville, TN*

Background:
Computer-based interventions, as a more economical and accessible option, are commonly used to teach much-needed skills to ASD individuals (Bekele et al., 2014). Virtual reality (VR) has been used to provide a realistic setting with interactive avatars, allowing ASD individuals controlled opportunities to practice and potentially improve their social interaction skills in a stable learning environment (Ramdoss et al., 2011). Avatars have aided in teaching emotion recognition, allowing ASD individuals to practice social interaction without the anxiety commonly associated with real-world interactions (Parsons, 2000; Golan & Baron-Cohen, 2006) and offer unique benefits such as their ability to be controlled and animated (Dyck et al., 2010), as well as customization of features such as physical appearance, emotion intensity, and gaze (Joyal, 2014). Despite the benefits of their use, we lack data directly comparing emotion recognition tasks utilizing avatars compared to humans in individuals with ASD.

Objectives:

The current project aims to provide a controlled, empirical assessment of the validity of virtual avatars with respect to emotion recognition intervention tasks for individuals with ASD.

Methods:

Virtual avatars were customized and rigged using Mixamo and Autodesk Maya then imported into Unity for final use in a virtual classroom environment. Avatars dynamically displayed the 7 universal emotions (anger, fear, disgust, happiness, sadness, surprise and contempt) at 3 levels of intensity, each display moving from a neutral expression to the emotion in 2 seconds. Twenty-two typically developing adolescents validated these prior to the study. Post validation, the avatar presentation of emotions was matched to human faces, also dynamically displaying 7 emotions at 3 levels of intensity, from neutral expression to emotion in 2 seconds. Human faces were selected from the Amsterdam Dynamic Facial Expression Set - Bath Intensity Variations (ADFES-BIV) database (Wingenbach et al., 2016). All participants selected the emotion displayed by human or avatar and provided a confidence rating for each response. Scores on the tasks were first compared to evaluate performance

differences between human vs. virtual presentations as well as group differences.

Results:

There was no significant difference ($t(24)= -1.796$, $p= 0.085$) between the overall scores for emotions presented by the avatar (M= 14.56, SD= 1.92) compared to human (M= 15.56, SD= 2.48). Certain emotions had significant differences between the avatar and human tasks (Figure 6). "Surprise" and "Contempt" were easier to identify when presented by human faces (surprise: M= 2.80, SD= 0.50; contempt: M= 1.56, SD= 1.04) compared to avatar faces (surprise: M= 2.04, SD= 0.61; contempt: M= 0.72, SD= 0.89), (surprise: $t(24)= -5.729$, $p < 0.001$; contempt: $t(24)= -3.280$, $p= .0003$). "Anger" however was more correctly identified in avatar faces (M= 2.68, SD= 0.48) compared to human faces (M= 2.12, SD= 0.88), ($t(24)= 2.682$, $p= 0.013$). There was no main effect for group (ASD vs. TD) on identifying emotions presented by avatars or humans.

Conclusions:

Virtual avatars may serve as an accurate and realistic comparison to human faces, making them suitable for measuring and teaching emotion recognition in ASD with promise for effective use in therapeutic interventions.

323 **149.323** Automatic Analysis of Temporal Patterns of Head Movement Discriminate between ASD Outcome Groups

K. B. Martin[1], *G. Ren*[2], *Z. Hammal*[3], *J. Cohn*[4], *J. Cassell*[3], *M. Ogihara*[5] *and D. S. Messinger*[6], *(1)Tobii Pro, Reston, VA, (2)Center for Computational Science, University of Miami, Coral Gables, FL, (3)Carnegie Mellon University, Pittsburgh, PA, (4)University of Pittsburgh, Pittsburgh, PA, (5)Universtiy of Miami, Coral Gables, FL, (6)University of Miami, Coral Gables, FL*

Background:

Recent work has shown the importance of quantifying head movement differences in children with and without ASD to better characterize the ASD phenotype (Martin et. al, 2017). However, these analyses relied on aggregated data and did not examine the temporal dynamics of head movement in children with and without ASD. Further, little is known about the head movement patterns in siblings of children with ASD. In this study, we performed a temporal pattern analysis to determine whether the sequential patterns of head movement differed by family history of ASD and ASD outcome.

Objectives:

A computational framework was implemented to extract the temporal patterns of head movement tracking data. We then examined whether these temporal patterns differentiated between ASD outcome groups.

Methods:

Fifty-four participants were 2.5-6.5-year-old children (mean=4.72 years, SD=1.14 years) with (high-risk, n=33) and without (low-risk, n=21) an older sibling with ASD. ASD diagnoses were confirmed for low- and high-risk children by a licensed clinical psychologist. We examined differences in head movement patterns in three independent groups: children with ASD (n=21), children at high-risk for ASD (n=12, HR/NoASD), and low-risk children (n=21, LR/NoASD). Children were video-recorded while watching a 16-minute video containing social and nonsocial stimuli. Three dimensions of rigid head movement—pitch, yaw, and roll (Figure 1) —were tracked using an automatic person-independent tracker (Zface). The temporal patterns were extracted from the head movement tracking data of multiple motion feature dimensions. The categorical timeline allocation process identified the imbalance of the temporal pattern distributions between groups using mean discriminative ratios (mDR). A higher mDR indexes greater differential occurrence of head movement patterns (their differential presence in one group but not another).

Results:

The categorical timeline allocation results show differential occurrence of sequential patterns between groups. Sequential patterns based on pitch, yaw, and roll differentiated ASD and HR/NoASD children, with mDRs of .91, .90, and .94, respectively. Sequential patterns based on pitch, yaw, and roll differentiated LR/NoASD and HR/NoASD children, with mDRs of .90, .92, .94, respectively. Sequential patterns based on pitch, yaw, and roll moderately differentiated ASD and LR/NoASD children, with mDRs of .52, .76, .64, respectively (Table 1). There were 7 patterns of pitch and yaw and 8 patterns of roll that were observed in the ASD but not the HR/NoASD group. There were 7 patterns of pitch and yaw and 8 patterns of roll that were observed in the LR/NoASD but not the HR/NoASD group. There were 2 patterns of pitch and roll and 5 patterns of yaw that were observed in the ASD but not the LR/NoASD group (Table 1).

Conclusions:

The presented analysis framework identified potential diagnostically-relevant head movement motion patterns in ASD. Temporal patterns extracted from head movement tracking data show the ability to discriminate between ASD outcomes. Many temporal patterns appear in one group but are absent in the other, suggesting that these unique patterns distinguish between groups. Together, the discriminative power of temporal patterns and their ability to distinguish between groups indicate the potential of these automatic methods for diagnostic utility in ASD.

324 **149.324** Challenges in the Use of Technology for Autism Spectrum Disorder in Low- and Middle-Income Countries

A. J. Kumm *and P. J. de Vries, Centre for Autism Research in Africa, Division of Child & Adolescent Psychiatry, University of Cape Town, Cape Town, South Africa*

Background:

Efforts to utilize technology to address the practical challenges people affected by ASD face every day, are laudable and important. However, the global ASD community is culturally, linguistic, socio-economically and geographically immensely diverse. If our overarching goal is to address the disparities in access to ASD screening, diagnosis, and treatment in low- income country (LMIC) settings using technology, these technologies need to be designed from the outset with this specific context, community and end user in mind. Many reviews have been performed of a range of technologies for ASD. However, the feasibility of the use of such technologies will depend on the ability to implement them including their accessibility, affordability, appropriateness, and scalability.

Objectives:

Here we set out to examine the feasibility of a range of ASD-related technologies for low- and middle-income settings.

Methods:

Six classes of ASD-related technologies were selected: 1) Personal Computers (PC) 2) Sensing Technologies (ST), 3) Robotics (RT); 4) Virtual Reality (VR), 5) Shared Active Surface (SAS), and 6) Mobile Technologies (MT). Technologies were evaluated for accessibility, affordability, appropriateness, and scalability. Two independent raters reviewed each methodology for each element of feasibility selected, and then provided an overall feasibility rating for implementation in LMIC. Ratings were then compared and consensus reached on all categories.

Results:

RT, VR and SAS were found to be the least affordable, required highly skilled technicians to operate and maintain the equipment and their use limited to research facilities and clinics therefore rating lowest in all categories evaluated. Although people in LMICs have access to PCs they typically are young, educated males living in cities. Furthermore, technologies using photography or video of people are forbidden in some cultures and therefore not universally appropriate.MT scored highest for relative cost (affordability), range of users, settings and purpose (accessibility and scalability).

Conclusions:

Our findings suggest that the feasibility of the majority of existing technologies are very limited in the context of affordability, accessibility, acceptability, cultural appropriateness and scalability. Given the widespread usage of mobile and smartphones and the increasing availability of affordable high speed mobile internet access in the majority of LMIC, mobile health (mHealth) seems to have the greatest potential to increase access to ASD screening, diagnosis and treatment in LMIC settings. There is, however, a striking difference between the large number of Apps available for public download and the small number of tested, evidence-based Apps. To our knowledge, no Apps for ASD have been evaluated specifically for a LMIC setting to date. To address the disparities in access to ASD screening, diagnosis, and treatment in low-resource settings using technology, research will be required to establish the feasibility of mHealth to provide access to quality metal health services and care to the culturally, linguistic, socio-economically and geographically diverse global ASD community.

325 **149.325** Comparing Autistic Children's Social Communication Behaviours in a Robot-Assisted Versus Adult-Led Activity

*C. Seddon[1], A. M. Alcorn[2] and **E. Pellicano**[3], (1)UCL Institute of Education, London, United Kingdom, (2)Centre for Research in Autism and Education, University College London, London, United Kingdom, (3)Macquarie University, Sydney, Australia*

Background: Autistic children experience difficulties with social communication behaviours (SCB). Robots have been proposed as potentially useful tools to support autistic children's SCB, based on claims that their predictable behaviour and simplified characteristics might be less socially demanding for autistic children than human interactions. Yet, very few studies have directly compared autistic children's SCB when interacting with robots versus humans.

Objectives: The DE-ENIGMA project is a large, collaborative project investigating the potential of humanoid robots as tools in autism education, including for teaching about social behaviours. Here, we directly compared autistic children's use of SCBs in child-robot versus child-adult interactions.

Methods: An initial feasibility study collected recordings from a large cohort (n=128) of 5- to 12-year-old autistic children in special education settings, in the context of a 6-step emotion-recognition teaching programme (based on Howlin et al., 1999). Children were randomly assigned to robot-assisted or adult-led teaching conditions. We selected a subset of 5- to 8-year-old participants with at least 15 minutes of recorded interaction during the feasibility study for annotation and analysis. Groups were well-matched for age (p=.699) and for autism severity symptoms, as measured by the CARS2-ST (p=.485). We designed a coding scheme based on the SCERTS model (Prizant et al., 2006) to identify a range of children's SCB in the video data, including *commenting*; *pointing*; *imitation*; *protesting*; *requesting; responding,* etc. Instances of shared affect were also annotated.

Results: Data annotation and analysis are ongoing. Of the data that have been annotated (n=12; 2 females; 6 children from each condition), there were 926 instances of SCBs (excluding shared affect) in a 180-minute sample (15 minutes/child). The median number of SCBs in the robot-assisted condition was 59.50 (*range* = 17 – 87), while in the adult-led condition was 84.50 (*range*= 35 – 198), although there was no significant difference between teaching conditions (Mann-Whitney *U*=24.00, *p*=.394, *r*=.28). When comparing the medians of each type of SCB, we found a significant difference for *imitative behaviours* between the adult-led condition (*Mdn*=1) and the robot-assisted condition (*Mdn*=14.50), *U*=33.50, *p*=.012, *r*=.72. There were no significant between-group differences for any other SCBs.

Shared affect was frequently combined with other behaviours; it is reported separately to give a clearer picture of its extent (Figure 1). We found a significant difference for *sharing positive affect* between the robot-assisted condition (*Mdn* = 10.5) and the adult-led condition (*Mdn* = 3), *U*=5.50, *p*=.045, *r*=-.58. *Sharing negative affect* did not significantly differ between teaching conditions (*U*=9.00, *p*=.059, *r*=-.55).

Conclusions: Of the data examined thus far, the results indicate that children's SCBs were similar in the robot-assisted and adult-led teaching conditions on the total number of SCBs observed, and on instances of most individual SCB types. It is encouraging that children shared more positive affect in the robot-assisted condition, indicating that a humanoid robot can be part of enjoyable, social interactions. Variance in children's SCBs *within* each group highlights the importance of considering individual differences when studying social communication in autistic children, particularly those with limited spoken communication.

326 **149.326** Dynamic Process of Obtaining Stakeholders' Feedback to Develop an Assistive Technology for Children with Asd; Increasing Social Participation

***P. Ghanouni**[1] and T. Jarus[2], (1)Dalhousie, Halifax, NS, Canada, (2)UBC, vancouver, BC, Canada*

Background:

Autism spectrum disorder (ASD) is characterized by difficulty with communication and reciprocal interaction affecting social participation. The common social impairments experienced by children with ASD have a profound impact on daily functioning. Virtual-reality programs are affordable tools that can be used to improve social skills among children with ASD. These programs have the potential to be applied as tele-rehabilitation, as an alternative and promising way, to improve accessibility of health services. Despite the importance of developing a customer-based tele-rehabilitation program for children with ASD, there is no program incorporating stakeholders' ideas.

Objectives:

This study aimed to involve stakeholders in designing and developing a tele-rehabilitation program to help children with ASD improve their socio-emotional skills.

Methods:

We involved over 100 stakeholders, including children with ASD (aged 8-11 years), youth with ASD (aged 13-17 years), their parents, and clinicians work in the field. Inclusion criteria were high functioning and verbal children and youth with ASD who can express their ideas; clinicians with at least one year working experiences in the field of ASD; and parents of a child diagnosed with ASD. All stakeholders needed to be able to communicate in English.

Using a participatory design approach to co-develop the product, this project included three stages of development.

(a) "pre-development phase" to explore ideas on direction and content of the program. First, 26 stakeholders (13 parents, four youth with ASD, and nine clinicians) were interviewed to highlight the focus and shape of the program, and then 63 stakeholders (39 parents and 24 clinicians) confirmed the content via online surveys.

(b) "Development phase". Using iterative process, 20 youth/children with ASD (10 youth, 10 children) and their parents provided feedback on the design of the program.

(c) "Post-development phase". The program was tested among 10 children with high functioning ASD. We evaluated the usability and efficacy of the program.

Results:

Findings showed that stakeholders emphasize the importance of perspective taking and social participation to target. Given the heterogeneity of children with ASD, stakeholders valued individualizing the program rather than trying to fit all children into one program. They described that adding adaptive features to customize the program based on stakeholders' preferences and clinicians' needs would optimize outcomes. Adjusting the audio-visual features and strategies to engage users such as modeling were also expressed. The program was easily used by children and they showed some improvements in socio-emotional skills, though it was not significant.

Conclusions:

This study introduces the development process of a novel program for children with ASD in collaboration with stakeholders. By involving stakeholders during the development, there will be an increased likelihood of uptake of the program. Stakeholders offer valuable perspectives that should be considered in rehabilitation settings both in research and practice.

327 **149.327** Employing K-Means Clustering to Identify Key Performance Indicators for Autism: Data from Eye-Tracking in Joint Attention Tasks

Q. Peng[1], *W. Cao*[1], *H. Zhu*[2] *and J. Chen*[1,3,4], *(1)South China Academy of Advanced Optoelectronics, South China Normal University, Guangzhou, China, (2)Child Developmental & Behavioral Center, Third Affiliated Hospital of SUN YAT-SEN University, Guangzhou, China, (3)School of Electrical Engineering and Computer Science, KTH Royal Institute of Technology, Stockholm, Sweden, (4)Chalmers University of Technology, Gothenburg, Sweden*

Background: Joint attention might be shown in the developmental deficits of children with autism spectrum disorder (ASD). To quantify performance of joint attention, eye-tracking data analysis is often considered, where there are several performance indicators, namely the proportion of fixation time in the area of interests (referred to as fixation time), the latency of the first fixation (referred to as the first fixation) and the longest common subsequence (LCS) similarity (to quantify how the participant's gaze dynamically follows the given logic of the stimulus). However, it is still a research question which performance indicators can properly reflect the difference of joint attention skills between children with autism and typical developing (TD) children. *K*-means clustering is a popular method for cluster analysis in data mining and could be potentially applied to identify the most relevant performance indicators for eye-tracking data analysis in joint attention tasks.
Objectives: This study aimed at implementing *K*-means clustering to explore which performance indicators are the most relevant ones to reflect the capacity of joint attention of autism. We did not only focus on the individual performance indicator, but also investigating their correlations.

Methods: 14 ASD (mean age: 4.96±1.10) and 16 age-matched TD children (4.53±0.90) participated in joint attention tasks. Video stimuli were used to induce joint attention behaviors of the participants. The video consisted of a man sitting behind the table together with three objects (left, middle and right side of the table). The man would turn his head to one object, and the eye movement was recorded by the Tobii X3-120 eye-tracker. The flowchart of the proposed *K*-means clustering algorithm is shown in Fig. 1.

Results: Figure 2 (a) and (d) show the distribution of measured eye-tracking data for ASD and TD children based on one performance indicator (LCS similarity) and a combination of two performance indicators (fixation time and the first fixation), respectively. The corresponding clustering results by applying the proposed *K*-means algorithm can be seen in Fig. 2(b) and (e), respectively. Figure 2(c) and (f) show the exact number of ASD and TD in the group clustered by the proposed *K*-means algorithm. Chi-squared test reveals that as an individual performance indicator, the LCS similarity shows the most significant difference (p=0.002), the fixation time (p=0.024) still reach the significance, but the first fixation (p=0.157) is not significant. However, the difference becomes significant when combining the first fixation to the fixation time(p=0.024) as well as the LCS similarity (p=0.037). When all three performance indicators are considered, there is no significant difference (p=0.063).

Conclusions: We applied *K*-means clustering to identify the key performance indicator for eye-tracking data analysis in joint attention tasks. We found that the LCS similarity was most likely (99.8%) to reflect the difference between ASD and TD children in joint attention tasks. Although the first fixation does not show a significant difference as an individual performance indicator, its correlation with the fixation time and LCS similarity greatly improves the significance.

328 **149.328** Examining the Effect of a Wearable Physiology-Based Anxiety Detection Technology on Self-Awareness of Anxiety Signs in Autism Spectrum Disorder: Data from the Pond Network

J. Nguyen[1], *E. Anagnostou*[1] *and A. Kushki*[2], *(1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Bloorview Research Institute, Toronto, ON, Canada*

Background:
Co-morbid anxiety is prevalent in autism spectrum disorder (ASD) and can negatively impact physical and mental health. Symptom awareness is fundamental to traditional anxiety treatments. However, self-awareness of anxiety symptomology can be challenging in ASD due to differences in emotional awareness and introspection. To address this challenge, we conducted a randomized controlled trial to assess the efficacy of the Anxiety Meter, a wearable, real-time anxiety detection technology, to support awareness of symptoms of anxiety in children and youth with ASD. The Anxiety Meter uses wearable sensors to translate heart rate into a visual display of anxiety (green = calm, red = anxious).

Objectives:

The objective is to determine if the Anxiety Meter can improve awareness of anxiety symptoms and increase self-initiation of relaxation techniques.

Methods:

Twenty-seven children and youth with ASD (Age = 12.9 ± 2.7, 16 males) participated in the study. All participants were part of the Province of Ontario Neurodevelopmental Disorders (POND) Network, had a full-scale IQ score above 50 (IQ = 98.7 ± 18.3), and had not previously received Cognitive Behaviour Therapy. All participants were trained on the use of the Anxiety Meter and taught a diaphragmatic breathing relaxation technique over three visits. On the fourth visit, participants were randomized to either receive feedback of their anxiety level (n = 14) or no feedback (n = 12) from the Anxiety Meter while completing a stress-eliciting task (public speaking) and asked to engage in deep breathing if anxious. Data from one participant in the no feedback group was excluded prior to analysis as the participant did not complete the task. The proportion of participants who initiated deep breathing in each group was measured.

Results:

The proportion of participants who initiated deep breathing to those who did not was significantly higher in the Anxiety Meter feedback group compared to the control group (14:0 versus 3:9; Fisher's exact, p<0.0001). Of those who initiated deep breathing, 10/14 in the Anxiety Meter feedback group and 3/3 in the control group reported feeling calmer after deep breathing.

Conclusions:

Feedback from the Anxiety Meter was associated with a significant increase in the proportion of children who initiated deep breathing in response to anxiety. The results support the feasibility of using a wearable device and real-time feedback to improve anxiety symptom awareness in children with ASD.

329 **149.329** Fully Automated Measurement of Imitation and Motor Learning Differences in Children with ASD

C. J. Zampella[1], *K. Bartley*[1], *E. Sariyanidi*[1], *B. Tunc*[1], *M. Cola*[2], *S. Plate*[2], *L. Bateman*[3], *A. de Marchena*[4], *E. S. Kim*[2], *J. D. Herrington*[5], *J. Parish-Morris*[1], *J. Pandey*[2] *and R. T. Schultz*[2], *(1)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)The Center for Autism Research/CHOP, Philadelphia, PA, (4)University of the Sciences, Philadelphia, PA, (5)Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA*

Background: Meta-analysis indicates that imitation impairments are strongly and specifically associated with ASD. While impairments are robust across tasks, how imitation is *operationalized* within studies moderates whether impairments are detected – i.e., measuring *form* distinguishes ASD from non-ASD better than simply measuring end states. Accurately measuring the *form* of actions as they unfold requires tools that are spatially and temporally granular – now achievable via computer vision. We used computer vision to quantify gross motor imitation in children during a brief task.
Objectives: Apply automated computer vision approaches to measure imitation accuracy and change over time; compare a scalable, open-source motion-tracking program against an established but more resource-intensive system.

Methods: Participants were 21 children with ASD and 18 matched typically developing children (TDC; see Table). Children imitated in real time a 2.5-minute video of a man making a sequence of body movements. The task was completed twice, separated by another brief task. Kinect V2 units collected front-facing whole body video at 30 frames/second. Joint movements were digitally tracked in coordinate space using two platforms: (1) 3D tracking with iPi Motion Capture; (2) 2D tracking with OpenPose (open-source software). Imitation performance was quantified through windowed cross-correlations (4-second sliding windows) between child joint coordinates and joint coordinates from the stimulus video. Results herein are for a subset of joints – child's left wrist relative to stimulus right wrist and vice versa. Mean peak cross-correlations were analyzed in the context of 2 (ASD/TDC) x 2 (Time 1/Time 2) mixed ANOVA.

Results: iPi (3D): There were significant group by timepoint interactions for both wrists, with large effect sizes [left: p=.02, η_p^2=.15; right: p=.01, η_p^2=.16]. TDC significantly outperformed ASD for both wrists at Time 2 [left: p=.002, d=1.07; right: p=.003, d=1.03], but not Time 1 [left: p=.11, d=.53; right: p=.17, d=.46]. TDC performance was significantly higher at Time 2 than Time 1 [left: p=.03, d=.54; right: p=.03, d=.54], whereas the ASD group did not differ significantly across timepoints [left: p=.15, d=-.34; right: p=.11, d=-.40], suggesting a lack of improvement with practice in ASD. OpenPose (2D): The pattern of results was highly similar to iPi (see Figure). There was a significant group effect for both wrists, with medium and large effect sizes respectively [left: p=.046, η_p^2=.10; right: p=.01, η_p^2=.16]. Neither interaction terms nor timepoint effects reached significance for either wrist. While iPi and OpenPose patterns were consistent, mean cross-correlations from OpenPose were lower and standard deviations were higher.

Conclusions: Results are consistent with literature documenting imitation differences in ASD, and are specifically suggestive of impaired motor learning. The novelty of our approach is direct acquisition of raw movement data, rather than reliance on human raters. Such granular measurement should improve imitation assessment, particularly of change over time (e.g., treatment outcomes). 3D motion tracking outperformed 2D tracking; the latter yielded somewhat higher levels of noise in movement representations. However, the freely available, fully automated 2D method yielded the same pattern of results and can be used with standard video (vs. Kinect), which holds promise for large-scale deployment.

330 **149.330** Gait Analysis in Children and Young Adults with Autism Spectrum Disorders Using Instrumented Insoles

H. Zhang[1], *R. Salazar*[2], *E. Cooke*[1], *D. Zanotto*[1], *J. Montes*[3], *J. M. Bain*[2] *and S. Goldman*[2], *(1)Stevens Institute of Technology Mechanical Engineering, Hoboken, NJ, (2)Department of Neurology, Division of Child Neurology, Columbia University Irving Medical Center, New York, NY, (3)Department of Rehabilitation & Regenerative Medicine, Columbia University Irving Medical Center, New York, NJ*

Background:
The diagnosis of autism spectrum disorder (ASD), is based on two behavioral criteria: (1) social and communication impairments; and (2) restricted interests and/or repetitive behaviors. Motor abnormalities, not considered "core" diagnostic criteria, are nonetheless prominent and lifelong in idiopathic or genetic-based ASD. Common clinical tools often lack the sensitivity to capture subtle differences to further define the motor profile across the lifetime. Consequently, the motor phenotype of ASD remains ill-defined. Moreover, due to lack of accuracy in measurement, motor behaviors are not considered valid outcome measures, despite their potential response to behavioral or pharmacological treatment. Among motor behaviors, gait in older children or adults with ASD have been analyzed using cumbersome equipment, and report mixed results in cadence, stride length and base of support. The advent of wearable technologies encourages the use of quantitative gait assessments that are independent of potential clinical assessment limitation.

Objectives:

This project addresses the challenge of accurately measuring gait in children and adults with HNRNPH2-variant who present ASD, anxiety, developmental delays and motor impairments. We used a novel unobtrusive wearable technology (instrumented insoles) developed by our team, to validate our gait methodology against usual command-based motor assessments, which often introduce bias in assessments due to the inherent behavioral constraints of ASD. Herein we show, in a naturalistic environment, the significant value of this technology to assess spatial and temporal features of gait that are not easily identifiable by an observer. The identification of precise gait abnormalities will shed light on underlying motor pathway dysfunctions such as the cerebellum involved in motor control and walking behavior

Methods:

Six patients with HNRNPH2/ASD and two typically developing controls, aged between 5 and 37 years were evaluated. Participants with ASD received complete neurological, neuropsychological, and clinical motor assessments using standardized instruments as well as ASD diagnosis using the gold standard battery. Wearing shoes equipped with comfortable instrumented insoles, participants performed gait (preferred and fast pace, running) and balance tasks (standing on one leg). The gold standard electronic walkway (Zeno mat) was used for comparison to the wearable device in quantifying spatial (stride length, velocity) and temporal (stride time, swing time) gait parameters as participants completed 4 full laps along a 16-meter long straight-line path. All sessions were videotaped.

Results:

All 6 subjects tolerated well the instrumented insoles and, performed safely the walking tasks. We found very good level of agreement between the wearable system and the reference system. In relative terms, mean-absolute-errors (MAE) in stride time, length and velocity were ≤4.2% and ≤1.6% for ASD and controls, respectively. For swing time, the percentage MAE was 5.3% for ASD and 3.0% for controls

Conclusions:

The study confirms, for the first time, the validity and ease of use of our instrumented insoles to accurately assess spatial and temporal gait parameters in individuals with ASD with low complain. These results provide strong support for further gait studies in order to interrogate motor pathways and to characterize the motor trajectory of children and adults with idiopathic or genetic-based ASD.

331 **149.331** Groopit: An Innovative Platform to Speed up Rare Genetic Disorder Research

M. M. Mahony[1], *M. R. Pepper*[2], *C. M. Hudac*[3], *T. Savage*[4], *J. Locke*[5] *and R. Bernier*[3], *(1)Bernier Lab, Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Psychiatry and Behavioral Sciences Department, University of Washington, Bernier Lab, Seattle, WA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)letsgroopit.com, Seattle, WA, (5)Speech & Hearing Sciences, University of Washington, Seattle, WA*

Background: One of the most prevalent disruptive single gene mutations strongly associated with Autism Spectrum Disorder (ASD) is *CHD8* (Bernier, 2014). Due to the rarity of this mutation, families affected by *CHD8* are geographically widespread and use social media, such as Facebook, as a community engagement tool to share experiences and symptoms. For example, aligned with scientific literature (Bernier, 2014), sleep issues are noted by parents as a problem in *CHD8*, however very little is known about the extent to which these problems interfere with daily life. A new mobile platform, GroopIt (letsgroopit.com), may be a useful data collection tool to research the *CHD8* phenotype at a faster pace than traditional research methods by reporting and tracking behaviors in real time.
Objectives: 1) To identify and characterize common sleep issues for individuals with *CHD8* to further understand the *CHD8* phenotype. 2) To evaluate parental engagement in fast-paced research via an online tool.

Methods: Parents from the *CHD8* Facebook group were invited to join the *CHD8* GroopIt. Parents posted real-time observations every day for one month (30 days) regarding characteristics of their child's sleep from the previous night (see figure 1). Analyses were run on the number of instances behaviors were reported as well as how many children experienced the behavior at all. We measured parental engagement by computing the number and frequency of responses over the 30-day period.

Results: Eight families (n=8) participated in the 30-day sleep tracker on GroopIt with at least one response; 63% of those families (n=5) were active participants with over 15 responses. At the end of the study, 159 responses were recorded for 8 children with *CHD8* (see figure 2). Sleep issues with the highest reported prevalence include: difficulty falling to/back to sleep (n=7, 88%), waking up in the middle of the night or very early in the morning (n=6, 75%), waking up crying and/or screaming (n=5, 63%), and sleep quality disturbances (e.g., restless sleep, nightmares; n=5, 63%).

Conclusions: This pilot study highlights the GroopIt platform as a successful research initiative to better outline the phenotype of rare genetic events of geographically dispersed individuals by virtually collecting relevant data longitudinally. We were able to track 159 nights of sleep behavior for 8 children with *CHD8* over 30 days. Our findings expand the existing literature by identifying specific areas of sleep concern for children with disruptive mutations to *CHD8* (e.g., problems falling and staying asleep, waking up early). This highlights particular areas for intervention to address difficulties with sleep. The response rate also shows that mobile platforms provide a useful medium for parental engagement in collecting key phenotypic information.

332 **149.332** How to Select Technologies for Autistic Users: A Co-Developed Evidence-Based Framework

V. Zervogianni[1], *S. Fletcher-Watson*[2], *G. Herrera*[3], *M. S. Goodwin*[4], *P. Pérez-Fuster*[5], *M. Brosnan*[6] *and O. Grynszpan*[7], *(1)Institute for Intelligent Systems*

and Robotics (ISIR), Sorbonne University, Paris, France, (2)University of Edinburgh, Edinburgh, United Kingdom, (3)IRTIC, University of Valencia, Paterna, Spain, (4)Northeastern University, Boston, MA, (5)University of Valencia, Valencia, Spain, (6)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland, (7)LIMSI CNRS UPR3251, Université Paris-Sud, Orsay, France

Background:
When seeking technology-based interventions, a particular challenge for members of the autistic community is identifying which of the multitude of digital technologies available is most appropriate. What kind of evidence do the autistic community use to inform their decisions regarding technology-based interventions? And to what extent does this match with any evidence provided by those developing or evaluating the digital interventions? This study is part of a project aiming to integrate the perspectives of the autistic, practitioner, developer and researcher communities as to what constitutes evidence for technology-based interventions.

Objectives:

To develop an agreed framework, shared among all relevant stakeholders, for good practice with regard to the provision of accessible evidence for technology-based interventions for autism.

Methods:

We carried out a Delphi-inspired qualitative study adopting Delphi methodology's iterative nature, participant anonymity and online communication (Hasson et al. 2000; Boulkedid et al., 2011) and performing a thematic analysis on the aggregated data. An international panel of 23 specialists (researchers, practitioners, developers, autistic community) in autism and digital technologies completed a four-phase Delphi consultation initially informed by a systematic literature review. Suggestions for evidence usage in technology-based interventions for autism were elicited from the panel, grouped and reviewed by a moderator and rated by the panel at every phase.

Results:

Three separate and distinct requirements emerged for technology-based interventions for autism, namely: reliability, engagement and efficiency. Four sources of evidence were consistently considered high-value by our expert panel, namely: hands-on experience, academic sources, expert views and online reviews. The relative weighting of the importance of each source of evidence varied between reliability, engagement and efficiency. For example, hands-on experience was thought to provide the strongest evidence for reliability and engagement, whereas academic sources were thought to provide the strongest evidence for efficiency. The panel also identified need for caution in relation to some sources of evidence, such as information provided by product developers themselves, as well as a detailed list of resources for digital products for the autism community.

Conclusions:

For the first time, a framework for considering the evidence for technology-based interventions for autism has been developed. The framework has been co-developed by all the relevant stakeholders and is an accessible guide to the available evidence. It can be quickly and easily applied to technology-based interventions for autism by the members of the autism community. This framework can be used as a guide when selecting or recommending a technology-based intervention for autistic people.

333 **149.333** Systematic Review of Evidence-Based Practice and User-Centered Design for Technology-Based Interventions for the Autistic Community

V. Zervogianni[1], *S. Fletcher-Watson*[2], *G. Herrera*[3], *M. S. Goodwin*[4], *P. Pérez-Fuster*[5], *E. Triquell*[1], *M. Brosnan*[6] *and O. Grynszpan*[7], *(1)Institute for Intelligent Systems and Robotics (ISIR), Sorbonne University, Paris, France, (2)University of Edinburgh, Edinburgh, United Kingdom, (3)IRTIC, University of Valencia, Paterna, Spain, (4)Northeastern University, Boston, MA, (5)University of Valencia, Valencia, Spain, (6)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland, (7)LIMSI CNRS UPR3251, Université Paris-Sud, Orsay, France*

Background:
The past decade has seen an exponential increase in the number of technology-based interventions for the autistic community. Interventions having robust evidence of effectiveness are rarely commercially available, whilst commercially available therapeutic technologies are infrequently evaluated in research (Constantin et al., 2017). Evidence-Based Practice (EBP) dictates that practitioners should ensure interventions are informed by good evidence (Reichow, 2008). While an EBP framework has been applied to traditional interventions for autism (Mesibov & Shea, 2011), this is not the case for technology-based supports. We argue that technology-based support requires not only a robust evidence base, but also the participation of the autistic community in the development process (Brosnan et al., 2016) to ensure the needs of the autistic community are satisfactorily met. According to ISO 9241-210:2010, User-Centred Design (UCD) is an iterative design approach based on explicit understanding of users, tasks and environments, driven by user evaluation and including multidisciplinary perspectives.

Objectives:

We aimed to systematically review the current state of EBP and UCD for technology-based interventions for the autism community. Additionally, we examined the potential link between EBP and UCD.

Methods:

We followed the PRISMA guidelines for systematic reviews and we used keywords pertaining to technology-based interventions combined with autism conditions. We searched in scientific databases of different foci to accommodate the multidisciplinary nature of the field. From 792 eligible articles we took a random sample of 30% (n= 215) to evaluate two dimensions:

1. EBP: We implemented Reichow's (2008) evaluative method that identifies evidence-based practices for autistic children and we gave group or single-subject designs a score according to a set of quality indicators.
2. UCD: We developed a scale evaluating the extent to which the end-users and their characteristics were taken into account in the development process. The scale was based on Druin's (1999) taxonomy of user participation and ISO norms for human-computer interaction.

Results:

The mean score on Reichow's scale was 1.055, 95% CI [0.915, 1.19] (with 1=weak) and on the UCD scale 3.555, 95% CI [3.36, 3.75] (in a range between 0 and 8). Reichow's scale was not applicable for 81 (38%) of the papers. 71 (33%) papers were rated as weak, 33 (15%) as adequate and 30 (14%) as strong in terms of research rigour. In terms of user-centeredness of the design, 59 (28%) papers received low scores, 135 (62%) medium and 21 (9%) high.

A marginally significant correlation was found between the ratings on the two scales (p=0.05153).

Conclusions:

The resulting ratings indicate a low level of evidence base and a medium to low user consideration and inclusion in the existing literature on technology for autism. Many of the included studies did not meet standard criteria of quality group or single-subject designs. In addition, many of the included studies did not involve end-users or proxies at all. EBP and UCD seem to have a marginally significant positive correlation. Neither framework is currently being applied within the majority of technology-based interventions for autism.

334 **149.334** Outcomes of a Robot-Assisted Social-Emotional Understanding Intervention for Young Children with Autism Spectrum Disorders

*F. Marino[1], **L. Ruta**[1], P. Chilà[1], S. Trusso Sfrazzetto[1], C. Carrozza[1], I. Crimi[1], C. Failla[1], B. Moretti[2], M. Busà[1], G. Bernava[1], G. Tartarisco[1], D. Vagni[1] and G. Pioggia[1], (1)Institute of Applied Sciences and Intelligent Systems, "Eduardo Caianiello" (ScienceApp) – National Research Council of Italy (CNR), Messina, Italy, (2)Società Cooperativa Sociale Occupazione e Solidarietà, Bari, Italy*

Background:

People in the autism spectrum show impairment in social emotional skills and these difficulties contribute to the impairments in initiating and sustaining typical peer relationships (Berenguer et al., 2018; Jones et al., 2018).

Social robots show great potential for boosting treatment outcomes in children with ASD and robot-assisted autism therapy (RAT) has become an emerging application area in the past few years (Scassellati et al., 2012).

Objectives:

This study is a randomized control trial aimed to test the role of a human-assisted social robot as a treatment mediator in a social emotional understanding protocol for children with autism spectrum disorders (ASD).

Hence, we aim to investigate the feasibility and efficacy of using a partially controlled social robot (NAO) in the context of a group-based CBT intervention trial focused on emotion comprehension and related mentalizing skills, knowledge of basic emotion lexicon and the ability to attribute appropriate emotions in relation to the context.

Methods:

A total of n= 14 high functioning ASD children (13M:2F) participated in the study and completed the intervention. Children were randomly assigned either to the robot-assisted intervention group (RG) (n= 7 children, 6M:1F, mean age in months= 73.3; SD = 16.1) or to the control group (CG) applying the same intervention protocol without the use of the assistive-robot (n= 7 children, 6M:1F, mean age in months=82.1; SD = 12.4).

The intervention consisted of 10 sessions (90 minutes each administered twice a week) of a group-based cognitive behavioural (CBT) emotional understanding skills training protocol based on the principles of the Rational Emotional Behaviour Therapy (REBT). The protocol was specifically designed for implementation with the assistance of a social robot actively interacting with the children and providing verbal antecedents, prompts and reinforcing consequences according to an Antecedent-Behaviour-Consequence (ABC) model.

Pre- and post-intervention assessments were conducted using the Test of Emotional Comprehension (TEC) (Pons & Harris, 2000) and the Emotional Lexicon Test (ELT) (Grazzani, Ornaghi, & Piralli, 2009).

Both the TEC and the ELT are objective measures of the child's performance related to Emotion Comprehension (EC) and Expression in specific social contexts.

Results:

Pre-treatment outcome measures were comparable between the two groups.

The RG displayed a significant improvement on TEC (U=47.0, W=75.0, Z=2.9, p=.001), with a gain of 59% in the total score. Conversely the CG, although improving on the TEC total score by 21%, did not show a significant change (U=32.5, W=60.5, Z=1.04, p=.16).

Likewise, post-treatment total scores on ELT increased by 48% in the RG and by 12% in the CG, showing a significant improvement in the RG (U=49.0, W=77.0, Z=3.4, p=.001), but not in the CG (U=36.5, W=64.5, Z=1.9, p=.06). Furthermore, following the intervention, all children in the RG, but none in the CG, reached the top scores on ELT (Table 3).

Conclusions:

Substantial improvements in contextualized emotion recognition, comprehension and emotional perspective taking through the use of human-assisted social robots were obtained.

335 **149.335** Probabilistic, Model-Based Eye-Tracking Using Machine Learning

***J. A. Olmstead**, A. Klin, S. Shultz and W. Jones, Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA*

Background:

Eye-tracking is a popular research method for neuroscience and biomedical research in general, and for studying social development and autism spectrum disorder (ASD) in particular (Jones & Klin, 2013). In theory, the technology is applicable to participants of all ages and all levels of cognitive and adaptive ability. In actuality, however, traditional calibration techniques required by many model-based eye-tracking technologies (i.e., those that use models of infrared corneal reflection and pupillary geometry to determine gaze, such as EyeLink, SMI, and ISCAN) are difficult to complete for neonates and for individuals with behavioral or cognitive challenges, including some individuals with ASD. This limitation can prevent data collection from important community stakeholders.

Objectives:

To circumvent pre-session calibration procedures for model-based eye-tracking using post-hoc machine learning techniques, while still enabling high-fidelity data collection for studies of social visual engagement in neonates and intellectually-disabled individuals with ASD.

Methods:

By using a set of accurately calibrated, high-quality eye-tracking sessions (N = 18, Table 1) as ground truth estimates during supervised machine learning (Google TensorFlow 1.12.0 library with Keras backend, Abadi et al., 2015), we empirically constructed a calibration transformation from 2-D eye-image space into 2-D screen-coordinate space (Figure 1a-b). We then used an independent set of accurately calibrated, high-quality eye-tracking sessions (N = 111, Table 1) to test the calibration transformation on novel data collected under the same lab conditions.

Results:

The median absolute point of gaze (POG) error (actual POG - predicted POG) subtended 2.64 degrees of visual angle (Figure 1b-c). We then used the empirical error distribution to demonstrate potential future area-of-interest (AOI) analyses: In videos that are segmented into AOIs at each frame, we can probabilistically determine what AOI is being fixated.

Conclusions:

Data collected through model-based eye trackers can be accurately calibrated post-session using machine learning. The estimated gaze position error can be minimized by quantifying and indexing covariates to discard data that are likely to be poorly estimated. Once an error distribution has been empirically determined, it may be used to probabilistically determine fixated elements in naturalistic social scenes. The strength of this eye-tracking approach is that it can be developed and deployed to collect data from participants for whom traditional eye-tracking experiments may not be possible—i.e., from neonates or from individuals with ASD with behavioral challenges or with substantial comorbid intellectual disability. Probabilistic eye-tracking analyses have the promise of extending quantitative research methods into populations of extreme interest, allowing insight into the earliest periods of development and the results of its disruption.

336 **149.336** Robustness Analysis for Computational Speech Features during Naturalistic Clinician-Child Interactions

M. Kumar[1], *K. Singla*[1], *G. Gunin*[2], *C. Lord*[3], *S. H. Kim*[4] *and S. Narayanan*[1], *(1)University of Southern California, Los Angeles, CA, (2)Psychiatry, Weill Cornell Medical College, White Plains, NY, (3)University of California Los Angeles, Los Angeles, CA, (4)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY*

Background:

Computational analysis of autism diagnostic sessions using automatically extracted features combined with machine learning has provided valuable insights (Bone et al., 2016). Specifically, speech and language features extracted from both child and the interacting clinician have shown to be significantly predictive of autism symptom severity (Bone et al., 2015). However, feature extraction is dependent on availability of *who spoke when and about what (*i.e., speaker labels, durations and transcripts), which can be time-consuming and expensive to obtain manually. Recent technological developments have enabled accurate automatic speaker segmentation, labeling and speech-to-text conversion. However, behavioral feature extraction using these algorithms need to be refined in order to obtain clinically meaningful interpretation for ASD.

Objectives:

We test the feasibility and validity of an automated end-to-end speech processing pipeline (consisting of speech detection, speaker diarization, automatic speech recognition (ASR) and role-assignment modules) to extract speech and language features from audio obtained from naturalistic clinician-child interactions. By replacing oracle labels with system outputs at each module, we simulated multiple error conditions which result in inaccurate features. For each condition, we studied the feature robustness across categories (lexical, turn-taking, prosodic) and the autism symptom severity.

Methods:

As a preliminary analysis, we selected 27 semi-structured, examiner-child interaction sessions from the new treatment outcome (Brief Observation of Social Communication Change [BOSCC; Grzadzinski et al., 2016]; n=24) and gold-standard diagnostic (Autism Diagnostic Observation Schedule-2 [ADOS-2, Lord et al., 2012]; n=3) measures (age: μ=9.3 years, σ=3.4; verbal IQ: μ=98.6, σ=24.3). Trained annotators labeled speaker boundaries and transcripts, which were used to extract session-level features (*oracle features*). Next, the speech pipeline was employed to extract an identical set of features *(pipeline features)* wherein at each module the oracle labels were replaced with previous module outputs. Feature robustness is estimated by comparing pipeline features to oracle features. For each type of module error, we used normalized mean squared error (NMSE) to identify a subset of robust features. Using linear regression models, we compared the ADOS calibrated severity scores (CSS) predicted using pipeline features versus oracle features to assess predictive power of symptom severity in the former.

Results:

We obtained perfect role assignment for all sessions, word error rates of 45.61% (clinician) and 75.63% (child) from the ASR system, speaker error of 9.42% from the speaker diarization system and an f-score of 0.90 from the speech detection system. Similar feature subsets were found to be robust under both conditions: (lexical) first-person pronoun use by clinician, (turn-taking) clinician speaking fraction and utterance lengths and (prosodic) intonation slope and intercept from both speakers (Table 1)**.** Further, the regression model (adjusted R^2=0.26, DF=16) trained from pipeline features predicted almost similar CSS scores (Fig. 1) when compared to the oracle features (NMSE=0.026).

Conclusions:

We built a fully automated speech pipeline to extract behavioral features during semi-structured, naturalistic examiner-child interactions. We identified features robust to different module errors. We further demonstrated similar predictive power between robust pipeline features and oracle features. These results are promising for more automated, scalable analyses fo speech while removing the need for manually annotated speaker labels.

337 **149.337** Spline Fitting for More Robust ERP Derived Dependent Variables

T. McAllister[1], *A. Naples*[1], *A. Bagdasarov*[1], *C. Carlos*[1], *C. C. Cukar-Capizzi*[1], *E. Hamo*[1], *E. Jarzabek*[1], *S. Kala*[1], *M. L. McNair*[1], *D. Stahl*[1], *T. Winkelman*[1], *J. Wolf*[1], *A. Anticevic*[2], *V. Srihari*[2] *and J. McPartland*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Division of Neurocognition, Neurocomputation, and Neurogenetics (N3), Yale University School of Medicine, New Haven, CT*

Background:

Electroencephalography (EEG) is a valuable tool for studying Autism Spectrum Disorder (ASD) due to its high temporal resolution. By repeated exposure of participants to stimuli, researchers can construct Event Related Potentials (ERPs). For statistical analysis, measures of ERP peaks often utilize automated window-based peak picking (AWPP) to find peak activity during a specified time window. AWPP offers no reliable way to assess accuracy of derived dependent variables (DVs), such as peak amplitude and latency to peak. Manual peak picking (MPP), in which humans select peaks based on visual inspection, offers this benefit but is significantly more time consuming and prone to human error. Splines are smooth lines made of Bezier curves. Fitting splines to ERPs presents an alternative method to derive DVs, which may offer a middle ground of performance assessment and time efficiency. Given the unusual waveform morphologies commonly observed in ASD, this would represent a significant advance, particularly in large samples.

Objectives:

We sought to: (1) develop an algorithm to fit splines to ERP data; (2) assess the success in both ASD and typical development (TD) using spline parameters instead of AWPP; (3) identify avenues for further development as a tool for analyzing EEG data in ASD.

Methods:

Data were collected across 106 EEG sessions with adult participants clinically diagnosed with ASD or TD controls. Participants were shown dynamic faces displaying emotional expressions. Data were processed with simple filtering and artifact detection and averaged across trials. AWPP was used to find a positive peak within a window of 40-190ms relative to the event (P100), and a negative peak in the window of 120-250ms (N170), both in averaged channel groups representing the left and right occipto-temporal scalp. A grand average was used to manually create a starting spline, which was then automatically fit to each ERP for the same channel groups by our algorithm. The parameters that defined the fit splines were used in analysis.

Results:

Based on simple ANOVAs using both AWPP values and corresponding spline control points values (SCPV), our algorithm was successful in extracting meaningful data from ERPs. A statistically significant difference between groups was detecting using both AWPP-derived N170 amplitude (p=.015) and the SCPV (p=.007). In addition to comparable performance in group discrimination, the SCPV offer a goodness of fit with R^2 values, and thus an estimation of divergence from recorded waveforms. Further, some SCPVs with no AWPP equivalent show promise of discriminatory power, indicating that our method may capture additional, novel aspects of waveform shape.

Conclusions:

Our promising results warrant further development of these methods. Given the same data, novel methods were able to extract equivalent meaningful information from the ERPs when compared to AWPP. Further, goodness of fit estimation and novel values with possible discriminatory power offer advantages over the traditional method. While our methods were not compared to MPP, the vastly lower cost in human effort highlights the value of this approach in quantifying individual differences in an automated and unbiased fashion. Ongoing analysis is examining our approach with other ERPs, such as Visual Evoked Potentials.

338 **149.338** Investigating ASD-Specific Salient Visual Features Using Discriminatory Convolutional Neural Networks: Results from the ABC-CT Interim Analysis

C. Carlos[1], *A. Naples*[1], *K. Chawarska*[1,2], *R. Bernier*[3], *S. Jeste*[4], *C. A. Nelson*[5], *G. Dawson*[6], *S. J. Webb*[3], *M. Murias*[7], *F. Shic*[8,9], *C. Sugar*[4] *and J. McPartland*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Yale School of Medicine, New Haven, CT, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)University of California, Los Angeles, Los Angeles, CA, (5)Boston Children's Hospital, Boston, MA, (6)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (7)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (8)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (9)Pediatrics, University of Washington School of Medicine, Seattle, WA*

Background: Autism spectrum disorder (ASD) is marked by atypical visual attention to socially meaningful visual stimuli. While reduced focus to social features is commonly studied, less research has been directed towards characterizing visual features that draw the attention of individuals with ASD. By training convolutional neural networks (CNNs) to discriminate among saliency maps of eye-tracking (ET) data from individuals with ASD vs. typical development (TD) vs. randomly generated maps, visual attention patterns associated with ASD can be described. Using the biophysically inspired CNN model, insight into the underlying mechanism of visual attention for ASD individuals may lead to better clinical treatment and intervention strategies.

Objectives: This study uses CNNs to model image characteristics that are most salient to ASD individuals relative to TD peers.

Methods: ET data were collected for 225 participants between the ages of 6 and 11 (ASD: N = 161, 131 male; TD: N = 64, 42 male) using an SR Eyelink 1000+ while participants viewed static images of social scenes. ET data were used to generate saliency maps, which were overlaid onto the respective trial's stimulus image. These masked images served as the dataset for the CNN models. A set of random saliency maps was also generated. Three identical CNNs were trained independently to discriminate between ASD and TD datasets (ASDvTD), ASD and random datasets (ASDvRAND), and TD and random datasets (TDvRAND). A consistency-of-gaze (CoG) metric was calculated to index a person's tendency to fixate on their most salient feature of a stimulus image by dividing the number of sampled viewings in the highest salient location by the total number of sampled viewing positions.

Results: A significant difference was found between the CoG metric for ASD and TD groups indicating less consistency of gaze in ASD; t(1333.7)=-3.76, p=1.8e-4. Validation set accuracy and mean squared error (MSE) assessed ability of CNNs to discriminate datasets. ASDvTD obtained accuracy=0.70, MSE=0.30. ASDvRAND obtained accuracy=0.59, MSE=0.41. TDvRAND obtained accuracy=0.86, MSE=0.11.

Conclusions: These data show that CNNs are capable of discriminating between groups based on saliency weighted image characteristics. CoG

significantly differed between diagnostic groups; this may reflect the previously reported tendency of TD participants in this sample, relative to ASD participants, to attend to faces in stimuli (Shic et al., 2018). This would also explain the high accuracy of TDvRAND, as the model was capable of easily learning head specific low-level visual patterns. The low accuracy of ASDvRAND suggests that, in contrast to the shared low-level features of TD salience, low-level ASD-specific features were not strongly distinct from random low-level visual features. Future research could add more convolutions to the model to increase the size of the receptive field for CNN. Such deeper model could test whether ASD-specific salient features are noisy and non-homogenous or whether that gaze in ASD individuals is mediated by a set of common visual features.

339 **149.339** Using a Participatory Approach to Iteratively Adapt a Collaborative Emotion Recognition Game for Non-Speaking Autistic Youth

K. Gillespie-Lynch[1], *D. S. Smith*[2], *A. Riccio*[3], *P. Asanov*[4], *L. Pisicolo*[4] *and D. Sturm*[4], *(1)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY, (2)College of Staten Island, CUNY, Staten Island, NY, (3)Department of Psychology, The Graduate Center, City University of New York (CUNY), New York, NY, (4)College of Staten Island, Staten Island, NY*

Background: Although autism is partially defined by social difficulties, some autistic people communicate more effectively through computers than in-person (Gillespie-Lynch et al., 2014). Consequently, computer-mediated supports for autistic people are proliferating (Fletcher-Watson, 2014). However, evidence that computer-mediated interventions help autistic people develop *generalizable* social-communicative skills remains limited (Whyte et al., 2015). Participatory research wherein autistic people collaborate in game design/evaluation may ameliorate the disconnect between the *potential* of computerized interventions and *limited benefits* documented thus far.
Objectives: By collaborating with speaking autistic people, we are developing a game to help non-speaking autistic people understand complex emotions and collaborate.

Methods: *Connecting through Kinect* uses animated tutorials rather than words to be accessible regardless of linguistic ability and promotes generalizable social-communicative skills by providing simultaneous opportunities to engage digitally and in-person. Players solve collaborative emotion matching puzzles using Kinect while standing together. Each puzzle depicts the outline of a figure in an emotional context. After constructing the body, players must agree on the correct emotion for the face by selecting from three emotions. This collaborative component was adapted from a task which promoted collaboration among minimally-verbal children (Holt & Yuill, 2014). In earlier iterations of game development (Sturm et al., 2018), autistic college students spearheaded many improvements including: demos, meaningful rewards, improved image quality, and a relatable storyline (an autistic child overcomes bullying through friendship with a friendly dragon; Figures). After qualitative coding revealed that autistic students initially looked at the screen rather than each other, we added a tutorial depicting collaborative play, an associated pause feature to encourage collaboration, and a face tracking component to automatically quantify collaboration. Autistic college students looked at one another more when playing the revised game. However, some played with mentors who prompted collaboration verbally. After incorporating extensive feedback from 10 autistic college students in our mentorship program, we asked 10 autistic adolescents from a technology camp for feedback.

Results: To evaluate if the game is accessible *without* spoken instructions, autistic adolescents played the revised game with a player who did *not* prompt interaction. They exhibited pronounced variability in emotion matching (0-16 errors), utterances (1-47) and looking at one another (0-6). They found the game useful/fun but critiqued motion control inefficiencies and found the collaboration animation confusing, indicating that it should be removed. They highlighted the need for tutorials to let players know that there is a "right answer." Some felt that "errors" were "glitches" and were surprised to realize that the background was relevant. An adolescent with low language skills kept approaching the Kinect asking "Why can't I help?" Findings indicate that emotion matching/collaboration are desired learning goals while highlighting areas for improvement.

Conclusions: Our autistic collaborators have spearheaded extensive improvements in game design. They remind us to incorporate key design principles that promote generalization but are often lacking in games designed for autistic people. After incorporating feedback, we will evaluate the game with non-speaking children this spring. The process of collaborating with speaking autistic people to develop computer-mediated interventions for non-speaking youth shows promise.

340 **149.340** Systematic Review of Web- and Smartphone-Based ASD Parent Trainings: Increasing Access and Improving Outcomes

E. Glenn[1], *H. Riehl*[2], *A. Taiwo*[1] *and L. L. McIntyre*[1], *(1)University of Oregon, Eugene, OR, (2)Tufts University, Boston, MA*

Background: Parents of children with ASD have difficulty obtaining services triple that of parents of children with other healthcare-related needs, with up to 56% of these parents reporting long wait-lists, local unavailability of services, or financial limitations (Montes, Halterman, Magyar, 2009). Telehealth coaching has begun to address issues of delivery of high-quality, efficacious services to more rural areas, but has not addressed issues of clinician availability, nor treatment costs. Online or app-based parent training have the ability to partially address these issues through providing triage, connecting parents with evidence informed practices and resources, and supplementing ongoing therapy. However, as studies on eLearning are rather nascent in comparison with tele-consultation, systematic reviews have yet to specifically explore the effects of parent eLearning programs on child social, emotional and behavioral outcomes.
Objectives: The aim of this systematic review was to evaluate the impact of web- and app- based parent trainings, not solely reliant on web-based video conferencing, on outcomes for children with ASD.

Methods: Using PRISMA methodology, we searched five different databases (EBSCO, ProQuest, PsychInfo, PubMed, Web of Science) for abstracts containing search terms in each of the following categories: ASD, web/smartphone, intervention, and parenting. The search results identified 1191 articles, with 737 unique articles once duplicates were removed. 40 relevant abstracts and 13 articles for inclusion resulted after screening for articles: 1) in English, 2) in a peer-reviewed journal, 3) included a parent-mediated intervention or training 4) intervention was disseminated at least partially online or in an app, 5) contained an online element besides teleconferencing, 6) reported child outcomes, and 7) were tested with an ASD population. Using the snowball method, we scanned the references of included articles, however failed to find additional articles that met inclusion criteria.

Results: Demographics for these studies largely represented middle class, college-educated, non-minority parents. Out of the 13 studies, 6 were single-subject multiple baseline designs, 5 were RCTs, and 2 consisted of pre- and post- measures with no control group. Interventions targeted

child social-communication skills, reciprocal imitation skills, joint attention, as well as secondary conditions such as anxiety. Parent skills targeted were modeling, prompting, reinforcement, creating visual supports, setting up behavior contingencies, and problem solving. Effect sizes for child outcomes ranged from d=0.58-2.2. Twelve studies supplemented online parent training with in-person or web-based coaching sessions. Eleven studies utilized web-based platforms, while 2 were application based. Programs varied in terms of length, online components, attrition, and research quality.

Conclusions: This review suggests that there is a burgeoning literature of promising online parenting programs. Published findings suggest moderate to large effect sizes for improving social-communication skills and reducing anxiety in children with ASD. Most of these studies were a hybrid of online and clinic or tele-health intervention modalities, thus, additional investigations are needed to test the independent contributions of online and tele-health components. Future studies should also explore factors that may moderate parent engagement and child outcomes. Additionally, future studies should target more diverse samples in terms of SES, parental education, and prior experience with parenting interventions.

9:00 Of Many Autisms or One Neurodevelopmental Disorder

***J. P. Lerch**, Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada; Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, United Kingdom*

Defining diagnostic boundaries is difficult. There is a case to be made for lumping disparate neurodevelopmental disorders, including autism, ADHD, and OCD, into a single category. Conversely, there are strong arguments for splitting autism into multiple, narrower diagnoses focused on genetics or other aetiological factors. Here I will use brain imaging data from both large human population samples as well as from over 100 mouse models related to the disorder to explore both the case for lumping and splitting. Human imaging finding, coming from structural MRI, diffusion imaging, and functional MRI indicates that the boundaries between different neurodevelopmental disorders are hard to recover in brain signatures. The mouse data indicates that there are 4 separate classes of models which share a neuroanatomical phenotype and link with known genetic pathways. The human and mouse data together suggest that our current nosological categories do not have a strong basis in biology, and that future choices of where to lump and where to split will be context dependent.

Panel Session
Adult Outcome: Medical, Cognitive, Behavioral, Social, Adaptive, Vocational
157 - Health and Well-Being in Transition-Age Youth and Adults with Autism Spectrum Disorder
10:30 AM - 12:30 PM - Room: 517C

Panel Chair: Beth Malow, *Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN*

Discussant: Susan Brasher, *Nursing, Emory University, Atlanta, GA*

Health and well-being are considered core domains of quality of life (QOL) in autism research and are synergistic with other QOL domains and transition success. For example, greater vocational independence and engagement have been related to subsequent reductions in maladaptive behaviors. Self-determination, which encompasses identifying one's wants and needs, problem-solving obstacles, advocating for one's self, and believing that one has the capability to make positive changes for one's own life path, provides an essential foundation for other core domains of QOL. Research focused on health and well-being in transition-age youth and adults with autism spectrum disorder (ASD) has lagged far behind other types of ASD-related research. With many individuals with ASD turning 18 years old (estimated at 500,000 over the next decade), broadening our understanding of health and well-being, while improving QOL, in this population is timely and relevant. This panel will focus on topics related to health in transition-age youth and adults with ASD including the barriers and facilitators of a smooth transition from pediatric to adult care, sex differences in physical health conditions and healthcare utilization, predictors of self-determination, and the associations of self-determination and autism identity with physical and psychological health and QOL.

10:30 **157.001** Are Health Care Providers Ready to Transition Teens with Autism Spectrum Disorders to Adult Care? a Survey of Clinical Providers in California.

L. A. Croen[1], *J. Ames*[1], *M. L. Massolo*[1], *Y. Qian*[1], *H. J. Cerros*[1] *and M. N. Davignon*[2,3], *(1)Division of Research, Kaiser Permanente, Oakland, CA, (2)Pediatric Specialties, Kaiser Roseville Medical Center, Roseville, CA, (3)Kaiser Permanente Northern California, Oakland, CA*

Background: Health care continuity during the transition from pediatric to adult health care is critical to helping individuals with autism spectrum disorders (ASD) manage complex medical and psychiatric co-morbidities that start in childhood and evolve with age. However, the transition process is often difficult to navigate for young adults and their families. Youth with ASD often receive fewer transition resources than their peers with other special health care needs (SHCN) and experience lapses in care. While several studies have examined the health care transition from the perspective of patients and their families, fewer have approached the problem from the perspective of the providers.
Objectives: To assess providers' departmental and personal practices surrounding the transition of patients with SHCN from pediatric to adult care.

Methods: In 2016, we conducted a brief online survey (~20 questions) of pediatric and adult health care providers at Kaiser Permanente Northern California (KPNC), a large integrated healthcare delivery system serving over 4.2 million members. The survey was developed in consultation with the "Got Transition" Project and piloted by KPNC pediatric and adult care providers. Questions assessed departmental policies and personal approaches to transitioning patients with SHCN and desired training and resources to improve the process. Response formats included Likert scale, multiple choice, or select all that apply as well as space for optional free response.

Results: A total of 354 pediatric (43%) and 715 adult providers (33%) completed the survey. Survey respondents were approximately 75% primary care and 25% mental health providers. We found that a large majority of departments do not have transition policies, practices, or mechanisms in place. Even when departmental policies do exist, this information is only transferred to medical staff and patients less than 50% of the time. Furthermore, the majority of providers do not provide transition resources, review legal changes, use a standardized assessment tool, or communicate with next/previous provider – strategies endorsed by the American Academy of Pediatrics. When a transition readiness assessment tool was used, approximately 60% of providers incorporated the results into a care plan and shared the care plan with patients and/or their families. Deficiencies in transition approaches were apparent in both primary care and mental health settings. Pediatric providers also reported starting the transition planning when the patient reached age 17+, despite current recommendations to initiate the process earlier. Ninety percent of pediatric providers desired training in the specific transition needs of patients with ASD.

Conclusions: Our findings indicate that most pediatric and adult providers do not have consistent approaches to the transition of care for youth with SHCN and feel inadequately prepared to handle the process for children with ASD. As the population of transition-age youth with ASD continues to grow, there is urgent need to understand how to best implement transition policies that promote early and clear communication between providers and families and track outcomes among transitioning patients with SHCN.

10:55 **157.002** Sex Differences in Health Outcomes Among Adults with ASD

L. E. Smith DaWalt[1], *J. L. Taylor*[2], *A. Movaghar*[3], *J. Hong*[3], *M. H. Brilliant*[4] *and M. Mailick*[1], *(1)University of Wisconsin-Madison Waisman Center, Madison, WI, (2)Vanderbilt Kennedy Center, Nashville, TN, (3)University of Wisconsin-Madison, Madison, WI, (4)Marshfield Clinic Research Institute, Marshfield, WI*

Background:
Individuals with autism spectrum disorder (ASD) face many challenges during adulthood, including elevated health problems relative to the general population. An emerging body of evidence suggests that females with ASD may be doubly-vulnerable for poor outcomes across a range of domains because of both their sex and their autism status. However, sex differences are rarely investigated in ASD studies, often because too few females are included. The present study used electronic health records (EHRs) to investigate health conditions of women with ASD compared to men with ASD as well as compared to men and women without ASD.

Objectives:

The present study examined (1) sex differences in health conditions and burden of disease for 2119 adults with ASD (458 females, 1661 males) and (2) if sex differences for adults with ASD were similar to or different from sex differences in the general population using a comparison group of 21,228 age- and sex-matched adults without disabilities.

Methods:

We utilized EHRs from the Marshfield Clinic population (a large, private, multispecialty group practice with records for over 1 million patients) to characterize health profiles. We selected for autism cases based on a patient having an ICD-9 code of pervasive developmental disorder (299) on at least two occasions (following procedures used by Croen et al., 2015). Based on past research, our initial analyses focused on five conditions: cardiovascular disease, sleep disorders, thyroid disease, constipation, and gastroesophageal reflux. Health conditions (presence=1, absence=0) were defined based on the presence of at least two ICD-9 codes in the health record for the particular condition. For individuals with a given condition, burden of disease was determined by a count of total number of ICD-9 codes, reflecting the number of medical visits, for that condition.

Results:

Preliminary findings found differences between autism and comparison groups in all five of the conditions we investigated. Individuals with ASD had higher rates than controls of cardiovascular disease (23.5% ASD vs 10.2% controls; p=.03), sleep disorders (13.8% ASD vs 3.4% control, p=.05), constipation (5.3% ASD vs 1.0% controls, p=.05), and gastroesophageal reflux (10.3% ASD vs 3.0% control, p=.04). There was a significant group (ASD vs control) by sex interaction for thyroid disease: women with ASD (14.6%) had a higher rate of thyroid disease than men with ASD (5.4%), men without ASD (1%), and women without ASD (4.7%; p=.00). When considering the burden of disease, women with ASD had a greater number of medical visits relative to the other groups for sleep disorder (p=.002), gastroesophageal reflux (p=.047), and constipation (p=.058).

Conclusions:

The present analyses suggest new ways in which women with ASD might be at greater risk than men (relative to their counterparts in the general population). Though both men and women with ASD were at greater risk for a number of conditions (consistent with extant research), our analyses suggest that women with ASD have more medical encounters once a condition is detected. Further analyses will examine other health

conditions, as well as whether sex differences are more apparent at different ages.

11:20 **157.003** Predictors of Self-Determination in Young Adults with Autism Spectrum Disorder

N. C. Cheak-Zamora[1,2] *and A. Maurer-Batjer*[3]*, (1)Health Sciences, University of Missouri, Columbia, MO, (2)Department of Health Sciences, University of Missouri, Columbia, MO, (3)University of Missouri, Columbia, MO*

Background: Young adults with Autism Spectrum Disorder (YA-ASD) have the lowest rates of independence of all young adults. Self-determination, the ability to set and work toward goals, is a prerequisite to independence. Research shows a connection between self-determination, independence, and quality of life. Unfortunately, few studies have examined self-determination within the autism community and have identified which factors promote self-determination in YA-ASD.

Objectives: This study aimed to examine rates of self-determination and contributing factors to self-determination among YA-ASD.

Methods: Caregivers of YA-ASD were recruited from five Autism Treatment Network sites and associated organizations across the U.S. (n=479) to complete surveys about their YA-ASD's transition experiences. Self-determination was examined using two components of the American Institutes for Research (AIR) self-determination assessment. The two components measured the young adults' capacity to be self-determined and the young adults' level of opportunity to be self-determined at home. Both component scores and the total score were used in all analyses.

Univariate analyses examined associations between self-determination and YA-ASD's demographics, ASD severity, and individual caregiver and family-level variables. Linear regression analyses explored whether individual demographics, individual condition severity, or caregiver and family factors were associated with level of self-determination for YA-ASD.

Results: YA-ASD ranged in age from 16 to 25 years old (M = 18.5; *SD* = 2.2), while caregivers ranged in age from 21 to 72 years (M = 49.33; SD=7.068). The majority of YA-ASD were reported to have moderate ASD symptoms (57.4%) and good to excellent verbal skills (74%). Thirty-three percent of young adults had an intellectual disability. Approximately 20% of YA-ASD had paid employment and 18.6% volunteered. The vast majority of caregivers were the young adult's mother (81%). Caregivers were more likely to be married (77%) and had a household income of $75,000 or more (52.4%).

YA-ASD's self-determination total ranged from 12-60-points with a possible score of 60. Caregivers reported their YA-ASD as having moderate overall self-determination (*x* = 38; *SD* = 9.04). Component measures, young adults' capacity and opportunities at home, ranged from the minimum score of 6 to the maximum score of 30 but had very different means. The mean for young adults' capacity to be self-determined were low (*x* = 15.3; SD = 5.67) while the mean for caregiver-rated young adults' opportunities at home was high (*x* = 23.1; *SD* = 4.59).

Barring severity, there were few significantly predictors of self-determination. Regression analyses indicated that YA-ASD's intellectual disability status, symptom severity, verbal communication level, and self-care skills were strong predictors of lower self-determination, whereas demographic and family variables accounted for little variance.

Conclusions: Our findings show a dissociation in self-determination ratings, with a lower mean for YA-ASD capacity and a higher mean for caregiver-rated opportunities for YA-ASD. Additionally, we found significant disparities in self-determination for YA-ASD with increased symptom severity and communication difficulties. Additional research is needed to examine how to most effectively encourage YA-ASD to develop and work towards their goals in school, healthcare settings, and at home.

11:45 **157.004** Physical and Psychological Health and Quality of Life in Adults with Autism: Role of Self-Determination and Autism Identity

T. A. M. McDonald[1]*, R. Fan*[2]*, F. Ye*[2]*, L. Jeradeh Boursoulian*[3] *and B. A. Malow*[1]*, (1)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN, (2)Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN, (3)Department of Pediatrics, Vanderbilt University Medical Center, Nashville, TN*

Background:

The steep rise in ASD prevalence is resulting in a large wave of individuals approaching adulthood. Although these individuals gain skills as they age, many continue to experience challenges in education, employment, social relationships, and other aspects of adult independence (Levy & Perry, 2011). Additionally, autistic adults face challenges with physical and mental health (Croen et al., 2015). While previous work has identified interrelationships of psychological health, quality of life (QOL), stigma, and autism identity (McDonald, 2017), the relationship of these factors with physical health and with self-determination has received limited study.

Objectives:

To understand the relationships between self-determination and autism identity with physical and psychological health and QOL in autistic adults in order to strengthen the design of programs, services, and interventions for this population.

Methods:

Thirty-one adults (20 men, 11 women) ages 18 to 35 years (mean = 24.1, standard deviation = 4.7) participated in a multicomponent self-determination program. Participants completed electronic surveys containing demographic questions and measures of health, wellbeing, autism identity, and components of self-determination at four time-points- two time-points prior to the intervention program and two time-points post-intervention. This presentation focuses on the pre-intervention measures. To identify key variables of self-determination and autism identity and minimize overlap, a cluster analysis incorporating a fast-backward variable selection multiple regression procedure was performed. Models incorporated validated measures of physical health (PHQ15), depression (PHQ9) and the World Health Organization Quality of Life Scale (WHOQOL-BREF) along with key variables of self-determination (e.g., Hope Scale -Agency) and autism identity (Autism Spectrum Identity Scale; ASIS) that were identified by the cluster analysis. The ASIS captures constructs including Spectrum Abilities (endorsing that one has autism-specific positive traits), Positive Difference (endorsing that being on the autism spectrum is a different but equally valid way of being), and Changeability (endorsement of the ability to change negative aspects of being on the autism spectrum).

Results:

Self-determination and autism identity factors accounted for 58% of the variance in scores on the PHQ15. Lower physical health symptoms were associated with higher Agency (p = 0.038), lower ASIS- Spectrum Abilities (p = 0.007) and higher ASIS-Positive Difference (p = 0.001) scores. Self-

determination and autism identity factors accounted for 55% of the variance in WHOQOL-Physical Health, with higher scores in Positive Difference relating to better physical health QOL (p =.006). Self-determination and autism identity factors accounted for 48% of the variance in scores on the PHQ9. Lower depressive symptoms were associated with higher Agency scores (0.0012). Finally, self-determination and autism identity factors accounted for 74% of the variance in scores in WHOQOL-Psychological Health. Psychological health QOL was positively associated with Agency (p = 0.034), ASIS-Positive Difference (p = 0.023), and ASIS-Changeability (p < .001).

Conclusions:

Factors related to both self-determination and autism identity are associated with physical and psychological health and quality of life. Programs, services, and interventions designed to improve physical and psychological health and quality of life for adults on the autism spectrum should consider incorporating elements that enhance aspects of self-determination and positive autism identity.

Biomarkers (molecular, phenotypic, neurophysiological, etc)
158 - The Multiple Powers of Eye Tracking in Early Developmental Research: From Mechanism to Diagnostic, Prognostic, and Clinical Characterization Utility
10:30 AM - 12:30 PM - Room: 517B

Panel Chair: Frederick Shic, *Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA*

Discussant: Declan Murphy, *Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

This panel highlights the multiple uses of eye tracking, from investigations of mechanisms, towards tools of clinical value. The first presentation (n=234) presents on brief, scalable, gaze-contingent eye tracking batteries that tap into social motivational processes and segregate children with and without ASD. The second (n=100) deconstructs factors underlying diminished face looking in toddlers with ASD, highlighting decreased attention to the mouth in ASD in response to speech and its relationship to autism symptoms. The third (n=129) uses a novel gaze-contingent value learning task to examine contribution of value learning to atypical selective social attention in toddlers with ASD, highlighting the potential disruption in the reward system network involved in value learning and signaling value-based attentional priorities during early stages of the disorder. The fourth (n=201) advances scalable eye-tracking-based measures designed specifically for clinical application in ASD, highlighting their strong psychometric properties and links with language ability. Together, these studies cut across the lifespan, inform our understanding of the earliest manifestations of ASD, employ some of the latest paradigms and technologies in both autism and eye-tracking research, help to isolate developmental and cognitive constructs, and bring us closer towards a future of eye tracking as a clinical tool.

10:30 **158.001** Using Gaze Contingent Technology to Characterize a Toddler's Preference for Motherese Speech: Towards Eye-Tracking Based Biomarkers of ASD within the First Years of Life

K. Pierce[1], *A. Moore*[2], *V. Gazestani*[1] *and A. Cheng*[3], *(1)Univeristy of California, San Diego, La Jolla, CA, (2)University of California, San Diego, La Jolla, CA, (3)University of San Diego, San Diego, CA*

Background:

When given a choice, typically developing infants prefer to listen to "motherese" – a speech style characterized by slower tempo and exaggerated speech contours and positive affect. This style is thought to play an important role in enhancing language acquisition, stimulating joint attention, and improving affective reactivity and emotion regulation. One previous study by Kuhl and colleagues (2005) noted that ~70% of 4-year old children with ASD preferred to listen to a computer generated voice rather than to motherese.

Objectives:

The purpose of the present study was to determine if toddlers much younger than the participants in the Kuhl study would also show a reduced preference for motherese speech using a gaze-contingent eye tracking test battery, and, if so, to determine the validation statistics associated with each eye tracking test.

Methods:

Using our general population early detection program, the *Get SET Early Model,* as the main recruitment mechanism, toddlers with ASD and other disorders (mean age 25 months; range 12-43) participated in 1-3 eye tracking tasks using gaze contingent technology wherein a toddler's fixation location controlled what he/she sees and hears. Toddlers were presented with ~60 second videos that depicted a woman engaging in animated motherese speech on one side of the video, in contrast to a non-social sound (e.g., highway traffic sounds) and associated image on the other. In Test 1, a toddler's preference for motherese speech was compared to his/her preference for flat affect speech (N=211; 94 ASD vs 117 non-ASD); in Test 2 versus highway noises (N=234; 109 ASD, 125 non-ASD); and in Test 3 (N=53; 23 ASD, 30 non-ASD), versus music. See Figure 1. Percent fixation within motherese and non-motherese AOIs was the main dependent variable. One-way anovas were conducted and significant findings followed up with t-tests. Validation statistics for specificity and PPV were calculated using traditional formulas, as were ROC curves.

Results:

Surprisingly, when a preference for motherese speech was isolated by comparing fixation towards motherese and flat affect speech while keeping the mother images constant (Test 1), toddlers with ASD performed similar to TD toddlers: they preferred motherese speech (F=1.03, p=.39; ASD mean motherese 63% vs 67% TD). However, when fixation towards motherese was compared to fixation towards non-social sounds and associated images in Tests 2 and 3, toddlers with ASD dropped their preference for motherese in favor of listening to non-social sounds and watching non-social images. Overall F tests were significant for both tests (F=10.5 and 7.6 respectively, p<.05). When cutoff thresholds were used to generate validation statistics (see dashed line in Figure), specificity and PPV were strong at 98% and 88% for Test 2, and 97% and 90% for Test 3, respectively.

Conclusions:

Eye tracking technology can be a powerful early diagnostic tool. Our results suggest that abnormalities in attention patterns in toddlers with ASD are strongly driven by what they see rather than what they hear. The power of combining multiple eye tracking tests and examination of age effects will also be discussed.

10:55 **158.002** Diminished Salience of Speech Underlies Diminished Face Looking in Toddlers with ASD: An Eye-Tracking Study

F. Shic[1,2], *Q. Wang*[3], *S. Macari*[3] *and K. Chawarska*[3], *(1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (2)Pediatrics, University of Washington School of Medicine, Seattle, WA, (3)Child Study Center, Yale University School of Medicine, New Haven, CT*

Abstract

Background: Under-responsivity to eye contact is considered a hallmark of autism spectrum disorders (ASD). However, real-world face-to-face social interactions often involve both eye contact and speech together. It is not clear whether children with ASD show limited salience for these features, or whether they find them aversive. Similarly, it is not clear how gaze and speech cues independently and synergistically impact looking at the face, eyes, and mouth, especially early in development, in children with ASD. Finally, it is unclear how modulation of gaze patterns in response to gaze and eye cues relate to clinical phenotype in ASD.

Objectives: To systematically examine the independent and emergent effects of direct eye contact and speech on face-looking profiles in toddlers with ASD using eye tracking.

Methods: Gaze patterns of 22-month-old toddlers with ASD (*n*=53) were compared to typically-developing toddlers (TD, *n*=47) on the Selective Social Attention 2.0 Task. This task manipulated direct gaze presence (DG+) or absence (DG-), and speech presence (SP+) or absence (SP-) in 4 randomly interleaved conditions sampled with 8 trials each. The task lasted 6 minutes total. Linear mixed effect models were used to examine group and condition effects. Eye tracking associations with clinical variables were assessed using Pearson's correlation coefficients.

Results: Both groups looked more at faces when DG and SP cues were present, but the increase was less pronounced in ASD (Δ% in DG+SP+) – (%Face in DG-SP-), TD: *d*=2.32, ASD: *d*=.73). Toddlers with ASD differed from TD toddlers in face looking only when the actress was speaking (DG-SP+: *d*=1.03, *p*<.001; DG+SP+: *d*=1.65, *p*< .001). Proportion of time spent looking at the actress's eyes did not differ between groups in any condition, but toddlers with ASD looked less at the mouth relative to TD toddlers when the actress was speaking (DG-SP+: *d*=.94, *p*< .001; DG+SP+: *d*=.81, *p*< .001). Lower responsivity to speech and gaze cues (Δ%Face) was concurrently and prospectively (40 months) associated with greater severity of autism symptoms (r=-.62, p<.001 concurrently; r=-.49, p=<.001 prospectively) and lower verbal (r=.59, p<.001; r=.44, p<.001) and nonverbal (r=.-54, p<.001; r=.31, p=.01) developmental ability. ROC analyses using Δ%Face yielded Sensitivity=88.4%, Specificity=80.0%, PPV=80.9%, NPV=87.8%, AUC=.89.

Conclusions: No evidence for face avoidance was observed. ASD-TD face looking differences were greatest when speech cues were present, suggesting limited salience for speech. Similarly, distribution of attention between eyes and mouth was perturbed in ASD only when speech was present and was indexed by lower attention to speaker's mouth. Responsivity to speech and gaze cues was concurrently and prospectively associated with developmental phenotype and also exhibited good group-discriminative ability, highlighting its potential as a marker for ASD. This study links poor attention to the faces of interactive partners in early stages of autism with the limited salience of speech rather than direct gaze. This work (1) suggests that early intervention in ASD may benefit from increased focus on orienting to audiovisual speech cues, and (2) may provide further motivation for research into the role of speech processing in the emergence of social disability in infancy.

11:20 **158.003** Atypical Value Driven Attention in Young Children with ASD

K. Chawarska *and Q. Wang, Child Study Center, Yale University School of Medicine, New Haven, CT*

Background: Poor attention to social targets such faces constitute one of the defining features of ASD in young children and has been documented in the laboratory and real-world contexts. Given the centrality of information conveyed through faces and facial gestures, poor attentional attunement to this class of stimuli during prodromal and early syndromal stages of the disorder, contributes to the variability in social, adaptive, and cognitive outcomes observed in preschoolers with ASD. We hypothesize this phenomenon is linked with disruption in the neural network involved in the signaling of value-based attentional priorities.

Objectives: To examine value learning for face and fractal stimuli and its effect on selective attention in preschoolers with ASD, and in developmentally delayed (DD) and typically developing (TD) controls. We hypothesized that unlike TD and DD controls, children with ASD will show selective impairment in value learning in Face but not in Fractal condition.

Methods: Children with ASD (*n*=55), DD (n=36) and TD (*n* =38) groups underwent value learning (VL) training in social (faces) and nonsocial (fractals) conditions implemented on a gaze-contingent eye-tracking platform. The VL task consists of the Baseline, Training, and Choice Test phases and represents an extension of our prior VL work by our team (Wang et al., 2018). The task measures whether reinforcement for attending to a given stimulus during Training biases visual attention toward the stimulus during subsequent Choice Test. The primary outcome variable was the proportion of looking time at the reinforced (high-value) stimulus during Choice Test.

Results: There were no pre-existing biases for specific stimuli during Baseline in either group and all groups completed a similar number of Training trials. During Choice Test, children with ASD showed evidence for learning in the Fractal (*p*<.001) but not in the Face (*p*=.809) condition. In contrast, the DD and TD groups, showed evidence for learning in the Face (*p*=.001, *p*=.002) but not in the Fractal (*p*=.703, p=.906) condition. Performance on the task was correlated with severity of autism symptoms.

Conclusions: Consistent with our hypothesis, children with ASD showed limited value learning of faces; however their leaning of fractal values was enhanced compared to the mental and chronological age-matched groups. Results suggest that atypical value learning in ASD facilitates attentional selection of nonsocial stimuli and hampers selective attention of faces. This pattern contrasts with that observed in controls matched for chronological age and developmental level. If present early in life, atypical value learning may affect selection for processing of social stimuli that are most relevant to adaptation and thus, may play a formative role in emergence of autism symptoms. The study replicates and extends our prior work and highlights the role of value-driven attentional network in atypical attention to faces in ASD.

11:45 **158.004** A Brief Remote Eye Tracking Paradigm May Enhance Clinical Evaluation of Autism Risk and Language Level

T. W. Frazier[1], *E. W. Klingemier*[2], *E. Youngstrom*[3] *and A. Y. Hardan*[4], *(1)Autism Speaks, New York, NY, (2)Cleveland Clinic Center for Autism, Cleveland, OH, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA*

Background: Brief, scalable, objective measures are needed to inform clinical assessment of children at risk for autism spectrum disorder (ASD). Numerous eye tracking studies have demonstrated social attention differences in people with autism that emerge early are relatively stable across development. Recent research has shown that aggregation of gaze measures across diverse stimuli has the potential to inform autism risk. Remote gaze tracking may also have the potential to rapidly evaluate cognitive functions, such as language ability, adding clinical value where traditional face-to-face testing is difficult to complete. Below we describe validation of an empirically derived autism risk measure and demonstrate how the paradigm can be extended to include rapid evaluation of language level.

Objectives: To evaluate aggregate gaze-based measures informing autism risk and language level.

Methods: Data were collected from 201 youth (ages 1.6-17.6) referred for clinical evaluation of ASD to empirically-derive (train and test) autism risk and symptom indices. After calibration, participants viewed an ~7-min stimulus battery that included 45 dynamic social stimuli from 8 distinct paradigms and 6 static receptive language arrays. Our published data from this sample indicated that autism risk and symptom indices had replicable validity for differentiating youth with ASD from a challenging comparison sample of referred individuals with other developmental conditions. Building on these data, we are collecting a separate validation sample of 30 youth (ages 2-14) referred for ASD evaluation viewed the same stimulus battery as the original cohort. Minor variations in the original procedures and equipment were intentionally implemented to ensure validity would be maintained during clinical implementation.

To develop a gaze-based language index, we evaluated a subset of our original cohort (n=114) that achieved a valid eye tracking and clinical language evaluation. The gaze-based language index was created by standardizing and averaging fixation time percent, fixation count, and average fixation duration to 16 receptive language targets. Analyses evaluated the relationships between the gaze-based language index and clinical language test scores.

Results: Initial results from the independent validation cohort indicated that the autism risk index differentiated ASD from non-ASD cases (AUC=.78). Gaze-based autism symptom indices showed significant correlations with ADOS-2 severity scores (r>.30). Using data from the original cohort, the gaze-based language measure had strong relationships with clinical language scores (Figure 1; r>.47) and good sensitivity to language impairment (Figure 2; AUC=.71; sensitivity=.82 at specificity=.71).

Conclusions: Brief, scalable, objective, eye-tracking measures aggregated across social and receptive language stimuli show strong potential to inform clinical assessment of autism and language level. Future research is needed to validate the gaze-based language measure, potentially adding stimuli to improve measurement across the full range of language levels. Additional studies of the autism risk and symptom indices are needed within clinical trials to evaluate sensitivity to change and in community or population samples to evaluate screening potential. Machine learning approaches may increase the validity of these promising gaze-based autism risk and language measures.

Panel Session
Family Issues and Stakeholder Experiences
159 - Parents As Mediators of Intervention and Functioning of Children and Adolescents with ASD
10:30 AM - 12:30 PM - Room: 524

Panel Chair: Ofer Golan, *Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel*

Discussant: Elizabeth Laugeson, *Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA*

From infancy to adulthood, parents are the key support figures of their children with ASD. However, parents' role in mediating the socialization of their children (Haven, Manangan, Sparrow, & Wilson, 2014), their role in overcoming obstacles associated with the diagnosis and with its comorbid conditions (Hayes & Watson, 2012), and their collaboration with professionals in the promotion of treatment (McConachie & Diggle, 2007), have mostly been studied in toddlers and preschoolers. The current panel examines how parenting practices are associated with the manifestation of their children's social communication and restricted and repetitive behaviors in childhood and adolescence, and how parental involvement with their children, and with therapists, promotes treatment-related progress in children and adolescents with ASD, in both core ASD symptoms and comorbid psychopathology. Taking a closer look into parental mediation of intervention and functioning of children and adolescents with ASD is of importance (Burrell & Borrego, 2012), as it may allow for personalized intervention to be based not only on the characteristics of the child, but also on those of the child's closest support figure – the parent. The nature of these characteristics will be presented and discussed in the panel.

10:30 **159.001** Family Accommodation in Autism

I. Feldman[1], *Y. Duchovni*[1], *E. Ben-Itzchak*[2], *E. R. Lebowitz*[3], *D. A. Zachor*[4] *and* ***J. Koller***[5], *(1)The Hebrew University of Jerusalem, Jerusalem, Israel, (2)Bruckner Center for Research in Autism, Communication Disorder, Ariel University, Ariel, Israel, (3)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (4)The Autism Center/Pediatrics, Tel Aviv University / Assaf Harofeh Medical Center, Zerifin, Israel, (5)Seymour Fox School of Education, Hebrew University of Jerusalem, Jerusalem, Israel*

Background: Family accommodation refers to the ways in which parents modify their behavior to help a child avoid or alleviate distress and negative affect caused by emotional disorders (Lebowitz & Bloch, 2012; Lebowitz, Scharfstein & Jones, 2014). Family accommodation is common among families of children with OCD and anxiety disorders and has been repeatedly associated with greater symptom severity, lower functioning, and poorer treatment outcomes for children, and with elevated distress in parents (Caporino et al., 2011; Lebowitz & Bloch, 2012; Lebowitz, Scharfstein & Jones, 2014; Storch et al., 2007).

The only published study of family accommodation in children with ASD focused on accommodation of anxiety symptoms. Family accommodation was similar to that reported by parents of anxious children without ASD and correlated with the severity of the anxiety symptoms (Storch et al., 2015). The current study, an extension of preliminary results presented at this conference last year, represents the first to examine family accommodation of RRBs and the associations between accommodation and autism symptomatology.

Objectives: To examine the presence of family accommodation of RRBs and its relationship to autism symptom severity and other clinical characteristics at the time of ASD diagnosis.

Methods: Participants include 97 children (24 females; mean age = 6.71, SD = 3.14) diagnosed with ASD at a tertiary autism center in Israel, and their parents. All participants underwent comprehensive assessments including medical, neurological, cognitive, adaptive behavior and diagnostic assessments. Measures include the Family Accommodation Scale for Restricted and Repetitive Behaviors, (developed for this study), Repetitive Behavior Scale-Revised (RBS-R; Bodfish, Symons, & Lewis, 1998), Autism Diagnostic Observation Schedule 2 (ADOS2; Lord, DiLavore & Gotham, 2012), and the Vineland Adaptive Behavior Scales 2 (VABS-2; Sparrow, Balla & Cicchetti, 2005).

Results: Accommodation was prevalent, with 74/97 participants (76.29%) reporting engaging in accommodation at least once a month and 50 (51.55%) reporting daily accommodation of their child's RRBs. Accommodation was positively correlated with RRB severity (r =.823, p <.001), indicating that increased accommodation was associated with increased severity of RRBs. RRB subtypes most highly correlated with family accommodation were ritualistic behaviors (r =.748, p <.001), insistence on sameness (r =.741, p <.001) and stereotypical behaviors (r =.727, p <.001). No significant correlation was found between family accommodation and ADOS comparison score (r =.112, p =.340). We further examined the correlations between family accommodation and the VABS subscales, finding a strong correlation between family accommodation and the VABS adaptive living skills and socialization subscales, respectively (r =-.404, p <.001; r =-.455, p <.001), but weaker correlation between the communication subscale and family accommodation (r =-.257, p =.024).

Conclusions: This study confirms initial evidence that parents of children with ASD commonly accommodate their child's RRBs and that this accommodation correlates with symptom severity. While accommodation of RRBs may follow a similar pattern to those reported in OCD and anxiety disorders, such accommodation may be more associated with adaptive behavior than overall autism severity or communication level. Finally, these findings highlight a heretofore-unexplored aspect of autism symptomatology and an unexamined opportunity for intervention.

10:55 **159.002** Parent-Adolescent Reciprocity in a Conflictual Situation Predicts Peer Interaction in Adolescents with ASD

*[1]. J. Rabin, E. Bamberger[2], I. Mor Snir[3], R. Feldman[2] and **O. Golan**[1], (1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Center for Developmental Social Neuroscience, Baruch Ivcher School of Psychology, Interdisciplinary Center, Herzliya, Israel, (3)Association for Children at Risk, Givat-Shmuel, Israel*

Background: The development of conflict management skills throughout childhood and adolescence has been shown to impact the individual's social adjustment. Parent-child reciprocity plays a significant role in shaping children's social interaction skills. The increase in conflictual interaction with one's parents during adolescence affects the transformation of parent-adolescent interaction into a more mutual, equal relationship. Adolescents with ASD and their parents may struggle in this type of interaction due to the adolescents' social and regulatory impairments, in addition to their dependence on their parents' involvement and guidance.
Objectives: The current study aimed to evaluate differences in the way adolescents with and without ASD interact with their parents in a conflictual situation. In addition, the association between parent-adolescent reciprocity and the adolescent's social interaction with an unfamiliar peer was examined in the ASD group.

Methods: Thirty adolescents (2 females), aged 12-17, clinically diagnosed with ASD (ADOS-2 validated) without comorbid intellectual impairment (IQ>70), and their parents (27 mothers) were compared to 30 typically developing adolescents, with no reported neurodevelopmental, psychiatric, or intellectual disability, and their parents. Groups were matched on adolescents' age and gender, as well as on parents' gender and education level. Parental (sensitivity, intrusiveness), adolescent's (involvement, withdrawal), and dyadic (reciprocity, negative states) factors were coded using the Coding of Interactive Behavior system (CIB, Feldman, 1998) . In addition, adolescents with ASD took part in a conversation with an unfamiliar peer, based on the Contextual Assessment for Social Skills (CASS, Ratto et al., 2011). Interactions were videotaped and coded by trained raters, (inter-rater reliability >.90 for CIB and >.86 for CASS).

Results: Findings indicate that during the conflictual interaction, compared to TD controls, adolescents with ASD were more involved in the conversation ($F[1,57]=4.41$ $p<.05$, $\eta^2=.13$) and less withdrawn ($F[1,57]=5.43$, $p<.01$, $\eta^2=.16$) from the parent, while their parents were more sensitive ($F[1,57]=5.33$ $p<.01$, $\eta^2=.16$) and less intrusive ($F[1,57]=5.13p<.01$, $\eta^2=.15$) towards them. However, dyadic reciprocity ($F[1,57]=5.27$ $p<.01$, $\eta^2=.16$) was poorer in the ASD group, compared to the TD group.

A regression analysis within the ASD group, predicting CASS scores was significant ($R^2=0.52$, $F[4,25]=6.69$, $p<.001$) revealing that parent-adolescent reciprocity in the ASD group was positively associated with the adolescents' social-conversational skills with a peer ($\beta=0.36$, $p<.05$).

Conclusions: These findings emphasize the different developmental trajectories parent-adolescent relationship take in adolescents with ASD, compared to their TD peers. Our findings suggest that a parent to an adolescent with ASD reacts to his child's deficits when handling an argument with greater encouragement and reduced strain. The adolescent with ASD on his part, responds positively to the parent's support and enhances his own involvement in the conflictual situation. Although both parties were highly involved, the ASD dyad struggled to interact fluently, which could be related to a lack of synchrony. These results also suggest that the relationship individuals with ASD have with their parents continue to promote their social functioning during adolescence.

11:20 **159.003** The Effect of Parenting Style on the Effectiveness of Parent-Mediated Social Skills Intervention for Adolescents with ASD

*[1]. **J. Rabin**, I. Mor Snir[2], E. A. Laugeson[3] and O. Golan[1], (1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Association for Children at Risk, Givat-Shmuel, Israel, (3)Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA*

Background: Many evidence-based intervention programs for children and adolescents with ASD include a parent training component as part of the intervention. Involving parents, who can coach their children in various daily life contexts, has the potential of assisting in overcoming generalization difficulties that often characterize ASD (Koegel et al, 1992).
However, the effect that parenting style has on the effectiveness of parent-mediated interventions has scarcely been investigated among adolescents with ASD. This should be investigated, mostly because of the nature of parent-adolescent relationships in adolescents with ASD, whose parents continue to play a central role in their socialization during adolescence (Maljaars et al., 2014).

Objectives: The main aim of the current study was to examine how parenting style affects the effectiveness of the parent-mediated Program for the Education and Enrichment of Relational Skills (PEERS; Laugeson & Frankel, 2010), a well-established evidence-based social skills program for

adolescents with ASD.

Methods: Eighty two participants (9 females) aged 12-18 (M= 14.40, S.D=1.75), who were diagnosed with ASD without an intellectual disability (diagnosis validated using the ADOS-2, intelligence assessed using the Wechsler Intelligence Scales) were randomly assigned to an immediate treatment group (IT, n=40) or a waiting-list group (WL, n=42). Parenting style was coded using the parent-adolescent conflict paradigm from the Coding of Interactive Behavior protocol (CIB; Feldman, 1998) and was evaluated at baseline for both groups. Intervention outcomes were assessed using the 'interested' condition from the Contextual Assessment of Social Skills (CASS; Ratto et al., 2011) pre and post intervention (for the IT group) or pre and post a waiting period (for the WL group) . Both interactions were videotaped and coded by trained, independent and blind judges (with inter-rater reliability of .90 for CIB and 0.85 for CASS).

Results: A repeated measures ANOVA revealed a group by time interaction ($F[1,74]=7.07$, $p<.01$, $\eta^2=.09$), showing improvements in social interaction abilities for adolescents in the IT but not in the WL group. In addition, a significant parenting style by group by time interaction ($F[1,70]=4.62$ $p<.05$, $\eta^2=.07$), indicated that within the IT group, adolescents whose parents exhibited low levels of pre-intervention parental sensitivity, improved more than adolescents whose parents exhibited high levels of pre-intervention parental sensitivity. This was not found in the WL group. A regression analysis predicting Post-pre CASS difference scores in the IT group reached statistical significance ($R^2=0.36$, $F(2,32)=9.00$, $p<.001$) and indicated that parents' emotional containment was negatively associated ($\beta=-1.27$, $p<.001$), and parents' supportive presence was positively associated ($\beta=1.01$, $p<.01$) with adolescents' improvement on the outcome measure.

Conclusions: Our study provides valuable information about the extent to which parental style affects the ability of adolescents with ASD to benefit from a manualized parent-mediated intervention, and the nature of parenting practices that may promote or hinder adolescents' intervention related progress. The PEERS protocol, which does not directly target parenting skills, seems to promote parents' ability to socially coach their children, especially for parents who have difficulties in this area pre-intervention.

11:45 **159.004** The Role of Parent Therapeutic Alliance in Cognitive Behaviour Therapy for Children with Autism

P. Burnham Riosa[1]*, M. Khan*[2] *and J. A. Weiss*[3]*, (1)Brock University, St. Catharines, ON, Canada, (2)Ontario Institute for Studies in Education, Toronto, ON, Canada, (3)Psychology, York University, Toronto, ON, Canada*

Background: Therapeutic alliance (TA) (i.e., the collaborative working relationship between a therapist and client) is an important component of treatment success across a range of treatment modalities among both child and adult populations. In empirically supported interventions designed to address emotional and behavioural challenges for children with ASD, TA is currently an under-studied treatment variable, especially parent-therapist alliance.

Objectives: The objectives of this study were to examine: (1) the psychometric properties of a behavioural measure of alliance, the *Therapy Process Observational Coding System–Alliance Scale* (TPOCS-A; McLeod, 2001), and (2) how parent-therapist and child-therapist alliance related to post-treatment outcomes in a sample of children with ASD who participated in a 10-session cognitive behavior therapy program targeting emotion regulation difficulties.

Methods: Twenty children (19 males) ages 8 to 12 years (*M*=9.8; *SD*=1.29) with ASD and their parents (15 mothers, 5 fathers) completed the *Secret Agent Society: Operation Regulation*; Beaumont, 2013), as part of a randomized waitlist controlled trial. Parents and children completed measures of child emotion regulation (*Emotion Regulation Checklist*,Shields & Cicchetti, 1997; *Children's Emotion Management Scale*, Zeman et al., 2010) and psychopathology (*Behavior Assessment System for Children, 2nd Edition*, Reynolds & Kamphaus, 2004) pre- and post-intervention. Trained coders rated early (Session 2), middle (Session 5), and late (Session 9) therapy sessions using the TPOCS-A. Interrater reliability was "excellent" (ICC=.95). Therapist-reported client involvement, alliance, and adherence were also assessed.

Results: Behavioural ratings of parent and child alliance were correlated (*r*=.48, *p*=.04) across sessions. Internal consistencies were "respectable" to "very good". Parent behavioural ratings were correlated with therapist-rated parent alliance (*r*=.63,*p*=.003) and a similar pattern was evident for child behavioural ratings and therapist-rated child alliance (*r*=.58, *p*=.008). Child behavioural ratings were related to therapist-reported treatment adherence (homework completion) (*r*=.69, *p*<.001) and therapist-reported client involvement (*r*=.55, *p*=.01). Regarding associations with child outcomes, higher levels of parent-therapist alliance early in treatment were related to improvements in child emotional inhibition [*F*(1, 17)=5.41, *p*=.03]; higher child-therapist alliance early in treatment was related to improvements in dysregulated expression [*F*(1, 16)=10.48, *p*=.005)]and improvements in internalizing symptoms [*F*(1, 17)=4.36, *p*=.05] post-intervention. Higher levels of child-therapist alliance late in treatment were related to improved emotion coping skills [*F*(1, 15) = 5.35, *p*= .04], improvements in dysregulation [*F*(1, 15)=4.52, *p*=.05], and less internalizing problems [*F*(1, 16)=6.59, *p*=.02]. Higher parent-therapist alliance at the end of therapy was related to improvements in child internalizing problems [*F*(1, 15)=5.36, *p*=.04] and adaptive regulation [*F*(1, 15)=9.72, *p*=.007].

Conclusions: Our findings provide support for the psychometric properties of a behavioural measure of TA and reveal positive associations between TA and improvements in child psychopathology and emotion regulation among a sample of children with ASD following intervention. Research and clinical implications of examining relational processes on child outcomes in empirically supported treatments for children with ASD and their families will be discussed.

Panel Session
Late Phase Drug Development
160 - Outcome Measures in Phase 2/3 Trials in ASD
10:30 AM - 12:30 PM - Room: 518

Panel Chair: Evdokia Anagnostou, *Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

Discussant: Jeremy Veenstra-Vander Weele, *Psychiatry, New York State Psychiatric Institute / Columbia University, New York, NY*

There are many barriers to optimizing clinical trials in ASD. including biological heterogeneity, limited targets, high placebo response, and uncertainty related to selection of outcome measures. Still, both the pharmaceutical industry and several academic networks are taking several compounds through to phase 2 and phase 3 programs. This panel represents an international public-private collaboration to examine the selection of primary and key secondary outcome measures in several current phase 2/3 programs, explore how such decisions get made and then use emerging data to evaluate how these measures have behaved. The panel will discuss lessons learnt, gaps, and future directions.

10:30 **160.001** Evaluation of Outcome Measures and Phase 2 Lessons from the Aberrant Behavior Scale

E. Anagnostou[1], *T. Bennett*[2], *S. Jacob*[3], *R. Nicolson*[4] *and M. Woodbury-Smith*[5], *(1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (3)Department of Psychiatry, University of Minnesota, Minneapolis, MN, (4)University of Western Ontario, London, ON, Canada, (5)Newcastle University, Institute of Neuroscience, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland*

Background: Suboptimal outcome measures have plagued the field of clinical trials in ASD. Measures currently used in trials present limitations in psychometric properties, sensitivity to change, placebo response, among others.
Methods: This abstract will set up the panel by reviewing the recommendations on outcome measures, based on a series of white papers produced by a think tank sponsored by Autism Speaks and NIH. We will then examine how these recommendations behaved in a series of phase 2 clinical trials in ASD in Canada (POND network and related networks)

Results: Sensitivity to change was documented for the ABC-Social withdrawal subscale. However the measure seems to also be associated with significant placebo response. Secondary measures discussed in the white papers will also be presented with data to confirm the limitations presented in the original reports (multiple constructs combined into a singe score, unusual distribution of items).

Conclusions: Some of the originally proposed clinical trials outcome measures by the Autism speaks/NIH think tank show sensitivity to change with a variety of compounds and targets, but are presenting with limitations related to placebo response and construct validity. Further refinement of existing measures and development of new measures is required to optimize endpoint measurement for clinical trials in ASD.

10:50 **160.002** Challenges in Evaluating Improvements in Soars-B: Study of Oxytocin in ASD for Enhancing Reciprocal Social Behaviors

L. Sikich[1], *A. Kolevzon*[2], *J. Veenstra-Vander Weele*[3], *C. McDougle*[4] *and B. King*[5], *(1)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (2)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Psychiatry, New York State Psychiatric Institute / Columbia University, New York, NY, (4)Lurie Center for Autism, Massachusetts General Hospital, Boston, MA, (5)UCSF, San Francisco, CA*

Background: The NIH-funded SOARS-B study was designed to evaluate the safety of six-month, twice-daily oxytocin across the full spectrum of children with autism spectrum disorders and to inform design of a future pivotal efficacy study with regard to inclusion criteria and primary outcome. The study included 277 children: 132 were minimally verbal and ages were evenly distributed between 3 and 17 years. In 2011, as now, there was no consensus about the most appropriate way to assess long-term changes in reciprocal social behaviors. The choice of a primary outcome measure was further complicated by the diversity of the planned sample, use of multiple sites and finite financial resources available for the project
Objectives: We sought a single primary outcome measure that could be reliably assessed across the pediatric age range and the full spectrum of cognitive and communicative abilities. The ideal outcome measure would also have the ability to be repeated multiple times over 24 weeks without learning effects and be sensitive to clinically meaningful changes in reciprocal social behaviors. It would measure positive behaviors as well as problem behaviors related to less well developed social skills interests and abilities.

***Methods*:** Available literature was reviewed to determine the performance of current social behavior measures in prior ASD treatment studies across the age and cognitive range planned for SOARS-B. The National Database for Autism Research (NDAR) was used to study the variability of measures in a broader population of children with ASD. We chose a modified 13 item version of the Aberrant Behavior Checklist (ABC) lethargy subscale (removing the 3 items that were associated with low physical activity and referred to as the ABC-SW) as the primary outcome. Multiple other social measures were also used to assess social behaviors. Descriptive statistics for changes in different social measures over time during the trial and correlations between the changes in these different measures will be provided for the entire sample and key subsamples (e.g. minimally verbal). The changes in these measures also will be correlated with the Clinical Global Impressions Scale Improvement item (CGI-I) and a continuous visual analog scale of change in social behavior to help define the best measure for future studies.

***Results*:** The analyses of the study results are currently in progress. We will report on the characteristics of our primary outcome measure - change in the ABC-SW - during the trial, its relationship with changes in other measures of social functioning including the Social Reciprocity Scale (SRS), the Pervasive Developmental Disorders Behavior Index Screening Version, the Vineland Adaptive Behavior Scales, and the CGI-I.

***Conclusions*:** Choosing a single well-validated measure to assess change in social behavior across a broad range of functional and developmental levels is challenging. Most available measures rely on caregiver report and cover a limited range of social behaviors. More objective social outcomes such as eye gaze tracking, EEG, or behavioral tasks may be limited by stimuli appropriateness across development, multi-site standardization, and cost.

11:10 **160.003** Evaluating Bumetanide in Autism

E. Lemonnier[1] *and Y. Ben-Ari*[2], *(1)centre expert autisme du limousin, CHU de limoges, Limoges, France, (2)Neurochlore, Marseille, France*

Background: Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental disorder characterized by social communication deficits and the presence of restricted interests and repetitive behaviors. The criteria that can be used are variable including biological ones which are more objective (biological variables, electrophysiological, brain imaging, eye tracking etc) or subjective depending on an evaluation by the treating doctor or the parents (ABC, CARS, BOSCC, SRS, CYBOCS, RRB, Conners, etc.) with some scales centered on developmental level (vineland), alterations of life quality (CGI).
Objectives: determine the efficacy of bumetanide in children with autism

Methods: In our various trials, we used primarily CARS) and CGI and more recently SRS and in parallel more pilot studies eye-tracking and fMRI.

Results: CARS (used as a primary criterion) allowed us to show an improvement on the main symptoms of autism including socialization. CGI revealed a general clinical improvement on the dimension of this improvement albeit not specific. Although limited in scope and number of patients, functional magnetic resonance imaging provided useful information on the activation by emotional faces of early visual areas, and areas involved in emotional, social and attentional processing. SRS was highly efficient to detect global changes.

Conclusions: Our results suggest that a heterogeneous disorder such as autism requires many evaluation criteria and objective measures by eye tracking and imaging studies to validate the working hypothesis. Future trials will include -but with a long duration track- alterations of developmental processes. Our experience with our selected primary and secondary outcome measures will be discussed.

11:30 **160.004** Evaluating Balovaptan for the Core Symptoms of Autism Using Vineland™-II Adaptive Behavior Scales: Present Experience and Future Directions

***K. Sanders**, Product Development Neuroscience, F. Hoffmann-La Roche Ltd., Basel, Switzerland*

Background: Despite the impact of behavioral therapies, interventions for the core symptoms (persistent social communication/interaction deficits and restricted/repetitive behaviors) of autism spectrum disorder (ASD) remain largely unmet. Furthermore, there are limited established assessments for evaluating these core symptoms in clinical trials. The vasopressin system, implicated in modulating social behaviors, is a potential target for addressing communication and social interaction symptoms of ASD. Balovaptan, an orally available, brain-penetrant, highly-selective, competitive antagonist of the vasopressin 1a receptor is being investigated as a treatment for social and communication challenges in adults and children/adolescents. The clinical program has been planned in collaboration with the ASD community, including experts and advocates.
Objectives: To present evidence from the balovaptan development program supporting Vineland™-II Adaptive Behavior Scales (Vineland-II) as an appropriate outcome measure in ASD clinical trials, and the rationale for a socialization and communication composite score as the primary endpoint in an ongoing phase 2 study in children and adolescents (aV1ation; NCT02901431) and phase 3 study in male and female adults (VIADUCT; NCT03504917).

Methods: The first balovaptan trial (VANILLA, NCT01793441) in adult males with ASD and IQ≥70 used the caregiver-rated Social Responsiveness Scale 2 (SRS-2) as the primary endpoint based on available evidence when the study was designed. With validated psychometric properties, inter-rater reliability and age-appropriate norms (0-90 years), Vineland-II was a key secondary endpoint, among others. Vineland-II assesses adaptive behaviors in 3 domains: communication, socialization, and daily living skills and is now recognized by clinical experts, autism advocates and regulatory bodies as a suitable measure of change in social communication within ASD trials. As the socialization and communication domains of Vineland-II are both reliable, independently validated endpoints in ASD trials, the Vineland-II 2-Domain Composite (2DC) score was developed to combine both into a single score.

Results: Consistent with several reports suggesting strong susceptibilities to placebo effects with SRS-2 in multicenter trials, in VANILLA, all groups, including placebo, showed improvement on the SRS-2. However, dose-dependent, significant, and clinically meaningful improvements (exceeding minimal clinically important difference threshold) on the Vineland-II composite score, driven by improvements in socialization and communication domains, were observed for participants treated with balovaptan 4 or 10 mg versus placebo.

The psychometric properties of the Vineland-II 2DC score were further validated using VANILLA data, demonstrating test-retest reliability, validity and sensitivity to change, supporting its use as the primary outcome measure for socialization and communication core symptoms, across the age/gender spectrum, in the balovaptan development program.

Conclusions: In the development program to date, balovaptan has demonstrated dose-dependent, significant, and clinically meaningful improvements on Vineland-II in adult males. This observation supports Vineland-II as an appropriate measure of change in socialization and communication core symptoms of ASD over time. Furthermore, the Vineland-II 2DC score has been chosen as the primary outcome measure enabling comprehensive assessment of these core symptoms in ongoing phase 2 and phase 3 studies of balovaptan in ASD. Balovaptan is being studied as a potential treatment option for ASD core symptoms as an amplifier of social learning, possibly by enhancing social motivation reward systems.

Panel Session
Molecular Genetics
161 - Genetic and Genomic Discovery in Autism: From SNPs, to Exomes and Genomes.
10:30 AM - 12:30 PM - Room: 517A

Panel Chairs: Joseph Buxbaum, *Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Margaret Pericak-Vance, *John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL*

This panel will summarize the state-of-the-art in autism genetics and genomics. Updates on common variant association studies, whole exome sequencing, and whole genome sequencing will be presented, as well as novel approaches aimed at the integration of the different classes of variation into a unified model of genomic risk architecture.

10:30 **161.001** Common Risk Variants Identified in Autism Spectrum Disorder

***J. Grove**[1,2] and .. The iPSYCH-Broad/MGH Autism Working Group[3], (1)Center for Genomics and Personalized Medicine, Department of Biomedicine - Human Genetics, Bioinformatics Research Centre, Aarhus University, Aarhus, Denmark, (2)The Lundbeck Foundation Initiative for Integrative Psychiatric Research, iPSYCH, Aarhus, Denmark, (3)iPSYCH/Broad/MGH, Aarhus, Denmark*

Background: Autism Spectrum Disorder (ASD) is a complex disorder, and the aetiology is largely unknown. The heritability is as high as 80% according to some estimates and common genetic variation is estimated to explain half of the genetic risk. Recently, iPSYCH and Broad/MGH

conducted the largest GWAS of ASD to date comprised of 13,076 cases and 22,664 controls from Denmark and meta-analyzed with 10,610 samples from the Psychiatric Genomics Consortium (PGC).

Objectives: To identify genetic loci associated with autism, derive insight into the underlying biology, and to dissect the polygenic architecture of autism and its clinical subtypes.

Methods: The iPSYCH sample is a population sample comprised of cases with one or more psychiatric diagnoses identified in the Danish Psychiatric Central Research Register and a control sample consisting of a 2% random sample from the corresponding birth cohort. The Danish Neonatal Screening Biobank supplied archived dried blood spot samples and DNA was extracted, whole-genome amplified and genotyped on the PsychChip, a customized HumanCoreExome chip. Quality control, imputation and principal component analyses were conducted using the Ricopili pipeline of PGC, as was the meta-analysis with the summary statistics from the PGC. ASD signals were followed up in a European sample consisting of 2,119 cases and 142,379 mainly from Iceland. Top hits were integrated with data of the 3d structure of the chromatin using the method Hi-C. SNP heritability and genetic correlations was estimated using LD score regression and GCTA, and polygenic risk scores were generated and analyzed in an in-house pipeline. Phenotypes with significantly overlapping genetic architectures (schizophrenia, major depression, and educational attainment) were employed to identify additional putative loci using the recent MTAG method.

Results: We identify 3 genome-wide significant loci in the iPSYCH-PGC sample and additional 2 when including the follow-up sample. Seven extra putative ASD loci were highlighted in the MTAG analysis leveraging data from the related phenotypes of schizophrenia, major depression, and educational attainment. Novel genetic correlations were estimated for eg. ADHD, rG=0.360 (SE=0.051) and major depression, rG=0.412 (SE=0.039). Indications of differences between diagnostic subtyped in genetic architecture was found in both estimates of SNP heritability (ranging from 0.03 for other pervasive developmental disorders to 0.10 for Asperger's syndrome, P = 0.001) and to a lesser extent in genetic correlations between hierarchical subtypes (rG ranging from 0.71 to 1). The differences were confirmed in a novel polygenic risk score (PRS) analysis comparing levels of PRS for various related phenotypes across subtypes.

Conclusions: We identified novel risk loci for ASD highlighting biological insights, particularly relating to neuronal function and corticogenesis. Interrogating the polygenic architecture through different means, we found heterogeneity across ASD subtypes. Overall, these results indicate that GWAS performed at scale will be much more productive in the near term in ASD.

10:55 **161.002** Exome Sequencing Identifies Genes Where Rare Disruptive Variants Confer Risk for Autism

***F. Satterstrom**, Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA*

Background: Rare genetic variants—particularly newly arising, or *de novo*, mutations—are major contributors to individual risk for autism spectrum disorder (ASD). As a class, the most impactful rare variants are those which disrupt gene function. These variants can be identified by exome sequencing, which captures the protein-coding portion of the genome. When individuals with ASD carry rare disruptive variants in a gene more often than expected by chance, it implicates that gene in risk for ASD. In this way, previous study (e.g. Sanders *et al*., 2015, *Neuron* 87:1215-1233) has identified upward of 65 genes associated with ASD at a false discovery rate (FDR) ≤ 0.1.

Objectives: We sought to 1) identify novel genes associated with ASD and 2) learn more about the neurobiology of ASD by analyzing the set of ASD-associated genes. To do this, we conducted the largest exome sequencing study to date focused on rare variation in ASD. We represent the Autism Sequencing Consortium, as well as the iPSYCH initiative for psychiatric research in Denmark, and our collaborative network enabled us to sequence samples from around the world.

Methods: Building upon previous work, our analysis included exome sequences from a total of 35,584 samples. We identified *de novo* variation in 6,430 ASD probands and 2,179 sibling controls for whom we had sequenced both parents, and we identified rare variation in an additional 5,556 ASD cases and 8,809 controls. We integrated the *de novo* and case-control variation using a Bayesian framework called TADA to identify ASD-associated genes. We improved the TADA model used in previous work by incorporating pLI score as a metric for weighting protein-truncating variants and MPC score as a metric for weighting missense variants. We then analyzed our list of ASD-associated genes in the light of multiple external datasets.

Results: We identify 102 genes associated with ASD at an FDR ≤ 0.1. Of these risk genes, 48 show higher frequencies of disruptive (i.e. protein-truncating or MPC ≥ 1 missense) *de novo* variants in individuals from a separate cohort ascertained for severe neurodevelopmental delay, while 51 show higher frequencies in individuals from our study ascertained for ASD, and comparing our ASD cases with disruptive mutations in the two groups of genes shows differences in phenotypes like IQ and age of walking. Expressed early in brain development, most of the risk genes have roles in neuronal communication or regulation of gene expression, and 12 fall within recurrent copy number variant loci. In human cortex single-cell gene expression data, expression of the 102 risk genes is also enriched in both excitatory and inhibitory neuronal lineages, implying that disruption of these genes alters the development of both neuron types.

Conclusions: Our identification of 102 ASD-associated genes represents a significant step forward from previous work. Next, we plan to jointly analyze our data with exome sequences from SPARK, the Simons Foundation study of ASD whose recent data release will nearly double our sample size. A few preliminary results may be ready to discuss at the meeting.

11:20 **161.003** Whole Genome Sequencing in Autism

***S. W. Scherer**, The Hospital for Sick Children, Toronto, ON, Canada*

Background:

Autism Spectrum Disorder (ASD) is heterogeneous, both phenotypically and in its genetic architecture. There are now hundreds of genes found associated with ASD, with risk contributed by multiple types of rare and common genome-wide variation. Some individuals carry single rare (*de novo* or inherited) penetrant gene alterations. Others have multiple variants, and for these and others with ASD, a whole host of (poly)-genic risk factors may be involved.

Objectives:

Whole genome sequencing (WGS) technology has been launched worldwide by large-scale projects to study thousands of families from ASD

cohorts and biobanks (e.g. AGRE, SFARI). The goal of this research is to decode entire genome sequences including all their genetic variants, link to available phenotype data, and make these massive genomic/phenotypic datasets available for scientific study. Before this, to find the complete spectrum of variants has required the incremental technologies of karyotyping, microarray, panel-sequencing and exome-sequencing. With WGS, an experiment costing about US$1000 can complete the task in a single comprehensive step.

Methods:

WGS is usually performed on DNA from whole blood (or sometimes other tissues), typically using 'short-read' sequencing technologies. Other useful data are arising from 'long-read' technologies. Bioinformatic pipelines are applied to raw sequence data to enable the robust identification of constitutional single nucleotide variants (SNVs), small insertion/deletions (indels), as well as copy number variants (CNVs), structural variants (SV; including short repeats), and mitochondrial variants. New algorithms further differentiate mutations occurring somatically from those present in all cells. Following approval of a Data Access Committee, primary and processed genomic data are then placed into different cloud- and web-based formats, to be accessible to the community.

Results:

WGS sequencing has identified new variants in protein-coding and non-coding (e.g., lncRNA, regulatory) regions, in or near genes missed by other technologies. A more complete view of the entire genome can increase the yield of findings relevant for ASD or its co-morbidities and provide context for their interpretation. Smaller CNVs and more complex SVs, often missed by other technologies, also contribute significantly in the etiology of ASD. Approximately 100 gene and CNV regions currently have value for testing in ASD diagnostics. Through data consistent across studies, we find genes involved in synaptic and neural adhesion, neural transcriptional regulation, and RNA processing to be involved in ASD, offering new entry points for drug development. Hundreds of scientists from around the world are using WGS data to enable their research studies.

Conclusion:

WGS data with accompanying phenotype information can greatly enable basic and clinical research in ASD. As the costs continue to decrease and WGS eventually moves into the diagnostic setting - supplanting microarray and exome-testing - thousands of additional genomes will become available for comparative analysis. The presentation will provide an overview of results of the major published studies, the data and resources available, and the most significant scientific advances, all based on WGS.

11:45 **161.004** Rare De Novo and Common Variations Affect Liability to Autism

***K. Roeder**, Statistics and Data Science, Carnegie Mellon University, Pittsburgh, PA*

Background: Early researchers hypothesized that Autism Spectrum Disorder (ASD) arises from polygenic inheritance. Subsequent results, however, such as the identification of mutations in certain genes that are responsible for syndromes associated with ASD, led others to propose that rare variants and *de novo* mutations of major effect would account for most cases. There is now ample evidence that both rare *de novo* and inherited variation play a role in risk for ASD. It is also well documented that common variation plays a substantial role in liability. How these two forces combine to determine liability in any particular individual is not yet well understood.
Objectives: I will discuss the current state of understanding of the interplay of rare and common variation.

Methods: We will integrate data and results from whole exome and genome wide association studies (GWAS), as well as a family studies, to describe statistically the relationship between rare and common variation and their relationship to heritability.

Results: While rare variation confers risk, both rare *de novo* and inherited variation acts within the context of a common-variant genetic load, and this load accounts for the largest portion of ASD liability. Even among individuals who carry rare highly damaging variants, there is often evidence for substantial common risk variation, a result that is contrary to popular beliefs.

Conclusions: "*Although clinical geneticists have told parents for years that a certain mutation found in the DNA of their offspring was likely the cause of ASD, we can no longer ignore some elephants in the room: for the typical person with ASD, their genetic load of common variation accounts for a substantial portion of their liability, and even for individuals known to carry a damaging mutation associated with ASD, the load of common variants they carry appears to be high. We need a way to accurately quantify this load, because this information will be useful for clinical geneticists who offer advice about recurrence risk to families.*" (Chaste et al., 2017, Annu Rev Genomics Hum Genet).

Panel Session
Service Delivery/Systems of Care
162 - Effectiveness of ASD Evidenced-Based Practices for End-Users: Examination of Child Outcomes in Multiple Community Service Settings
10:30 AM - 12:30 PM - Room: 516ABC

Panel Chair: Aubyn Stahmer, *Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA*

Discussant: Lauren Brookman-Frazee, *Psychiatry, University of California, San Diego, San Diego, CA*

The purpose of this panel is to describe research examining the community effectiveness of evidenced-based interventions (EBIs) for youth with ASD implemented in multiple community-based settings. These studies share a common focus of examination the effectiveness of several EBIs developed to enhance child outcomes in routine care settings, with an additional focus on key moderators (e.g., age, race/ethnicity). Focused on early intervention settings, the first project described the impact of a parent-mediated naturalistic developmental behavioral intervention adapted for use with toddlers at risk for ASD on child and family outcomes. The second project describes the impact of an adapted behavioral intervention designed for implementation in school settings. The third project examines the effectiveness of a behavioral EBI implemented in publicly-funded mental health settings. Finally, the fourth project examines the measurement of clinical outcomes across several community care settings. Dr. Lauren Brookman-Frazee (discussant) will draw on her expertise in implementation and evaluation of EBIs to synthesize the results and offer recommendations for the use and examination of EBI implementation to improve community service settings, especially among diverse populations.

10:30 **162.001** Project Impact for Toddlers: Pilot Outcomes of Community Adaptation of an Evidence-Based Intervention for ASD Risk

K. S. Dickson[1,2], *S. R. Rieth*[1,2], *A. C. Stahmer*[3], *K. L. Searcy*[4,5], *J. Feder*[6] *and L. Brookman-Frazee*[7], *(1)Child and Adolescent Services Research Center, San Diego, CA, (2)San Diego State University, San Diego, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (4)Speech & Language, San Diego State University, San Diego, CA, (5)TERI Crimson Center for Speech & Language, San Diego, CA, (6)Child and Family Psychiatrist Tertiary Outpatient and Neurobehavioral Medicine Private Practice, Solana Beach, CA, (7)Psychiatry, University of California, San Diego, San Diego, CA*

Background: Parent-mediated naturalistic developmental behavioral interventions (NDBI) have demonstrated positive child and family outcomes for young children with ASD (Zwaigenbaum et al., 2015; Burrell & Borrego, 2012). Intervening at the first signs of ASD risk, prior to a formal diagnosis, may be a powerful option and prevent the onset of symptoms for some children (Dawson, 2008; Lavelle et al., 2014). Despite demonstrated benefits, however, there has been little dissemination of parent-mediated NDBI into community settings, where the majority of children receive services (Stahmer et al., 2016). Community providers with expertise in both the NDBI strategy use and partnering with parents are needed to effectively deliver NDBIs. Based on the range of funding mechanisms and agencies through which children with ASD may receive services, however, community providers have variable educational backgrounds and ASD specific experience. As communities struggle to serve the growing number of young children with ASD with effective interventions, more information is needed about whether community implemented parent-mediated NDBI leads to improved family outcomes.

Objectives:

The objective of this presentation is to demonstrate parent and child outcomes from a community effectiveness pilot study of an evidence-based, parent-mediated NDBI (Project ImPACT for Toddlers or *PI*^{T}; Ingersoll & Dvortscak, 2010).

Methods:

A quasi-experimental design was used to examine effectiveness of *PI*^{T} implemented in low-intensity, public early intervention. Families of children with social communication challenges and/or risk for ASD were assigned by the early intervention coordinator to a provider trained in *PI*^{T} or to usual care (UC), based on typical referral practices. The final sample included 25 caregiver/child dyads (*PI*^{T} n=12; UC n=13). Measures included an ADOS and Mullen Scales of Early Learning to characterize the sample. Parent outcome measures included objective ratings of parent use of *PI*^{T} strategies with their child, general positive parent-child interaction, satisfaction, social support, and intervention engagement. Child outcomes included the Infant Toddler Checklist, MacArthur Bates CDI, and Vineland Adaptive Behavior Scales. Dependent measures were collected at intake, post intervention, and at a 3-month follow up.

Results:

Children were 68% male, averaged 23 months of age at intake, and had average developmental scores of 72.14 (SD=16.97). Caregivers were all mothers. were 48% Hispanic/Latinx and 28% received services in Spanish. Mothers represented a wide range of maternal education and employment. Groups were comparable at intake. Parents in the *PI*^{T} group had higher engagement in the intervention compared to UC ($t(21)=-2.66$, $p<.02$), but similar rates of parent satisfaction and social support. Significant differences were seen in favor of the *PI*^{T} group in all areas of parent-child interaction. Children in the *PI*^{T} group had significantly greater words produced and CSBS Symbolic Composite and had generally larger effect sizes in many areas. Most changes maintained or improved at follow up.

Conclusions:

This study represents one of the first demonstrations of effectiveness for an adapted evidence-based practice in community early intervention programs. The results indicate promise for use of parent-implemented interventions in community early intervention to support children and families, even prior to an ASD diagnosis.

10:55 **162.002** Examining Effectiveness of Classroom Pivotal Response Teaching in Public Schools

A. C. Stahmer[1], *J. Suhrheinrich*[2], *S. R. Rieth*[2,3], *K. S. Dickson*[3], *S. F. Vejnoska*[4] *and S. Roesch*[2], *(1)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (2)San Diego State University, San Diego, CA, (3)Child and Adolescent Services Research Center, San Diego, CA, (4)University of California, Davis, Sacramento, CA*

Background:

Autism interventions that are shown to be efficacious in controlled research settings are often not well integrated into schools, demonstrating the need for translation or adaptation for classroom use. These practices can be systematically adapted to ensure a fit with student and classroom characteristics while maintaining the active ingredients of the intervention. Such adaptations should improve teachers' use of the strategies and thus facilitate better outcomes for students (e.g., Durlak & DuPre, 2008; O'Donnell, 2008; Sanetti & Kratochwill, 2009; Stahmer & Gist, 2001). Classroom Pivotal Response Teaching (CPRT) is a behavioral intervention for children with ASD adapted from Pivotal Response Training through an iterative process in collaboration with researchers, teachers, and school administrators (Stahmer, Suhrheinrich, & Rieth, 2017).

Objectives:

This presentation will provide child outcomes from a large-scale community effectiveness trail of CPRT in schools.

Methods:

The study used a randomized waitlist-control design with 108 classrooms over three years. Teachers (n=108) and students (n=256) from 17 school districts participated. Training procedures included 12 hours of small group didactic instruction, including goal setting, supervised exercises and role-playing. Individual coaching followed at weekly, then monthly intervals upon completion of didactic training. During coaching, teachers worked with their own students during regular classroom activities. Each teacher enrolled two students in their classroom to follow for the duration of the study. Child measures included the Autism Diagnostic Observation Schedule- 2nd Edition (ADOS-2), student educational goals, cognitive assessment, Vineland Adaptive Behavior Scales (VABS) and Pervasive Developmental Disability Behavioral Index (PDDBI). The VABS and PDDBI were collected from both parent and teacher respondents.

Results:

A diverse sample of students with ASD who were 35% Hispanic/Latinx, with a mean age of 5.8 years (r=3-11) participated. Student data indicate that overall students made significant progress in distal measures of cognitive and adaptive skills, but no differences were seen by group. However, results indicate significantly greater change on PDDBI scales of core ASD symptoms, including sensory/perceptual approach behaviors

(p=.004) and repetitive/ pragmatic problems (p=.07) for students with CPRT-trained teachers versus observation classrooms. Scores on some scales were moderated by student age, teacher experience and classroom quality. Additionally, significant differences in student active engagement were identified between the observation year and the CPRT training period (p=.002), and this increased engagement maintained during a follow-up year (after CPRT training; p=.001). Students in the CPRT group demonstrated significantly more progress on social goals (t (64)=3.60, p<.001) than the observation group. Additional moderators, including the impact of race/ethnicity, are currently being examined.

Conclusions:

Results indicate CPRT training for teachers can lead to improved student outcomes, especially in the area of student engagement and social development, for students with ASD. Classroom quality and teacher experience may moderate outcomes, providing recommendations for potential prerequisite training needed prior to EBP implementation.

11:20 **162.003** The Impact of Training Community Mental Health Providers to Deliver a Mental Health Intervention for Children with ASD on Caregiver Outcomes

C. Chlebowski[1], *M. Villodas*[2,3], *K. S. Dickson*[3] *and L. Brookman-Frazee*[4], *(1)National Institute of Mental Health, Bethesda, MD, (2)Psychology, San Diego State University, San Diego, CA, (3)Child and Adolescent Services Research Center, San Diego, CA, (4)Psychiatry, University of California, San Diego, San Diego, CA*

Background: Publicly-funded mental health (MH) services play an important role in caring for school-age children with ASD. AIM HI ("An Individualized Mental Health Intervention for ASD," Brookman-Frazee and Drahota, 2010) is a package of parent mediated and child-focused behavioral strategies designed to reduce challenging behaviors for children with ASD in MH settings. The current study examined the impact of training community therapists to deliver AIM HI. Data were drawn from a large-scale randomized community effectiveness trial of AIM HI conducted in 29 publicly-funded outpatient and school-based MH programs from 2012-2017. Initial examination of parent report of child outcomes (ECBI) indicate statistically significant GroupXTime interactions for the ECBI Intensity and Problem scales, with significantly larger decline in ECBI Intensity in the AIM HI group relative to the UC group.Therapist fidelity mediated these intervention effects (Brookman-Frazee et al., under review). The current study was designed to expand on these child outcomes to look at caregiver outcomes for caregivers involved in the AIM HI with their child and a participating therapist.

Objectives: Test the effectiveness of training therapists to deliver the AIM HI intervention on associated caregiver outcomes over 18 months.

Methods: A total of 202 client/therapist dyads were enrolled in the trial. Children were 84% male (M age =9.13 years). Caregivers were 94% female and 52% Hispanic; 30% identified Spanish as preferred language. Therapists were 86% female and 48% were MFTs. Session-level therapist fidelity was collected over the 6 month training period during which video recordings of 1,153 psychotherapy sessions were coded for adherence to AIM HI active teaching strategies. Data collected at baseline, 6 months (post), and 12 and 18 month follow up included caregiver reported outcomes using the Parenting Sense of Competence scale (PSOC) and the Caregiver Strain Questionnaire (CGSQ).

Results: Multilevel analyses of caregiver outcomes showed significant group X Time interactions for linear (B = 3.52p = .009) and quadratic (B = -.94p =.029) trajectories of Parenting Sense of Competence Scale. The increases in PSOC over 18 months were greater when therapists receive AIM HI training, but decelerated over time. There were no significant differences in linear (B=1.55, p=.106) or quadratic (B=-.381, p =.178) trajectories by group for the PSOC. Results indicate child clinical and parent sociodemographic characteristics moderated outcomes. The effects of the AIM HI intervention on reducing caregiver strain were stronger for families with children with higher cognitive abilities, as measured by the WASI-II. Caregiver preferred language was a moderator of PSOC outcomes as AIM HI moderated increases in parental feeling of competence for English speaking caregivers, but not caregivers who identified Spanish as a preferred language.

Conclusions: Findings build on initial child outcome findings and add to the empirical support for the effectiveness of AIM HI when delivered by community mental health providers. Moderation analyses provide important information for refinement of the intervention and are consistent with current work developing a toolkit to supplement the AIM HI intervention for Latinx families.

11:45 **162.004** Comparing Child-Directed and Parent-Mediated Interventions Delivered in Community Care Settings with Diverse Children with ASD

M. Baker-Ericzen[1], *M. O. Mazurek*[2] *and S. Kanne*[3], *(1)Rady Children's Hospital San Diego, San Diego, CA, (2)University of Virginia, Charlottesville, VA, (3)Thompson Center for Autism and Neurodevelopmental Disorders, Columbia, MO*

Background:

There has been increasing support for the efficacy of both child-directed and parent-mediated interventions to improve skills in children with Autism Spectrum Disorder (ASD)(Kasari et al., 2010). There continues to be a need for effectiveness intervention studies when implemented in diverse community settings (e.g., National Advisory Mental Health Council, 2018; IACC, 2013). Thus, this study examines the effectiveness of 4 evidence-based intervention models implemented in ethnically diverse community-based settings.

Objectives:

The purpose of this study was to evaluate change across multiple distinct well-established treatments delivered in community care settings including 2 child-directed and 2 parent-directed interventions. Using a longitudinal repeated measures design, this study examined the degree to which specific autism symptom domain scores changed over time in response to separate treatments delivered in community care.

Methods:

This sample includes 264 children (82% male) ages 2-9 years (*M* = 4.4 years; *SD* = 2.2) and their primary caregivers. All children had a diagnosis of Autism Spectrum Disorder (all cases validated by positive ADOS-2), and 63% identified as racial or ethnic minority. The treatment groups included: ImPACT; *n*=69 (parent-mediated), PBS/PRT; *n*=33 (parent-mediated), EIBI; *n*=122 (child-directed) and PLAYC; *n*=40 (child-directed preschool program). All participants were assessed at baseline and approximate 6-week intervals over the course of treatment. Participants receiving the briefest intervention (ImPACT=3 month tx) were assessed at 3 time points, those receiving medium-term interventions (PBS/PRT=4.5 month tx) were assessed at 4 time points, and those receiving ongoing long-term interventions (EIBI & PLAYC=7.5 months tx) were assessed at 5 time points. The primary outcome measure, Autism Impact Measure (AIM), was collected for all participants at each assessment time point. The AIM is a

parent-report questionnaire that includes 41 items rated on corresponding 5-point scales regarding the frequency and includes the following 5 domains: Repetitive Behavior, Atypical Behavior, Communication, Social Reciprocity, and Peer Interaction (Mazurek et al., 2018). To examine the degree to which AIM scores changed over time in response to treatment, the study focused on AIM domains and the nature of change over time across all individuals. Measurement models of growth were built separately for each AIM domain using the mixed model procedure in SAS 9.4. In addition, the model estimated average T-score for AIM domains at both baseline and final time points which are presented along with the average difference in T-scores between baseline and final time point, and the effect size of this difference.

Results:

Each model found significant treatment effects. Parent-mediated treatments (ImPACT and PBS-PRT) showed greater change T-scores and effect sizes on 3 of the 5 domains including repetitive behaviors, atypical behaviors and social reciprocity. The PBS-PRT group also showed the greatest gains in the communication domain and ImPACT showed the greatest gains in peer interaction domain. The PLAYC preschool group revealed the least gains in most domains. Refer to Tables.

Conclusions:

Overall, the current study provides the first large-scale examination of change across well-established treatments delivered in community care. The results indicate that parent-directed interventions outperform child-directed treatment modalities delivered in a community setting.

Poster Session
163 - Technology Demonstration / Devices
10:00 AM - 1:30 PM - Room: 710

152 **163.152** A Digital Health Solution to the Wait Time Crisis for ASD

D. Grodberg[1], *C. Campbell*[2] *and R. Glynne-Owen*[3], *(1)Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Blue Sky Autism Project, Stirling, United Kingdom, (3)Blue Sky Autism Project, London, United Kingdom*

Background: The average age of autism spectrum disorder (ASD) diagnosis is after 4 years despite the fact that children with ASD can be diagnosed as early as 2 years old and despite evidence that parents may detect developmental concerns in children with ASD before 12 months. Barriers to timely diagnosis include the large time burden and cost of comprehensive assessments, shortage of providers, and lack of resources in primary care settings. Delayed diagnosis results in delayed entry into early intervention programs and in many parts of the United States, parents wait over 1 year for services. Moreover, in many parts of the world, there may be no diagnostic assessment and no intervention services available at all. To address the problem of delayed access to intervention services, we developed a digital health platform that supports the delivery of parent-mediated Naturalistic Developmental Behavioral Interventions (NDBI)[7]. This scalable tool is intended to help parents and caregivers learn how to implement evidence-based interventions with their children while they are on lengthy wait lists for services. The tool uses microlearning approaches powered by an artificial intelligence (AI) framework that supports structured conversation, natural language processing and real time analytics. The tool supports training and practice, coaching, and measurement of fidelity as well as target goal identification and tracking. Training content comprises critical skills and strategies that are considered universal to all NDBI's.
Objectives: This technology presentation aims to 1. Report on a Quality Improvement project that utilizes this system; and 2. To demonstrate this technology to audience members at INSAR. Specifically, audience members will interact with a chatbot that will teach them critical skills required to implement NDBI's.

Methods: We initiated a quality improvement project in an autism provider network in the United Kingdom (Blue Sky Autism Project) to assess 1. The ease of technical and clinical workflow integration; 2. Acceptability and feasibility among clinicians who served as coaches for the families. As part of the QI project, we determined completion rates of users and collected feedback from clinicians who served as coaches.

Results: Integration of the system into the provider network's workflow was uneventful and successful. Provider network clinicians trained in the system rated it as acceptable, feasible, and described high user satisfaction.

Conclusions: Scalable digital health tools hold promise to deliver evidence-based training for parent-mediated interventions for autism spectrum disorder. This approach of large-scale dissemination of evidence-based practice may allow parents to develop the capacity to start using basic interventions while they wait for clinic-based services.

153 **163.153** A Virtual Reality-Based Interactive System with an Assistive Avatar to Influence Visual Attention in Children with ASD

A. Amat[1], *A. S. Weitlauf*[2], ***A. Swanson***[3], *N. Sarkar*[4] *and Z. Warren*[5], *(1)Electrical Engineering, Vanderbilt University, Nashville, TN, (2)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, NASHVILLE, TN, (4)Adaptive Technology Consulting, Murfreesboro, TN, (5)Vanderbilt University Medical Center, Nashville, TN*

Background:
Individuals with ASD often spend less time looking at another person's facial features (particularly the eye region) compared to non-facial areas. Reduced eye gaze during social interaction negatively impacts social skills development, facial expression processing and information sharing. Virtual reality platforms, which can present social games while tracking performance and recording continuous quantitative measures, may offer a promising avenue for eye gaze detection and training.

Objectives:

This study developed and implemented an assistive avatar system that autonomously tracks and responds to participants' gaze patterns in a game-like setting to influence visual attention to eyes. The system, which uses a virtual avatar with head and eye animation control, provides a closed loop interaction, gives users performance feedback, adaptively changes task difficulty level, and tracks eye gaze in real-time.. System objectives were to 1) improve ability to follow the avatar's gaze, 2) improve ability to identify gaze cues in social tasks settings, and 3) study the effect of gaze sharing and gaze following on emotion recognition.

Methods:

20 participants (10 ASD, 10 TD) ranging from 7 to 12 years of age completed three visits (pre- and post-tests and 33 training tasks). Participants provided input to the system using a Tobii eye tracker which monitored their gaze shifts and told the system to respond accordingly. Training tasks consisted of a virtual avatar surrounded by grayed out puzzle pieces, each of which corresponded to a colored target image at the bottom of the screen. The avatar's eye gaze shifted to the target piece, requiring the participant to follow the avatar's gaze to select a piece and finish the puzzle,

The game was developed in Unity v5, using finite state machines to model the system (game-, avatar-, and puzzle- states). Avatars were developed using Maya Autodesk and displayed 7 distinct gaze directions (positions on screen) at 3 different levels: head/eyes moving together, moderate eye movement only, minimal eye movement. Adaptive difficulty levels added challenge as skills improved (e.g., speed of avatar's gaze at object; time for participant to respond). The pre- and post-test was a bubble popping game using the same game architecture as the training tasks.

Results:

Preliminary analyses on eye gaze data between pre- and post-test gaze tasks showed significant improvement in performance and gaze following skills in participants with ASD after completing the training games (improvement in time to complete games, response time to avatar's gaze cues, gaze fixation on eye region). No significant improvements were observed in the TD group. Data from training games will be analyzed to obtain the gaze fixation patterns and duration. Results of analysis for the ASD vs TD groups will be compared to evaluate differences in visual interaction processing.

Conclusions:

We developed a virtual-reality based assistive avatar embedded in an interactive system that monitors participant eye gaze to assess visual attention as part of social tasks. Pilot results indicate that after completing training sessions, children with ASD show improvement in joint attention skills.

154 **163.154** Advancements in Automated Visual & Speech Analysis of ASD Symptom Domains

*L. Soorya[1], **Z. Tősér**[2], Z. Arnold[1], E. V. Ocampo[1], M. Pollack[1], A. Wainer[1], A. Lorincz[3], R. Bellon[4], M. Csakvari[3], M. Olasz[4] and A. Sarkany[4,5], (1)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (2)Argus Cognitive, Inc., Lebanon, NH, (3)Department of Software Technology & Methdology, Eotvos Lorand University, Budapest, Hungary, (4)Argus Cognitive, Inc., Budapest, Hungary, (5)Eotvos Lorand University, Budapest, Hungary*

Background: The enormous promise of emerging machine learning applications in clinical/research settings relies on the prioritization of both technology and clinical science. This exhibit presents advancements in our application of automated AI methods to detect and monitor social-communication behaviors associated with ASD and related neuropsychiatric conditions.

Objectives: To evaluate feasibility (e.g. detection), data processing (e.g. time, variables) requirements, and clinical correlates of automated visual and speech analytic tools during clinical evaluations. This presentation expands the prior evaluation of eye gaze and facial expressions to additional domains including gestures, repetitive behaviors, and speech.

Methods: Data are presented on 48 individuals with ASD (mean=9.3 years, SD=3.1). Stimuli were collected with off-the-shelf 2D cameras and microphones, and Tobii Pro Glasses 2 worn by the examiner during the ADOS-2 (Modules 1-3). Software estimated facial, body, and speech landmarks, identified patients, analyzed target behaviors and generated detailed behavior metrics. For the purposes of this analysis, metrics included frequency, duration, initiation, responsiveness, and percentage of time. These metrics were collected for gaze, facial expressions of emotion, nodding, pitch, touching, and mouthing. For pitch, standard deviation was used as a metric of monotone, "robotic" speech. Additionally, data on recently added metrics which includes pitch, nodding, and sensory stimulation were compared in age matched, verbally fluent children with and without ASD (n_{ASD}=8; n_{TD}=8).

Results: Metrics derived from visual and speech analysis software were associated with respective item level data on the ADOS2. In the ASD sample, negative valence emotions were moderately and significantly correlated with Facial expressions directed to examiner (Spearman's rho=-.393, p=.018). Several gaze metrics were significantly correlated with Unusual Eye Contact including responsive gaze (Spearman's rho=-.436, p=.011), patient looking at clinician with (Spearman's rho=-.457, p=.007), and initiated gaze (Spearman's rho=-.419, p=.015). Comparisons across developmentally matched controls suggest machine learning methods identified unusual and atypical behaviors, and these behaviors distinguished ASD from matched TD samples. Specifically, higher levels of repetitive behaviors including touching (z=-2.17, p=.030) and mouthing (z=-1.852, p=.064). Of interest, results suggest reduced pitch range in the ASD sample relative to age-matched peers.

Conclusions: Computerized assessments are engaging, adaptive, and provide nuanced output. Our results continue to support the promise of training machine learning models to not only identify behavioral signatures characteristic of ASD but also measure novel phenotypic markers (e.g. pitch). In addition to capturing social communication skills, these results support the software's capacity to capture repetitive behaviors. Overall, findings support initial feasibility of a minimally intrusive protocol for automated analysis of core ASD symptoms with potential to support identification, treatment monitoring, and biomarker investigations of NDDs.

155 **163.155** Choreografish: A Virtual Reality Game Developed with Young Adults with Autism

***E. Handman**[1], R. Altizer[2], G. Bayles[3], C. Wright[4], T. Russell[5] and V. D'Astous[6], (1)Dance, University of Utah, SLC, UT, (2)GApp Lab, University of Utah, SLC, UT, (3)Entertainment Arts and Engineering, University of Utah, SLC, UT, (4)University of Utah, Salt Lake City, UT, (5)Biology, University of Utah, SLC, UT, (6)FCS, University of Utah, SLC, UT*

Background: This virtual reality game was developed in full collaboration with 17 young adults with autism. From our first meeting exploring what the game should be about, these students provided input and as the game was developed they regularly evaluated the content and provided critical evaluation.

Objectives: One focus of the game was anxiety reduction. The purpose of this *pilot research was* to determine if Choreografish had the potential to decrease anxiety in young adults with ASD.

Methods: This research used the VR game called *Choreografish*, which was developed by an interdisciplinary research team and students with ASD. Participants choose their own music to choreograph the swim patterns of virtual fish within the VR environment.

To measure anxiety levels, we created three similar assessments based on the *Generalized Anxiety Disorder questionnaire* (GAD-7). The GAD-7*

provides 7 questions regarding anxiety and a subject ranks his/her responses according to a 4-point scale; 1 being “Not at all” and 4 being “Nearly every day.”

Seven young adults with ASD were recruited to evaluate the game Choreografish and participant in the research related to anxiety reduction. These students provided a baseline of their anxiety and a pre-assessment of anxiety prior to playing the game. After playing the VR game, participants were asked to take a post-assessment and provide feedback on how the game could be improved and/or modified to further the development of anxiety reduction

- Results: Overall, our collected data shows a *trend of decreasing anxiety* among the participants after playing the VR game Choreografish. These results *support our hypothesis* and suggest VR gaming as a potential method of anxiety reduction due to its controlled environment, soothing color scheme, and predictable pattern

Conclusions: The preliminary results in anxiety reduction are promising. And equally important is the empowerment of these young adults with autism as part of our research and development team. They were an important part of the team and their ideas and suggestions were incorporated into the game design.

156 **163.156** Connected Robot Platform for Children with Autism Spectrum Disorders

X. Jin[1], *Z. Tan*[1], *W. Cao*[1], *H. Zhu*[2] *and J. Chen*[1,3,4], *(1)South China Academy of Advanced Optoelectronics, South China Normal University, Guangzhou, China, (2)Child Developmental & Behavioral Center, Third Affiliated Hospital of SUN YAT-SEN University, Guangzhou, China, (3)Chalmers University of Technology, Gothenburg, Sweden, (4)School of Electrical Engineering and Computer Science, KTH Royal Institute of Technology, Stockholm, Sweden*

Background: Children with autism spectrum disorders (ASD) often show certain barriers to language and behavior compared to typical developing children. By introducing real-time human-robot interactions, social robots could be applied for language and behavior training for children with ASD in daily life. However, data processing, such as emotion and gesture recognitions, can be computing-intensive tasks, which might be difficult to be realized with high quality if only using limited computation power offered by the robot itself.

Objectives: We aim at building cloud computing enabled social robot platform for children with ASD. Specifically, we are adding emotion and gesture recognition modules on top of the existing platform. Such functions could greatly help recognize children’s emotion states and gestures, based on which the robots could react in a real-time manner to children with ASD.

Methods: As shown in Figure 1, we use the social robot NAO as a front end to interact with the participants. NAO can record the audio and video data together with the surrounding equipment, including microphones, high-definition video cameras, motion sensing input devices (e.g., Kinect produced by Microsoft), and eye-trackers. Emotion recognition can be either carried out by local processing at NAO or a third-party cloud platform, e.g., FACE++, which is a commercially-available facial recognition and image recognition service platform (https://www.faceplusplus.com.cn/). Local processing means NAO runs emotion recognition locally to identify the participants' emotions. Participants' emotions can be obtained via NAOQi interface, which is a hardware interface to control Nao using a web client. NAO can also upload its collected image data to FACE++ through Internet for emotion recognition. Apart from a third-party cloud platform, video and audio data can also be sent to our own data center for gesture recognition and other services.

Results: We measured the accuracy and total waiting time of emotion recognition, 10 times for each tested emotion. The total waiting time here is defined as the time duration from the moment of taking pictures by NAO to that Nao receives emotion information. The results for each emotion are listed in Table 1. The accuracy of emotion recognition carried out by Nao directly is not as good as FACE++, although the average total waiting time is much lower in local processing compared to using a third-party cloud platform. It is because the total waiting time is greatly affected by network delay when using a third-party cloud platform.

Conclusions: We have been working on adding emotion and gesture recognition functions on top of our existing cloud computing enabled social robot platform. The results revealed that using cloud computing certainly helped improving the quality of emotion recognition but suffering from higher response time. Improving Internet connection or pushing computing facility close to the user end (referred to as edge/fog computing) can be a potential solution to address the latency issue in our connected robot platform.

157 **163.157** Development of an Augmentative and Alternative Communication Mobile App for Facilitating Communication in the Speech Impaired Children with Autism Spectrum Disorders

V. Sharma[1], *R. Juneja*[2] *and R. Jalan*[3,4], *(1)Mata Bhagwanti Chadha Niketan, a Charitable School for Special Needs, The Ponty Chadha Foundation, Noida, India, (2)Centre for Research, The Ponty Chadha Foundation, New Delhi, India, (3)Marketing, Health and Wellness, CSR, Wave Infratech Pvt Ltd., Noida, India, (4)Centre for Research, Innovation and Technology, The Ponty Chadha Foundation, Noida, India*

Background: Mobile Touchscreen devices are currently being used as Speech Generating Devices(SGDs) and have been shown to promote the communication skills in the speech impaired particularly the communication skills of the children with autism spectrum disorders. The mobile based App aims to empower individuals afflicted with speech problems to carry out the communicative functions of their day-to-day lives i.e. communicating personal needs, thoughts, ideas, feelings and emotions. This App accommodates the individual needs of the user or learner. The ease of access facilitates use in different situations-at school, home, shopping, traveling, hospitals, recreational activities.

Objectives:

To Develop the Prototype of a Mobile Based Alternative and Augmentative Communication App for Facilitating Communication in the Speech Impaired.

Methods:

Mata Bhagwanti Chadha Niketan, a special school, launched the Prototype of an AAC, mobile phone based App, called VAAKYA (The Sentence) in 2017 to facilitate communication among the non-verbal students. Technology used for programming VAAKYA was Hybrid PhoneGap language. The App uses picture and corresponding spoken sentences for teaching communication. The prototype accesses the pictures from the phone library and spoken sentences corresponding to the picture can be recorded simultaneously. The unique features of the app are flexibility of recording spoken sentence in any language, customization to individual user, multiple users for single download and free download from android play store

worldwide. A structured training protocol, preceded by training the trainers and parents, was used for promoting requesting behavior among 40 students with speech impairment. Out of these 25 were with ASD between ages 8-12 years . The App was introduced in a phased manner among the speech impaired students. Students were initiated into the app at different times over the course of the year. The app was customized for each student by using the picture of the students doing the request activity. The students were trained to use the app to convey at least 5 personal needs or requests.

Results: A year after the app was first introduced, the trainers were asked to fill a feedback questionnaire to delineate the problems in use, suggestions for improvement for the iteration and evaluate student's response to the app. The educators found the App easy to use. 10 ASD students who had been using the app for a period of 11 months were at different levels in use of the app. 2 learnt to use the app independently to convey personal needs. For the remaining 8 the app had to be opened and then they pointed to the request picture without prompt. The 15 students who have been using the app for less than 7 months require physical prompts to point to the request picture. The training in the App is still continuing. The educators observed reduction in hyperactivity, temper tantrums and improvement in eye contact and attention span in these children.

Conclusions: Our data suggests that VAAKYA is a useful tool for speech impaired children with ASD to communicate personal needs. The App can be upgraded to next version.

158 **163.158** Development and Evaluation of an Augmentative and Alternative and Communication Mobile App for Facilitating Communication in the Speech Impaired Children with Autism Spectrum Disorders

ABSTRACT WITHDRAWN

Background: Mobile Touchscreen devices are currently being used as Speech Generating Devices(SGDs) and have been shown to promote the communication skills in the speech impaired particularly the communication skills of the children with autism spectrum disorders. A prototype of an Augmentative and Alternative Communication, mobile phone based App, VAAKYA (The Sentence) was developed in 2016 by Mata Bhagwanti Chadha Niketan, a special school, to facilitate communication among the non-verbal students. The unique features of the app, which relies on images and recorded sentences, are flexibility of use in any language, vast picture library, customization to individual user, multiple users for single download and free download from Google store. The App once configured doesn't require internet connection. The App aims to empower individuals afflicted with speech problems to carry out the communicative functions of their day-to-day lives i.e. communicating personal needs, thoughts, ideas, feelings and emotions. This App accommodates the individual needs of the user or learner. The ease of access facilitates use in different situations-at school, home, shopping, traveling, hospitals, recreational activities.

Objectives: To develop an Alternative and Augmentative Communication App for facilitating communication in the Speech Impaired.

To develop an App which has flexibility of use in any language

To develop an app which can be customized to individual user

To ensure easy access by developing it on mobile interface and download from online App stores

To evaluate the benefits of the App

Methods: The trial of the prototype towards the first iteration was conducted among 30 speech impaired students with autism at MBCN Special School. The Trainers (special educators) were first trained in the use of the App and then they proceeded to train the 30 student and parents. The students were trained to use the app to convey personal needs. Six months after the introduction of the App the trainers were asked to fill a feedback questionnaire to delineate the problems in use and suggestions for improvement. The student's response to the app was also evaluated through a questionnaire filled by the special educators.

Results: the students with mild intellectual disability easily learnt the use of the app as compared to students severe level of intellectual disability. There was an improvement in attention span and level of communication, some students moved from being non verbal to verbal. Improvement were observed in maladaptive behaviours such as hyperactivity, temper tantrums of the students with autism.

Conclusions: Our date suggests that VAAKYA is a suitable App for helping children with autism spectrum disorders to communicate

159 **163.159** Development of a Health Care Social Stories App

*S. S. Qin[1], S. Chao[1] and **C. Bays-Muchmore**[2], (1)Developmental and Behavioral Pediatrics, Boston Medical Center, Boston, MA, (2)The Autism Program, Boston Medial Center, Boston, MA*

Background: The communication impairments and sensory sensitivities of patients with autism spectrum disorder (ASD) can make medical care particularly challenging (Bultas et. al, 2016). Social stories, short stories that use text and pictures to break down processes into smaller, understandable steps, are one way to mitigate the communication difficulties. They help patients better understand what to do in specific situations, such as getting a flu shot. Social stories may reduce patients' disruptive behaviors (Scattone et al., 2002), ease anxiety, and set expectations about what will happen.

Objectives: We aimed to develop a free, publicly available mobile application that contains social stories about the experience of accessing care at Boston Medical Center to better prepare our patients with ASD for upcoming encounters.

Methods: We conducted a review of the available social story apps, and found that many either were not free, or did not focus on medical encounters. To better understand the specific needs of our patients and families, we involved parents who are members of the Parent Leadership in Autism Network (PLAN) at BMC. In addition to parent and patient feedback, we collected perspectives from the Steering Committee of the Autism Friendly Initiative, which includes stakeholders from nursing, security, and developmental and behavioral pediatrics among other departments. A BCBA also provided guidance on the language for the social stories. Our needs assessment informed the design of the app.

Results: The app contains seven social stories including measuring height and weight, measuring blood pressure, getting a shot, getting blood drawn, doing a physical exam, visiting the dentist, and navigating to a doctor's office on the campus of Boston Medical Center (BMC). The social stories that describe medical procedures are illustrated using Picture Exchange Communication System (PECS) images, since this is a format often used by education professionals, and would likely be familiar to many of our patients.

For the social story about navigating to the doctor's office, we wanted to enable patients to preview the experience of coming into Boston Medical

Center. This story has photos of actual locations on campus, such as building exteriors, building lobbies, individual floor hallways, and each department's front desk and waiting area. To customize the experience further, the social story allows the user to select the desired starting point, building, and department. Then, each step is its own screen that has a descriptive sentence paired with a picture, enabling the patient to virtually "walk" from the parking lot, through elevators and corridors, all the way to the actual exam room. After each step there is a "reward screen" that depicts a rotating star to commend the user for completing the step to make for a positive and engaging user experience.

Conclusions: Social stories are valuable in supporting patients with ASD with preparing for medical encounters. Our app is designed to increase access to social stories, and to enable our patients to be better prepared for medical encounters, and ideally to have a better experience.

160 **163.160** Creating a Socially Inclusive Environment for Autistic Children with the Cozmo Robot

*E. Skoulikari[1], H. Brown[1], D. Stanton Fraser[2] and **M. Brosnan**[3], (1)University of Bath, Bath, United Kingdom, (2)10 West Department of Psychology, University of Bath, Bath, United Kingdom, (3)Centre for Applied Autism Research, University of Bath, Bath, United Kingdom of Great Britain and Northern Ireland*

Background:

Recent research has shown that autistic children can demonstrate a preference for interacting with social robots and that socially assistive robots placed within the home can result in tangible social benefits in autistic children. However, any benefits diminish when the robot is removed from the home after the intervention. In addition members of the autistic community have questioned whether social robots are an appropriate methodology for modelling human social skills. To address this concern, the approach in this study used robots to create a socially-inclusive environment within which autistic children can be motivated to engage in social communication.

Objectives:

This study used an affordable commercially available robot 'Cozmo', which was developed with the capacity to model social-emotional processing during interaction with humans. We aimed to explore robot-child interaction in addition to child-child interaction elicited in autistic and non-autistic pairs of children while they played with two Cozmos.

Methods:

We analysed the social and informational interactions between two pairs of autistic children and two pairs of non-autistic children. The children, aged 9-11 years, took part in two play sessions with Cozmo, one unstructured (free play) session and one structured (task-based) session. The children played in pairs to enable analysis of child-robot and child-child interactions. The sessions were video recorded and independently analysed by two researchers.

Results:

All children rated playing with Cozmo as 'excellent'. Video analysis revealed that autistic children initiated social communication with both Cozmo and the other child, see Table 1. Both groups directed more social communication at Cozmo in the unstructured play session and more social communication at the other child in the structured session. While autistic children initiated less social communication than non-autistic children, these differences were markedly reduced in the structured play session. See Table 1.

Conclusions:

This study was not designed to be an intervention, rather to explore the social interaction that can be spontaneously elicited whilst playing with Cozmo. Autistic children enjoyed this and engaged with Cozmo and the other child in a social manner. Structuring the play environment can markedly reduce social communication differences between autistic and non-autistic children whilst playing with Cozmo. Future work can focus on how autistic children's play with robots can best be structured and supported to maximise the benefits for child-child social communication. This initial study was small, and in addition to increasing numbers, future research can explore mixed pairs of autistic and non-autistic children. Overall, this research demonstrates initial support for the approach of using robots to create a socially-inclusive environment (rather than focusing on socially assistive robots teaching social skills to autistic children). The commercially available nature of the robot also means that any benefits can extend beyond discrete research projects.

The Demonstration will provide a poster of the findings, a Cozmo and a film of two autistic children playing with the robot.

Declaration: This research was funded by Anki who produce Cozmo. All children were allowed to keep a Cozmo as a thank you for participating.

161 **163.161** Development of an Interactive, E-Learning Tool to Support Parent Implementation of an Executive Function Intervention

***K. C. Alexander**[1], L. Kenworthy[2], D. Childress[3], A. C. Armour[2], A. Verbalis[2], M. Troxel[4], K. Kocher[3], Y. Myrick[2], M. A. Werner[5], L. Cannon[6] and L. Anthony[4], (1)The Occupational Therapy Institute, La Mesa, CA, (2)Children's National Health System, Washington, DC, (3)3C Institute, Durham, NC, (4)University of Colorado, Denver, Aurora, CO, (5)Program Development and Training, Ivymount School, Rockville, MD, (6)Ivymount School, Rockville, MD*

Background: Research has shown that parenting an autistic child is often characterized as complex (Hayes & Watson, 2013), requiring particular vigilance (Woodgate et al., 2008) and advocacy (Boshoff et al., 2016), as parents leverage available resources to overcome barriers and manage constraints, notably those related to time, finances, and discontinuous service provision (Brown, Ouellette-Kuntz, Kelley, & Cobigo, 2012). Parents of autistic children work to promote success in daily life while remaining highly future-oriented in their pursuit to optimize long-term outcomes. Research has also shown that parents are effective at using professional guidance to teach their autistic children specific skills (Wong et al., 2015). Web-based learning can be a cost-effective way to manage the constraints parents frequently encounter while preparing them to teach specific skills.

Executive function (EF) skills are a promising skill acquisition target because of their impact on adaptive behavior, successful participation in daily life, and long-term outcomes. A recent home- and school- based EF intervention, *Unstuck and On Target* (UOT; Cannon et al., 2011; 2018) has been shown to be effective in two RCTs (Kenworthy, et al. 2014; Anthony, et al., in prep) at improving EF skills and classroom behavior. *E-Unstuck* adapts essential UOT intervention components into e-learning modules. Should research find that *e-Unstuck* is effective, it would also need to be an acceptable, appealing, and valuable product in order to elicit intervention uptake. Therefore, product evaluation data is a critical step in the development process.

Objectives: Develop an interactive, e-learning program for parents of autistic children using a stepwise process.

Systematically evaluate product quality, value, and usability.

Methods: Parents (n=44) of children on the autism spectrum without an intellectual disability (mean age=10.0 years; mean IQ=103.6) participated in *e-Unstuck* learning modules. Parents also completed an online product evaluation, providing feedback on aspects including quality, value, usefulness, and appeal through 5-point Likert scale items (1= strongly disagree to 5= strongly agree) and open-ended questions. Parents were also invited to provide additional product evaluation feedback through focus groups.

Results: The quality, value, and usability of *e-Unstuck* were all rated highly by parents (M ≥ 4 on a 5-point scale). Furthermore, parents reported that they would use *e-Unstuck* again (M = 4.68, SD = .53) and recommend *e-Unstuck* to a friend (M = 4.54, SD = .77). They also indicated that *e-Unstuck* would make UOT training more accessible to parents of children with ASDwoID (M=4.49, SD=.65). A consensus of parent responses to open-ended product evaluation questions and focus group discussions showed important positive feedback related to the flexibility and convenience of self-paced module completion. Parents also reported a primary barrier related to the difficulty in setting aside time to complete each module; however, this is a potential barrier for any intervention.

Conclusions: These findings indicate that *e-Unstuck* is an e-learning tool of high quality, value, and usability. Parent experiences also support that *e-Unstuck* can help make intervention more accessible to parents, offering flexibility that accommodates time constraints while providing useful information.

162 **163.162** Feasibility and Preliminary Efficacy of Gazefinder Eye-Tracking Technology for Use with Infants Showing Early Signs of Autism

K. Hudry[1], *K. J. Varcin*[2], *L. Chetcuti*[3], *M. Boutrus*[4], *C. A. Bent*[5] *and A. J. Whitehouse*[2], *(1)Victorian Autism Specific Early Learning and Care Center, Olga Tennison Autism Research Centre, Melbourne, Australia, (2)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (3)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (4)Telethon Kids Institute, University of Western Australia, Perth, Australia, (5)Olga Tennison Autism Research Center, La Trobe University, Melbourne, Australia*

Background: Identification and diagnosis of autism currently relies on the appraisal of overt behavioural difficulties. Manufactured by JVCKENWOOD Corporation, *Gazefinder* is a bespoke eye-tracker which may support accurate and efficient autism identification across the lifespan. *Gazefinder* includes an infra-red eye-tracker, short 2-minute stimulus sequence, and automated visualisation of results and data extraction. Stimulus trials target referential attention to pointed-at objects (vs. distractors), and preferential attention to eyes (vs. mouth), people (vs. geometry) and biological motion (upright vs. inverted point-light displays). Previous studies – all conducted in Japan – suggest *Gazefinder* differentiates people with and without autism in childhood (Fujisawa et al., 2014) and adolescence/adulthood (Fujioka et al., 2016). The short stimulus sequence is also well tolerated by young, typically developing children (Nishizato et al., 2017). However, the efficacy of *Gazefinder* to support early identification of autism in infants has yet to be evaluated.
Objectives: To trial the feasible use of *Gazefinder* – by an independent team, in a Western country –including evaluating preliminary efficacy for supporting the early identification of autism.

Methods: Participants were 54 infants (75% boys) aged 9-16 months (*M*=12, *SD*=2) who were eligible for the study on the basis of showing early behavioural signs of autism according to the Social Attention and Communication Surveillance (SACS) protocol (Barbaro and Dissanayake, 2010). Specifically, we recruited infants showing ≥3 (of 5) key markers on SACS 12-month checklist (i.e., absent/atypical eye-contact, response to name, imitation, pointing, and other gestures – for which Barbaro et al. (2018) have reported 72% positive predictive value for later autism diagnosis. We assessed infants with *Gazefinder*, the Autism Observation Scale for Infants (AOSI; Bryson et al., 2008) and the Mullen Scales of Early Learning (MSEL; Mullen, 1995).

Results: *Gazefinder* captured tracking data ranging from 0% (*n*=3; no data due to examiner error) to >99% (*M*=72, *SD*=28), including rates >80% for half of the sample. Among the 51 infants with some tracking data, referential attention to pointed-at objects (vs. distractors) and preferential attention – toward eyes (vs. mouth) of a human face, and to people (vs. geometry) – were as expected, suggesting ecological validity of the stimulus sequence. Variation in attention to pointed-at objects was associated with MSEL verbal skills (*r*=.33, *p*=.020). Further, greater attention to geometry (vs. people) was associated with poorer verbal skills (*r*= -.39, *p*=.008) and with more behavioural signs of autism (AOSI; *r*= -.42, *p*=.002) suggesting potential utility for *Gazefinder* to aide early identification.

Conclusions: Tracking rates captured by *Gazefinder* exceeded the standard often accepted by researchers conducting eye-tracking studies with infants at high-risk for autism using other technologies (i.e., ~30%). The large majority of infants tolerated the *Gazefinder* procedure very well. Researchers more familiar with behavioural assessments found the apparatus easy to use. Initial evidence suggests that some gaze data automatically exportable from *Gazefinder* may be associated with concurrent behavioural signs of autism and language skill among 9-16-month-old infants referred with early social-communication atypicalities. *Gazefinder* may facilitate the early identification and diagnosis of autism in clinical settings, warranting a larger scale trial.

163 **163.163** Free Choice Response Assessment Reveals Basic Cognitive and Sensorimotor Properties in Autism Spectrum Disorders

E. Davydova[1], *D. Davydov*[2] *and* ***A. Sorokin***[1,3,4], *(1)FRC, Moscow State University of Psychology and Education, Moscow, Russian Federation, (2)self-employed, Moscow, Russian Federation, (3)Pediatric Institute, PIMU, Nizhny Novgorod, Russian Federation, (4)Haskins Laboratories, New Haven*

Background: Orienting response is associated with motivation and cognitive functions and can give insight into peculiarities of mental processes in ASD and be instructive for planning education and interventions. Unfortunately, most psychophysiological protocols require cooperation from subjects. We introduced a method that does not rely on verbal instruction and measures parameters reflecting basic sensorimotor and cognitive functions. A series of simple intuitive tasks are presented on a touchscreen, and within several minutes a comprehensive set of data is collected. Earlier studies showed high levels of correlation of acquired basic parameters with results of psychological testing, including adaptive behavior in typically developing individuals (TD).
Objectives: We tested the applicability of Free-Choice Response software (patent pending) to assess basic cognitive and sensorimotor functions in children with ASD and compare the results with TD and other clinical groups.

Methods: 20 children with ASD (16 boys, age 3 to 10 years) participated, two outliers with average response time over 10 sec were excluded. The TD group included 47 children 5 to 10 years of age (21 boys). All children were silently or verbally encouraged to “play” with the touchscreen. No

detailed instruction was given, the adults in the room did not comment on the performance. During the first series the subject touched the colored disc on the screen so that it disappeared and appeared at a different location. The exposure was not limited. Free response time (FRT) and number of misses were recorded. In subsequent series the exposure time reduced progressively, the disc changed color, the disc of one color did not disappear after touching. In the last series, an array of discs was presented with only one color sensitive for touch. Corresponding changes in performance were recorded.

Results: Children with ASD demonstrated longer FRT (first series 2654 ms vs 945 ms, second series 2320 vs 742 ms; 2376 ms vs 886 ms; all $p<0.00001$) compared to TD children. Analysis of individual data revealed that longer FRT in ASD is controlled not by general slowness, but rather speed inconsistency and distraction periods. Children with ASD had on average more misses (in four series: 24 vs 1, 23 vs 8, 38 vs 11, 29 vs 10 respectively; all $p<0.00001$) Similar results, reported elsewhere, were obtained from comparison of ASD and other clinical groups (ADHD, learning disabilities, fragile X syndrome – each with a distinct profile). They reflect differential diagnostic potential of the method. The stereotypic behaviors called for a higher number of repetitive responses in ASD.

Conclusions: Free-Response Choice method can collect a large amount of relevant information within a short period of time. The obtained data translate into terms of basic sensorimotor and cognitive functions as well as level of motivation. It is one of few tools not requiring verbal instruction and in such a manner can be used with all populations including individuals with extremely low IQ and very limited cooperation.

164 **163.164** Knowledge Trainings on Autism Spectrum Disorders for Teachers in Tanzania: The Mobile Phone Solution.

*N. Naqvi[1], **D. Martino**[1], A. Martinge[2] and E. Elibariki[3], (1)Iona College, New Rochelle, NY, (2)OMPACO, Lexington, MA, (3)Arusha City Council, Arusha, Tanzania, United Republic of*

Background: In Tanzania, there is emerging awareness of Autism Spectrum Disorders (ASD) in the general population and few resources dedicated to serving the needs of children with ASD (Manji & Hogan, 2013). The use of distance learning interventions has emerged as a feasible option for promoting ASD knowledge. Tanzania has a mobile phone penetration rate close to 70 percent and counts telecommunications as its fastest-growing sector (Reuters, 2016), so this intervention specifically capitalizes on the fast developing technology infrastructure in the country.
Objectives: The current project delivers a sustainable alternative to face to face ASD knowledge trainings for teachers in Tanzania. This project is the first virtual ASD training conducted in the country and is unique in that it has enabled participants to use their phones to access trainings with flexibility of completion time and location.

Methods: The training launched in July 2018 with 100 teachers in Arusha, Tanzania. The training will be available online until December 31st 2018. Seventy nine users have accessed the training to date with 35 users completing the entire training (female, N=27; male, N=8). The training was developed by clinicians from a U.S. based social benefit orgranization, (OMPACO). The content of the training is based on live trainings the organization currently provides in Tanzania. The training included information about ASD in seven modules and is available to teachers in English and Swahili. Teachers access the training through a website and the training is formatted to be viewed on both SMART phones and feature phones. A pre-test measure established baseline autism knowledge, and five-item quizzes at the end of each module that assessed user learning of information from each module.

Results: Reliability results for the pretest measure were fair (Cronbach's alpha=.542) and the mean pretest score for all users was 35.72 correct out of a possible 48 items. The training modules with the highest user participation were Etiology (English, N=28; Swahili, N=22) and Assessment and Diagnosis (English, N=24; Swahili, N=24). The highest average quiz scores was on the module related to IEP development (English, N=96%; Swahili, N=73%).

Conclusions: Total user participation was high (79 users out of 100). On the section quizzes, there was a high completion rate and high scores across the modules. The mean pretest score of 35.72 indicated fair to high baseline autism knowledge among teachers who completed the training (74% score on the measure). Future research could explore the possibility of providing trainings to the general community as a way of scaling up the intervention to a larger populatoin. For a pilot launch, these results provide an encouraging step towards bringing awareness of ASD to the teacher community in Tanzania via the use of mobile phone technology.

165 **163.165** Loris Platform for Automating Clinical Workflows and Multimodal Data Management

ABSTRACT WITHDRAWN

Background:
The growing quantity and diversity of data collections in autism research require robust data systems for harmonizing multi-modal cohorts across large-scale distributed collaborations. Enabling researchers to query and manage diverse brain, behaviour and genotypic data types in one comprehensive platform is pivotal to the future of neurodevelopmental research. By leveraging the computational customizability of specialized neuroinformatics platforms, research teams can optimize labour-intensive clinical workflows and accelerate the return of results.

Objectives:

LORIS is an open-source web-based data management software developed at the Montreal Neurological Institute (MNI). Its modular design aims to automate high-value processes and tasks from data capture, quality control, visualization and analysis workflows. Embedded tools for normalized scoring and data verification provide computational validation for labour-intensive tasks otherwise requiring clinical expertise.

Native clinical and imaging workflows are customizable and extensible across other data modalities supported by LORIS, including electrophysiological (EEG), biobanking and summary genetic data types. Coupled with the CBRAIN processing platform and embedded BrainBrowser visualization tool, this combined neuroinformatics environment endeavors to address the challenges of large-scale, multi-modal data collection analysis.

Methods:

Complex instrument scoring using norms tables and scales can be computed automatically in LORIS during data entry, reducing error and time-cost in manual scoring. Clinical algorithms can be updated and re-calculated to validate accuracy and reproducibility of results.

Multi-modal querying of longitudinal cohorts using the Data Querying Tool enables users to build, save and export queries across timepoints. At-a-glance data summaries are visualized in interactive Dashboard graphs, and detailed in the Statistics module.

Salient demographic variables are easily accessed and queried along with longitudinal data. The Candidate Profile module transparently captures top-level enrolment, demographic, and consent information at every stage of a study. Related participants are cross-linked through the Family Information sub-module.

Results:

In autism and neurodevelopmental research, projects such as the IBIS network, the Baby Connectome Project, and the NIHPD database use LORIS as a combined gene-brain-behaviour longitudinal data platform. In such instances, clinical norm algorithms are embedded in behavioural forms, providing instant return of results to clinicians. No external calculations or manual checks are needed to validate complex scores. These initiatives have also contributed significantly to the data standards and interoperability of the NIMH Data Archive (NDA).

For large, multidisciplinary data collections, this native ability to link and query participant data across modalities in one system conserves time and expertise that would otherwise be spent coordinating and maintaining multiple data systems in parallel.

Recent integrations of EEG data and interoperability with the BIDS data structure increase the global utility of LORIS. Interoperability with processing platforms such as CBRAIN facilitates the flow of data from storage platform to analysis toolkits.

Conclusions:

Customizable for large-scale multi-modal collections, the LORIS platform allows investigators to amplify the translational impact of data assets in autism and neurodevelopmental research. Equipped with powerful tools for cross-modal querying of longitudinal datasets, verifiable scoring of complex algorithms, and multi-level data validation and review, research teams can reduce error and efficiently utilize clinical expertise via a single neuroinformatics platform.

166 **163.166** Myway Employability: Enhancing Independence, Job Readiness and Inclusion for Young People on the Autism Spectrum

*C. Mangan[1] and **M. Ciccarelli**[2], (1)Autism CRC, Indooroopilly, Australia, (2)Curtin University, Perth, Australia*

Background: In 2012, Australians on the autism spectrum had a 41% unemployment rate; over three times that of people with disability and almost six times the rate of people without disability. Only 44% of autistic adolescents are likely to attend post-secondary education and training which is significantly less than their peers with other disabilities. Unsuccessful transition to work increases the risk of labour-force and social exclusion, as well physical and mental health issues.

A better transition from school to adult life can lead to earlier potential for employment, higher job satisfaction and productivity in the workplace, and greater capacity for independent living. Better Outcomes and Successful Transitions for Autism (BOOST-A) is an online transition-planning tool for adolescents on the autism spectrum to plan for life after school. BOOST-A was developed collaboratively with young people on the spectrum and the adults who support them, and provides a step-by-step guide to career exploration, goal setting, creating work experiences, and developing networks for employment. An Australian-wide controlled trial found that high school students on the spectrum who used BOOST-A had more confidence and self-determination to achieve their employment goals, than students involved in generic transition-planning (N=94 young people on the spectrum). Our challenge was to incorporate the evidence-based BOOST-A into a holistic career planning and employability service, accessible and engaging for young people on the spectrum.

My Way Employability is a mobile-first web application to empower young people to plan and prepare for future study, training and employment. We adopted a five-stage process to design this holistic service: (i) Discovery; (ii) Problem exploration; (iii) Solution exploration; (iv) Market validation; and (v) Preparation for growth and scale. We engaged over 250 stakeholders through interviews, workshops, user testing sessions, and informal conversations to co-design and validate a service that supports young people transitioning from school to adulthood. This involved young people on the spectrum, parents, and allied health and education professionals.

Objectives: In this interactive demonstration, we will conduct live user testing of the MyWay Employability prototype; gathering important feedback to inform the ongoing refinement of user experience.

Methods: The 90-minute demonstration will include:

1. An overview of stakeholder engagement at various touchpoints in the design process
2. A summary of universal design principles and engagement strategies identified by young people on the spectrum that were central to our technology solution
3. Live user-testing and feedback on the MyWay Employability prototype
4. Explanation of the knowledge translation and service design processes used that may have future relevance and utility for audience members

Results: We will present key findings and insights from the design phase of the project, and explain how these recommendations were translated into content and design features to engage young people on the spectrum with MyWay Employability.

Conclusions: Through our reflections of our journey to develop MyWay Employability we will challenge the research community to consider how they might engage key stakeholders in a knowledge translation process and find market opportunities to turn their research outputs into a service that is beneficial and valued by the community.

167 **163.167** Neurofeedback of the Event Binding EEG Rhythm (40 Hz.) Improves Autistic Issues

***J. Cowan**, Peak Achievement Training, Goshen, KY*

Background: Forgotten research from the early '90s by Rudolpho Llinas found a 40 Hertz (cycles/second) MEG and EEG rhythm which binds together inputs and memories to form an event. It originates in the intralaminar nucleii of the thalamus and scans the brain 40 times a second, bringing the most relevant information back to the thalamus to be integrated (bound) into an event.
I hypothesize that disorders of this event binding system, which vary individually, are the basic flaw leading to many autistic issues.

We call this system "Neureka!" due to its role in discovery and new learning. We have developed a measurement of the particular 40 Hertz rhythm, the Neureka! Protocol, which isolates it from other 40 Hertz rhythms and EMG artifact, and developed a professional brainwave biofeedback system, the Peak BrainHappiness Trainer. This uses neurofeedback designs which combine training to enhance control of Neureka! and single pointed Focus—the InhibitAll protocol. The Neureka! level controls the size of the video or DVD playback, while Focus enhances the brightness. Low levels of either stop the playback.

Objectives: We tested its effectiveness in autistic teenagers in several studies. Its success led us to simplify the Trainer and create a home and clinical training system, the Socialize ACE, for the PC, which I will demonstrate. This provides the advantages of more frequent, less expensive sessions, which should improve learning.

Methods: The most recent study built on previous published work, and tested the design's effectiveness as part of our Peak BrainHappiness Trainer, training two to three times a week during the summer instead of once in previous studies. It is ongoing at the University of South Carolina in Greenville.

Results: After 18 sessions of training, the first 8 subjects showed very significant improvements of parent ratings on the Achenbach scales for problems with Depression (p = .009), Attention (p = .001), Oppositional Defiant Behavior (p = .002), and p = .09 for Anxiety. The group average for each of these scales started out in the abnormal range and finished below the normal cutoff. The mean total score on the Social Responsiveness Scale-2 decreased very significantly (p = .006), or 51% toward the normal zone boundary of 59. These results appear to be better than the previously published work.

The training improves the user's mood and they are very motivated to continue.

Conclusions: There is mounting evidence that the combination of 40 cycle Neureka! training and the InhibitAll Focus Training produces real and rapid improvements in several autistic issues. Also, a published study in normal subjects found significant gains in their memory and attention, and a significant improvement in happiness that lasted at least four months after only 12 sessions.

The results of the studies support the hypothesis that disorders of the 40 cycle Neureka! system, as well as focusing problems, may be important in the etiology of ASD.

168 **163.168** Providing Professional Development through Interactive, Game-Based, E-Learning Modules

A. Sam[1], *J. R. Steinbrenner*[2], *S. W. Nowell*[3], *S. Szendrey*[4] *and S. Odom*[2], *(1)Frank Porter Graham Child Development Institute, Carrboro, NC, (2)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)University of North Carolina - Chapel Hill, Chapel Hill, NC, (4)Allied Health, University of North Carolina, Chapel Hill, NC*

Background:
Over recent years, there has been an increase in paraprofessionals providing service to students with disabilities. The literature suggests that training for paraprofessionals about evidence-based practices (EBPs) for students with ASD has been minimal, and when it does occur it tends to be in the form of workshops with little follow-up. The Supporting paraprofessionals-teachers Use of Evidence-base practices with Learners having Autism (STELA) research development grant focuses on developing a professional development model for elementary paraprofessionals working with students with ASD. In Phase 1 of the project, the STELA research team conducted a survey and classroom observations of paraprofessionals to guide initial development of the STELA model.

Objectives:

1. Determine professional development needs and preferences for elementary paraprofessionals working with students with ASD.
2. Examine frequency and fidelity of use of foundational evidence-based practices (EBPs) of paraprofessionals working with students with ASD.
3. Describe how data informed the development of the STELA modules
4. Demonstrate the use of STELA e-learning modules

Methods:

Mixed methods were used to address these questions and inform the iterative development process of the STELA professional development model. The research team collected survey data from 209 elementary paraprofessionals working with students with autism that represented 24 different states/territories across the United States. Research staff observed 20 paraprofessionals' use of foundational EBPs. They used partial interval coding during a 2-hour observation, noting the presence or absence of each EBP and rating the fidelity of EBPs. The research team examined descriptive data including means, standard deviations, and ranges.

Results:

See Table 1 for a summary of key data from the survey. The survey results showed that 93% of paraprofessionals identify a need for professional development on specific EBPs, but identified limited time (25%) and lack of offered training (22%) as barriers.

Based on proportion of intervals, the paraprofessionals used least to most prompting (mean=51%) and reinforcement (mean = 36%) the most. Paraprofessionals used visual schedules (mean=3%) and visual cues (mean=6% of intervals) less. Time delay was not used by any of the observed paraprofessionals. The paraprofessionals rarely collected data (mean = 3%) or facilitated peer interactions (mean < 1%).See Table 2 for a summary of key data from the classroom observations.

Conclusions:

The research team analyzed the data to develop the initial protocol for the STELA model and prototypes for the targeted EBPs. The STELA model consists of (1) in-person workshops for paraprofessionals and supervising teachers (overview of autism, roles and responsibilities, teaming and communication), (2) e-learning modules that introduce foundational EBPs, and (3) performance feedback cycles between paraprofessionals and

supervising teachers. For example, the survey data indicated that e-learning modules needed to be brief, and thus were designed to take 30 minutes. Also, the team used the observation data to determine which EBP steps may have needed more support (e.g., data collection).

Discussions will focus on creating e-learning modules using an iterative, instructional design process through negotiating the balance between feasibility and efficacy and the challenges associated with incorporating feedback while maintaining project timelines.

169 **163.169** Scalable Mobile Apps for Active Closed-Loop Behavioral Coding in Autism Spectrum Disorders

J. Hashemi[1,2], *Z. Chang*[1], *K. L. Carpenter*[3], *S. Espinosa*[1], *A. Kaniuka*[4], *G. Dawson*[5] *and G. Sapiro*[1], *(1)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (2)Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (3)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (4)Duke Center for Autism and Brain Development, Duke University, Durham, NC, (5)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC*

Background: Observational behavior analysis of children plays a key role for the evaluation, monitoring, and discovery of behaviors related to Autism. To date, these analyses are done in-person by a trained clinician who administers assessments and manually codes the children's behaviors. With emerging technology and methods in computer vision and machine learning, new scalable and objective methods of behavioral elicitation and analysis of children are feasible. These include designing and displaying specific (for example) visual, auditory, tactile, and memory stimuli on mobile devices while simultaneously recording the child with the device and coding behaviors of the child while they are interacting with the device.

Objectives: To develop and deploy an all-in-one mobile-paradigm that incorporates questionnaires and movie stimuli designed to elicit behaviors relevant to ASD screening while simultaneously capturing and coding the child's behavior in an unsupervised manner.

Methods: This work is an interdisciplinary collaboration between mental health professionals, computer vision and machine learning scientists, and app developers. Caregivers are able to digitally fill out demographic questionnaires and parental reports on the device. Additionally, multiple short video stimuli (<1 minute) designed to elicit specific social and emotional responses are displayed on a mobile-device, while at the same time the front facing camera records a video of the child's face. Computer vision algorithms detect and track the child's face throughout the video recording. Automatically computed facial landmark are used to compute the child's head pose, whether the child turns their head, the degree to which the child is attending, and the movement of the child's head. Image regions around key facial landmark points are used to estimate the child's facial affect. The facial landmarks are also used to estimate the eye regions of the child, which, along with the face image, are fed into a neural network to estimate the child's gaze locations on the screen.

Results: The data collected from our developed mobile applications contain features related to ASD risk behaviors. For example, we are able to assess total time child is attending to a given stimulus; number of times child disengages their attention; detecting a name-call prompt; whether or not a child performs a head turn; how quickly the child performs a head turn; the probability a child is displaying a positive/negative/neutral facial affect and the range of facial affect; gaze fixation patterns; preferential gaze; and postural sway. Our apps have been used in in-clinic and at-home studies.

Conclusions: We developed mobile applications that displays visual and interactive stimuli designed to elicit behaviors relevant to ASD and incorporates digital questionnaires. The mobile applications also record the child's face with the front facing camera, and with our developed computer vision and machine learning algorithms we are able to automatically extract ASD relevant behaviors from the child. Applications such as the one presented here could lead to new or refined behavioral risk marker assessments, and novel screening and monitoring methods outside of clinical settings.

170 **163.170** Tabatha: A Mobile Health Platform to Evaluate Stereotypical Behaviors in Autism

ABSTRACT WITHDRAWN

Background: Children with Autism Spectrum Disorder (ASD) face challenges in undertaking daily activities if they have stereotypical behaviors, such as hand flapping, head banging, repetitive movement, and vocal protest. Accurate detection of these behaviors through wearable devices and other sensing technologies can allow researchers to characterize their nature objectively and identify triggers for their occurrence. Sensing technologies can also be used to monitor therapeutic interventions and assess their efficacy in an unbiased manner.

Objectives: Our primary objective is to create an end-to-end mobile health (mHealth) platform (called TABATHA) to support research on challenging behaviors in ASD. Researchers can use TABATHA to collect and store sensor readings, validate physiological parameters, and analyze the data to discover novel biomarkers and triggers for vocal protest and motor stereotypy. Our secondary objective is to ensure that the data collection approach complies with human subject regulations, such as subject privacy.

Methods: The TABATHA platform consists of a commercially available smartwatch (Motorola Moto 360), Android tablet, Hyperledger Blockchain, and IBM Cloud. The smartwatch collects raw sensor data sampled at high frequency: accelerometer (96 Hz), gyroscope (48 Hz), photoplethysmogram (24 Hz), Heart rate (1 Hz), and the acoustics (44.1 kHz). To minimize the re-identification risk, we have developed software within the smartwatch to anonymize the sensed samples right at the source. We obfuscate the identifiable traits captured by acoustic sensing by computing and storing time and frequency domain speech features. The anonymized streaming data is sent to the tablet on which researchers note the occurrence of stereotypical behaviors; both the anonymized data and identified behavioral occurrences are sent to the IBM Cloud, where we can apply machine learning algorithms. TABATHA also uses Blockchain to support privacy and security. Prior to enrollment, consent information, collected from subjects, are securely stored on the immutable ledger. Study data ownership, access rights, and secondary data usage are enforced by smart contracts written into the Blockchain.

Results: The design of TABATHA can facilitate six central roles within an ASD research environment: subject (uses a wearable); parent (who provide consent); primary investigator (monitors, manages, and approves the ongoing activities), study coordinator (recruits subjects, acquires informed consent, and administers study sessions), auditor (evaluate the protocol compliance), and third-party collaborator (access anonymized study data).

We have validated TABATHA by conducting a feasibility study to detect stereotypical motor behaviors in the presence of other confounding child-type playing activities, such as card matching and drawing. We obtained a nearly 93% accuracy in a cross-subject evaluation. Moreover, we hand-

curated a speech dataset on vocal protest (defined as sensory overload induces crying or screaming among children with autism) and developed neural network-based detection models with accuracy over 93%.

Conclusions: We have developed a novel mHealth platform to collect research data on stereotypical behaviors of children with ASD. The developed platform facilitates consent management, annotation, anonymized datasets, and summaries of the occurrence of behaviors. Future work will involve using TABATHA to conduct a field study on children with ASD and identify triggers for challenging behaviors.

171 **163.171** The Global Reach of Autism Navigator® Mobile Technology to Improve Early Detection

A. Wetherby[1], *A. Delehanty*[1], *C. Nottke*[1], *N. Chambers*[2], *E. Schrader*[3], *A. Casler*[4], *I. Davis*[5], *T. Walton-Walker*[6], *K. Sohl*[7] *and J. Woods*[8], *(1)Florida State University Autism Institute, Tallahassee, FL, (2)University of Cape Town, Paarl, South Africa, (3)College of Medicine, Florida State University, Tallahassee, FL, (4)College of Medicine, Florida State University, Orlando, FL, (5)School of Communication Science and Disorders, Florida State University, Tallahassee, FL, (6)Autism Institute, Florida State University, Tallahassee, FL, (7)Thompson Center for Autism, University of Missouri - School of Medicine, Columbia, MO, (8)Florida State University, Tallahassee, FL*

Background: Advances in research have documented that ASD can be diagnosed by trained professionals at 18-24 months of age, and yet the median age of diagnosis in the US still hovers at 4 years. There is currently a research-to-practice gap in high-resource countries, and this gap widens for professionals and families in low-resource countries. Autism Navigator® is a collection of web-based courses and tools that has used an implementation science framework to promote coordinated change to support community uptake and sustained utilization in medical, social service, and early intervention systems. Access to mobile technology is increasing worldwide and offers one potential solution to bridging the research-to-practice gap that offers the potential for rapid access globally.

Objectives: This technology demonstration will showcase the web-based Autism Navigator for Primary Care that uses extensive video and offers a new online screening tool with links to our *Seamless Path for Families* to lower the age of detection and referral and report on the deployment.

Methods: The Autism Navigator collection of web-based resources was developed by the FSU Autism Institute. Autism Navigator for Primary Care is an 8-hour online course using interactive slides with narration, closed captions, and illustrative video clips of two-dozen toddlers with ASD. Providers who complete the course can use the online automated Smart ESAC (*Early Screening for Autism and Communication*) screening tool with provider and family portals linking to 5 resources. Families of all children are invited to the 16-by-16 Lookbooks and Social Communication Growth Charts. Families of children with a positive autism screen are invited to About Autism in Toddlers, ASD Video Glossary and the How-To Guide for Families. Input from advisory boards and focus groups involving stakeholders informed the development of content built through an iterative process of feedback, review of material for cultural appropriateness, and revolving enhancements to the portal.

Results: We will describe the deployment of the courses and family resources over the past 4 years beginning in Florida and expanding to other states in the US and other countries including South Africa. About Autism in Toddlers was first launched in April 2015 and enrollment has increased incrementally to 29,713 unique users from 152 countries to date. Autism Navigator for Primary Care was launched in 2016 and has 1,690 unique users enrolled from 6 countries. The How-to Guide for Families was launched in 2017 and has 562 unique users from 10 countries. Strategies to engage physicians, community health workers, and childcare providers in the US and South Africa and lower the age of referral will be highlighted. Tablet computers will available to experience the screening tool and web-based resources.

Conclusions: Innovative models to increase the number of culturally and ethnically diverse professionals who can deliver evidence-based services are vital to improving global competence in early detection and intervention. Autism Navigator provides a highly-needed cost-efficient platform for professionals and families, using mobile technology to combine an automated screening tool, parent and provider portals, and links to interactive resources that are built for rapid scalability.

172 **163.172** The Use of Immersive Virtual Reality to Teach Safety Skills to Children with Autism Spectrum Disorder

C. Miyake[1], *E. Hong*[1,2] *and D. Dixon*[1], *(1)Center for Autism and Related Disorders, Woodland Hills, CA, (2)Louisiana State University, Baton Rouge, CA*

Background: Individuals with autism spectrum disorder (ASD) experience impairments across a wide range of skill domains, including safety skills. Teaching safety skills to individuals with ASD is critical, given the potentially dangerous and fatal consequences. Although several methods (e.g., video training, mock simulations, natural environment training) have been used to teach street-crossing skills to children with ASD, these methods have largely been ineffective in teaching generalization of skills to real-life street-crossing scenarios. While natural environment training poses the lowest barriers to teaching generalization, it often proves to be the most difficult to implement due to safety and logistical challenges (i.e., the ability to present both safe and unsafe conditions in an efficient manner). Virtual reality (VR) technology may be a solution to teaching safety skills to individuals with ASD, such that VR environments provide immersive, realistic scenarios in a safe, efficient, and controlled manner.

Objectives: The objectives of this study were to determine if (1) safety skills could be taught in the VR environment and (2) safety skills learned in the VR environment could be generalized to the natural environment.

Methods: The current study used a multiple baseline design to teach three children with ASD (5-8 years old) street-crossing skills. All natural environment pre-treatment, post-treatment, and probe sessions were conducted in-vivo, in uncontrolled traffic areas. All immersive VR probe and training sessions were conducted using the Oculus Rift headset and sensors. The training sessions were conducted in a 10'x12' therapy room equipped with a table that contained the Oculus Rift headset and sensors. The primary investigator used a laptop connected to the Oculus Rift to monitor what the participant was seeing in the VR environment, in order to present the questions and to score the participants' responses. The video clips were hosted on YouTube and accessed through the Oculus and Steam software.

Following completion of the pre-treatment baseline and probe sessions, participants began immersive VR training using short, 10-second video clips of safe (i.e., no car present) or unsafe (i.e., car present) conditions. Depending on the participant's progress after VR training using the short clips, they either proceeded to training using 10-second video clips with added audio distraction (e.g., dogs barking, lawnmowers, etc.) or directly to long, 3-5-minute uncut clips of a street.

Results: During the pre-treatment baseline sessions, all three participants averaged below 50% on their identification of safe and unsafe conditions in the natural environment. Following treatment, all three participants scored 100% in the post-treatment probe sessions. Participants 2 and 3 only needed the short clip and long clip training video types to reach mastery criterion in the natural environment, while participant 1 needed training in all three training video types.

Conclusions: The current findings suggest that immersive VR training may be a safe and viable method of teaching safety skills to individuals with ASD.

173 **163.173** Vrsensory: Developing Virtual Play Spaces Based on Sensory Preferences

*L. E. Boyd[1], **B. Wasserman**[2], B. Prunell[3], A. Muse[3] and B. M. Makin[3], (1)Computer Science and Software Engineering, Chapman University, Orange, CA, (2)Chapman University, Orange, CA, (3)Software Engineering, Chapman University, Orange, CA*

Background:
Assistive and therapeutic technologies have traditionally been aimed at recognizing or correcting atypical behavior, teaching skills, and prompting—thus addressing only the behavioral and cognitive aspects of the condition. A more limited set of efforts have explicitly considered the core challenge of sensory processing. Sensory processing patterns and challenges impact activities of daily living not only for people with autism but also for those with ADHD, dyslexia, and typical development. By addressing sensory needs first in design, we not only aim to support users with autism, but also other neurodiverse conditions, as well as neurotypical children in a way that promotes the inclusion of diverse children in mainstream leisure activities. Addressing multiple abilities that include both users with and without disabilities results in better design for all users. As "similar sensory subtypes are present in the general population of children, addressing sensory needs is a mainstream need as well as an assistive need. As an assistive need, focus on sensory processing needs to be increased as many best- practice therapeutic interventions and assistive technologies for autism and ADHD view sensory processing challenges as secondary to social and learning challenges. This work shifts this thinking by focusing on underlying sensory needs supported by customized virtual environments that are tailored to these needs as well as the end user's leisure interests.

Objectives:

By addressing the user's often hidden sensory needs as system requirements, we translate the recent findings of neurologists who argue sensory differences are the basis for differences in social behavior and learning. Sensory factors impact many aspects of daily life such as social participation, cognition, temperament, and participation. This approach directs us to shift to supporting foundational skills of learning by addressing sensory preferences before addressing social or functional skills.

Methods:

We employed a user-centered design process in which we conducted a series of paper and digital prototyping session with the three participants. We analyzed the data we collected via interviews with family and children, direct observations during use, video recording in use, and screen capture. As the final multi user study evolved into a game, we employed a framework borrowed from game design research as a lens for that analysis.

Results:

We designed three custom virtual reality applications based on extant occupational therapy research regarding four distinct sensory patterns. Specifically, we employ the concept of sensory quadrants described in the Sensory Profile 2 (W. Dunn 2014). Dunn's theory of sensory information processing explains how modulating oneself to the environment is inherent in engaging in activities. All participants were comfortable and played in each module independently and they were socially engaged in the most passive play module.

Conclusions:

This work demonstrates that by using sensory preferences to guide design interaction styles and virtual environmental features, we can support comfortable and engaging virtual space in which neurodiverse children can play together.

174 **163.174** Visualization-Guided Analysis of Eye Movements in Children with Autism Spectrum Disorder: Results from the ABC-CT Interim Analysis

***A. Atyabi**[1], M. C. Aubertine[2], Y. Luo[3], A. Naples[4], S. J. Webb[5], M. Murias[6], C. Sugar[7], R. Bernier[5], G. Dawson[8], S. Jeste[7], J. McPartland[4], C. A. Nelson[9] and F. Shic[10,11], (1)Seattle Children's Research institute University of Washington, Seattle, WA, (2)Seattle Children's Hospital and Research Institute, Seattle, WA, (3)Child Health, Behavior & Devel, Seattle Children's Research Institute, Seattle, WA, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (6)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)University of California, Los Angeles, Los Angeles, CA, (8)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (9)Boston Children's Hospital, Boston, MA, (10)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (11)Pediatrics, University of Washington School of Medicine, Seattle, WA*

Background: Biomarker discovery in neuropsychiatric disorders often employs automated, statistical, data-driven, high-throughput machinery. Less explored are the ways human insight can be rapidly, scalably, and effectively leveraged. Computer visualization techniques can transform raw data into intuitive representations accessible by those without data expertise. An appropriate match between data and visualization can provide a common ground for allowing clinical insights to be utilized in facilitating data explorations associated with biobehavioral biomarker discovery. One area where visualization technology has advanced rapidly, and where the role of visualizations in bridging clinical insights with data mining expertise has great potential, is in the use of eye tracking for studying gaze differences between individuals with autism spectrum disorder(ASD) and typically-developing(TD) individuals.
Objectives: (1)To identify visualization strategies of promise that are appealing, accessible, and informative to autism clinical experts without significant data analysis or eye-tracking expertise. (2)To show visualizations of gaze patterns during an eye tracking experiment to clinicians, to obtain their feedback regarding between group or questions of clinical phenotype, to distill this feedback into testable hypotheses through qualitative data extraction, and then to statistical test these hypotheses as a template for a visualization-guided analysis of eye movements in children with ASD.

Methods: Visualizations:(1)gaze points represented by participant identifier; (2)300 ms historical gaze trajectory; (3)"heatmap" color representation of groups (i.e. gaze points convolved with Gaussian kernels); (4)combination of (1)+(3); (5)thresholded version of (3). Visualizations were applied to Activity Monitoring(AM) eye-tracking data from the interim dataset (Summer 2018; 6-to-12-year-old children(TD:n=64; ASD:n=161)) of the Autism Biomarkers Consortium for Clinical Trials (ABC-CT). AM-gaze visualizations were presented to clinicians at a metropolitan autism

center (ARNP/RN *n*=11, BCBA *n*=2, MD *n*=1, Clinical Psychologist/Therapist *n*=8, Family services/CRA *n*=2; combined clinical experience= 287 years), and feedback regarding visualization preferences, as well as clinical insights from visualizations aimed at describing (1)ASD-TD between-group differences; and (2)Lower(LIQ; IQ<85) from Higher(HIQ; IQ>85) IQ, were requested.

Results: 14 out of 15 clinicians favored the "Threshold-HeatMap" visualization (5), see Figure. Qualitative data extraction revealed the following insights by clinicians, some of which were investigated statistically:

1. in TD vs ASD,

- TD>ASD on looking at people/faces on overall (p<.001,d=0.97),
- TD>ASD on looking at peoples when
    - People reached for the object (p=.001,d=0.94),
    - Actors were not talking and/or in anticipation of speech or activity (p<.001,d=.91),
- ASD>TD on looking at toys and the central activity(p<.001,d=-1.07;p<.001,d=-1.06 during speech;p<.001,d=-1.09 during non-speech),
- ASD seemed more likely to reference faces after speech,
- ASD was slower to disengage from objects/people.

2. Comparing lower versus higher IQ in ASD,

- LIQ>HIQ on looking at distractors(p<.001,d=.76),
- LIQ responded to conversation less in overall (p<.001,d=.82), and more slowly,
- LIQ showed more scattered gaze patterns,
- LIQ spent more time looking at background objects(p<.001,d=.59).

Conclusions: Results indicated that a simplified, thresholded visualization was preferred by clinicians. Clinicians were able to identify multiple hypotheses which were then confirmed analytically. This process may provide a template for future explorations that will increase accessibility to experimental data, allowing clinical expertise to be leveraged in biomarker discovery, moving us to a future where crowdsourcing may help us identify new analytical and data insights.

Poster Session
164 - Animal Models
11:30 AM - 1:30 PM - Room: 710

1 **164.001** A New Objective Electrophysiological Technique As a Measure of Central Auditory Processing in a Rat Model of Autism Spectrum Disorder

A. A. Eshraghi[1], *R. Mittal*[2], *M. M. Perdomo*[2], *T. Yassa*[2], *J. Mittal*[2] *and J. Bohorquez*[3], *(1)Otolaryngology and Neurological Surgery, University of Miami Miller School of Medicine, Miami, FL, (2)University of Miami School of Medicine, Miami, FL, (3)University of Miami School of Medicine, 33136, FL*

Background: Gaps embedded in noise (GIN) have been used as acoustic stimulus to evaluate the auditory temporal processing of different study populations such as in subjects with central auditory processing disorders (CAPD). Since GIN are very short as miliseconds (ms), they have been used to evaluate temporal resolution which is defined as the ability to detect small changes in sound over time, or slight discontinuities in ongoing stimuli. Poor temporal resolution has been shown to correlate with speech recognition difficulties. The gap detection threshold (GDT) is defined as the shortest gap that can be perceived in an otherwise continuous background stimulus. Electrophysiological assessment of GIN has focused mainly on Late Latency Responses requiring awake alert subjects (humans or animals). As rat models are commonly employed to understand the molecular mechanisms underlying auditory and neurological disorders, there is a need to develop techniques to determine central auditory processing (CAP) in experimental animal models.
Objectives: One of the most commonly reported sensory processing impairments in individuals with autism spectrum disorder (ASD) is the abnormalities in CAP. ASD patients consistently exhibit atypical behaviors in response to auditory stimuli and CAPD, which refers to a complex and heterogeneous group of auditory-specific disorders. There is still not a reliable electrophysiological technique to determine CAPD in ASD patients. The aim of this study was to develop an electrophysiological technique that can be used as an objective measure of CAP in anesthetized rat model.

Methods: We developed a method to determine the Objective Gap Detection Threshold (OGDT) in rats. QSSR elicited by noise modulated by 40Hz gaps of different durations were analyzed in time and frequency domains using wild-type (WT) and rat model of ASD. The detection was performed in frequency domain, by applying the Hotelling';s T2 test to the 40Hz complex fundamental frequency component. The OGDT is estimated by analyzing the confidence ellipses of the 40Hz spectral component.

Results: When the confidence ellipses (p=0.05) contain the origin of the complex plane, we observed that the subject is not significantly detecting the noise gap. We observed that the rats were detecting noise gaps of 12, 10 and 8ms and not detecting the 6ms gap. We also observed the "vanishing" of response into the background noise when a 4ms noise gap is applied. The 5ms OGDT result was verified by the statistical T2 test and is consistent with the previous animal studies with awake rats. The OGDT values were significantly increased in our rat model of ASD in agreement with findings observed in humans having ASD.

Conclusions: We have developed an electrophysiological method to determine GDT as a measure of CAPD in an anesthetized rat model. This technique eliminates the need for being alert and awake during the test bringing a new dimension especially in animal experiments regarding central auditory evaluation. The availability of novel objective techniques to determine CAPD will help in its early detection in patients diagnosed with ASD or suspicion of being on the spectrum leading to early intervention and hence better clinical outcomes.

2 **164.002** A Novel Posner-Style Cueing Task to Assess Attention Orienting in Mouse Models of Autism

S. Li[1,2], *C. May*[2], *A. J. Hannan*[2], *K. A. Johnson*[1] *and E. L. Burrows*[2], *(1)School of Psychological Sciences, University of Melbourne, Parkville, VIC, Australia, (2)Florey Institute of Neuroscience and Mental Health, University of Melbourne, Parkville, VIC, Australia*

Background: A deficit in attention orienting may be one of the earliest features in people with Autism Spectrum Disorder (ASD). Attention orienting is comprised of two components - exogenous and endogenous orienting. Exogenous orienting of attention is a stimulus-driven process in which one's attention is drawn automatically to salient external stimuli. Endogenous orienting of attention represents a goal-directed process in which expectations and/or knowledge of an individual determine where and when one's attention is given. To date, the neural mechanisms underlying the atypical attention orienting in autism remain unclear.

Genetic mouse models are useful tools to investigate the neurobiology of cognition, but a well-established assessment of attention orienting in mice is missing. The Posner cueing task is a widely used visual-spatial orienting task in humans. It has been adapted in studies of rats and fish, but rarely used in mice. It is important to develop a mouse version of the Posner cueing task before investigating the association between attention orienting and ASD-associated genetic mutations.

Objectives: Our objective was to adapt the human Posner cueing task for use in mice using recently developed touchscreen technology. This mouse paradigm will be used to investigate attention orienting in mouse models expressing ASD-associated genetic mutations.

Methods: Thirty-two C57BL/6 mice were trained and tested in automated touchscreen chambers. Several versions of the exogenous and endogenous cueing tasks were piloted. The mice were randomly assigned to the exogenous (n = 16) and endogenous task (n = 16).

Mice were trained to sustain their nose-poke to a central dim square until the display of a peripheral target (a bright square). They were rewarded with strawberry milkshake for nose-poking the target. The targets were either validly or invalidly cued. In the exogenous tasks, the cue was a flash of light in the peripheral square. In the endogenous tasks, the cue was a centrally-presented spatially-predictive grating – 145 degree gratings predicted the target on the left, while 45 degree gratings predicted the target on the right. The validity of cues were 50% in the exogenous tasks, and above 80% in the endogenous tasks.

Results: In both the exogenous and endogenous tasks, mice showed higher accuracy and shorter response times in the validly cued trials, compared to invalidly cued trials. This effect is consistent with results in the human Posner task. While mice were able to maintain their nose-poke at centre, this was negatively correlated with increased stimulus-onset asynchrony (SOA).

Conclusions: In this study, we have successfully adapted the human Posner task to mice. Mice responded faster to validly cued stimuli, in line with results in humans. This mouse Posner task can be used to assess attention orienting in mice containing ASD-associated genetic mutations. This approach will enable a greater understanding of neural mechanisms underlying deficits of attention orienting in ASD.

3 **164.003** ARID1B Haploinsufficiency Reveals Early Divergent Neuroanatomical Phenotypes through Development and Sex

A. Kinman[1], *L. R. Qiu*[2], *D. Fernandes*[1], *Z. Lindenmaier*[1], *S. Petkova*[3], *J. Ellegood*[2], *J. L. Silverman*[4] *and J. P. Lerch*[2], *(1)Mouse Imaging Centre, Neuroscience and Mental Health, Hospital for Sick Children, Toronto, ON, Canada, (2)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada, (3)MIND Institute and Department of Psychiatry and Behavioral Sciences, Sacramento, CA, (4)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis School of Medicine, Sacramento, CA*

Background: Haploinsufficiency of ARID1B, the chromatin remodelling AT-Rich Interactive Gene 1B, has been implicated in autism spectrum disorder (ASD), intellectual disability and Coffin-Siris syndrome (O'Roak et al., 2012; Fitzgerald et al. 2015; Celen et al., 2017). Although ARID1B haploinsufficiency is implicated in multiple neuropsychiatric disorders, little is known about its effect on neuroanatomical development.

Objectives: This study explores the structural neuroimaging phenotypes associated with the ARID1B mutation using *in vivo* magnetic resonance imaging (MRI) in mice. Our aim is to elucidate any developmental and sex differences in neuroanatomical phenotypes associated with haploinsufficiency of ARID1B.

Methods: A novel *Arid1b* mouse model was generated in-house at the Toronto Centre for Phenogenomics. The sample consists of 11 males and 11 females, 5 of which were mutants and 6 of which were wildtype controls of each sex. Male and female *Arid1b* mice were scanned longitudinally over 5 early postnatal day (p) time-points: p4, p6, p8, p10 and p17. A 7.0 Tesla MRI scanner with cryocoils was used to acquire images of the mouse brains with a resolution of 75 um isotropic. Scan data was analyzed using image registration and deformation based morphometry approaches described in Qiu et al (2018). From this, the volumes of 182 distinct regions were calculated (Dorr et al 2008, Ullmann et al 2013, Steadman et al 2014). We used linear mixed effects models to determine the effect of genotype, sex and their interaction on the volumes of each region of interest over time.

Results: We found both age and sex to have a significant interaction with genotype. A significant interaction with age was discovered, showing that mutants demonstrate different growth rates, mainly decreased growth rates in the cerebellum. Upon further investigation, a significant interaction between sex and genotype demonstrated a divergent neurodevelopmental pattern in males and females. Male mice showed a stable developmental pattern of a smaller cerebellum and larger cortex over development. Female mice showed the opposite pattern initially (larger cerebellum and smaller cortex) and then demonstrated a reversal of this pattern around p12 to match male developmental patterns.

Conclusions: We plan to replicate this finding and extend the timepoints past p17 to gain a better understanding of this sex-dependent neurodevelopmental trajectory. This work demonstrates, for the first time, that structural neuroanatomical phenotypes are different for male and female *Arid1b* mice early in development but this divergence dissipates before p17. Given the sex differences in the prevalence of ASD and Coffin-Siris syndrome, these findings suggest that ARID1B's interaction with neurodevelopmental patterns may be one underlying cause of this disparity.

4 **164.004** Autistic Phenotype in the N-Ethylmaleimide Sensitive Factor Gene Lacking Mice

M. J. Xie[1,2], *K. Iwata*[1,2], *Y. Ishikawa*[3], *Y. Fukazawa*[1,4] *and* ***H. Matsuzaki***[1,2], *(1)Research Center for Child Mental Development, University of Fukui, Fukui, Japan, (2)United Graduate School of Child Development, Osaka University, Kanazawa University, Hamamatsu University School of Medicine, Chiba University and University of Fukui, Osaka, Japan, (3)Department of Systems Life Engineering, Maebashi Institute of Technology, Maebashi, Japan, (4)Division of Brain Structures and function, Department of Morphological and Physiological Sciences, Graduate School of Medical Sciences, University of Fukui, Fukui, Japan*

Background: Autism, characterized by profound impairment in social interactions and communicative skills, is the most common neurodevelopmental disorder. Many studies on the mechanisms of autism have focused on the serotonergic system but its underlying molecular mechanisms remain controversial. In our previous report, we reidentified *N*-ethylmaleimide-sensitive factor (NSF) as new serotonin transporter (SERT) binding protein (Iwata et al 2014).
Objectives: In this study, we generated the *NSF*$^{+/-}$ mice and investigated their phenotypes.

Methods: As previous report has already shown that NSF is necessary for AMPA-type ionotropic glutamate receptors (AMPARs) location in the synapse, we examined SERT and AMPAR location in the synapse of the *NSF*$^{+/-}$ mice by using freeze-fractured replica-immunolabeling study at first. In next, we assessed behavioral test including the social interaction behaviors by the three-chambered task and the social communication by ultrasonic vocalizations. Finally, we examined whether hippocampal long-term depression (LTD) deficits can be restored in the *NSF*$^{+/-}$ mice for checking the excitatory/inhibitory (E/I) synaptic balance.

Results: We found the membrane expression of SERT half-reduced in the raphe and the significant decrease in postsynaptic expression of AMPAR in CA1 of the hippocampus of the *NSF*$^{+/-}$ mice, compared with wild mice. Then, we found that the spending time near the chamber with a newly introduced mouse (stranger), were significantly reduced in the *NSF*$^{+/-}$ mice, and found that the ultrasonic vocalizations significantly reduced in the *NSF*$^{+/-}$ mice, compared with wild mice respectively. Field electrophysiology performed on brain slices confirmed that NSF gene lacking significantly reduced dorsal CA1 hippocampal LTD in mice.

Conclusions: The present results suggest that cellular trafficking turbulence of synaptic molecules by lacking NSF gene might be related to the pathophysiology of autistic properties.

5 **164.005** CRISPR/Cas9 Induced shank3 Zebrafish Mutants Display Autism-like Behaviors

C. Liu[1], *C. Hu*[2] *and X. Xu*[2], *(1)Children's Hospital of Fudan University, Shanghai, China, (2)Children's Hospital of Fudan University, Shanghai, China*

Background:
Human genetics and genomics studies have supported a strong causal role of *SHANK3* deficiency in autism spectrum disorder (ASD). The molecular mechanism underlying *SHANK3* deficiency causing ASD is not fully understood. Recently, zebrafish become a popular organism to model ASD because of its high efficiency of genetic manipulation and robust behavioral phenotypes. However, a stable ASD zebrafish mutant model for *shank3* has not been reported. Human *SHANK3* is duplicated in zebrafish genome and has two homologs: *shank3a* and *shank3b*. Previous studies have reported *shank3* morphants in zebrafish using morphlino method. Here we report generation using CRISPR/Cas9 genome editing technique and characterization of *shank3* mutant zebrafish at larva and adult age.

Objectives: N/A

Methods:

We used CRISPR/Cas9 to generate a *shank3* loss-of-function mutant (*shank3a*$^{-/-}$, *shank3b*$^{-/-}$ and *shank3a&b*$^{-/-}$) in zebrafish. A series of morphological measurements, behavioral tests and molecular analyses were performed to systematically characterize the behavioral and molecular changes in *shank3* mutant zebrafish.

Results:

shank3a$^{-/-}$, *shank3b*$^{-/-}$ and *shank3a&b*$^{-/-}$ zebrafish exhibited abnormal morphology at early developmental stage. They displayed reduced locomotor activity both at larva and adult age. They also showed multiple autism-like behaviors in adulthood, including reduced social interaction, reduced time spent near conspecifics, loose schools and significant repetitive behaviors. Additionally, the levels of both postsynaptic homer1 and presynaptic synaptophysin were significantly reduced in the adult brains of *shank3* deficient zebrafish.

Conclusions:

We generated the first inheritable *shank3* mutant zebrafish model (*shank3a*$^{-/-}$, *shank3b*$^{-/-}$ and *shank3a&b*$^{-/-}$) using CRISPR/Cas9 gene editing approach. All *shank3* mutant zebrafish displayed robust autism-like behaviors and altered synaptic proteins of homer1 and synaptophysin. The versatility of zebrafish as a model of studying neurodevelopment and conducting drug screen will likely have a significant contribution to future studies of examining human *SHANK3* function and ASD.

6 **164.006** Cardiac Comorbidities and Their Effect on Brain Structure

S. Assimopoulos[1,2], *A. Beauchamp*[1,2], *J. Ellegood*[2] *and J. P. Lerch*[1,2], *(1)Medical Biophysics, University of Toronto, Toronto, ON, Canada, (2)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada*

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder with an occurrence rate greater than 1%, characterized by high heterogeneity in etiology and symptomology (Kim et al., 2014). It is associated primarily with neurodevelopmental and behavioural deficits, but has various associated comorbidities, amongst which cardiac comorbidities are common (Kohane et al., 2012). Cardiac abnormalities range from mild cardiac defects to severe congenital heart disease (CHD) (Doshi-Velez, et al., 2014). Accumulating evidence suggests that severe cardiac abnormalities are present and also contribute to the observed neurodevelopment (Ortinau, et al., 2012).
Objectives: Here we explore the association between anatomical brain characteristics and cardiac abnormalities, in a diverse set of prominent ASD mouse models.

Methods: Fixed (ex-vivo) brains of 66 prominent ASD mouse models were scanned using a 3D T2-weighted MRI protocol on a 7 Tesla Agilent scanner (Santa Clara, CA). MRI data were analyzed using image registration and deformation-based morphometry to obtain anatomical volumetric information on 336 brain structures. Data from 19 models (224 females, 497 males; 378 wild-types, 340 mutants) for which a cardiac annotation was found in literature were used. Each model was assigned a normal (7 models) or abnormal (12 models) cardiac phenotype. For example, Arid1b gene is associated with ASD and CHD (Homsy, et al., 2015). So, the Arib1b knockout mouse model was assigned an abnormal cardiac phenotype. We further examined 12 of those models having either normal or CHD-related abnormal cardiac phenotype (134 females, 290 males; 223 wild-types, 201 mutants). Appropriate controls were used, all assigned a normal cardiac phenotype.

Statistical analysis using a linear mixed effects model was performed to test for the effect of cardiac phenotype on the volumetric differences between mutant and wild-type mice, for each mouse model across 336 brain regions. FDR correction for multiple comparisons was performed.

Results: At 5% FDR there was no significant effect of abnormal cardiac phenotype on the volumetric differences between mutants and wild-types. At 20% FDR, however, there was a significant effect of CHD-related cardiac abnormalities in the left trabenular commissure (FDR = 20%, T=3.54).

Conclusions: Cardiac dysfunction is an ASD comorbidity (Memari, et al., 2012). Additionally, CHD newborns show abnormal brain development (Limperopoulos et al., 2010). For a set of prominent ASD mouse models, an effect of abnormal cardiac phenotype on neurodevelopment would be expected. Preliminary results did not show a significant effect at an FDR of 5%. The inability to observe an effect may be a result of two factors, both related to cardiac phenotype being a binary variable. Firstly, the type of cardiac abnormality may influence the strength and direction of the neurodevelopmental effect. Then, with a group-wise analysis these patterns would disappear or cancel out. Secondly, the lack of measurement-based cardiac phenotyping may have resulted in low sensitivity. However, at an FDR of 20%, a trending effect of CHD-related cardiac abnormalities was observed for the left trabenular commissure. To address the above limitations, we will obtain measurements assessing cardiac function for each model and perform further analysis possibly using a more powerful model.

7 **164.007** Characterization of a Novel Mouse Model of DDX3X Syndrome, a Recently Identified Neurodevelopmental Disorder

A. Boitnott[1,2,3], *D. Ung*[1,2,3], *D. Mendonca*[1,2,3], *K. Niblo*[1,2], *E. Drapeau*[1,2] *and S. De Rubeis*[1,2,3], *(1)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (3)Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY*

Background:

DDX3X syndrome, first described in 2015, is a rare genetic neurodevelopmental disorder that accounts for up to 2% of unexplained intellectual disability (ID) in females, attributable to *de novo* mutations in *DEAD box helicase 3, X-linked* (*Ddx3x*). However, there have been a few reported cases of males with DDX3X syndrome, where a pathogenic *Ddx3x* mutation is inherited from an unaffected mother. The neurobiology of *Ddx3x* underlying this sex specificity is unexplored, leaving pharmacological treatment for this disorder currently intangible. Individuals diagnosed with DDX3X syndrome are characterized by developmental delay/ID, neurological anomalies, motor impairments, and atypical behavior, such as Autism Spectrum Disorder (ASD). Despite clinical classification, there are no mouse models characterized for DDX3X syndrome.

Objectives:

We aim to assess the effect of DDX3X deficiency on neurodevelopment and behavior, while establishing a pre-clinical mouse model for DDX3X syndrome. The animal model will be essential in advancing knowledge regarding this disorder, revealing critical data that may advise successful treatment plans for DDX3X syndrome and, more broadly, ID and ASD.

Methods:

We have generated a mouse line with construct validity for DDX3X syndrome, where *Ddx3x* is ablated only in embryonic tissues using a Sox-Cre driver line. Neurodevelopment and behavior of these mice is assessed by a battery of physical, sensory, and motor milestone tasks between postnatal days 1-21. Innate anxiety, motor coordination, memory, sociability, and fear conditioning is assessed on adult mice to characterize cognitive and behavioral abnormalities. During postnatal development, brain morphology and microanatomy is assessed using Nissl staining and mouse MRI brain imaging.

Results:

We have found that *Ddx3x* ablation in males is lethal, as no Ddx3x null male mice ($Ddx3x^{-/y}$) are born. Also, female mice heterozygous for *Ddx3x* ($Ddx3x^{+/-}$) are born less frequently. We show that $Ddx3x^{+/-}$ females have reduced protein expression in total cortex and cortical synapses. Behavior and development assessments show that $Ddx3x^{+/-}$ mice have various delayed developmental milestones—physical, such as reduced weight; sensory, such as delayed auditory startle response; and motor, such as delayed surface righting—as well as motor impairments, such as gait anomalies. These results are consistent with clinical features observed in DDX3X syndrome, supporting face validity of the mouse model. Additionally, we have found no gross differences in brain morphology between adult $Ddx3x^{+/-}$ and control mice and are investigating morphology during earlier development.

Conclusions:

We have generated a mouse model with construct validity for DDX3X syndrome and initial evidence, from observations of developmental delay, for face validity. This model is useful to understand the mechanisms underlying DDX3X syndrome and develop future therapies for DDX3X syndrome that might be applicable to the broader ID and ASD populations.

8 **164.008** Cntnap2-KO Autism Model Mice Exhibit Perturbed Parvalbumin-Positive Interneuron Input and Output in Primary Visual Cortex V1

M. Bridi *and S. Huang, Hussman Institute for Autism, Baltimore, MD*

Background: Sensory processing dysfunction is a key feature and common challenge in autism. The refinement and maintenance of sensory processing depends on GABAergic inhibition. Studies in humans and animals suggest that altered excitatory/inhibitory balance or impaired inhibition could underlie the development of autism, and altering inhibitory circuitry can change the neuronal response to sensory stimulation. Low-level sensory processing alterations could exert larger downstream effects on higher-level behaviors relying sensory input. Changes in genes related to synaptic function and connectivity are risk factors for autism. *Cntnap2* encodes CASPR2, a neurexin-family cell-adhesion molecule expressed throughout the brain. *Cntnap2* knockout (KO) mice are an established model of autism that exhibit phenotypes including repetitive/stereotyped behavior, hyperactivity, reduced social interaction, seizures, synaptic spine instability, and changes in excitatory and inhibitory transmission, but the role of *Cntnap2* in visual processing remains unknown.

Objectives: We sought to investigate the effects of *Cntnap2* deletion on inhibitory circuitry in primary visual cortex, V1. Because we have previously demonstrated that *Cntnap2* deletion leads to a developmentally-dependent reduction in tonic inhibitory currents and decreased spontaneous IPSC frequency in layer 2/3 pyramidal cells, we set out to investigate the impact of *Cntnap2* deletion on the function of fast-spiking parvalbumin-positive (PV+) interneurons within V1.

Methods: We used whole-cell patch-clamp electrophysiology to record from L2/3 pyramidal cells and PV+ interneurons in slices made from V1 of *Cntnap2*-WT and -KO mice at 8 weeks of age. AAV injection was used to express fluorophores and/or ChR2 in PV+ interneurons in $Cntnap2^{-/-}$×PV^{Cre}

mice, for identification and optogenetic stimulation.

Results: We have previously shown that L2/3 pyramidal cells from 8-week-old *Cntnap2*-KO mice exhibit lower spontaneous IPSC frequency and reduced tonic inhibitory conductance mediated by δ-subunit containing $GABA_A$Rs. Stimulation of the feed-forward L4 to L2/3 pathway to evoke monosynaptic EPSCs and disynaptic IPSCs in pyramidal neurons resulted in a higher E/I ratio in KO mice compared to WT controls, indicating reduced inhibition. We did not observe an effect of genotype on intrinsic somatic properties of PV+ interneurons of V1, but optogenetic stimulation of PV+ terminals to evoke IPSC trains in pyramidal cells in L2/3 revealed increased paired-pulse depression at these inhibitory synapses. We again used stimulation of feed-forward L4 to L2/3 synapses to measure the NMDA/AMPA ratio in PV+ interneurons, and found that KO cells exhibited a significantly reduced NMDA/AMPA ratio.

Conclusions: Attenuated $GABA_A$R tonic currents and spontaneous IPSC frequency indicate fewer GABAergic synapses in *Cntnap2*-KO animals. Changes in evoked E/I balance and PV+ interneuron-generated IPSCs in V1 pyramidal cells suggests deficits in inhibition by fast-spiking interneurons. While PV+ interneuron properties were largely unaffected by the deletion of *Cntnap2*, the reduction of the NMDA/AMPA ratio suggests major deficits in neuronal information processing and integration in the cortical inhibitory circuit. Increased paired-pulse depression at PV-IN inhibitory synapses suggests higher initial GABA release and could indicate axonal dysfunction. Future studies should investigate the cellular/molecular mechanisms that bridge the gap between *Cntnap2* mutation and inhibitory dysfunction, as well as the effects of diminished inhibition on the function of the V1 cortical circuit.

9 **164.009** Contribution of Severity of Autism and Age on Dog Attraction to Children with Autism Spectrum Disorder

N. Dollion[1], *M. Grandgeorge*[2], *M. Trudel*[3] *and N. Champagne*[4], *(1)Psychology, University of Montreal & Mira Foundation, Montreal, QC, Canada, (2)EthoS (Ethologie animale et humaine) - UMR 6552, University of Rennes 1, Paimpont, France, (3)Psychoeducation, University of Sherbrooke, Sherbrooke, QC, Canada, (4)Mira Foundation, Sainte-Madeleine, QC, Canada*

Background: Positive effects of pets at home on children with autism spectrum disorders (ASD) are well known (Grandgeorge et al., 2012; Viau et al., 2010). These benefits are linked to the strength of the bond established between the child and the animal (Carliste, 2014; 2015). However, we do not know what are the antecedents or variables that would facilitate or limit the effects of the dog's assignment at home.
Objectives: The present research aims to identify indicators of attraction for dogs observed in ASD children before introducing the animal into the family, and to determine if and how this attraction is influenced by factors such as severity of ASD, sex and age.

Methods: This project was realized in collaboration with Mira Foundation, a non-profit organization involved in the training and donation of assistance dogs since 1987. All participating families have an ASD child and applied to receive a dog from the Foundation. As a first step in the evaluation of families' application by the Foundation, all families must participate to a videorecorded assessment session, in which child and parents interact freely with a trained dog for approximately 20 minutes. Those videorecording are then coded using two evaluation instruments, (1) the Childhood Autism Rating Scale (CARS; Schopler et al., 1988) and (2) an observation grid assessing 12 behaviors related to the attraction for the dog (grid created by MIRA's team and research collaboration). A total of 748 ASD children (17.5% of girls) and their families were involved in the study. ASD children were aged between two and sixteen years old (Mean age: 7.2 ±3.4) and were diagnosed with ASD by independent teams of physicians and professionals based on DSM-IV criteria.

Results: Preliminary results highlighted the reliability of the two instruments (Cronbach alpha: .90 for each). Factor analyzes with varimax rotation identified 2 main factors (53,4% of the total variance) for the CARS associated with: (1) the deficits in social communication, (2) the child emotional reactivity (anxiety, emotion, adaptation). This result partially replicated the factor structure reported in previous researches (DiLalla & Rogers, 1994; Park & Kim, 2015). Furthermore, analysis on the attraction grid revealed two factors (60,5% of the total variance) associated with: (1) the child's behaviors toward the dog (look, proximity, contact, manipulation), (2) the type of interactions expressed in presence of the dog (facial, verbal, playful). When crossing the two evaluation instruments, our main findings revealed a strong correlation between social communication (CARS) and physical engagement of the child (attraction grid) (r= .43 **). Sex did not have any influence on these covariations. In addition, child's age was significantly related to the first factor of attraction for the dog (r= - .33 **). ASD severity and child's age had an independent influence on the attraction toward dogs (all $p<0.05$).

Conclusions: Our study may provide relevant information for predicting which ASD children could be attracted by dogs and would benefit the most from the dog assignment at home.

10 **164.010** Development of Gaze Following in Infant Rhesus Macaques (Macaca mulatta)

A. Wang[1], *C. Payne*[2], *J. Bachevalier*[3] *and W. Jones*[4], *(1)Emory University, Atlanta, GA, (2)Marcus Autism Center, Atlanta, GA, (3)Yerkes National Primate Research Center, Emory University, Atlanta, GA, (4)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA*

Background:
Gaze following represents a foundational behavior for establishing joint attention and higher-level social cognition (Emery, 2000). Atypical gaze following has been reported in children with Autism Spectrum Disorder and Williams Syndrome (Riby et al., 2013; Lord et al., 2012; Mundy, 2017). To advance our understanding of mechanisms underlying the development of gaze following, rhesus macaques offer an ideal model system: they develop rich and complex social behaviors from infancy onward, similar to humans, and their behavior may help elucidate sensitive periods in the development of gaze following and its neural substrates. Although studies have shown gaze following in older primates living in natural habitats (Maestripieri & Wallen, 1997; Redican, 1975), and a study of semi-free-ranging animals suggests that gaze following emerges by 6-7 months (Rosati et al., 2016), the development of this skill and of its neural underpinning is not well understood.

Objectives:

To study the longitudinal development of gaze following in mother-reared infant rhesus macaques raised in semi-naturalistic groups that allow for typical emergence of rich social behavior.

Methods:

Twenty-three infant male rhesus macaques were tested every 2 weeks from 2-24 weeks to obtain densely-sampled measures. Gaze following was

measured via eye-tracking technology with procedures similar to those used in human infant eye-tracking studies, facilitating interspecies comparisons (Jones & Klin, 2013). Infants viewed semi-naturalistic videos of unfamiliar adult and juvenile male and female macaques. Gaze following comprising of an initial look to the eyes of the onscreen monkey—a moment of "mutual eye contact" when the onscreen monkey was looking directly at the viewer (see Figure 1A)—followed by a gaze shift in the direction in which the onscreen animal subsequently looked (see Figure 1B).

Results:

At 1 month, infants looked at the eyes during 22% (±2) of presented mutual gaze cues (mean (±sem)), then engaged in gaze following 57% (±5) of the time. By the 3rd month, infants increased attention to mutual gaze cues, looking at 36% (±2) of presented cues, and engaged in gaze following 57% (±4) of the time. Attention to mutual gaze cues and subsequent gaze following reached a peak at 4 months, looking at 41% (±3) of mutual gaze cues and following gaze 70% (±4) of the time. Thereafter, attention to mutual gaze cues and gaze following decreased to 30% (±7) and 46% (±3) at 5 months.

Conclusions:

Steady increase in attention to mutual gaze cues suggests important changes in infants' awareness of the social saliency of conspecifics' eyes. At 4 months, the peak in attention to mutual gaze cues and subsequent gaze following suggests significant maturation in social-visual attention and social motivation. The decrease in these skills after 4 months coincides with the beginning of the weaning process (Fooden, 2000), leading to higher reactivity to mutual gaze (a threatening gesture in macaques) and increase in appeasement gestures (i.e. gaze avoidance). In future research, neuroimaging data obtained in the same animals will allow us to connect these shifts with changes in brain development.

11 **164.011** Developmental Trajectory of Sleep Disturbances in a Shank3 Mouse Model

H. Schoch[1], *A. M. Ingiosi*[1], *T. Wintler*[1], *K. Singletary*[2], *E. Medina*[3], *M. Frank*[1] *and L. Peixoto*[2], *(1)Washington State University Elson S. Floyd College of Medicine, Spokane, WA, (2)Washington State University, Spokane, WA, (3)Washington State University, Spokane, Spokane, WA*

Background: Sleep problems affect a higher proportion of children with autism spectrum disorder (ASD) compared to typically developing children and are a strong predictor of severity of ASD core symptoms as well as behavioral problems. Children with ASD have difficulty falling and staying asleep from very young ages, resulting in chronic sleep deficiency throughout the developmental period. Studies in animal models suggest that sleep is important for brain development and function, but little is known about what causes sleep disturbances in ASD.
We focused our studies on *SHANK3*, a high confidence ASD gene candidate. Individuals with Phelan-McDermid Syndrome (PMS) carry deletions in chromosome 22q13.3, a region that includes *SHANK3*. Approximately 85% of PMS individuals have an ASD diagnosis and about half report chronic sleep problems, but the link between *SHANK3* mutations and poor sleep is not understood. Sleep is a homeostatic process, in that sleep need accumulates with time awake and discharges during sleep. Typically, insufficient sleep (high sleep need) increases drive to fall asleep, but in ASD insufficient sleep and problems falling asleep co-occur. During development, both sleep need and the brain's response to sleep loss change significantly. We hypothesize that loss of SHANK3 during development disconnects sleep need from sleep initiation, leading to problems falling and staying asleep.

Objectives: Determine the developmental emergence of sleep problems in Phelan-McDermid syndrome, and in *Shank3* mutant mice.

Methods: In this study, we used questionnaire data to guide our studies in mouse models to understand how sleep problems develop in ASD. We obtained sleep questionnaire data from PMS individuals with *SHANK3* mutations from the PMS Foundation International Registry. Sleep loss in mice and humans elicits specific changes in electroencephalographic (EEG) activity patterns that can be used to track sleep need. In Shank3ΔC and control mice, we collected EEG and electromyographic (EMG) data to determine sleep-wake patterns, and used sleep-deprivation to induce periods of high sleep need.

Results: We find that *SHANK3* mutations are associated with sleep disturbances in both humans and mice. Children with PMS develop sleep problems between 5-12 years of age, including problems falling asleep, repeated awakening, and reduced sleep time. Similarly, we find that adult Shank3ΔC mutant mice have reduced sleep time, delayed sleep initiation following sleep deprivation, and reduced low-frequency EEG activity in non-rapid eye movement (NREM) sleep relative to littermate control mice. We find that adult responses to sleep deprivation emerge during adolescence in mice. Prior to this transition, low-frequency EEG activity during NREM sleep is normal in juvenile Shank3ΔC mice.

Conclusions: We show that sleep problems in PMS individuals emerge during early childhood. Sleep problems in Shank3ΔC mice also change across development. Adult Shank3ΔC mutant mice sleep less but have difficulty falling asleep following sleep deprivation. Changes in NREM EEG activity in Shank3ΔC mice are present in adults but not juveniles, suggesting that they are the result of abnormal post-natal development. Overall, our study shows that SHANK3 is an important modulator of sleep during development.

12 **164.012** Dysregulation of Insulin Receptor in Fragile X Mouse Model

J. Popic, *I. Gantois and N. Sonenberg, Biochemistry, McGill University, Montreal, QC, Canada*

Background: Fragile X syndrome (FXS) is the most common monogenic cause of autism spectrum disorders (ASD) and hereditary intellectual disability (ID). FXS is caused by silencing of the *FMR1* gene and subsequent loss of the fragile X mental retardation protein (FMRP). Fmr1 knockout mice (*Fmr1*$^{-/y}$) recapitulate many of FXS phenotypes, such as increased repetitive behaviors, impairment in social novelty, macroorchidism, increased general protein synthesis (mRNA translation), exaggerated LTD and abnormal dendritic spine morphology. Impaired translational mechanisms represent one of the features of FXS. Insulin, a pancreatic hormone, is the main regulator of glucose levels in the blood. Insulin acts by binding to insulin receptors (IR), stimulating their autophosphorylation and activation. Dysregulated insulin signaling has been shown in diabetes and cancer, and has recently been implicated in cognitive dysfunctions in neurodegenerative disorders such as Alzheimer's disease. Recently, dysregulated insulin signaling has been shown to underlie cognitive deficits in Drosophila FXS model.
Objectives: The objective of this study is to investigate aberrant insulin and insulin receptor β in the brain and periphery of FXS mice in order to understand its role in the pathophysiology of the disease.

Methods: We have collected tissues of the brain areas implicated in autism etiology (prefrontal cortex and hippocampus), as well as peripheral tissues (liver, white adipose tissue and serum) from adult male wild-type (WT) and *Fmr1*$^{-/y}$ mice. We measured the protein levels of IRβ in four

above-mentioned tissues by Western blot (N= 6 per group). FMRP and GAPDH were used as a genotype and loading controls, respectively. To measure gene expression, the levels of IR mRNA in the prefrontal cortex and hippocampus were measured by quantitative RT-PCR (N= 6 per group). Insulin levels in the serum were measured by ELISA (N= 8 per group).

Results: We discovered that the expression of IRβ protein is upregulated in the *Fmr1*$^{-/y}$ mice compared to WT, not only in the brain (hippocampus and prefrontal cortex), but also in peripheral tissues (liver and white adipose tissue). The levels of IR mRNA are not changed in *Fmr1*$^{-/y}$ compared to WT mice. Insulin levels in the serum of *Fmr1*$^{-/y}$ are decreased compared to WT mice.

Conclusions: The results from this study will provide knowledge in the dysregulated insulin receptor signaling that contribute to translational control in FXS, and might introduce new pharmaco-therapeutical directions for the prevention of phenotypic impairments in FXS.

13 **164.013** Eye-Tracking As a Translational Tool to Study Social Development in Preclinical Nonhuman Primate Models of ASD

A. M. Ryan[1,2,3], *T. Murai*[4], *A. R. Lau*[2,3], *C. Hogrefe*[3], *A. K. McAllister*[5], *C. S. Carter*[2] *and M. D. Bauman*[1,2,3], *(1)UC Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, University of California Davis, Sacramento, CA, (3)California National Primate Research Center, Davis, CA, (4)Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan, (5)Center for Neuroscience, University of California Davis, Davis, CA*

Background: Deficits in social behavior are prominent features of neurodevelopmental disorders (NDDs) such as autism spectrum disorder (ASD) and schizophrenia (SZ). Eye tracking studies provide insight into how individuals with ASD and SZ process social information and have consistently documented atypical gaze patterns to social stimuli in these patient populations. Similar eye-tracking methods can be applied to preclinical animal model systems to explore social impairments relevant to symptoms observed in people with NDDs. Like humans, rhesus macaques (*Macaca mulatta*) use vision as their primary sensory modality and display complex social signals such as facial expressions, gestures, and vocalizations. Given the complexity behind potential causes and behaviors affected by NDDs, the use of eye-tracking paradigms in concordance with other measures in rhesus macaques may serve to bridge the gap between translational research efforts in rodent animal models and patient populations.

Objectives: In order to apply eye-tracking technology to animal models for human disease, it is first essential to understand the typical development of visual attention and social cognition in rhesus macaques. Using longitudinal social development data, we investigated the relationship between how young rhesus macaques view social stimuli in an eye-tracking paradigm and how they interact with their mother and similar-aged peers.

Methods: We studied 14 male rhesus macaques that serve as a control group for a nonhuman primate maternal immune activation study. Monkeys were mother-reared, received access to social groups, and participated in assessments throughout development such as eye-tracking and behavioral observations using a standard ethogram of social and nonsocial behavior. Eye-tracking data were collected using a modified incubator box that allowed for opportunistic sampling from unrestrained monkeys. We presented the monkeys with the same naturalistic monkey social stimuli across multiple time points from 1 month through 6 months old with additional preliminary data at 2 years old. The social development data presented here span from approximately 1 month of age through 2 years old.

Results: In our eye-tracking paradigm, monkeys viewed the social stimuli for a significantly longer time when they were 6 months old than in their first three months ($p<0.05$). Furthermore, preliminary analyses suggest that there is a significant positive correlation between monkeys' looking time duration for social stimuli in the eye-tracking paradigm and the number of initiated social interactions with their peers ($p<0.05$).

Conclusions: Our results suggest that rather than habituation to stimuli presented during the eye-tracking paradigm, monkeys may develop an increased interest in social stimuli during this early critical period of social development. Furthermore, this propensity to view social stimuli may be related to similar propensities to interact with their peers. Continued analyses of how other measures of social behavior and cognition relate to visual attention can help to both understand the development of social cognition in rhesus macaques as well as how eye-tracking in monkeys can maximize the translational utility of preclinical models of NDDs.

14 **164.014** Genotype:Phenotype Correlations of Social Deficits of Relevance for Autism Spectrum Disorder (ASD) in an NHP Model

C. Gunter[1], *A. Harris*[2], *Z. Kovacs Balint*[3], *M. Raveendran*[2], *V. Michopoulos*[3], *J. Bachevalier*[3], *J. Raper*[3], *M. Sanchez*[3] *and J. Rogers*[2], *(1)Marcus Autism Center, Emory University School of Medicine, Atlanta, GA, (2)Baylor College of Medicine, Houston, TX, (3)Yerkes National Primate Research Center, Emory University, Atlanta, GA*

Background:

Despite the important mechanistic information on neurodevelopmental processes provided to date by genetic rodent models of autism spectrum disorder (ASD), it is necessary to examine those processes in nonhuman primate (NHP) models with social behaviors and brain anatomy, function and development that more closely resemble that of our species. One NHP well-suited to such analyses is the macaque [rhesus monkey (*M. mulatta*)], where both typical and atypical social behaviors can be observed in complex social groups and genomic similarity to humans is much higher than in rodents. The macaque Social Responsiveness Scale (mSRS) has also been adapted to adult macaques from the human SRS used for clinical ASD assessments. Both genotypic and phenotypic analyses, particularly during development, are critical to further develop a NHP animal model of genetic risk for ASD of high translational value to humans.

Objectives:

The purpose of the present study is to identify genetic variants in a clinically relevant juvenile macaque NHP model housed in a semi-naturalistic environment, and compare variants to social behavioral phenotypes of relevance for ASD. We focused first on correlations between social phenotypes and variants identified in a list of 87 genes of interest in ASD in humans.

Methods:

We made behavioral observations by two methods: first, at the Yerkes National Primate Research Center breeding colony, we collected 30-minute behavioral observations on 4 different days using a detailed and well-established ethogram for rhesus monkeys based on published methods. In addition, social impairments were assessed using a modified version of the adult mSRS adapted to juvenile macaques. For genomic analyses on 91 individuals, we enriched rhesus macaque DNA samples for exome sequences using the Rhexome v2 capture reagent and sequenced using the Illumina NovaSeq system. Reads were aligned to the rhesus Mmul_8.01 (rheMac8) reference genome using BWAmem. We called genomic variants

using GATK and annotated them with VEP; associations with social phenotypes were made with PLINK and FaST-LMM. We further examined variants of interest by lifting the rhesus positions over to the orthologous human position and performing CADD analysis that predicts the functional impact of variants.

Results:

Our behavioral observations, including the mSRS, identified outliers on the social behavior spectrum in our macaque colony. Exploratory exome sequencing yielded a total of 169,240 SNVs and 7,201 indels in the 91 individuals. This includes 1,350 SNVs and 95 indels in the 87 genes of interest. We saw single-hit SNVs in several genes of top interest in humans (Satterstrom et al. 2018, https://www.biorxiv.org/content/early/2018/12/01/484113), including *KDM6B* and *ASH1L*, and these corresponded to observable changes in social behavior. We also observed individuals with combinations of common variants in a number of the 87 genes of interest.

Conclusions:

Our pilot study indicates that we are able to identify juvenile macaques on extreme ends of a social behavior phenotype spectrum using different behavioral approaches. We also saw correlations between behavioral phenotypes of several animals and variants in genes associated with ASD in humans, particularly when the variants were also predicted to be damaging in the macaques.

15 **164.015** In Vivo Magnetic Resonance Imaging and Spectroscopy Detect Alterations of Brain Metabolites in a Rat Model of Maternal Autoantibody-Related Autism

M. R. Bruce[1], *D. J. Rowland*[1], *R. J. Maddock*[2], *M. D. Bauman*[3] *and J. Van de Water*[4], *(1)University of California - Davis, Davis, CA, (2)Psychiatry and Behavioral Sciences, University of California - Davis, Davis, CA, (3)MIND Institute, University of California Davis, Davis, CA, (4)MIND Institute, University of California, Davis, Davis, CA*

Background:

Dysregulation of the maternal immune system has been linked to various neurodevelopmental disorders in offspring, particularly Autism Spectrum Disorder (ASD). A number of recent studies, by our group and others, have focused on the relationship between the presence of specific autoantibodies found in the maternal circulation and the diagnosis of ASD in children. We previously characterized a set of antigenic epitopes on proteins, known to be important for neurodevelopment, which serve as targets for these maternally-derived autoantibodies and are present in up to 25% of mothers whose children go on to be diagnosed with ASD. Our work, and that of collaborators, has found ASD-relevant behavioral and cellular alterations in response to maternal autoantibody exposure during gestation in mouse, rat and non-human primate models. Specifically, embryonic studies suggest that the autoantibodies are able to bind radial glial cells in the developing cortex of rodents and influence progenitor cell migration, proliferation and subsequent neuronal cell size in adulthood.

Objectives:

We sought to examine the structural changes associated with the presence of maternal autoantibodies in our novel rat model of maternal autoantibody-related (MAR) ASD rat model. Further, as neurochemical imbalances are linked to ASD and these neurotransmitters and metabolic signals play an important role in brain development and function, we also aimed to evaluate the neurochemical profile in our rat model.

Methods:

To develop our model, we first immunized rat dams with MAR-ASD specific peptides from LDHA, LDHB, CRMP1 and STIP1 to generate autoantibodies to these peptides in dams prior to breeding. Once offspring were born, we performed *In vivo* longitudinal magnetic resonance imaging and spectroscopy (MRI/S) in the frontal cortex of offspring to evaluate differences in levels of metabolites between MAR autoantibody exposed (n= 8) and control rats (n= 8) at pre- and post-pubertal time points (postnatal days 30 and 70, respectively).

Results:

Treatment of rat dams with MAR-ASD specific peptides resulted in high serum titers of antigen-specific peptides throughout and following gestation, as quantified by ELISA. Magnetic resonance spectroscopy analysis of frontal cortical neurometabolites in MAR-ASD exposed rat offspring evidenced altered levels of Taurine and Choline. Significant increases were seen in Taurine, alongside significant decreases in Choline levels at both 30 and 70-day time points. No specific differences were seen when evaluating sex as a variable.

Conclusions:

As taurine is an abundant amino acid in the brain and choline-containing compounds are critical components of cell membranes and myelin, it is likely that altered levels of these metabolites in the frontal cortex may contribute, either directly or indirectly, to the ASD-relevant phenotypes seen in our MAR-ASD rat model.

16 **164.016** Investigation of the Function of ASD-Associated Gene Neurexin in Drosophila and C. Elegans

K. A. Levy[1], *M. P. Hart*[2], *E. D. Weisz*[2], *Z. Zhou*[2], *E. S. Brodkin*[3], *M. Bucan*[2] *and T. A. Jongens*[2], *(1)Department of Neuroscience, University of Pennsylvania, Philadelphia, PA, (2)Department of Genetics, University of Pennsylvania, Philadelphia, PA, (3)Department of Psychiatry, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA*

Background: Mutations in a gene encoding a synaptic cell adhesion molecule, *NEUREXIN1* (*NRXN1)*, are significantly enriched in individuals with Autism spectrum disorder (ASD), indicating that *NRXN1* may play a role in the pathophysiology of ASD, albeit through an unknown mechanism. In mammals, there are three *NRXN* genes (*NRXN1-3),* each of which has two promoters for two main isoforms: α-NRXN (long isoform) and β-NRXN (short isoform). *NRXN1* is also subject to extensive alternative splicing, resulting in potentially thousands of variants. Invertebrates such as *Drosophila melanogaster* and *Caenorhabditis elegans* have only one *neurexin-1* gene that encodes a protein that is structurally similar to α-NRXN in vertebrates. Therefore, *Drosophila* and *C. elegans* serve as useful systems to study *NRXN1* involvement in ASD due to the reduced complexity and highly conserved nature of *neurexin-1*.

Objectives: The goals of our current studies are to identify conserved ASD-related behavioral phenotypes, such as sleep and stress responses, in both flies and worms and to determine the underlying mechanism(s) by which *neurexin* may regulate these behaviors.

Methods: To monitor sleep and activity we utilize the Drosophila Activity Monitoring system (DAM) and the WorMotel for *Drosophila* and *C. elegans,* respectively. For starvation stress experiments, the same activity monitoring systems are used except animals are given only water.

Results: To date, we have observed conserved defects in sleep and in behavioral responses to starvation stress. We find that *neurexin*-null mutants show decreased activity and fragmented sleep when compared to control animals. Fragmented sleep in *neurexin*-null *Drosophila* has been shown previously (Larkin et al., 2015; Tong et al., 2016), and thus our findings confirm these results and reveal that this is a conserved defect across species in both flies and worms. Additionally, we have identified decreased responding to starvation stress in *neurexin*-null *Drosophila* and *C. elegans*. When put under starvation conditions both *Drosophila* and *C. elegans* become hyperactive, with *Drosophila* also suppressing their sleep, which is thought to promote acquisition of food. *Neurexin*-null flies and worms however, show abnormalities in this stress response, wherein they display delayed, decreased hyperactivity and a failure to suppress sleep during starvation.

Conclusions: Our findings show that *neurexin*-null flies and worms show conserved deficits in sleep and stress response behaviors, both of which can be affected in individuals with ASD. Future studies will investigate the spatial and temporal sufficiency of *neurexin* in promoting sleep and starvation-stress response behavior using genetic techniques to restore neurexin expression in specific neuronal subsets during adulthood. These studies will have an impact on how we think about the ability of treating individuals with *NRXN1* mutations after early developmental periods have ended. Additionally, we would like to investigate how *neurexin* may regulate octopamine, which is a neurotransmitter that has been shown to be required for starvation hyperactivity. By using two model organisms we have the unique ability to study *neurexin* functioning in simpler neural systems, and our consistent phenotypic observations between both systems provide confidence that the mechanisms by which *neurexin* functions to promote ASD-related behaviors are conserved across species.

17 **164.017** Maternal and Offspring Mthfr Deficiency As a Risk Factor for Social Deficits and Alternation in Cortical Interneurons Populations in Rodents.

H. M. Golan[1,2], *N. Sadigurschi*[3] *and J. Hirrlinger*[4], *(1)Physiology, Ben-Gurion University of the Negev, Beer Sheva, Israel, (2)Zlotowski Center for Neuroscience, Ben-Gurion University of the Negev, Beer-Sheva, Israel, (3)Physiology, Ben-Gurion University of the Negev, Beer-Sheva, Israel, (4)Carl-Ludwig-Institute for Physiology, Leipzig, Germany*

Background:

A significant environmental risk factor for autism spectrum disorder (ASD) is prenatal environment. Methylenetetrahydrofolate reductase (MTHFR) shows high prevalence of polymorphism in ASD patients and their mothers. Excitation – inhibition imbalance has been suggested in the pathogenesis of ASD, supported by significant alternations in the GABA pathway. In a previous study, we showed both maternal and offspring Mthfr+/- genotype predisposes mice toward ASD-like behavior. Therefore, it is possible that these mice present alterations in cortical interneurons, as shown in human and mouse models of ASD.

Objectives:

To investigate the interaction between maternal and offspring Mthfr+/- genotype, ASD-like behavior and cortical interneuron distribution were examined

Methods:

Mthfr+/+ and Mthfr-/+ female mice on a Balb/cAnNCrlBR background were mated with male tg-GAD65-tdTomato on a C57/Bl6 background to generate Mthfr+/+(WT) and Mthfr+/-(HT), all carrying GAD65-tdTomato. Three groups representing maternal:offspring genotypes were created: 1.WT:WT 2.HT:WT 3.HT:HT. Six male mice per group were evaluated for ASD-like behavior using the following tests: Nest building, Marble burying and Social proximity (pairs with similar maternal and offspring genotype). Tests were recorded and analyzed offline by an observer blind to mouse identity. After the last test, mice were anesthetized and perfused with 4% PFA. Immunofluorescent staining was performed on sagittal brain sections for the detection of GAD, NeuN and Parvalbumin positive neurons.

Results:

A social deficit was found in the social proximity test where maternal HT genotype was associated with shorter sniffing time by mice of the HT:WT and HT:HT groups (51% and 41%, respectively), compare to WT:WT ($F_{1,13}$=10.35, p<0.01). In addition, offspring HT genotype suppressed dominant behavior, represented by whisker trimming ($F_{1,14}$=9.6, p<0.01). Mice were categorized as social or asocial, on the basis of their behavior (sniffing and non-aggressive behavior), regardless of their genotype, in order to evaluate the relation between phenotype and interneuron laminar distribution. Social phenotype correlated with GAD/NeuN ratio, so that social mice had higher GAD/NeuN ratio in deep layers of the cingulate cortex (layers 4-6, for example, 0.38 vs. 0.12 for layer 6), as represented by the interaction between layer x social phenotype ($F_{1,13}$=10.43 p=0.007). Mice with repetitive behavior phenotype differed in the laminar distribution of parvalbumin neurons in the cingulate cortex (layer x repetitive behavior phenotype, $F_{1,13}$=4.4 p=0.05). Mice presenting the repetitive behavior phenotype had a high density of parvalbumin neurons in layers 2-3 compared to mice that did not have this phenotype.

To further evaluate the excitation–inhibition balance associated with maternal and offspring genotype, seizure susceptibility was tested. Maternal genotype increased susceptibility to seizures induced by PTZ (50mg/kg, i.p). WT:HT pups exhibiting a greater amount of convulsion episodes in response to PTZ injection ($F_{1,33}$=13.25 p=0.001). Moreover, an interaction between genotype x maternal genotype was found ($F_{1,33}$=19.76 p<0.001).

Conclusions:

The interaction found between laminar distribution of interneurons and behavioral phenotype emphasizes a possible causal relation between cortical circuit organization and the pathophysiology of the social deficit seen in *Mthfr+/-* mice.

18 **164.018** Placental Infection By Group B Streptococcus Induces Sex-Specific Maternofetal Inflammatory Responses Associated with ASD-like Behaviors in Males

M. J. Allard[1], *A. Giraud*[2], *M. Segura*[3] *and G. Sebire*[1], *(1)Pediatrics, McGill University, Montreal, QC, Canada, (2)Pediatrics and Neonatal Intensive Care Unit, Saint-Etienne University Hospital, Saint-Etienne, France, (3)Pathology and Microbiology, Universite de Montreal, St-Hyacinthe, QC, Canada*

Background: Clinical and preclinical evidence support relationships between placental infection and inflammation (chorioamnionitis), preterm births and brain damage, contributing to disorders including autism spectrum disorder (ASD). Group B *Streptococcus* (GBS) is isolated in 15% of chorioamnionitis. Changes in placental histology may impact fetal outcomes by altering nutrient transport, hormone production, as well as inflammatory factor releases in fetal circulation. Dysregulation of proinflammatory cytokines in maternofetal tissues has been associated with

higher risks of having a child with ASD. Placental infection by GBS in rats has been shown to induce a histological chorioamnionitis - characterized by an increased density of polymorphonuclear cells (PMN) in male compared to female placentas - and led to ASD-like behavioral impairments in males (Allard et al., *Autism Research*, 2017). In human, males are known to be more sensitive to maternal infection, which convey increased risks for long-term cognitive and behavioral deficits. We hypothesized that placental infection by GBS will induce sex-specific inflammatory processes associated with increased PMN infiltrates in male *versus* female placentas.
Objectives: To map out the PMN recruitment and expression profiles of PMN-associated cytokines and chemokines within GBS-infected placentas, and comparing this immune profile between male and female tissues.

Methods: Lewis rats were injected intraperitoneally on gestational day 19 with β-hemolytic serotype Ia GBS (10^8 CFU) or saline (controls). Caesarean-sections were performed at 24, 48 and 72 h post-injection to collect maternofetal tissues (placenta, maternal and fetal blood). Placental GBS and PMN infiltrates, the PMN chemoattractant CINC-1/CXCL1, the alarmin S100A9, and proinflammatory (interleukin(IL)-1β, tumor necrosis factor (TNF)-α, IL-6, IL-18) and anti-inflammatory (IL-10) cytokines' expressions were measured by ELISA and immunohistochemistry.

Results: At 72 h post-inoculation, GBS-exposed male placentas presented increased PMN densities compared to same-sex controls and a 3.0-fold increase compared to litter-matched GBS -exposed females. GBS-infected placentas associated with males – but not females – presented increased CINC-1 titers at 72 h. Both male and female placentas exposed to GBS displayed increased titers of S100A9, although levels were higher in males compared to females at 72 h. GBS-infected placentas displayed increased titers of IL-1β, TNF-α, IL-6 and IL-10 in both sexes at 48 and 72 h, and sole IL-1β titers were higher in males compared to females at 72 h. The detected levels of IL-1β were correlating positively with levels of CINC-1 in GBS-exposed male placentas. At 72 h, an increased concentration of IL-1β was detected in the sera of GBS-exposed male – but not female – fetuses. At 48 and 72 h, increased titers of IL-1β, TNF-α, IL-6, and CINC-1 were detected in GBS-exposed maternal sera.

Conclusions: Our results suggest the implication of IL-1β - triggering the production of CINC-1 - in the induction of sex-specific PMN infiltrates. The sex-specific placental and fetal inflammatory responses we uncovered are interesting in regard to the higher susceptibility of the male population for preterm birth, brain injuries and ASD. Innovative insights into the mechanistic underpinning the pathophysiology of pathogen-induced placental injuries are needed to identify prenatal maternal biomarkers, and to develop appropriate novel therapeutic interventions.

19 **164.019** Pre-Attentive and Cognitive Sensory Processing in Rats Lacking the Autism Candidate Gene CNTNAP2

***K. Scott**, S. Schmid and B. Allman, Anatomy and Cell Biology, Western University, London, ON, Canada*

Background: Pre-attentive and cognitive processing of sensory information is necessary for appropriate interactions with our environment. In individuals with autism spectrum disorder (ASD), impairments in lower-level sensory filtering and processing can impact higher-order functions that rely on the ability to decipher complex sensory signals. For example, sensory disturbances have been suggested to contribute to social communication weakness in the autism population, with central auditory processing and audiovisual temporal acuity being linked to auditory hyper- and hypo- sensitivities and language deficits. However, at present, the neural basis for these behavioural deficits remains unresolved. Preclinical animal models could help to reveal the mechanisms of altered sensory processing if they can first show high face validity for ASD-related behavioral deficits.
Objectives: To assess both 1. sound intensity and 2. multisensory processing on the pre-attentive and cognitive level in rats lacking the autism candidate gene *CNTNAP2* (*Cntnap2*$^{-/-}$ rats) using translational behavioural paradigms.

Methods: In male and female adult Sprague-Dawley *Cntnap2* homozygous knockout, heterozygous knockout, and wildtype rats, pre-attentive processing was examined utilizing the acoustic startle response (ASR; 20 ms, 110 dB SPL) and its modulation by a stimulus (i.e. prepulse) which occurred before the acoustic startle-eliciting stimulus. Prepulse conditions included an acoustic noise burst at varying intensities (A; 10 ms, 62 – 92 dB SPL in 3 dB steps), a visual LED flash (V; 10 ms, 70 lux), or a combined audiovisual stimulus (AV; 10 ms, 68 dB SPL, 70 lux). For cognitive testing, two-alternative forced choice, appetitive paradigms assessed the rats' ability to discriminate the relative sound intensity of acoustic noise bursts (71 dB SPL – 89 dB SPL in 3 dB steps) or the relative timing (temporal order judgement – TOJ) of audiovisual stimuli (stimulus asynchronies used: A400V, A200V, A100V, AV, V100A, V200A, V400A) consistent with studies on humans. Moreover, discrimination training on sound intensity was conducted to determine the differential plasticity of pre-attentive and cognitive loudness processing.

Results: As expected, the *Cntnap2*$^{-/-}$ rats exhibited a general impairment in prepulse inhibition of the ASR compared to age-matched wildtype controls. Interestingly, *Cntnap2*$^{-/-}$ rats, like wildtypes, showed a greater level of prepulse inhibition when the audiovisual (AV) prepulse was presented compared to the unimodal (A or V) prepulse conditions; findings which indicate that the brainstem of knockout rats was still able to integrate auditory and visual stimuli. *Cntnap2*$^{-/-}$ rats showed no deficit in loudness discrimination or temporal order perception. Upon training, genotypic differences arose in the plasticity of acoustic discriminations.

Conclusions: The general PPI deficit observed relates to research suggesting pathological sensory processing underpins the emergence of ASD-related phenotypes. While the audiovisual results are consistent with previous studies in the autistic population performing the TOJ task with simple flash-beep stimuli, the lack of differences in loudness discrimination appears contrary to reports of moderate sound intensities being reported as distressing. However, discrimination ability is not homologous to the objective perception of acoustic stimuli. Taken together, these results highlight the validity of *Cntnap2*$^{-/-}$ rats as a preclinical model for studying sensory processing associated with ASD.

20 **164.020** Shank3 Modulates Sleep and Expression of Circadian Transcription Factors

*A. M. Ingiosi[1], **T. Wintler**[1], H. Schoch[1], K. Singletary[2], D. Righelli[3], L. Roser[1], D. Risso[4], M. Frank[1] and L. Peixoto[2], (1)Washington State University Elson S. Floyd College of Medicine, Spokane, WA, (2)Washington State University, Spokane, WA, (3)Consiglio Nazionale delle Ricerche, Napoli, Italy, (4)Weill Cornell Medical College, New York, NY*

Background: Autism Spectrum Disorder (ASD) is the most prevalent neurodevelopmental disorder in the United States and often co-represents with sleep problems. Sleep problems in ASD predict the severity of ASD core diagnostic symptoms and have a considerable impact on the quality of life of caregivers. Little is known, however, about the underlying molecular mechanisms. We investigated the role of Shank3, a high confidence ASD gene candidate, in sleep architecture and regulation.
Objectives: To better understand the mechanisms underlying sleep problems in ASD, we use an animal model that can closely recapitulate sleep phenotypes observed in clinical populations.

Methods: Sleep questionnaire data from Phelan-McDermid syndrome (PMS) patients with Shank3 mutations was obtained through the PMSIR foundation. To assess the sleep-wake behavior in Shank3$^{\Delta C}$ mice, we surgically implanted mutant mice and their wild type littermates with electroencephalographic (EEG) and electromyographic (EMG) electrodes. The EEG/EMG data was used to determine sleep architecture. Genome wide gene expression was performed to assess the differences in gene expression sleep deprivation induces in the prefrontal cortex of Shank3ΔC mice and wild type littermates. Continuous running wheel behavior of Shank3$^{\Delta C}$ mice and wild type mice was monitored to assess circadian rhythms in constant darkness.

Results: Through examination of sleep in PMS patients with Shank3 mutations we show that PMS patients have trouble falling and staying asleep similar to what is observed in the general ASD population. We also show that mice lacking exon 21 of Shank3 have problems falling asleep even when sleepy and sleep less deeply. Using RNA-seq we show that sleep deprivation increases the differences in gene expression between mutants and wild types, downregulating circadian transcription factors Per3, Dec2, Hlf, Tef, and Reverbα. Shank3 mutants also have trouble regulating wheel-running activity in constant darkness. Overall our study shows that Shank3 is an important modulator of sleep and clock gene expressions.

Conclusions: We show that both PMS patients and Shank3$^{\Delta C}$ mutant mice have trouble falling asleep. Shank3$^{\Delta C}$ mice have problems falling asleep when sleep pressure is high at the end of their active period or following sleep deprivation. They also sleep less deeply, but show no gross abnormalities in sleep homeostasis or circadian rhythms which suggests that the sleep deficit is due to difficulty with sleep onset. Our molecular studies show that sleep deprivation increases differences in gene expression between Shank3$^{\Delta C}$ mice and wild type mice, with differences pointing to the downregulation of circadian transcription factors. Shank3$^{\Delta C}$ mice do not show a disruption in circadian rhythmicity but a large reduction in wheel-running activity in response to constant darkness. This suggests the mutant sleep phenotype involves clock gene function outside their central time-keeping role.

21 **164.021** The Role of the E3 Ubiquitin Ligase Cul3 in Brain Development and Neurodevelopmental Disorders

J. Morandell *and G. Novarino, IST Austria, Klosterneuburg, Austria*

Background: The past decade has seen a rapid development of technological advancements in genetics and genomics, allowing unprecedented precision in the identification of mutations underlying neurodevelopmental conditions. Neurodevelopmental disorders, such as autism spectrum disorders (ASDs) and intellectual disability (ID), affect more than 3% of children worldwide, yet for the majority of the cases there are no curative therapies and the underlying molecular causes remain elusive. Here we analyze the molecular and behavioral changes of a mouse model haploinsufficient for the high risk ASD gene *Cul3*. *Cul3* encodes a E3 ubiquitin ligase, involved in the recognition and recruitment of target proteins for ubiquitination.

Objectives: We chose to analyze Cul3 in brain development and function, because of its strong link to the ASDs and its putative role in dynamically regulating brain protein composition. Our aim is to uncover the pathological pathways causing the observed behavioral abnormalities in *Cul3*$^{+/-}$ animals.

Methods: We first assessed *Cul3* expression throughout mouse development and in the adult brain by western blot and qPCR analysis. Furthermore, we employed a large battery of histological, molecular and behavioral assays in *Cul3*$^{+/-}$ adult animals (2-4 month old) and their sex-matched littermates (n > 10). Additionally, we investigated the effect of forebrain specific *Cul3* homozygous deletion in embryos and newborn animals, making use of *Cul3*^{flox}/*Emx1-Cre* double transgenic animals.

Results: *Cul3* haploinsufficient animals display mild but significant motor defects, abnormal behavior in the three chamber sociability test and aberrant freezing behavior in the contextual fear conditioning task. Phenotypes that were previously also described in mouse models for ASD and ID. In addition, *Cul3*$^{flox/flox}$/*Emx1-Cre* transgenic animals present severe brain abnormalities at postnatal day 1 and do not survive into adulthood. To investigate the effects of Cul3 loss on the protein composition of the brain, whole quantitative proteomic analysis is ongoing for different timepoints and on multiple brain regions.

Conclusions: Currently, there are no effective pharmacological therapies for autism spectrum disorders. Many factors contribute to this absence of effective treatments, not least the lack of a clear understanding of their neurobiological causes, genetic and phenotype heterogeneity. *Cul3*$^{+/-}$ adult animals present with ASD relevant phenotypes linked to abnormal brain development and regulation of protein composition in the brain. Our findings indicate a pivotal role of the E3 ubiquitin ligase Cul3 for normal brain development and function.

22 **164.022** The Transgenerational Effects of Prenatal Maternal Voluntary Wheel Running on Autistic Characteristics in BTBR T+ Itp3 Tf/J Mice

K. K. Chadman[1] *and R. Feingold*[2]*, (1)New York State Institute for Basic Research, Staten Island, NY, (2)Center for Developmental Neuroscience, CUNY CSI, Staten Island, NY*

Background: Autism spectrum disorder (ASD) is a group of neurodevelopmental disorders that are characterized by deficits in social communication and restricted, repetitive patterns of behavior, interests, or activities. Prenatal exercise is thought to be beneficial for fetal brain development and was examined in the BTBR T^{+} Itpr3 ^{tf}/J (BTBR) inbred strain of mice that is often compared to the more typical C57BL/6J (B6) mice. The BTBR mice exhibit reduced sociability and high levels of repetitive behaviors compared to the B6 mice. The transgenerational effects of prenatal paternal voluntary exercise have been examined briefly in the B6 mice, but prenatal maternal voluntary exercise has not been studied in either strain.

Objectives: To determine if maternal voluntary exercise perinatally leads to lessened autistic-like behaviors in the BTBR offspring.

Methods: In this study, female B6 and BTBR females were given access to running wheels in the home cage for an 8-week period, beginning 2 weeks prior to breeding and continuing until the pups were weaned. The offspring were allowed to age with minimal intervention and were examined as adults. Sociability, anxiety, repetitive behaviors, and learning and memory were tested and compared to the offspring from non-wheel exposed controls from both strains, to determine if prenatal maternal exercise altered these behaviors.

Results: Prenatal exercise only affected a few behaviors in the offspring, and those effects were often the opposite of what was expected. For example, wheel running had only a mild effect on the autistic-like behaviors found in the BTBR mice. Social behavior was unchanged in the BTBR mice following prenatal exercise exposure. Repetitive behaviors were mildly affected, as the male BTBR mice exposed to prenatal wheel running spent more time grooming than any of the other mice in the open field, and all of the BTBR offspring from the wheel running dams were impaired

in reversal learning in the water T-maze. However, despite this influence on self-grooming and reversal learning, voluntary wheel running did not affect repetitive digging in the marble burying test. BTBR mice exposed to prenatal maternal voluntary wheel running also showed increased anxiety associated behaviors.

Conclusions: Maternal voluntary exercise appears to mildly increase the development of repetitive behaviors but not social behaviors in the BTBR mice and had a mild effect of increasing anxiety-like behaviors. Thus, these results suggest that maternal voluntary wheel running does not lessen autistic-like behaviors in the BTBR mice.

23 **164.023** Transcriptional Alterations and Attentional Deficits in a Rat Model of Fragile X Syndrome

C. Golden[1], *M. S. Breen*[2], *S. De Rubeis*[2], *J. Buxbaum*[3] *and H. Harony-Nicolas*[2], *(1)Icahn School of Medicine at Mount Sinai, New York, NY, (2)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (3)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: Fragile X Syndrome (FXS) is a neurodevelopmental disorder caused by mutations in the *FMR1* gene. It is a leading monogenic cause of autism spectrum disorder and inherited intellectual disability and is often comorbid with attention deficits. Most FXS cases are due to an expansion of CGG repeats at the 5' untranslated region of the *FMR1* gene leading to suppressed expression of fragile X mental retardation protein (FMRP), an RNA-binding protein involved in mRNA metabolism. We found that a previously published *Fmr1* knockout (KO) rat model actually expresses an *Fmr1* transcript with an in-frame deletion of exon 8, which encodes a K-homology (KH) RNA-binding domain, KH1. It so happens that several of the few point mutations that are known to cause FXS are found within the KH domains.

Objectives: We aimed to determine whether this previously published *Fmr1* KO rat has deficits in attention and in transcriptomic regulation in a region underlying attention, the medial prefrontal cortex (mPFC).

Methods: We used the five-choice serial reaction time task (5-CSRTT) to measure visuospatial attention and RNAseq to evaluate the transcriptional profile of the mPFC.

Results: We observed that an exon 8 deletion in both male and female rats leads to mPFC-associated sustained attention deficits on the 5-CSRTT, similar to what has been observed in FXS patients and *Fmr1* KO mice. Furthermore, we found that this deletion leads to alterations in the expression of transcripts within the mPFC, which mapped to two weighted gene co-expression network modules. These modules are conserved in human frontal cortex and enriched for known FMRP targets. Hub genes in these modules represent potential targets for FXS.

Conclusions: The deficit in sustained attention resembles a typical FXS-associated phenotype and suggests that this *Fmr1*-$^{\Delta}$exon 8 rat models FXS with face validity. Furthermore, these findings provide support for a prefrontal deficit in FXS, indicate that attentional testing might be a reliable cross-species tool for investigating FXS, and identify dysregulated conserved gene networks in a relevant brain region.

24 **164.024** Translational Assessments in Two Genetic Preclinical Models of Disrupted Chromatin Processes: Development and Motor Outcomes

S. Petkova[1], *C. P. Canales*[2], *A. S. Nord*[3], *J. Ellegood*[4], *J. P. Lerch*[4] *and J. L. Silverman*[5], *(1)MIND Institute and Department of Psychiatry and Behavioral Sciences, Sacramento, CA, (2)Center for Neuroscience | MIND Institute, Department of Psychiatry and Behavioral Sciences, University of California Davis, Davis, CA, (3)Center for Neuroscience, Department of Neurobiology, Physiology, & Behavior, University of California, Davis, Davis, CA, (4)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada, (5)MIND Institute and Department of Psychiatry and Behavioral Sciences, University of California Davis School of Medicine, Sacramento, CA*

Background:

Numerous genes related to chromatin modification processes are among the top autism -associated risk genes, including AT-Interactive Domain 1B (*ARID1B*) and Chromodomain-Helicase DNA Binding Protein 8 (*CHD8*) (Cook & Scherer, 2008, O'Roak & State, 2008, O Roak 2014, Lossifov 2014, Werling 2018). These two candidate genes have related functional activities albeit act via differential pathways: *ARID1B* is a SWI/SNF complex protein in neuronal BAF chromatin complexes, and *CHD8* encodes an ATP-dependent chromatin helicase.

Objectives:

To examine developmental outcomes such as physical growth and neurological reflexes in two preclinical models of genetically defined ASD.

To focus on motor as a key domain because: a) there is a strong correlation between motor and social communication, b) there is a strong correlation between motor skills and assessment of cognitive abilities, and c) motor is highly translatable between preclinical models and human studies.

Methods:

Heterozygous *Arid1b*$^{+/-}$ generated by the Toronto Centre for Phenogenomics, *Chd8*$^{+/del5}$ from the Nord laboratory (Gompers et al., 2017) and wildtype littermate, sex and age matched controls were assayed in developmental milestones on postnatal days (PND) 2-14, similar to those previously described (Fox, 1965) with extended detail. Physical measurements such as body weight, length, and head width were measured. Progress of motor reflexes such as negative geotaxis, cliff avoidance, righting reflex and circle transverse assayed for neonatal hypotonia and ataxia. Milestones for tracking development of fore and hind limb strength were forelimb grasp, forelimb bar holding, forelimb and hindlimb hang tests. Adult gross and fine motor abilities including balance, strength, coordination, locomotive activity, and gait were evaluated using classic tests such as the open field, rotarod and innovative gait mapping using the treadmill scanning DigiGait™ system.

Results:

Arid1b$^{+/-}$ pups were impaired on several parameters of developmental milestones compared to littermate *Arid1b*$^{+/+}$ controls. Body weight, length and head width were smaller in *Arid1b*$^{+/-}$, indicating atypical growth and development. Longer latencies to reverse from an inclined position in negative geotaxis and to traverse out of circle were detected in *Arid1b*$^{+/-}$, highlighting delayed motor-related neurological reflexes and the onset of walking. Adult *Arid1b*$^{+/-}$ were also impaired on multiple parameters of locomotive activity. In contrast, *Chd8*$^{+/del5}$ showed no substantial delays nor deficits in growth, motor skill development or strength during neonatal testing, compared to wildtype littermates. Adult *Chd8*$^{+/del5}$ also exhibited few gait abnormalities.

Conclusions:

Many neurodevelopmental disorders ranging from the broadly defined ASD to the rare genetic syndromes have common features of developmental delay and motor dysfunction. An emphasis on finely detailed motor skill analyses across development as outcome measures has been understudied. Broadly, *CHD8* and *ARID1B* function as chromatin modification proteins. Herein, we described developmental delays and numerous motor outcomes using finely tuned clinically-relevant assays in genetic preclinical models of these two ASD risk genes. Investigation of motor outcomes is essential for demonstrating the test the utility of innovative drug designs and validate other traditional medicinal therapies that may be in the drug discovery pipeline.

25 **164.025** Trials and Tribulations: Co-Clinical Trials of Autism in Mice and Humans

Z. Lindenmaier[1,2], *A. Kinman*[1], *T. Chien*[3], *K. Easson*[3], *D. Fernandes*[1], *E. Chater-Diehl*[4], *M. T. Siu*[4], *D. Butcher*[5], *J. Ellegood*[6], *R. Weksberg*[4,7], *J. A. Foster*[8], *E. Anagnostou*[9,10,11] *and J. P. Lerch*[2,6], *(1)Mouse Imaging Centre, Neuroscience and Mental Health, Hospital for Sick Children, Toronto, ON, Canada, (2)Medical Biophysics, University of Toronto, Toronto, ON, Canada, (3)Mouse Imaging Center, Neuroscience and Mental Health, Hospital for Sick Children, Toronto, ON, Canada, (4)Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada, (5)Department of Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada, (6)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada, (7)Institute of Medical Sciences, Unviersity of Toronto, Toronto, ON, Canada, (8)Department of Psychiatry & Behavioural Neurosciences, McMaster University, Hamilton, ON, Canada, (9)Department of Paediatrics, University of Toronto, Toronto, ON, Canada, (10)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (11)Hospital for Sick Children, Toronto, ON, Canada*

Background:
Despite promise in animal models, novel therapeutics consistently fail in clinical trials of autism. Due to the heterogeneous nature of autism, treatment will likely only ameliorate symptoms in a subset of patients.

Objectives:

There is a need to simultaneously test promising new compounds while understanding and predicting which patients will respond to each therapy. To determine what might contribute to response susceptibility, we propose the implementation of co-clinical trials in autism. In co-clinical trials, novel compounds, with established safety profiles, are simultaneously tested in mouse models of autism as well as in Phase 2 trials in humans with autism.

Methods:

A high-throughput protocol for mouse models of autism with genetic modifications in known autism genes is discussed, which encompassess chronic treatment over development, multiple magnetic resonance imaging time-points, behavioural tests before, during, and after treatment, and microbiome and epigenetic analyses. Human subjects also follow an extensive phenotyping protocol, including behavioural testing, as well as genetics, epigenetics, and imaging assessments. To ensure scientific rigor, both the preclinical and clinical studies are blinded, with placebo-treated controls, with sample size deteremined by power analyses. To establish the optimal regime, three co-clinical trials were created assessing promising therapeutics in autism: oxytocin, Tideglusib (a glycogen synthase kinase 3b inhibitor), and Arbaclofen (a GABA agonist). The protocol was modified with each iteration, optimizing the protocol based on the findings from each trial.

Results:

The first trial found no differential response to oxytocin treatment in mouse models in both neuroanatomical and behavioural phenotypes, and only some trending effects in humans on higher cognition measures. The protocol was modified for the Tideglusib trial, by narrowing the focus of the behavioural tests, increasing power by backcrossing onto the same background strain, changing the administration method, as well as by altering some other procedures. Analysis to date shows some differential treatment response was seen in the mouse models, with the Shank3 knock-out mouse model showing exacerbated hyperactivity (q=0.00) and non-anxiety (q=0.043) , and the Arid1b heterozygous deletion showing significant (q=0.01) changes in the volume of the insular cortex with treatment. The human trials also demonstrated some treatment response, with significant (q=0.05) differences on measures of social withdrawal, repetitive behaviours, as well as daily living skills, memory, and sleep quality.

Conclusions:

A comparison across species in both drugs remains to be performed. The next co-clinical trial will be on the drug Arbaclofen, and the protocol will again be modified to address issues of the former trials. Ultimately, we hope to establish a rigorous multi-modal, multi-species approach of assessing treatment, with the intention of stratification by response susceptibility.

26 **164.026** Understanding the Role of Oxytocin in Autism: Establishment of Zebrafish MODEL

S. Shams[1], *J. Landin*[2], *K. Tsui*[3], *P. Kettunen*[4] *and L. Westberg*[5], *(1)Pharmacology, University of Gothenburg, Gothenburg, Sweden, (2)Department of Pharmacology, University of Gothenburg, Gothenburg, Sweden, (3)Pharmacology, University of Gothenburg, Göteborg, Sweden, (4)Department of Clinical Neurosciences, University of Oxford, Oxford, United Kingdom, (5)University of Gothenburg, Gothenburg, Sweden*

Background: Oxytocin is a neuropeptide that regulates a wide range of mammalian social and non-social behaviors relevant to autism, such as bonding, social recognition, anxiety, and aggression. Recently, intranasal administration of oxytocin has been reported to improve social function in autistic patients and has shown promise as a potential treatment of social impairments seen in autism. Since the mechanisms underlying autism and oxytocin's role in allaying social symptoms in autistic patients are not well-understood, animal models with capacity for sophisticated genetic manipulation are necessary. Zebrafish (*Danio rerio*) is a highly social vertebrate with phylogenetic conservation in oxytocin and key neurotransmitter systems and we exploit these features to develop an animal model of autism in zebrafish.
Objectives: Importance of the oxytocinergic system in mammalian social behavior is well-established, but less is known about its homologous system in zebrafish. Our aim is to investigate social interaction and neurochemistry in zebrafish mutants with genetically manipulated oxytocin system.

Methods: Using adult male and female CRISPR-Cas9-mutants lacking either of the two zebrafish oxytocin receptor genes, *oxtr* and *oxtrl*, we performed a battery of tests for social and non-social behaviors. We measured behavioral responses ($n \geq 16$ for each group) to experimentally-induced aggression and anxiety-related behavior, and ability to recognize previously encountered social stimulus in mutant and wildtype control fish. We also quantified the levels of neurotransmitters (dopamine, serotonin, norepinephrine, glutamate, glycine, GABA) in multiple brain regions

of these mutants using high precision liquid chromatography.

Results: Our data show that zebrafish lacking oxytocin receptors display impairments in aggressive, social, and anxiety-related behavior, in a receptor-specific and sex-dependent manner. We also found significant differences in neurotransmitter levels in the measured brain regions (olfactory bulbs and telencephalon, mesencephalon, diencephalon, cerebellum & hindbrain), indicating a role of oxytocin in regulation of other neurotransmitters.

Conclusions: These results advance our understanding of neural mechanisms underlying oxytocin-regulated social interaction in zebrafish and further highlight the potential of future investigation of zebrafish oxytocin system towards generating better therapeutic treatments for autism.

27 **165.027** Autism Spectrum Disorder and Additional Areas of Difficulty: Patterns of Difficulties in a Population-Based Twin Sample

***E. Colvert**, V. L. Milner and F. Happé, Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:
There is increasing interest and concern regarding additional psychiatric problems that co-occur with Autism Spectrum Disorder (ASD), as reflected in recent changes to diagnostic schemes. Since additional disorders may add to the burden for individuals with ASD and their carers, and may be amenable to treatment, recognition and diagnosis are important. Previous studies have reported raised rates of additional psychiatric difficulties in ASD, however, the majority of these have included clinic samples, which may be biased towards more complex or severely impaired cases.

Objectives:

The study aims to establish, for the first time, the rates and patterns of co-occurring difficulties in a large population-based twin sample covering the full range of the autism spectrum, and to examine possible risk factors.

Methods:

Three groups of participants were included: 135 twins who met criteria for a research diagnosis of ASD (87% male; mean age 13 years 5 months); 55 non-ASD co-twins (36% male; mean age 13 years 6 months); 144 comparison twins (69% male; mean age 12 years 9 months). Participants and their parents completed the Strengths and Difficulties Questionnaire (SDQ) as part of a wider research assessment. The SDQ includes five domains of difficulties: emotional, conduct, hyperactivity, peer and pro-social; and produces mean and cut-off scores. Measures of possible risk factors were also included: age, full scale IQ, SES, sex, zygosity and autism severity (ADI-R, ADOS-G, Childhood Autism Spectrum Test).

Results:

For both mean scores and cut-offs on the SDQ the ASD twin group showed significantly higher levels of difficulties than both the non-ASD co-twins and the comparison twins. No differences were seen between the co-twins and the comparison group.

The frequency of multiple problems was examined (limited to the emotional, conduct and hyperactivity domains), showing 46% of the ASD twin group had difficulties in more than one domain. In contrast, 11% of the co-twins and 7% of the comparison group showed multiple areas of difficulty.

Analyses of risk factors found that for all three sample groups autism severity was the biggest contributor in terms of the mean SDQ scores. The higher participants scored in terms of autism severity the higher their SDQ scores. This link occurred for cut-off scores, albeit reduced and confined to the ASD group only.

Conclusions:

The results of the study support previous research findings of high levels of comorbid difficulties for those with ASD. The population-based design and the use of standardised measures allow a clearer understanding of the rates and the nature of those difficulties for the group across the full autism spectrum. The severity of ASD symptoms was the risk factor most strongly associated with SDQ ratings and rates of multiple problems, for all three sample groups, with other risk factors showing fewer connections. The very high rates of difficulties shown by the ASD group indicate that comorbidity of difficulties is a serious issue and more evidence concerning the nature of comorbid difficulties is needed to help develop and target interventions for those with ASD.

28 **165.028** A Gene First Approach to Understanding Sleep Problems in Autism

***R. Tesfaye**[1], G. Huguet[2], Z. Schmilovich[3], O. Diallo[4], A. Dionne-Laporte[5], A. Yusuf[6], B. Chaumette[3], M. Elsabbagh[7], G. A. Rouleau[1] and S. Jacquemont[8], (1)Neurology and Neurosurgery, McGill University, Montreal, QC, Canada, (2)Research Center of UHC Sainte-Justine, Montreal, QC, Canada, (3)Human Genetics, McGill University, Montreal, QC, Canada, (4)MNI Brain Tumour Research Center, McGill University, Montreal Neurological Institute, Montreal, QC, Canada, (5)MNI Brain Tumour Research Center, McGill University, Montreal, QC, Canada, (6)Psychiatry, McGill University, Montreal, QC, Canada, (7)McGill University, Montreal, PQ, Canada, (8)CHU Sainte Justine, University of Montreal, Montreal, QC, Canada*

Background: Sleep is disturbed in up to 80% of youth with autism spectrum disorder (ASD). It's suggested that these sleep problems may be attributed to genetic abnormalities. It is well established that the circadian rhythm is regulated by a network of core circadian clock genes expressed in the suprachiasmatic nucleus. However, the genetic contribution to the two most prevalent sleep complaints in ASD, namely insomnia and sleep duration abnormality, remains unknown. A recent genome wide association studies (GWAS) including over one million adults, implicated 959 candidate genes with insomnia symptomatology, 203 for poor sleep duration, and other risk genes for various sleep traits. New GWAS findings, in addition to established circadian genes, may provide a gene-first approach to bridge the current knowledge gap in understanding the neurobiological underpinnings of sleep disturbance in ASD.
Objectives: Our goal was to determine whether differences in genetic variants within a) core circadian clock genes b) circadian pathway genes and

c) sleep trait candidate genes, are observed between individuals with ASD and their unaffected siblings. We expect significantly more copy number variants (CNVs) encompassing sleep in individuals with ASD in comparison to siblings without a diagnosis.

Methods: We used available data from the Simons Simplex Collection (SSC), a comprehensive phenotyped and genotyped sample of more than 2,583 individuals with ASD (4 -18 years) and their families (parents and non-diagnosed sibling). A list of circadian clock genes were identified in existing literature, pathway genes were extracted from published databases (KEEGPathway and GeneOntology) and GWAS sleep trait candidate genes were taken from Jansen et al, 2018. Microarray technology was used to identify CNVs, pipeline detections from our previous publications were applied to call relevant CNVs. We first investigated the risk of ASD by comparing diagnosed youth to siblings who were carriers or not of rare CNVs (< 0.1%), using the sleep genes identified.

Results: After a microarray quality control, 2091 pairs of ASD youth and siblings remained. When CNVs were filtered by all genes present in our different sleep lists, we found 5% of ASD youth with a rare deletion compared to 3.1% of siblings, while 7.9% of youth with ASD had a rare duplication compared to 6.4% of siblings. A Fisher's exact test revealed a significant excess of deletions encompassing sleep genes in individuals with ASD compared to unaffected siblings (p=0.003; Odds ratio 1.6; CI95% [1.2 ; 2.3]).

Conclusions:This is the first study to examine CNVs related to sleep in ASD. Our findings demonstrate that variations within sleep-related genes are more frequent in youth with ASD compared to sibling controls. This suggests that sleep disturbance may be inherently linked to the biological etiology of ASD. Future investigations between genetic variants of sleep, brain connectivity and behavioural/cognitive phenotypes will be conducted on a subset of this ASD population.

29 **165.029** Associating Autism Polygenic Risk Scores with Early Measures of Social Attention in Infants

R. Harrison[1], *A. Gui*[1], *A. Hendry*[2], *T. Gliga*[1], *C. Tye*[3], *G. Pasco*[4], *M. Elsabbagh*[5], *T. Charman*[6], *M. H. Johnson*[7], *E. J. Jones*[8], *E. Meaburn*[9] *and &. The BASIS Team*[1], *(1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (2)Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom, (3)Department of Child & Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)McGill University, Montreal, PQ, Canada, (6)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (8)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (9)Psychological Sciences, Birkbeck College, London, United Kingdom*

Background:

Alterations in social attention in early development have been reported in infants who later develop autism spectrum disorder (ASD). However, we do not know whether social attention lies on the causal path from genetic and environmental risk to later diagnosis. We explore whether polygenic risk scores (PRS) for ASD associate with dimensional measures of social attention in an infant sibling cohort. First, we examine the speed and amplitude of event-related neural responses (ERP) to faces at 6-10 months, which is altered in infants with later autism (Jones et al., 2016). Second, we examine the proportion of time infants spend looking at faces on static slides with social and non-social content. Declines in face looking over time have been previously associated with autism outcome (Jones & Klin, 2013; Ozonoff et al., 2010).

Objectives:

The primary objective of this study was to investigate whether atypical social attention in early infancy is associated with polygenic risk for autism.

Methods:

ASD PRSs were generated for 138 infants of Caucasian ancestry derived from the British Autism Study of Infant Siblings (BASIS), a longitudinal prospective study of infants at high and low familial risk for ASD. PRS were generated using PRSice-2 and summary statistics from the Integrative Psychiatric Research Consortium (Grove et al.,2017). Social attention was assessed through i) event-related neural responses to gaze shift (P1,P400 latency and amplitude) and responses to faces and matched visual noise (N290) (Elsabbagh et al., 2012); ii) proportion of time infants spend looking at faces during a series of slides featuring faces, visual noise and objects (Gliga et al., 2010). ASD PRS were compared between infants with (N=23) and without (N= 115) an ASD diagnosis at 36 months. The association between the cross-sectional ERP responses to faces and PRS (n=138) was investigated. Longitudinal trajectories of proportion of attention to face generated using K-means for longitudinal data (KML) identified two parallel, downward-trending trajectories. PRS were compared between infants with different trajectories.

Results:

ASD PRS discriminated between infants with later ASD and those with typical or other atypical development (R2= 0.075, p = 0.0063). There was a trend association (p <0.1, r =-0.17) between PRS and N290 Latency, but not between P1 or P400. Face attention decreased over time in both identified trajectories. Infants on the lowest face attention trajectory had a slightly higher PRS (p <0.1), but there was no association with ASD diagnosis.

Conclusions:

ASD PRS clearly discriminates ASD and non-ASD outcomes and finds trend associations with measures of N290 latency. N290 latency has been previously associated on the phenotypic level with ASD diagnosis (Elsabbagh et al., 2012) and with dimensional scores on behavioural measures of social development (Webb et al., 2011). Further, there were trend-level associations between trajectories of social attention and PRS, suggesting that infants with a higher polygenic load may show a diminished interest in faces throughout infancy. Taken together, this shows the promise of taking a translational neurodevelopmental approach to dissecting developmental paths to autism.

31 **165.031** Genomic and Behavioral Analysis of Autism Spectrum Disorders Based on Different Brain Imaging Modalities

G. Barnes[1], *M. Elmogy*[2], *A. Switala*[3], *O. Dekhil*[4], *E. Rouchka*[5], *R. Keynton*[6] *and A. S. El-Baz*[3], *(1)University of Louisville School of Medicine, Louisville, KY, (2)University of Louisville Speed School of Engineering, Louisville, KY, (3)University of Louisville, Louisville, KY, (4)Bioengineering, university of Louisville, Louisville, KY, (5)Computer Science, University of Louisville Speed School of Engineering, Louisville, KY, (6)Bioengineering, University of Louisville, Louisville, KY*

Background:
Autism spectrum disorder (ASD) is a complex condition that can be defined as a group of diverse neurodevelopmental disorders. ASD is identified by early conditions which change information processing of the nervous system and impact the communication and social development of the patients. In addition to environmental factors, many genes of various pathways can be represented as varied risk factors for developing ASD.

Objectives: To merge genomic and behavioral data with multi modal MRI using Big Data Techniques

Methods: 200 individuals (80 with ASD and 120 controls) from the NDAR database were selected as having both T1-weighted MRI and single nucleotide polymorphism (SNP) genotyping. Of these, 74 also had available resting-state functional MRI (rs-fMRI) time series. Structural MRI scans were processed from which two vector-valued shape descriptors were derived. A "global" descriptor was obtained by approximating the surface with an 81st-order SPHARM model and calculating the power spectrum from the spherical harmonic coefficients. A vector of "local" descriptors was built by aligning each surface with a map of select Brodmann areas, 25 per hemisphere, and taking the average Gaussian curvature of the surface within each region. The pattern of activity from Rs-fMRI scans within each independent component was scored as consistent with ASD using a fuzzy, neural network-based classifier, and these scores form a vector of functional connectivity descriptors. All SNP genotyping had been performed using the Illumina HumanOmni 2.5-8 whole-genome kit. The extracted descriptors from both sMRI and fMRI were used as phenotypic information in the genomic linkage analysis performed using PLINK software to identify genomic variants (SNP Cclls from GenomeStudio software) significantly associated with each of the three descriptor vectors. Significant SNPs were identified by rs# in dbSNP, and any associated genes were cross-referenced with Uniprot, GeneCards, and the SFARI database

Results:

Using a false discovery rate (FDR) of 0.1, twelve SNPs were found to be significantly associated with regional brain curvature on sMRI, including four intron variants, two coding variants, and six within intergenic DNA. Of the SNPs most strongly associated with global brain shape, with FDR = 0.1, five were intronic and two intergenic. The top 5 SNPs linked with ASD-related functional connectivity, with uncorrected $p < 10^{-5}$, were intronic or intergenic. However, none of these was significant at FDR = 0.1. The sample size being much lower than for sMRI analyses. Implicated genes include several associated with vesicles/vesicle transport (*AP1G2*, *STON2*, *SYTL1*), including synaptic vesicles, with metal ion transport including calcium ions (*HCN1*, *SLC12A8*, *STIM1*), and with embryonic development (*STOX2*) and neural migration in particular (*ASTN2*). Other affected genes may have a membrane or chromatin regulatory function (*MDGA2*, *NXPE2*/*NXPE4*, *UHRF1*) or are non-protein coding (*LINC01800*, *MIR99AHG*). Only two of the genes identified, *ASTN2* and *HCN1*, are currently listed in the SFARI database.

Conclusions: In summary, distinct novel genes or traditional autism risk genes may be identified differently by Rs-fMRI, or local vs global descriptors of sMRI that map, along with behaviors, to RDoC defined neural circuits relevant to ASD.

32 **165.032** Genotype-Phenotype Correlation in Brazilian Patients with Phelan-Mcdermid Syndrome : New Insights for a Better Clinical and Genetic Counseling Management

E. V. Branco[1], *M. R. Passos-Bueno*[2], *C. I. Samogy Costa*[1], *F. Monfardini*[1], *H. Ferraz*[3], *R. Fock*[4], *R. A. Barbosa*[5], *A. B. Perez*[4], *N. Lourenço*[1], *M. Vibranovski*[1], *A. Krepischi*[1] *and C. Rosenberg*[1], *(1)Universidade de São Paulo, São Paulo, Brazil, (2)Centro de Pesquisas Sobre o Genoma Humano e Células-Tronco, Instituto de Biociências, Universidade de São Paulo, Sao Paulo, Brazil, (3)Chemical Engineering Program, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, (4)Universidade Federal do Estado de São Paulo, São Paulo, Brazil, (5)Morfologia e Genética, Universidade Federal de São Paulo, São Paulo, Brazil*

Background:
Phelan-McDermid Syndrome (PMS) is a rare genetic disorder characterized by global developmental delay, intellectual disability and mild dysmorphisms associated with several comorbidities. PMS results from *SHANK3* loss of function, mainly caused by copy number variations (CNVs) of different sizes. Although *SHANK3* haploinsufficiency has been associated with the major neurological symptoms of PMS, it cannot explain the great clinical variability seen among patients.

Objectives:

Our goals were to characterize a Brazilian cohort of PMS patients, explore the genotype-phenotype correlation underlying this syndrome and estimate the frequency of PMS among ASD and ID individuals.

Methods:

A total of 34 PMS patients were clinically and genetically evaluated. The data were obtained by a questionnaire answered by parents and dismorphic features were evaluated using patients' pictures. We have analysed the 22q13.3 CNVs and and other potentially pathogenic CNVs. We also performed a genotype-phenotype correlation analysis in order to determine whether comorbidities, speech status and autism spectrum disorder correlate with deletion size. Finally, a cohort composed by 829 ASD individuals and another composed by 2297 ID patients were used to determine the frequency of PMS among these disorders.

Results:

In our clinical data, sparse eyebrows were a prominent clinical feature (80%). Genotype-phenotype correlation allowed us to restrict minimum regions of deletion at 22q13.3 which are neither associated with renal complications (<1.3 Mb) or with lymphedema (<4.3Mb). We also confirmed a positive association between language impairment and deletion size. About 21% of the patients showed an additional rare CNV, which may contribute to a more severe phenotype or clinical features not commonly seen in PMS. Among ASD Brazilian or ID patients referred to CNV analyses the frequency of 22q13.3 deletion was 0.6% (5/829) and 0.65% (15/2297), respectively, confirming its relevance among neurodevelopmental disorders.

Conclusions:

To date, this is the first work describing a cohort of Brazilian patients with PMS and it highlights the importance of second hits in this condition. Taken together, our data show that the clinical history of PMS in a different ethnicity and culture did not differ significantly from other countries, which represents a baseline for any future management.

33 **165.033** Identifying Mechanisms Underlying Neurodevelopmental Disorders: Family-Wide and Inherited Influences on Early Social Attention Skills

A. Gui[1], *A. Hendry*[2], *T. Gliga*[1], *L. Mason*[1], *C. Cheung*[1], *G. Pasco*[3], *T. Charman*[4], *M. H. Johnson*[5], *E. Meaburn*[6], *E. J. Jones*[7] *and &. the BASIS Team*[1], *(1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (2)Department of Experimental Psychology, University of Oxford, Oxford, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (6)Psychological Sciences, Birkbeck College, London, United Kingdom, (7)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom*

Background: To understand mechanisms underlying the emergence of Autism Spectrum Disorder (ASD) and co-occurring conditions, we need to identify processes that mediate between genetic risk and later symptoms. One candidate process is attention, which gates what the child can learn. In fact, attention to people in the first years is highly heritable and atypical in infants who later receive diagnosis of ASD. However, this could be related to both social features of ASD, and co-occurring attention difficulties like Attention Deficit/Hyperactivity Disorder (ADHD). Here we test whether disruptions in attention towards faces could lie between genetic risk and outcome by looking at i) familial risk-group difference; ii) its association with quantitative familial risk for ASD and ADHD; iii) its association with polygenic scores.

Objectives: To investigate contribution of familial likelihood of early social and attention problems, wecombined genotypic, phenotypic and eye-tracking data from 334 14-month-old infants who participated in the British Autism Study of Infant Siblings (BASIS: http://www.basisnetwork.org/) and their older siblings.

Methods: i) For risk-group analysis, mean duration of the longest look at the face stimulus (henceforth, peak-look duration) during a face pop-out task was calculated for 222 infants with an older sibling with ASD and/or ADHD (high-risk), compared to 112 infants without family history of ASD (low-risk); ii) For relation to quantitative familial load, the Social Communication Questionnaire (SCQ) and Strengths and Difficulties Questionnaire (SDQ) were used to measure social and attentional problems in a subset of the infants' older siblings with ASD (N=114); iii) To understand to what extent the aggregate effect of common genetic variants explains atypicalities in early social attention behavior, polygenic risk scores (PGS) for two neurodevelopmental disorders were obtained for 198 infants (173 high-risk, 62 low-risk). Summary statistics by the Integrative Psychiatric Research and the Psychiatric Genomics Consortium were used to compute PGS for ASD and ADHD.

Results: i) Peak-look to faces was longer in high-risk vs. low-risk infants ($F(1,327)=19.4$, $p<0.001$, Figure 1). ii) Longer peak-look duration was associated with more parent-reported social ($b=0.02$, $p=0.009$) and attention ($b=0.08$, $p=0.013$) difficulties in the older sibling with ASD. This confirmed that early differences in this measure of visual attention to social stimuli might be associated with familial burden for both ASD and ADHD. iii) Peak-look duration was not significantly predicted by ASD-PGS (Nagelgerke's $R^2= 0.017$, $p=0.072$) after controlling for possible design-related confounders such as recruitment phase, number of valid trials and age in months ($b=945.97$, $p=0.23$). ADHD-PGS significantly predicted peak-look duration (Nagelgerke's $R^2= 0.22$, $p=0.038$), even when controlling for design-related covariates ($b=160.27$, $p=0.023$, Figure 2).

Conclusions:

Disruptions in early social attention in high-risk infants quantitatively vary with ASD and ADHD symptoms in their older sibling. Moreover, a modest but significant contribution of genetic risk for ADHD might influence infants' looking behavior when paying attention to people, having cascading effects on learning. Further work will examine the longitudinal relation to ASD and ADHD symptoms in toddlerhood. Taken together, our work highlights a promising new approach to understanding developmental mechanisms that underlie the emergence of neurodevelopmental disorders.

1.

34 **165.034** Modeling Disordered Eating in Terms of Core Autism Symptoms Increases Heritability Estimates

N. R. Pottschmidt*, L. Brueggeman and J. J. Michaelson, Psychiatry, University of Iowa, Iowa City, IA*

Modeling disordered eating in terms of core autism symptoms increases heritability estimates

Background: Although aberrant eating behaviors are a well-established problem among individuals with autism, it remains unclear whether those behaviors are related to core autism symptomatology. The answer to this question has implications both for our basic understanding of the neurobiology of autism and for the design of therapeutic interventions. If aberrant eating behaviors and core autism symptomatology arise from a shared latent neuropathology, one might expect that treatment affecting one domain could also show efficacy in the other.

Objectives: Using a sample of over 5,000 families with autism, we aimed to model aberrant eating behaviors in terms of core autism symptomatology, and determine whether these models could demonstrate a significant association between the two domains. We further aimed to quantify the SNP-heritability of traits related to aberrant eating behaviors, thus laying the groundwork for identifying biological risk mechanisms.

Methods: In partnership with the nationwide (US) genetic study, SPARK for Autism, we distributed online self-report surveys assessing sleep, eating, and gastrointestinal patterns to SPARK participants (children with autism and their parents). The analysis presented here is our first look at the NIAS data from this study, a nine-item instrument for measuring aberrant eating behaviors. The NIAS has three sub-scales: picky eating, diminished appetite, and fear of eating consequences. We trained Random Forest classifiers to predict each NIAS sub-scale score in children, using item-level data from the SCQ (measuring social communication) and the RBS-R (measuring restricted and repetitive behaviors) as predictor variables. SNP-heritability estimates were carried out on a sub-sample of 2,627 children who also had complete genetic data available.

Results: Both SCQ- and RBS-R-based multivariate models of NIAS subscales showed significant association between disordered eating and core autism symptoms (all three NIAS subscales $p<0.000001$). Family history of eating disorders corresponded with a significant increase in total NIAS scores in both unaffected adults ($t=7.38$, $p<0.0001$) and affected individuals ($t=3.86$, $p<0.001$). Additionally, total child NIAS scores were significantly associated with mothers' scores on the EAT-26 ($n=3676$ dyads, $r=0.10$, $p<0.0001$). Despite this evidence suggestive of familiality, none of the three NIAS subscales, as reported by participants, showed significant SNP-heritability in this sample. However, the fear subscale, as predicted by the SCQ and RBS-R Random Forest, showed significant SNP-heritability (h2=0.28; S.E.=0.16). Interestingly, this subscale was the only NIAS measure significantly linked to a family history of specifically anorexia nervosa ($t=4.38$, $p<0.00001$).

Conclusions: These results suggest that disordered eating in autism is significantly linked to its core symptomatology (social communication

deficits and restricted and repetitive behaviors). The lack of SNP-heritability present in NIAS subscales, and its emergence when disordered eating is modeled in terms of core autism symptoms, may suggest that further work is needed to develop instruments that measure eating behaviors in a way that is both biologically and clinically meaningful. Work is now underway to further characterize the nature of the interplay between traits related to eating, socialization, and restricted and repetitive behaviors.

35 **166.035** Role of the Gut Microbiome in Autism-Related Behaviors

A. Osman[1], *N. Mervosh*[2] *and D. D. Kiraly*[2], *(1)Psychiatry, Ichan School of Medicine at Mount Sinai, New York, NY, (2)Ichan School of Medicine at Mount Sinai, New York, NY*

Background:
Phelan-McDermid syndrome (PMS) is a neurodevelopmental disorder caused by haploinsufficiency of the Shank3 gene. Patients with this mutation are also commonly diagnosed with autism spectrum disorder (ASD). In fact, PMS has been identified as one of the most frequent monogenic causes of ASD. In clinical populations there is marked heterogeneity in the severity of the PMS phenotype, while these differences may be due to variety in the mutations involved, it is important to consider potential contributing environmental influences. Interestingly, a significant subset of patients with ASD present with gastrointestinal disturbances, and sequencing of the gut microbiota has shown significant alterations in the bacterial makeup of stool from patients with ASD. Additionally, there is a large body of evidence linking the composition of the gut microbiome to brain development and behavior. To this end, we investigated changes in gut microbiome and metabolites as well as effects of microbiome depletion in a recently developed Shank3 mouse model with exons 4-22 deleted (SHANK3$^{\Delta 4\text{-}22}$) resulting in knockout of all detectable SHANK3 isoforms.

Objectives:

To examine the effect of Shank3 deletion on the microbiome and metabolome as well as assessing the effects of the lack of a diverse gut microbiome on autism-like behaviors in the SHANK3$^{\Delta 4\text{-}22}$ model.

Methods:

Heterozygous SHANK3$^{\Delta 4\text{-}22}$ breeders produced (Wt), heterozygous and homozygous KO offspring. Offspring (both males and females) were weaned on postnatal day (PND) 21 and split into two treatment groups – control drinking water and antibiotic depletion (Abx). The Abx group received a cocktail of broad spectrum non-absorbable antibiotics (Bacitracin 0.5mg/ml, Neomycin 2mg/ml, Vancomycin 0.2mg/ml, Pimaricin 1.2ug/ml) via their home cage drinking water, while the control groups received untreated water. When animals reached PND60 they were subjected to behavioral tests including three-chambered social interaction, marble burying and open field. After behavioral assessment animals were culled and brains were collected for molecular analysis and cecal contents for 16S rRNA sequencing and metabolomic profiling.

Results:

Cecal content analysis demonstrated marked differences in microbiome composition at the phylum and class level between SHANK3$^{\Delta 4\text{-}22}$ KO and Wt controls. Additionally, SHANK3$^{\Delta 4\text{-}22}$ KO mice were found to have an altered cecal metabolic profile as shown by increased levels of a number of amino acids including phenylalanine and methionine, as well as decreases in levels of several short-chain fatty acids. Behaviorally, SHANK3 $^{\Delta 4\text{-}22}$ Het & SHANK3$^{\Delta 4\text{-}22}$ KO mice demonstrated decreased social interaction compared to Wt in the three-chambered social interaction paradigm and this deficit was exacerbated by microbiome depletion.

Conclusions:

Mice constitutively lacking the Shank3 gene demonstrate alterations in the content of their gut flora and the resultant metabolome even when diet and environment are controlled. Additionally, the autistic-like behaviors seen in SHANK3 $^{\Delta 4\text{-}22}$ mutant mice are influenced by alterations to the endogenous flora. Taken together, these studies suggest a gene x microbiome interaction may be contributing to the phenotype of PMS. Although these findings are preliminary, they raise the possibility that interventions targeted at normalizing the gut flora and metabolome may have translational potential in PMS or other causes of ASD.

36 **166.036** A New LIVE MOUSE Tracking System Reveals That SHANK2 and SHANK3 Mutant MICE Display Opposite Abnormal Behaviours in Object Exploration and HOME-Cage Social Conditions

E. Ey[1,2], *F. de Chaumont*[3], *J. C. Olivo-Marin*[3] *and T. Bourgeron*[1], *(1)Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France, (2)UMR 3571, CNRS, Paris, France, (3)Institut Pasteur, Paris, France*

Background: Mutations in genes coding for synaptic proteins were shown to increase susceptibility to autism spectrum disorder (ASD). Among the causative proteins, cell adhesion molecules such as neuroligins and neurexins as well as scaffolding proteins such as SHANK3 and SHANK2 were robustly associated with ASD in independent patients. We previously analysed transgenic knockout mice lacking *Shank2*. These mice displayed abnormal glutamatergic receptor expression and neurotransmission, as well as hyperactivity, longer grooming bouts and subtle abnormalities in social interactions and communication.
Objectives: The aim of the present project was to develop new protocols to investigate further the behavioural deficits in *Shank2* mutant mice in object exploration and in the home cage. We conducted a comparative study in *Shank3* mutant mice. Such new ways of phenotyping within the home cage allow to characterise behavioural abnormalities at a finer level of details and in a more comprehensive way than the classical tests, that trigger a high level of stress in the mice. Testing mice together without intervention also permits to better control experimental conditions.
Methods: Comparisons were drawn between *Shank2*$^{-/-}$ (deletion of exon 16), *Shank3*$^{-/-}$ (deletion of exon 11) and their respective wild-type adult female littermates (generated on a C57BL/6J background). We tested 12-18 animals per genotype. We tested locomotor activity and reactions to a novel object in a single mouse, as well as mixed-genotype group home cage behaviour. We used a newly developed tracking system (Live Mouse

Tracker). This system allows to follow individually each mouse within a group over several days and to record its individual behaviours and social interactions.

Results: We were able to show that later generations of *Shank2* mutant mice still displayed a high hyperactivity in comparison with their wild-type littermates, while *Shank3*$^{-/-}$ mice displayed a reduced activity in comparison with their wild-type littermates. *Shank2*$^{-/-}$ mice lacked risk assessment behaviour when confronted with a novel object, in contrast to their wild-type littermates and to *Shank3*$^{-/-}$ mice. Home cage behaviour was minimally affected in *Shank3* mutant mice while social behaviours were significantly perturbed in *Shank2* mutant mice.

Conclusions: In conclusion, the Live Mouse Tracker system allows to describe fine behavioural specificities in mouse models of autism. Indeed, both models display abnormal locomotor activity and social behaviour, but not in the same direction. These results highlight that in mice carrying mutations in similar synaptic genes associated with ASD like *SHANK2* and *SHANK3* can impact social behaviour but with apparently different mechanisms and consequences.

37 **166.037** Altered Behavior of Prenatally Valproic Acid-Exposed Rats Group-Housed in Automated Home Cages

V. Roman[1], *P. Pelsoczi*[2], *C. Csolle*[1], *K. Kelemen*[2], *A. Varga*[1] *and G. Levay*[2], *(1)Neurodevelopmental Biology, Gedeon Richter Plc., Budapest, Hungary, (2)Cognitive Pharmacology, Gedeon Richter Plc., Budapest, Hungary*

Background: Autism spectrum disorder (ASD) is characterized by impaired socio-communicational function and repetitive/restricted behaviors. Prenatal valproic acid (VPA) administration in rodents shows several similarities to ASD symptoms (also frequently seen after fetal VPA exposure in humans), hence it is used as a preclinical disease model of ASD with high translational value.
Objectives: The aim of the present study was to characterize ASD-relevant behaviors of communities of individually identifiable rats in automated home cages without human intervention.

Methods: Ten prenatally VPA-exposed (E12.5, 300 mg/kg i.p.) and ten control (E12.5, physiological saline i.p.) Wistar rats were housed in two IntelliCages (TSE Systems, Germany). An IntelliCage unit consisted of an open communal space and four recording chambers in the corners with two drinking bottles per corner behind remotely controlled doors. Rats were individually implanted with a transponder which allowed recording visits and drinking behavior. To open the controlled doors, animals had to perform a nosepoke. The behavior of the animals and activity within the corners of the cage was monitored using a tracking software (IntelliCage Plus, TSE Systems). The principal parameters reflecting activity were number of visits to any of the four corners, initiated nosepokes, lick number, and duration of these parameters. The stay at the IntelliCages was divided into phases of 1) acclimation (unlimited drinking opportunity), 2) nosepoke learning (drinking for 7 sec allowed after a nosepoke), 3) side preference learning (limited water access with bottles evenly assigned to rats), 4) reversal learning (pseudorandom switch of the previously allowed bottle) and 5) competition (water available from only one bottle for all the rats).

Results: Although rodents normally tend to explore their new environment, the prenatally VPA-exposed rats showed a drastic impairment in initial exploratory behavior (visit without drinking). A generally reduced exploratory behavior was seen throughout the experiment which may indicate an increased level of anxiety. The circadian activity peak of the VPA group was shifted by approximately two hours during the acclimation period when water was available without restriction. The VPA group displayed excessive drinking, which could be a sign of increased repetitive behavior, since the general physiological status and blood chemistry of the VPA group did not show a significant difference compared to the vehicle group. Vehicle and VPA group did not differ in side preference or reversal learning abilities. In the competitive phase, the vehicle group switched to uneven resource distribution, where only a few dominant animals had access to water. Interestingly, they secured their chance to drink with frequent iterating visits, thereby “guarding” the water resource. VPA animals did not switch to uneven distribution, they shared the water access more evenly between each other and displayed no evidence of guarding behavior.

Conclusions: Investigating prenatally VPA-exposed rats in the IntelliCage allowed us to detect novel features of the model that further increase the translational value of the model, potentially provide a better understanding of the disorder and may facilitate ASD drug discovery.

38 **166.038** An Association between Sensory Responsiveness and Cortical GABA Concentration in Autism-Spectrum Disorder

T. Atsumi[1,2], *Y. Umesawa*[1], *M. Chakrabarty*[1], *R. Fukatsu*[1] *and M. Ide*[1], *(1)Department of Rehabilitation for Brain Functions, Research Institute of National Rehabilitation Center for Persons with Disabilities, Tokorozawa, Saitama, Japan, (2)Japan Society for the Promotion of Science, Chiyoda-ku, Tokyo, Japan*

Background: Individuals with autism spectrum disorders (ASD) often show sensory abnormalities (Marco et al., 2011). Studies have argued that an altered γ-aminobutyric acid (GABA)-mediated signaling within particular brain circuits may explain this symptom in ASD (Cellot and Cherubini, 2014). We previously found increased sensory hyper-responsiveness in ASD associates with greater temporal resolution to discriminate two successive sensory stimuli that were temporally spaced by varying intervals (Ide et al., 2017). Functional magnetic resonance imaging (fMRI) experiment revealed that neural activity in few brain regions associate with high temporal resolution of stimuli. The ventral premotor cortex (vPMC) was especially associated with the severity of sensory hyper-responsiveness (Ide et al., 2018, submitted). However, whether GABA concentration in vPMC mediates excitatory / inhibitory roles contributing to the overall severity of sensory hyper- / hypo- responsivity still remains unclear.
Objectives: We sought to determine whether sensory hyper- / hypo- responsiveness are associated with cortical GABA concentration and hypothesized that altered GABAergic signaling within the brain circuit involving vPMC induces aberrant sensory processing.

Methods: We recruited 12 typically developing participants (TD; 5 males) and 3 male ASDs. We took their responses on Adolescent / Adult Sensory Profile (AASP; Brown et al., 2001) for characterization of altered sensation. The questionnaire has four sub-scales: Low Registration and Sensation Seeking (passive and active hypo-responsiveness), Sensory Sensitivity and Sensation Avoiding (passive and active hyper-responsiveness).

We performed in vivo measurement of GABA concentration with proton magnetic resonance spectroscopy (H^1-MRS). We initially performed 3D-MPRAGE imaging for anatomical images to locate regions of interest (ROIs) in participants and then ran MEGA-PRESS sequence twice to quantify GABA: one for vPMC and another for primary visual cortex (V1) as a control region. We calculated the ratio of GABA to N-acetyl aspartate (NAA) and N-acetylaspartylglutamate (NAAG) for each ROI and used them as within subject indices for metabolite concentration.

Results: A correlation between the ratio of vPMC to V1 of GABA concentration and AASP scores showed a positive association between subjective Sensation Seeking scores and GABA concentration across all participants (r = 0.66, p < 0.01; Figure 1). The same analysis excluding the three ASDs

revealed that the GABA level positively correlated with Low Registration (r = 0.58, p = 0.05) and Sensation Seeking (r = 0.60, p = 0.04), respectively. There was no association of other scores with GABA concentration.

Conclusions: Our preliminary results comprising of TDs and ASDs suggest that a higher GABA concentration may show reduced sensitivity and behavioral reactivity to stimuli. Taken together with our earlier finding of an association between vPMC and sensory hypersensitivity, there is a possibility that atypical facilitatory / inhibitory roles played by relative GABA concentration in vPMC may result in dysfunctions of sensory processing as regards hyper- / hypo- responsiveness.

Our current, small sample size limits us from concluding unequivocally about the relationship, between GABA concentration of vPMC and sensory processing in ASD. We are measuring more number of patients to elucidate whether GABAergic neural signalling in ASD could be involved with different aspects of sensory responsiveness.

39 **166.039** Atypical Body Movements during Sleep in Young Children with Autism Spectrum Disorder

N. Naito[1], *M. Kikuchi*[2] *and Y. Minabe*[2], *(1)Psychiatry&Behavioral Science, Kanazawa University Graduate School of Medicine, Kanzawa, Japan, (2)Research Center for Child Mental Development, Kanazawa University, Kanazawa, Japan*

Background: Children with autism spectrum disorder (ASD) reportedly suffer from sleep problems at a higher rate than typically developing (TD) children. Several previous studies have reported differences in sleep indices (e.g., sleep latency) in children with ASD. However, no previous studies have focused specifically on the time course of body movements.
Objectives: We investigate the time course of body movements in young TD children and young children with ASD as well as the relationship between body movements during sleep and social ability.

Methods: Seventeen TD children and 17 children with ASD participated in this study (5 to 8 years old). We used an accelerometer attached to the waist to record movements during sleep and measured the average time course of body movements for 3 nights.

Results: Our results demonstrated that the rate of body movement 2 to 3 hours after sleep onset was higher in children with ASD than in TD children. In addition, the higher rate of body movement at 0.5 to 1 hour after sleep onset was associated with a lower social ability in the children with ASD.

Conclusions: Our results suggested that the time course of body movements is an objective behavioural index for young children with ASD.

40 **166.040** Atypical Perception in Autism: Characterizing Inference in Basic Perceptual Processing

ABSTRACT WITHDRAWN

Background: Perceptual atypicalities are a widely acknowledged but poorly understood feature of autism. Prevailing models, formulized in Bayesian terms, suggest that reduced top-down influences underlie atypicalities in perception. Within this framework, changes in bottom-up factors, if they exist at all, are considered *quantitative*, mostly involving changes in noise levels. Thus, testing has been generally limited to examining top-down factors without much recourse to potential underlying constraints of sensory processing.
Objectives: We have recently demonstrated violation of Weber's law in autism, in the visual and tactic modalities, suggesting a modality-independent mechanism of abnormal stimulus encoding. Specifically, JNDs in individuals with ASD are not scaled with intensities, indicating deficits in the low-level calibration mechanism. Here, we examined whether this modulated mechanism of stimulus encoding is associated with the reduced effects of priors (e.g., anchoring, range effects). The typical pattern of increased biases for noisier measurements may not be evident in autism, where scalar variability (Weber ratio) does not seem to hold.

Methods: In *Experiment 1*, we extended our recent findings by demonstrating the violation of Weber's law in autism also in the auditory domain, while manipulating the effect of perceptual anchoring. We examined discrimination thresholds for empty tones intervals using three standards duration. JNDs were compared between the different duration and between two conditions: (1) blocked presentation, in which an anchoring is created for each standard (2) random presentation, in which anchoring is weaker. *Experiment 2*, was design to directly examine the relationship between the precision of the sensory input and the utilization of priors. The height-width illusion was used to manipulate perceptual bias (i.e., higher rectangles are perceived narrower than lower ones), and level of contour blurriness (i.e., precision of the measurement). Greater biases were expected in neurotypicals (TD) for the noisier measurements.

Preliminary Results: In *Experiment 1*, 17/17 of our TD showed the expected increase of JNDs with increasing duration, and the effect of anchoring, resulting in higher JNDs for random presentation. Interestingly, 4/7 of our ASD did not show any scaling of JNDs with magnitude but a sub-group of 3/7 showed adherence to Weber's law. Perceptual anchoring was smaller in this group and did not increase with duration to the same extent as in TD. *Experiment 2* demonstrated substantial increase in the amount of the height-width illusion as a function of blurriness for TD, while ASD tended to show the illusion only when the input became noisier, and JNDs did not scaled with the increase in blurriness.

Conclusions: We replicated the violation of Weber's law in the auditory modality (but only for a sub-group of our ASD participants), and demonstrated that individuals with autism exhibit utilization of priors under certain conditions. Clear susceptibility to perceptual illusions is seen in ASD; however, when precision in the sensory input is high, the otherwise mandatory prior effects do not bias perception.

41 **166.041** Reduced Fronto-Temporal Coherence during Speech Production in Fragile-X Syndrome

L. M. Schmitt[1], *J. Wang*[2], *N. Friedman*[1], *E. Pedapati*[3], *A. J. Thurman*[4], *L. Abbeduto*[4], *C. A. Erickson*[3] *and J. A. Sweeney*[5], *(1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Zhejiang Normal University, Jinhua, Zhejiang Province, China, (3)Division of Child and Adolescent Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)M.I.N.D. Institute, UC Davis, Sacramento, CA, (5)Psychiatry, University of Cincinnati, Cincinnati, OH*

Background: Fragile X Syndrome (FXS) is the most common inherited intellectual disability and monogenic cause of autism spectrum disorder (ASD). Expressive language deficits are nearly ubiquitous among individuals with FXS, but our understanding of the neurological bases for these deficits remains limited. Speech production depends on feedforward control and the synchronization of neural oscillations between speech-related areas of left inferior frontal gyrus (IFG) and auditory cortex in left superior temporal gyrus (STG). Fronto-temporal coherence prior to

vocalization is thought to reflect the corollary discharge of intended speech generated from an efference copy of the speech command against which the actual speech sound is compared. This process reduces the neural response to self-generated speech ("N1 suppression") and is critical for making adjustments for future speech.

Objectives: Using the Talk/Listen paradigm during EEG recordings, we aimed to determine whether alterations in coherence between left frontal and temporal cortices prior to speech production are present in individuals with FXS and relate to language dysfunction.

Methods: Twenty-one right-handed participants with full-mutation FXS (8 female, aged 7-55 years old) and 20 healthy controls (HC; matched on age, sex, and handedness) completed the Talk/Listen paradigm during continuous EEG recording using the 132-channel EGI system. During the Talk condition, participants repeatedly pronounced short vocalizations of the phoneme "ah" every 1-2 seconds for a total of 180 seconds. Vocalizations were recorded using a microphone and transmitted back to the participants in real-time. During the Listening condition, participants passively listened to their recordings from the Talk condition. We compared pre-speech ERP activity, N1 suppression, P2 amplitude, single trial gamma power, and fronto-temporal coherence between groups and in relation to performance during a naturalistic expressive language task (narrating a wordless picture book).

Results: Prior to speech production, FXS participants showed reduced pre-speech activity in left IFG and reduced coherent activity between left frontal and temporal cortices as well as greater background gamma activity compared to controls. Though N1 suppression was similar between groups, N1 suppression was associated with greater coherence during talking in HC. In contrast, P2 amplitude was associated with N1 amplitude and fronto-temporal coherence during talking in FXS. Reduced N1 suppression and fronto-temporal coherence and increased gamma activity prior to speech production were related to greater reductions in narrative measures of talkativeness, intelligibility, and lexical complexity in FXS patients.

Conclusions: Our findings indicate that the coordination of pre-speech activity between left frontal and temporal that reflects the transmission of an efference copy of the intended speech sound to auditory cortex is disrupted in FXS. Intact N1 suppression suggests individuals with FXS are able to send a sufficient corollary discharge to auditory cortex to signal impending speech production, but that the signal may be degraded and contain less precise information about intended speech sounds based on its association with the perceptual response to self-generated speech (P2). This degradation and diminished perceptual response may interfere with feedforward processes necessary for making adjustments for future speech, ultimately impacting the overall complexity and intelligibility of speech productions.

42 **166.042** Effects of Sensory Distractors on Interoceptive Processing in ASD

A. Zoltowski[1], *S. L. Davis*[2], *M. D. Failla*[3], *L. E. Mash*[4,5], *B. H. Heflin*[6] *and C. J. Cascio*[7], *(1)Vanderbilt University, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Psychiatry, Vanderbilt University, Nashville, TN, (4)Brain Development Imaging Laboratories, Department of Psychology, San Diego State University, San Diego, CA, (5)Joint Doctoral Program in Clinical Psychology, SDSU / UC San Diego, San Diego, CA, (6)Florida International University, Miami, FL, (7)Vanderbilt University School of Medicine, Nashville, TN*

Background: Our sense of our body's internal signals ("interoception") influences our emotional states, so it is a parsimonious target of study to understand both sensory and emotional processing in autism spectrum disorders (ASD). There is emerging evidence that individuals with ASD show nuanced strengths and weaknesses in this sensory system compared to typical development (TD), and these nuances have been linked to emotional outcomes such as anxiety. However, the few studies of this sensory system in ASD so far have mostly considered interoception in isolation from other senses. This study aims to investigate the extent to which individuals attend to interoceptive cues in the presence of competing, external sensory information, as we are always processing our internal signals in the context of ongoing sights, sounds, or touch. Though individuals with ASD are generally more distracted by competing sensory information, prior data from our lab looking at heartbeat counting over different temporal intervals suggests that individuals' with ASD may show more "sticky" attention to their internal signals (Schauder et al., 2015).

Objectives: The objective of this study was to investigate how a competing tactile signal affects the ability to perceive one's heartbeat, compared in ASD versus TD.

Methods: N=45 participants (ASD: N=23, ages 8-43, TD: N=22, ages 6-53) completed a heartbeat counting task across each of four temporal intervals (25s, 35s, 45s, and 100s). Participants completed one block with distracting, 25 Hz vibrations of either "low" or "high" amplitude (randomized by participant) applied to their finger via a device, plus one block without any vibrotactile input. Reported number of heartbeats was compared to actual heartbeats, measured with a pulse oximeter. Accuracy data was analyzed with a mixed effects model predicting accuracy by distractor level per diagnostic group, including covariates of age by diagnosis (as in Mash et al., 2017) and IQ.

Results: The TD group showed resilience in performance across lengths and distractor levels (all coefficients n.s.). Qualitatively, the group showed a slight performance decrement in the high distractor condition (t=-0.39), consistent with the expected difficulty of this condition. Conversely, the ASD group showed a trend of worse performance in the low distractor condition (t=-1.90, p=0.058) but relatively better performance in the high distractor condition, compared to low. The results suggest a preliminary difference in the level of distractor to which the ASD group is most susceptible to distraction, compared to TD.

Conclusions: While this pattern of results is inconsistent with an overall group difference in tracking internal signals when distracted by other cues, they do suggest that the level that is most distracting may be different in ASD versus TD. The ASD group showed the greatest performance decrement in response to the low tactile distractor, whereas the TD group only showed somewhat of a decrement in response to the high tactile distractor. While this effect requires follow-up to confirm, future work will also consider the timing of low versus high pulses relative to the individual's heartbeat, as the timing of multisensory inputs crucially affects their integration versus competition.

43 **166.043** Effects of the Co-Occurrence of Anxiety and Attention-Deficit/Hyperactivity Disorder on Intrinsic Functional Network Centrality Among Children with Autism Spectrum Disorder

B. Wan[1], *Z. Wang*[1], *M. Jung*[2], *Y. Lu*[3], *H. He*[3], *Q. Chen*[1] *and Y. Jin*[1], *(1)Sun Yat-sen University, Guangzhou, China, (2)University of Fukui, Yosidagunn, Japan, (3)Sun Yat-sen University Cancer Center, Guangzhou, China*

Background: Children with autism spectrum disorder (ASD) present with a high co-occurrence of anxiety and attention-deficit/hyperactivity disorder (ADHD). However, it remains unclear whether the co-occurrence of anxiety and ADHD in children with ASD alters whole-brain functional networks.

Objectives: Here, we aimed to examine anxiety- and ADHD-related brain network centrality in children with ASD separately and their relationships with ASD symptoms.

Methods: We assessed clinical anxiety and ADHD levels in children with ASD, aged 6 to 13 years old. Participants were categorized into four groups: ASD only, ASD+anxiety, ASD+ADHD, and ASD+both anxiety and ADHD. Autism Diagnostic Interview-Revised (ADI-R) was used to measure ASD symptoms in four specific domains: social, verbal, nonverbal, and restricted repetitive behaviors (RRB). Subsequently, we compared voxel-wise network degree centrality (DC) among the four groups.

Results: We found seven significant clusters in the main effect test and they were centered on the left middle temporal gyrus (MTG), the right lingual gyrus (LG), the left occipital lobe (OL)/cuneus, the left middle occipital gyrus (MOG), the right sub-gyral/extra-nuclear/carcarine, the right precuneus, and the left superior frontal gyrus (SFG). Least significant difference (LSD) post hoc comparisons revealed that, compared with ASD only, ASD+ADHD and ASD+both showed higher DC level in the right calcarine, and ASD+anxiety showed no significant difference. Moreover, a similar pattern was observed in the left superior frontal gyrus (SFG). The DC level of the right calcarine was positively correlated with ADI-R nonverbal scores, while the left SFG was negatively correlated with ADI-R social scores.

Conclusions: Our findings suggest that the right calcarine and left SFG act as important nodes in the co-occurrence of anxiety and ADHD among children with ASD. Our works shed light on the brain mechanisms underlying behavioral changes related to the co-occurrence of anxiety and ADHD in children with ASD.

44 **166.044** Examining Executive Functioning in Adolescents and Young Adults with Autism Spectrum Disorder Using the Nih Toolbox

R. M. Geddert[1], *V. P. Reinhardt*[1], *M. K. Krug*[1], *T. A. Niendam*[2], *D. L. Hessl*[1] *and M. Solomon*[1], *(1)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (2)Imaging Research Center, Sacramento, CA*

Background:

Adolescents with autism spectrum disorder (ASD) often exhibit impairments in executive functioning (EF; Hill, 2004; Ozonoff et al., 2004, Solomon et al., 2017). However, previous work reporting these deficits has been inconsistent, and it remains unclear in which specific cognitive domains deficits exist. Furthermore, little is known about how the cognitive profiles of those with ASD change over time, particularly in the transition from adolescence into early adulthood, as well as the impact of EF impairments on pivotal outcomes, including adaptive functioning.

Objectives:

1) To characterize the EF profiles of adolescents and young adults with ASD and typical development (TD) in a large IQ-matched sample using well-validated measures of cognition and 2) to examine associations between EF profiles and adaptive outcomes.

Methods:

Participants were 66 youth with TD and 66 age, gender and FSIQ matched individuals with ASD (ages 12 – 22), who were qualified using gold standard ASD diagnostic measures (Figure 1). Participants completed the NIH Toolbox Cognition Battery (NTCB), a well validated suite of computer tasks consisting of measures of fluid intelligence, including cognitive flexibility (Dimensional Change Card Sorting; DCCS), inhibitory control (Flanker), episodic memory (Picture Sequence Memory; PSM), list-sorting working memory (LSWM), and processing speed (Pattern Comparison Processing Speed; PCPS), as well as crystallized intelligence, including picture vocabulary (PV) and oral reading (ORT; Akshoomoff et al., 2014). Participants also completed an updated version of the Global Social Global Role (GSGR), a clinician-administered assessment of social competence and engagement in age-appropriate roles (Cornblatt et al. 2007).

Results:

The ASD group performed significantly worse on Flanker, DCCS, and PCPS ($p < .001$, all $BF_{10} > 9000$). Participants with ASD also performed worse on PSM ($p = .018$), but evidence was insubstantial ($BF_{10} < 2$) and differences were not observed in LSWM. There were no differences in measures of crystallized intelligence (Figure 2). These findings generalized to the composites, with significant differences in fluid ($p < .001$) but not crystallized composite scores. Stepwise discriminant function analysis was used to examine the combination of NTCB measures that best predicted diagnosis. The extracted function consisted of PCPS and DCCS, and accounted for 34% of the variance in each group's cognitive performance (Wilks $\lambda = .757$; Chi-square = 35.048, df = 2, $p < .001$). Additionally, higher fluid intelligence composite scores were positively associated with GSGR social functioning in ASD ($r_s = .29$, $p < .05$).

Conclusions:

Compared to a well IQ-matched TD sample, adolescents and young adults with ASD exhibited specific weaknesses in measures of fluid intelligence, specifically processing speed, cognitive flexibility, and inhibitory control. Furthermore, EF was positively associated with higher social competence, suggesting that the social impairments observed in ASD may be exacerbated or driven by EF impairments. Finally, discriminant function analysis suggests that reduced cognitive flexibility and processing speed may uniquely contribute to the cognitive profiles of individuals with ASD. These results further our understanding of the cognitive profiles of ASD and their influence on the adaptive outcomes observed in adolescence and early adulthood.

45 **166.045** PAIN Peception in Adults with High Functioning Autism Spectrum Disorder: Subjective Vs. Objective Measures

T. Bar-Shalita[1], *Y. Granovsky*[2], *T. Hoffman*[3], *Y. Dori*[3], *E. Gal*[3] *and I. Weissman-Fogel*[3], *(1)Occupational Therapy, Tel Aviv University, Tel Aviv, Israel, (2)Department of Neurology, Rambam Health Care Campus and the Laboratory of Clinical Neurophysiology, Faculty of Medicine, Technion, Haifa Israel, Haifa, Israel, (3)University of Haifa, Haifa, Israel*

Background:

Pain research in autism spectrum disorder (ASD) is scarce, with limited methodology, resulting in a paucity of knowledge comprising conflicting findings on the pain sensitivity profile of individuals with ASD. Overall neural hyper-responsiveness that underpins the ASD pathology is one of the manifestations of the excitatory/inhibitory (E/I) imbalance, which may also account for pain hyper-sensitivity. Yet, difficulties in

communicating socially appropriate responses to pain may cause underestimated judgment of pain by selves or others, and indeed pain hypo-sensitivity is suggested to characterize individuals with ASD.

Objectives:

To explore the pain sensitivity profile in individuals with ASD using both subjective (i.e. self-report) and objective (i.e. cortical event-related potentials) responses to experimental pain stimuli. Specifically, to investigate whether the two measures differ (i) in people with ASD compared to typically developed controls, and (ii) in the within group correlations between subjective and objective measures.

Methods:

This study included 24 high functioning individuals diagnosed with ASD based on the ADOS-2, and 24 healthy controls (CTRL), aged mean (SD): 28 (11); 26 (4); (p>0.05), respectively, with verbal performance and full-scale estimate of 80 and above on the IQ Wechsler Abbreviated Scale of Intelligence® - Second Edition (WASI®-II). Psychophysical testing comprised of phasic noxious heat stimuli that were delivered to the dominant volar forearm (572.5mm^2 thermode, PATHWAY system, MEDOC, Ramat Yishai, Israel) at 49°C, and 52°C, using a stimuli train of 20 repetitions (ISIs of 8 to 12 sec.) for each intensity. Pain ratings were obtained after each stimulus using a 0-100 numerical pain scale (NPS). Contact heat-evoked potentials (CHEPs) were recorded simultaneously and the N2 and P2 amplitudes, considered an objective tool for assessment of central pain transmitting pathways and pain quantification, was extracted for each participant.

Results:

Increase pain ratings in-line with temperature rise were found in both groups. Groups differed across the 2 temperature trains of stimuli. The ASD group reported lower NPS ratings in comparison to controls [CTRL *vs.* ASD: Mean (SD); 49°C: 37.59 (22.25) *vs.* 26.15 (18.98); p=0.05 , 52°C: 52.88 (25.63) *vs.* 34.97 (23.29); p=0.01]. In contrast, greater N2-P2 amplitude (μV), at Cz location in response to 52°C stimuli, was found in ASD *vs.* the control group [CTRL *vs.* ASD; Mean (SD); 29.98 (16.93) *vs.* 40.24 (14.15); p=0.01]. Moreover, an interaction was found between group X pain ratings on P2 amplitude (p=0.03); while controls demonstrated a significant association between pain ratings and P2 amplitude (r= 0.66; p=0.05), the ASD group did not (r=0.20; p=0.48).

Conclusions:

This is the first study exploring self-report pain ratings and evoked potentials during experimental heat pain stimuli. Our exploratory findings point at a mismatch between the individual's subjective pain reports and the neurophysiological responses. While behaviorally individuals with ASD demonstrate pain hypo-sensitivity, the brain responses imply neural hyper-responsiveness. This finding confirms our hypothesis that E/I imbalance may also shape the pain processing in ASD.

46 **166.046** Predicting ASD Severity from Stereotypies Complexity Patterns through an Innovative Machine Learning System: A Proof of Concept Study.

E. Grossi, *E. Caminada, F. Vanzulli, B. Vescovo and E. Alfiedi, Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy*

Background: Stereotypies, despite their high frequency and strong diagnostic significance within autism, have not yet been fully elucidated due to their broad spectrum of presentation and pattern complexity. The VICTORY project (A Video Catalogue from Observational Retrospective Study on Stereotypies) a cross-sectional cohort study assessing presentation patterns, clinical Severity, and extinction modalities of stereotypies in autism, offers a new possibility to relate the complexity of stereotypies presentation to autism severity.
Objectives: The aim of this study is to assess the feasibility of predicting ASD severity in individual subjects from stereotypies patterns using innovative machine learning systems. This possibility would also enable further understanding as to which factors are significantly involved.

Methods: Twenty expert caregivers wearing a body cam recorded specific stereotypic behavior in a natural context during the everyday activities of 67 autistic subjects for 3 months of close follow-up. After a few minutes of recording, the possibility to interrupt their behavior by intervening physically to divert attention was recorded. A team consisting of one senior child neuro-psychiatrist together with a senior psychologist reviewed all the video recordings (1868) selecting 780 of them as the most meaningful to summarize the whole spectrum in each individual within the given time window. Each video was classified according to components (motor, sensorial, vocal, intellective), complexity (2 classes, simple and complex), body parts involved, sensory channels involved (hearing, sight, proprioception, taste, pain, smell), extinction modality and basic demographic features. Ninety-two variables were used to represent the input for preprocessing. The existence of a poor linear correlation among features of stereotypies patterns and ADOS score prompted us to use a machine learning system approach. An evolutionary algorithm (a TWIST system based on the KNN algorithm) was used to subdivide the dataset into training and testing sets as well as to select features yielding the maximum amount of information. After this pre-processing, 19 input variables were selected and different machine learning systems were used to develop a predictive model based on a training testing crossover procedure able to distinguish subject with an ADOS total score ranging from 8 to 20 from those with an ADOS total score ranging from 22 to 28.

Results: Acting on these inputs, the best supervised machine learning system(MLS) obtained a global accuracy of 84.96% (85.12 % - sensitivity and 84.79 % -specificity) in predicting the ADOS score class. Most of the stereotypies features selected by the algorithm were complex, with 2 or 3 different components in the same pattern among motor, sensorial, intellectual and vocal. A semantic connectivity map based on fourth generation unsupervised MLS depicted the association among high severity ADOS class with stereotypies made-up of 3 different components.

Conclusions: Machine-learning systems show a promising potential in highlighting the complex relationship between stereotypies patterns and ASD severity .

47 **166.047** Direct Assessment of Aggressive Behavior in Low Functioning Autism: A Cohort Observational Study.

E. Grossi, *S. Cattaldo and C. Colognesi, Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy*

Background: Aggressive behavior (AB) refers to directed acts of aggression that can potentially harm, or already have harmed others, themselves or destroyed property. Parents frequently report that aggression in their child is more distressing than poor adaptive skills. Most studies on this topic rely on the use of specific scales like the Children's Scale for Hostility and Aggression.
Objectives: The aim of the study is to quantify the expression of AB in a cohort of subjects with ASD admitted to a Rehabilitation Institute by means of direct careful observation of their behavior for 28 consecutive days. To our knowledge, this is the first study to explore directly observed

AB and to correlate its intensity with autism severity.

Methods: Twenty consecutive children and adolescents (mean age 15.15 yrs; range: 5-19; 19 males) with autism, admitted to our Institute took part to this observational study. The ASD subjects were diagnosed according to the DSM V criteria, then confirmed through ADOS 2. Ten expert female educators continuously monitored the subjects for 28 consecutive days recording the occurrence of the following AB: aggression of peers or educators by punching, kicking, boosts, biting, spitting, scratching; or self-inflicted injury with bites, scratches, punches to body or to head. The total sum of aggression and self-inflicted injury acts during the four weeks were taken as biomarkers of AB in the specific subject. These values were correlated with the ADOS total score and with the number of stereotypies patterns, derived from a video catalogue developed for a parallel specific study.

Results:

Five out of 20 subjects (mean age 14.8) showed zero aggression acts during the study period. Their mean ADOS score was 21.2. Fifteen subjects showed from 2 to 31 acts of aggression (mean= 7.46) during the study period. Their mean ADOS score was 19.06. Eleven out of twenty subjects showed zero self-injury acts during the study period. Their mean ADOS score was 18.09. Nine subjects showed from 1 to 37 acts of self-injury (mean = 13.22) during the study period. Their mean ADOS score was 21.44.The Pearson correlation index between the four-week number of aggression acts and ADOS scores and between four-week number of self-injury acts and ADOS scores resulted in 0.06 (NS) and 0.80 (p =0.009) respectively. In the same subgroups, the Pearson correlation index between the total number of aggression acts and the number of stereotypies patterns, and between the total number of self-injury acts and number of stereotypies patterns resulted in -0.24 (NS) and 0.74 (P = 0.001) respectively.

Conclusions: Our pilot study suggest that while self-injury behavior is highly correlated to Autism severity and stereotypies intensity, aggression per se is not at all correlated to both autism severity and stereotypies intensity. Future studies with direct observation on larger samples are needed to explain the nature of this difference.

48 **166.048** Subgrouping of Resting-State Limbic System Connectivity in Co-Occurring Autism and Social Anxiety Disorder

M. Coffman[1]*, L. Antezana*[2]*, A. Kirkpatrick*[1]*, C. Brown*[1]*, M. Maurin*[1]*, J. Voyack*[1] *and J. A. Richey*[1]*, (1)Virginia Tech, Blacksburg, VA, (2)Virginia Polytechnic Institute and State University, Blacksburg, VA*

Background:

Anxiety disorders occur in 42-85% of individuals with an ASD (Joshi et al., 2013). The limbic system (LS) is associated with the regulation of fear (Anad et. al 2005) and previous work has found that LS connectivity at rest correlates with anxiety (Mucci et. al, 2018). Social anxiety disorder (SAD), which is characterized by social fears, has been associated with hyperconnectivity of LS-related regions (Arnold et. al, 2014). Considering the high comorbidity of SAD in ASD, understanding heterogeneity in LS connectivity may elucidate pathways for tailored treatment and response. However, no studies have examined LS connectivity transdiagnostically, including individuals with comorbid Autism Spectrum Disorder (ASD+SAD), Moreover, it is not known whether individuals with ASD+SAD show similar patterns of connectivity in the LS compared to those without ASD.

Objectives:

To elucidate heterogeneous patterns of LS connectivity across adolescents with varying degrees of social impairment. Specifically, we used a graph theory approach, Group Iterative Multiple Model Estimation (GIMME) with community detection on fMRI resting state data to examine whether LS connectivity can robustly differentiate SAD, ASD+SAD, and controls (CON). Secondary analyses examine the relationship between the LS and measures of autism severity and social anxiety symptoms. We predicted that LS subgroups will emerge such that scores on measures of ASD and SAD severity will be distinct among diagnostic classifications.

Methods:

Adolescents with ASD+SAD, SAD only, and CON participated in this study (20 per group; N=60). Participants were matched on age (M=15.19) and FSIQ (M=108.38). Diagnoses were confirmed with semi-structured clinical interviews. fMRI data were collected on a 3T TIMTrio. Functional regions of the LS were identified via Neurosynth (Yarkoni, 2011) and included: bilateral amygdala, thalamus, anterior cingulate cortex, and bilateral orbitalfrontal cortex. GIMME was used with resting-state data from each subject. Subsequently, a community detection algorithm was used to identify subgroups characterized by LS connectivity patterns (Gates et al., 2014). Autism severity was measured via self-report on the Social Responsiveness Scale (SRS-2). Social anxiety was measured via self-report with the Leibowitz Social Anxiety Scale-Child Adolescent (LSAS-CA).

Results:

Analyses revealed two distinct subgroups based on LS functioning (Fig. 1). Group one represents a hyperconnected group, whereas Group 2 displayed hypoconnectivity among the LS. Additional analyses revealed no relationship between autism severity and social anxiety symptoms between the two groups (*ps*>.05; Table 1).

Conclusions:

The data did not support the hypothesis that self-reported ASD or SAD symptoms are related to distinct neural signatures. Findings indicate the development of the LS may not be related specifically to clinical symptoms or diagnostic classification. Rather, results indicate that although symptom expression may be consistent, underlying neural connectivity in the LS connectivity may better explain heterogeneity. This finding holds importance for the development individualized, and neuroscience-informed interventions.

49 **166.049** The Default Mode Network in Autism Spectrum Disorders and Attention Deficit Hyperactivity Disorder

ABSTRACT WITHDRAWN

Background:

Autism Spectrum Disorders (ASD) and Attention Deficit Hyperactivity Disorder (ADHD) are neurodevelopmental disorders with overlapping phenotypic symptomatology and shared genetic makeup. Previous studies have investigated ASD and ADHD using resting state functional magnetic resonance imaging (rfMRI). One particular functional network of interest is the Default Mode Network (DMN) as it has been implicated in several mental disorders. ASD studies have reported mixed trends of increased and decreased functional connectivity (FC) in the DMN, whereas ADHD studies have reported increased FC.

Objectives:

Previous studies have investigated DMN alterations in ASD and ADHD separately, considering these two disorders as unique clinical conditions. Current research has done little work to address NIH's recent Research Domain Criteria (RDoC) that mental disorders may lie on a continuum. To better understand shared characteristics between ASD and ADHD, this study analyzed the DMN FC in both ASD and ADHD children. ADHD-Combined (ADHD-C) and ADHD-Inattentive (ADHD-I) subtypes were also investigated.

Methods:

Archival datasets from Autism Brain Imaging Data Exchange (ABIDE)-I and ADHD-200 datasets were used, with 33 ADHD, 35 ASD, and 32 typically developing (TD) males (ages = 7–17 years) used in the study. The Data Processing Assistant for RfMRI Advanced Edition (DPARSF-A, Version 4.3_171210) as well as comparisons between global signal regression (GSR) versus no GSR were used. 11 regions of interest (ROIs) from the Dosenbach-160 (DOS-160) atlas related to executive functioning (EF) and attentional network regions were investigated due to deficits in EF and attentional networks noted in existing ASD and ADHD literature. Effects of demographic covariates and motion (age, IQ, group, meanFD) on average FC and individual ROI pairs were also studied using general linear models (GLMs).

Results:

FC correlations were compared across the ASD, ADHD, and TD groups with three comparisons: ADHD-TD, ASD-TD, and ADHD-ASD. Average and individual DMN connectivity across the 11 ROIs were also calculated. Increased positive correlations were seen post GSR in ADHD-TD comparisons, with positive correlations between the inferior temporal cortex (inf-temp) and the anterior cingulate cortex (ACC) *($p<0.05$)*. Positive correlations between the mPFC and vlPFC were also present after applying GSR ($p < 0.05$). Finally, ASD-TD t-test results showed decreased negative correlations after applying GSR, with only one negative correlation between the ACC and occipital DMN regions. After plotting correlational trends pre and post GSR, ADHD-C subtype and ASD groups presented similar patterns of average DMN FC, whereas ADHD-C and ADHD-I subtypes showed opposing trends of average DMN FC. Individual FC between the 11 DMN ROI pairs showed that negative correlations increased for ADHD-ASD between ROIs, such as vlPFC and sup-front*($p<0.05$)* in the GLM with age, VIQ, and group after running GSR.

Conclusions:

These results confirmed our RDoC based hypothesis that ASD and ADHD share similar negative correlational patterns in DMN related ROIs. This lays the framework for investigating additional overlapping brain-behavior deficits in executive functioning and attentional network regions in the DMN. However, additional brain-behavioral analysis, as well as a larger sample size comparing ASD, ADHD, and TD groups is warranted.

50 **166.050** The Interaction of Cue Modality and Response Type: Audiovisual Integration Advantage or Visuomotor Disadvantage?

J. C. Sutton[1], I. Naiman[2], C. M. Peters[1], A. Waddell[1], M. J. Brown[1] and ***C. M. Glazebrook****[3], (1)University of Manitoba, Winnipeg, MB, Canada, (2)University of Toronto, Toronto, ON, Canada, (3)University of Manitoba, Winnipeg, MB, CANADA*

Background: Movement, coordination and multisensory integration are important components for communication and social interactions. There are known differences in the development of perception, communication and motor control in individuals with autism. However, there is little understanding as to how movement complexity and multisensory integration interact, and how the characteristics of a movement relate to communication skills in individuals with autism. Previous research has shown that young adults respond more quickly to visual versus auditory cues when performing eyes-only, key-press, and reach-to-point motor responses.
Objectives: The present study investigated if individuals with autism use similar movement control strategies when completing a multisensory-motor integration task. We predicted that integrating auditory information would be more challenging, leading to a larger difference between visual and auditory conditions.

Methods: Ten young adults with autism (Mean age 26.5years; 8 male/2 female; 10 right-handed) sat at a touchscreen monitor and EyeLink 1000plus gaze-tracker (500Hz). Participants were shown two potential visual targets (2degrees of visual angle; 16.5degrees from central fixation), and a subsequent central visual or auditory cue that identified the correct target. Participants responded either with: eyes-only, key-press, or a reach-to-point motor response. The two cue types and three response conditions were blocked and counter-balanced. Reaction time (RT) and movement time (MT) were collected using Experiment Builder (SR Research). Participants also completed the Broad Autism Phenotype Questionnaire, Raven's Progressive Matrices, and the Peabody Picture Vocabulary Test to assess the effect of perceived social communication skills, pattern recognition, and vocabulary on movement and coordination, respectively.

Results: Saccade RT did not vary based on modality or condition. There was a significant effect of condition on Saccade MT with longer MT in the reach-to-point condition compared to the key-press condition, suggesting that additional time is required for the saccade when the task is more complex. There was a significant main effect of condition for Hand RT in which the reach-to-point condition had a significantly shorter hand RT than the key-press condition. Consistent with TD adults, movement planning, but not execution, was significantly influenced by knowledge of the limb. The reach-to-point condition also had significantly more trial-to-trial variability than the eyes-only and key-press conditions in Saccade RT and MT, and Hand RT, suggesting increased performance variability with an increase in task complexity.

Conclusions: When compared to previous research, adults with autism used similar movement strategies related to the three movement conditions. However, the overall advantage of visual cues for temporal measures of motor performance was not seen. The present results are consistent with evidence that visual-motor integration is more challenging for individuals with autism.

51 **166.051** The Relation between Social Functioning and Executive Control in Preschool-Aged Children with and without ASD

G. A. MacNaughton*[1], A. M. Cremone-Caira[2] and S. Faja[3], (1)Boston Children's Hospital: Labs of Cognitive Neuroscience, Boston, MA, (2)Boston Children's Hospital Labs of Cognitive Neuroscience, Boston, MA, (3)Boston Children's Hospital, Boston, MA*

Background: A hallmark of ASD is reduced social functioning. Additionally, impaired executive control (EC), the ability to manage higher-order cognitive functions that underlie goal-directed behaviors, has been identified in many children with ASD. Research suggests that EC is needed for proper development of social functioning. Given that EC and social functioning are impaired in ASD, it is important to examine the relation between these two constructs in this population.
Objectives: To examine relations between EC and social functioning in preschool-aged children (two and four year-olds) with and without ASD.

Methods: As part of an ongoing study, two and four year-olds with ASD (n=21) and typically developing controls (TD; n=21) completed tasks that measured EC and social functioning. In line with previous research, performance on a Joint Attention task (Miller & Marcovich, 2015), which consisted of gaze following, object spectacle, and book presentation tests, measured social functioning. The total instances of initiating joint attention (IJA) was the primary outcome. Additionally, lower-level joint attention behaviors were measured: Total instances of responding to joint attention (RJA) and initiating behavioral requests (IBR). Consistent with previous studies, performance on two looking tasks (A-not-B; Bell & Adams, 1999 and A-not-B with invisible displacement (ID); Morasch & Bell, 2011) measured EC. The total number of correct reversals summed across these tasks was used as the primary outcome to measure inhibitory control of the prepotent response, a critical component of EC. Higher scores indicated better performance for both tasks.

Results: The results of an ANCOVA, controlling for age and IQ, indicated that IJA did not differ significantly between groups (p>.05). Although IQ had a significant effect (F(1,36)=5.76, p=.022), age did not (p>.05). For total correct reversals, age (F(1,38)=19.56, p<.001) but not IQ (p>.05) had a significant effect and groups differed significantly (F(1,38)=4.55, p=.039; ASD worse than TD), above and beyond age and IQ. Finally, within-group partial correlations, controlling for age and IQ, showed a significant, moderate positive correlation between IJA and total correct reversals (r=.488, p=.047) among children with ASD. No significant correlation was found between IJA and total correct reversals for the TD group (p>.05). Further, no significant correlations were found between total correct reversals and RJA nor IBR within either diagnostic group (p's>.05).

Conclusions: The results from these analyses suggest that there is a significant relationship between social functioning and EC in preschool-aged children with ASD. Children with ASD who had more instances of IJA performed better on a task measuring inhibitory control. These findings are notable given the link between EC and successful social functioning. However, while *all* children with ASD are socially impaired, the degree to which this population experiences executive dysfunction likely varies greatly between individuals. This heterogeneric presentation is important when building a behavioral profile of children with ASD to guide treatment-related decisions. Higher-powered, future analyses will continue to examine the individual behavioral differences among ASD children over time.

52 **167.052** Autism-Associated Variants of Syntaxin Binding Protein 5 (STXBP5) Disrupt Dendritic Morphology Via the Regulation of Rho Signaling

***W. Shen**, M. Kilander, M. Bridi, S. Huang and Y. C. Lin, Hussman Institute for Autism, Baltimore, MD*

Background:
Autism is a neurological condition characterized by marked qualitative differences in communication and social interaction. Genetic studies have implicated numerous genes, including those encoding proteins important for synaptic development and function that may contribute to the diverse autism phenotypes. Deletion and mutation of syntaxin binding protein 5 (STXBP5) have been identified in individuals with autism. STXBP5 encodes the protein tomosyn which contains an N-terminal WD40 domain and a C-terminal SNARE motif. Tomosyn was first identified as a syntaxin binding protein that negatively regulates neurotransmitter release. However, tomosyn has also been shown to regulate neurite outgrowth in immature neurons via interaction with ROCK, the downstream effector of RhoA. Here we examined the mechanism by which tomosyn controls the structural stability of mature neurons and also evaluated the hypothesis that the autism-associated mutation of STXBP5/tomosyn disrupts dendritic morphology by altering the Rho signaling pathway.

Objectives: We first examined the effect of the loss of tomosyn in primary cultured neurons and investigated alterations in the Rho signaling pathway as a mechanism underlying the affected cellular phenotype. We then determined the functional domain of STXBP5/tomosyn that is responsible for regulating Rho activity. We further evaluated whether two variants of STXBP5 identified from individuals with autism resulted in the disruption of the Rho signaling pathway and compromised the structural stability of neurons.

Methods:

We used shRNA to knock down tomosyn in mouse primary hippocampal neurons and examined dendritic morphology using morphometric analysis. Miniature excitatory post-synaptic currents (mEPSC) were measured to determine the synaptic function using whole-cell patch-clamp electrophysiology. Rho activity was measured by an intramolecular Forster Resonance Energy Transfer (FRET) assay with co-expression of the RhoA biosensor. Domain deletions and autism-associated variants of STXBP5/tomosyn were engineered and the effects on Rho activity and dendritic morphology were measured using the approaches mentioned above.

Results:

Tomosyn knockdown neurons exhibited compromised dendrite arborization and reduced dendritic spine density. These neurons also showed decreased mEPSC amplitude and frequency. Increased Rho activity was identified in tomosyn knockdown neurons measured by Rho biosensor FRET. Inhibiting Rho activity with dominant negative RhoA or C3 transferase was sufficient to restore complete dendritic morphology. Neurons expressing the C-terminus of tomosyn (tomosyn-DN) showed increased Rho activity and reduction in dendrite length similar to the knockdown, suggesting the N-terminus of tomosyn is responsible for regulating Rho activity. Two STXBP5 variants (L412V and Y502C) found in individuals with autism exhibit single mutations at the N-terminal WD40 domain of tomosyn. The shRNA-resistant wildtype tomosyn, but not autism-associated variants, rescued the dendritic phenotype in tomosyn knockdown neurons.

Conclusions:

We showed that tomosyn controls dendritic morphology via regulation of Rho signaling. Two STXBP5 variants found in individuals with autism contain single mutations at the N-terminus that may contribute to cellular pathophysiology of autism by disrupting Rho regulation and the structural stability of neurons.

53 **167.053** Failure of Homeostatic Plasticity Caused By Novel Autism Gene-Genome Interactions

***O. Genc**[1], R. Fetter[2], J. Y. An[3], Y. Kulik[1], S. Sanders[3] and G. Davis[1], (1)Biochemistry, University of California, San Francisco, San Francisco, CA,*

(2)Biochemistry & Biophysics, University of California, San Francisco, San Francisco, CA, (3)Psychiatry, University of California San Francisco, San Francisco, CA

Background: Autism spectrum disorder (ASD) has a strong genetic basis and a large number of genes have been identified that confer high risk for ASD in humans. But, it remains unknown how genetic risk translates into the phenotypic severity of ASD for a given individual.
Objectives: We hypothesize that the phenotypic severity of a heterozygous de novo autism gene mutation can be altered/modified by second site, heterozygous loss of function mutations in the genetic background of an individual.

Methods: To test this hypothesis, we took advantage of Drosophila as a model system. First, we demonstrate that heterozygous ASD mutations do not impair baseline synaptic transmission or presynaptic homeostatic plasticity (PHP). Next, we systematically combined a heterozygous ASD mutations with heterozygous chromosomal deletions that uncover defined regions of the Drosophila genome. In each double-heterozygous combination, we assessed the expression of PHP by direct quantification of synaptic transmission, entailing more than one thousand intracellular recordings.

Results: We have screened two thirds of the Drosophila genome and identified 40 loci that impair homeostatic plasticity when combined with a heterozygous autism mutation. We selected five of these loci and tested each against four additional ASD genes; CHD2, CHD8, WDFY3 and ASH1L. Assaying this set of double heterozygous mutant combinations, we discovered that more than two-thirds of the double heterozygous combinations caused impaired homeostatic plasticity. This rate of homeostatic impairment is far greater than predicted by chance ($p<0.01x10-13$). RNAseq analysis of double heterozygous mutant combinations, and additional phenotypic characterization of double heterozygous mutant at the electrophysiological and ultrastructural levels will be presented.

Conclusions: We propose that impaired homeostatic plasticity could be a common pathophysiology related to the phenotypic severity of ASD caused by a rare de novo mutation in a given individual. By extension, our data may define a means by which diverse categories of ASD gene mutations could converge upon a common human phenotype.

54 **167.054** Glutamatergic Activity Is Sufficient to Drive Striatal Spine Formation and Long-Term Plasticity Induction in Cortico-Striatal Co-Cultures

N. Kuhlmann[1]*, M. Farrer*[2] *and A. Milnerwood*[3]*, (1)University of British Columbia & McGill University, Montreal, QC, Canada, (2)Medical Genetics, University of British Columbia, Vancouver, BC, Canada, (3)McGill University, Montreal Neurological Institute, Montreal, QC, Canada*

Background: Altered dendritic morphology and synaptic dysfunction are implicated in the pathophysiology of numerous neurological disorders. Clinical findings and research in genetic mouse models of autism spectrum disorder (ASD) are converging on alterations to striatal structure and function, suggesting that synaptic development and plasticity of striatal neurons may play an important role in ASD symptomatology and etiology. While the mechanisms regulating synaptic plasticity and dendritic spine development are well described at glutamatergic synapses in excitatory cortical and hippocampal neurons, less is known of how these principles translate to GABAergic striatal spiny projection neurons (SPNs), which receive glutamatergic input from cortical and thalamic neurons and form the sole output pathways to the basal ganglia.
Objectives: We sought to examine how manipulating glutamatergic activity at the cortico-striatal synapse affects spine formation and functional plasticity in SPNs. We used cortico-striatal co-cultures from wild-type male and female embryonic mice to examine the functional and structural consequences of altering the excitatory input from cortical neurons on SPNs. The aim was to develop rapid pharmacological assays that can be used in genetic mouse models, in order to study the vulnerability of striatal neurons neurological disorders such as ASD.

Methods: We examined the effects of chronic and acute action-potential silencing (by applying tetrodotoxin to the cultures), as well as the requirement for residual glutamatergic activity through AMPA and NMDA receptors, on presynaptic protein Synapsin-1 and spine/filopodia density in SPNs. To assess rapid activity-dependent plasticity, we used a 3-min glycine application in magnesium-free solution, which results in NMDAR-dependent LTP in other cell types, and measured both electrophysiological and structural outcomes. All experiments were repeated in at least 3 separate cultures, with experimenter blind to treatment condition during analysis.

Results: Chronic and medium-term silencing induced dendritic spine loss, increased filopodia density, and altered Synapsin-1 clusters in SPNs. The application of AMPA- and NMDA-type glutamate receptor antagonists prevented spine but not filopodia alterations, suggesting these are distinct processes. Glycine application was sufficient to increase spine and AMPAR subunit GluA1 cluster density and co-localization, and increased presynaptic glutamatergic release as indicated by whole-cell voltage clamp recordings.

Conclusions: These findings suggest that silencing-induced spine loss, but not filopodial proliferation, is an active process requiring residual glutamate receptor activity in SPNs. Furthermore, NMDA receptor activation in the absence of magnesium is sufficient to drive LTP-like structural and functional plasticity changes in co-cultured SPNs. Together, the data elucidate the importance of glutamate in shaping striatal structure and function even in the absence of neuromodulators such as dopamine, and how the cortico-striatal co-culture system may be useful for studying the role of striatal synapse changes in ASD.

55 **167.055** Granularity and Connectivity in Brains and Cognition: Toward an Information Processing Model of the Cognitive Styles over ASD and TD Populations

H. Kozima*, Graduate School of Education, Tohoku University, Sendai, Japan*

Background:
ASD has two diagnostic criteria: impairments of communication and restricted interests. While accompanied by disturbances of perception and/or motor coordination, most people with ASD are often good at handling objects and machines. However, we do not have a unified model that can explain these diverse characteristics. ASD models proposed so far often focus only on parts of the aspects, and a new unified model is needed for future innovative research and therapeutic practices.

Objectives:

We reconsider the phenotypical diversity of ASD from the viewpoint of "cognitive granularity" that we have been advocating, by which we consider the possibility of modeling ASD in a unified way. Cognitive granularity represents the size of semantic units (schema, basic level categories, etc.) for the agent to articulate and recognize the environment, and is involved in predicting and controlling the environment including the behavior of

others. From the accumulated facts on the behavioral characteristics and the abnormality in the brain structure, it is predicted that ASD people have finer cognitive granularity. Based on the idea, we formulate a unified cognitive model over the diverse behavioral characteristics not only of ASD but also of TD on the continuous axis of cognitive granularity.

Methods:

As evidence to support the finer cognitive granularity in ASD, Casanova reported that mini-columns in ASD brains have a higher density than that of TD. A mini-column is a columnar structure of approximately 100 neurons vertically arranged through the cortical layers; being bundled up together, mini-columns cover the entire surface of the brain, forming the cerebral cortex. Mini-columns are considered to be the smallest functional unit of the brain, whose higher density suggests that (1) ASD brains employ a larger number of mini-columns in information processing, and (2) ASD brains process information in a less integrated way because the smaller mini-columns reduce long-distance connection between them [Fig. 1].

Results:

The abnormality of granularity and connectivity in ASD brains well-explains the information processing styles of the ASD population. (1) ASD people use more mini-columns to represent the environment, suggesting that they acquire categories with finer and specific distinction, often in obsessively detailed manners. (2) ASD people have difficulties in integrating information represented by distantly distributed mini-columns, resulting in the failure of sensory integration and motor coordination as well as of perceiving gestalt and forming "central coherence".

Moreover, finer granularity in ASD also explains their difficulties in mentalizing other's behavior. With the finer cognitive granularity, a variation of human actions that share the same goal would look like arbitrary sequences of causal micro-actions without shared invariants, namely, "intentions" [Fig. 2]. This implies that "theory of mind" or "mentalization" would stem from coarser cognitive granularity that enables TD people to see the mental gestalt in other's physical behavior.

Conclusions:

We believe that cognitive granularity works as the unified model, or endophenotype, of ASD, which explains the continuum of cognitive styles over ASD and TD populations. The idea is still in a hypothetical phase; we need in-depth discussions with INSAR community.

56 **167.056** Role of IL-1b in Inflammation-Mediated Neural Circuit Formation Defects In Vivo

***C. M. Solek**, N. A. Farooqi and E. S. Ruthazer, Montreal Neurological Institute/McGill University, Montreal, QC, Canada*

Background: Neuroinflammation initiated by maternal infection during fetal development has been strongly implicated in the etiology of neurodevelopmental disorders, including autism spectrum disorders (ASD) and schizophrenia. Little is yet known about the precise mechanisms that contribute to neurodevelopmental defects caused by inflammation.

Objectives: Using the zebrafish larva as a genetically tractable model, we sought to study the effects of inflammatory insults on neurodevelopmental programs in the retinotectal system *in vivo*.

Methods: Zygotic microinjection of Brn3c:Gal4 and UAS:mYFP plasmids allowed for sparse labeling of retinal ganglion cell (RGC) axons. At 3 days post-fertilization (dpf), when RGCs enter the optic tectum, we treated the larvae with bacterial lipopolysaccharide (LPS) to induce inflammation. We imaged the cells *in vivo* by 2-photon microscopy and reconstructed the arbors for morphometric analysis. The experimenter was blinded to the condition until the analysis was completed.

Results: We show that treatment of zebrafish larvae with LPS causes an increase in RGC branching dynamics immediately after the inflammatory insult (145.4% increase in number of branches added, P = 0.0068, 119.7% increase in number of branches lost, P = 0.033, 2-way ANOVA, n = 10 LPS treated, n = 9 untreated). We also saw an increase in overall size and branch numbers in LPS treated animals over the following several days (121.9% increase in total arbor length at 6 dpf, P = 0.0075, 158% increase in total number of branches, P = 0.0077, 2-way ANOVA, n = 18 LPS treated, n = 18 untreated). mRNA levels of the pro-inflammatory cytokine IL-1b levels are increased 6.8-fold following LPS treatment (P = 0.012, K-W test, n = 7), and morpholino oligonucleotide (MO) knock-down of this cytokine negates the effects of LPS treatment. Delay of specification of the myeloid lineage, which includes microglia, by MO knockdown of the PU.1 transcription factor, eliminates the immediate effects on RGC branching dynamics (90.3% of number of branches added, P = 0.6445, 112.1% of number of branches lost, P = 0.345, 2-way ANOVA, n = 8 LPS treated, n = 7 untreated), indicating a role for microglia in the mechanisms that mediate inflammation-induced neuronal defects.

Conclusions: We have shown that inflammation during neuronal development causes immediate changes in branching dynamics and long-term morphological defects in arborization. IL-1b is a critical cytokine in this process and mediates the effects of inflammatory stimulus on neuronal growth. Microglia are also involved in mediating the immediate effects of LPS treatment on cellular dynamics. Zebrafish larvae can be genetically manipulated in large numbers, permitting rapid candidate signal screening in vivo. Our findings will inform translational studies that can help us better understand and ultimately may prevent the occurrence of neurodevelopmental disorders such as autism.

57 **167.057** Synaptic Proteins and Structure Defects in Adolescent Rats Following Prenatal Exposure to Valproic Acid

***A. Adamczyk**[1], M. Gassowska-Dobrowolska[1], M. Cieslik[1], H. Jesko[1], M. Gewartowska[2] and M. Frontczak-Baniewicz[2], (1)Department of Cellular Signalling, Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland, (2)Electron Microscopy Platform, Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland*

Background: Autism Spectrum Disorders (ASDs) are a heterogenous group of neurodevelopmental brain diseases. The number of cases is steadily increasing, currently 1 child in 100 is diagnosed with autism, while the prevalence in the U.S. is estimated to be 1 in 50 children. Their typical symptoms include impaired communication (verbal and non-verbal) as well as social interactions along with stereotyped, repetitive behaviors and restricted interests. Recent genetic studies in affected individuals with ASDs indicate the exist of the mutations in a number of genes coding proteins involved in the development and function of synapses, suggested the synapses as a possible site of autism origin. However, the cause of the defects of synaptic proteins and their roles in the pathogenesis of idiopathic autism remain obscure.

Objectives: The aim of this study was to investigate the effect of prenatal exposure to valproic acid (VPA), - rodent model of environmentally triggered ASDs - on the synaptic structure as well as the synaptic protein level in adolescent rat offspring.

Methods: Pregnant Wistar rats received a single intraperitoneal (*i.p.*) injection of VPA (400 mg/kg of body weight) on gestational day (GD) 12.5.

Controls received a single *i.p.* dose of solvent (sterile 0.9 % NaCl). On postnatal day (PND) 22 to 23, rat pups were separated. In order to study social disorders at neonatal stage, we analyzed vocalization of the offspring in response to maternal isolation in all infant rats at PND 11 and anxiety-related behavior (open field test) in adolescent male offspring (PND 40). Males offspring were decapitated at PND 52, their brains removed and cerebral cortex including hippocampus isolated. We determined the gene expression of neuroinflammatory factors, changes in levels of key pre- and postsynaptic proteins, as well as abnormalities of synaptic morphology in cerebral cortex and hippocampus.

Results: Our data showed that embryological exposure to VPA impairs early communication (lower vocalization) in neonatal and enhances anxiety-like behavior in adolescent rats. Prenatal exposure to VPA promotes pathological changes in synapses in both analyzed structures including nerve endings swelling, blurred and thickened synaptic cleft structure as well as swelling the pre- and postsynaptic parts accompanied with lysis and disruption of their synaptic membranes. Together with ultrastructural changes we observed alterations in proteins involved in the synaptic vesicles regulation and neurotransmitter release, increased expression of synaptobrevin (VAMP1/2), synaptophysin and synapsin-1 while the level of presynaptic membrane protein SNAP25 was decreased. In addition, analysis of postsynaptic proteins revealed the lowering level of PSD95 in both hippocampus and cerebral cortex whereas neuroligin-1 (NLGN1) decreased exclusively in cortex. Moreover, we observed changes in the expression of Shank family proteins (*SHANK1*, *SHANK2*, and *SHANK3*) compared to control rats. Prenatal exposure to VPA also upregulated the expression of pro-inflammatory cytokine interleukin 6 (IL-6) and cyclooxygenase-2 (COX-2) in adolescent rat offspring.

Conclusions: These results demonstrate that prenatal VPA exposure affected the synaptic proteins level which could be responsible for synaptic structure and plasticity changes and subsequently contributing to behavioral abnormalities in ASDs.

Poster Session
168 - Communication and Language
11:30 AM - 1:30 PM - Room: 710

58 **168.058** Developmental Academic Profiles in Siblings of Individuals with ASD

J. Guilfoyle[1], *L. Bush*[2], *E. Landau*[3], *M. Winston*[1], *K. Nayar*[1], *G. E. Martin*[4] *and M. Losh*[3], *(1)Feinberg School of Medicine, Department of Psychiatry and Behavioral Sciences, Northwestern University, Evanston, IL, (2)Northwestern Feinberg School of Medicine, Chicago, IL, (3)Communication Sciences and Disorders, Northwestern University, Evanston, IL, (4)Communication Sciences and Disorders, St. John's University, Staten Island, NY*

Background: The broad autism phenotype (BAP) refers to a set of subclinical personality and language traits that exist in a subgroup of unaffected relatives of individuals with autism spectrum disorder (ASD) that are qualitatively similar to the defining features of ASD. Studies have begun to disaggregate the neuropsychological and developmental underpinnings of the BAP. In recent work using archival academic testing data, specific childhood academic profiles were reported in individuals who later went on to have a child with ASD, where language skills developed more slowly than reading and math. These profiles predicted both the BAP in adulthood and the severity of their child's ASD symptoms (Losh et al., 2017), suggesting a potential childhood marker of genetic liability to ASD. Using archival data, this study extended these analyses to siblings of individuals with ASD to investigate whether specific childhood academic profiles may index genetic liability to ASD in clinically unaffected first degree relatives.

Objectives: To examine whether specific childhood developmental academic profiles are evident among siblings of individuals with ASD, constituting a developmental signature reflecting genetic liability.

Methods: Academic test data from the Iowa Test of Basic Skills (ITBS)(Hoover, Dunbar, & Frisbie, 2001) were obtained from siblings of individuals with ASD (n=25) and controls without a personal or family history of ASD (n=32). The ITBS assesses language, reading, and math in grades K-12. Participants also completed an extensive battery of clinical-behavioral and neuropsychological measures.

Results: Differences emerged between groups in language abilities (ps<.04), but not in reading or math (ps>.62). Differences in language were driven by the Language Usage and Capitalization subtests, which assess ability to detect grammatical errors in extended passages and make judgements regarding proper capitalization usage (e.g, distinguishing proper versus common nouns), respectively. Lower performance in language and reading tests were associated with poorer performance on tasks of social cognition later in development (rs>.582, ps<.05) and language fluency (rs>.585, ps< .04), although no associations were found between academic performance and Social Responsiveness Scale or Autism Diagnostic Observation Schedule scores (ps>.22).

Conclusions: Findings suggest a pattern of academic performance in siblings of individuals with ASD that mirrors the profile previously reported in parents, with lower performance in language tests but no differences in reading or math. Also consistent with findings in parents, academic performance was linked to some phenotypic markers associated with ASD suggesting early academic language skills may represent an indicator of later developing social-communication atypicalities related to ASD. Taken together, these findings suggest that academic-related language abilities serve as a potential developmental marker of genetic liability to ASD that might be studied to investigate inter-generational transmission of broader traits associated with ASD.

59 **168.059** Discourse Profiles of Mothers of Children with ASD and Female FMR1 Premutation Carriers

N. Maltman[1], *J. N. Barstein*[2], *G. E. Martin*[3], *N. L. Dunbar*[1], *E. K. Patterson*[1] *and M. Losh*[4], *(1)Northwestern University, Evanston, IL, (2)Feinberg School of Medicine, Department of Psychiatry and Behavioral Sciences, Northwestern University, Evanston, IL, (3)Communication Sciences and Disorders, St. John's University, Staten Island, NY, (4)Communication Sciences and Disorders, Northwestern University, Evanston, IL*

Background: Subclinical pragmatic language differences comprise a core feature of the broad autism phenotype (BAP), believed to reflect genetic liability to ASD. Similar pragmatic language profiles among *FMR1* premutation carriers (PM; Losh et al., 2012) suggest a potential role of the *FMR1* gene in ASD-related pragmatic language (Lee et al., 2017). An important next step is to investigate linguistic contributions to these broader pragmatic differences. Discourse markers (e.g., filled pauses, backchannels) are words and nonverbal behaviors that manage conversations, promote turn-taking, and create rapport; even subtle deviations in their use can significantly influence the course of conversation. This study examined potential overlap in patterns of discourse marker use in mothers of individuals with ASD (M-ASD) and PM carriers, compared to

controls, to investigate similarities in previously documented pragmatic differences in these groups.
Objectives: Characterize and compare patterns of conversational discourse marker use in mothers of individuals with ASD, female PM carriers, and controls, and evaluate links to global pragmatic language skills.

Methods: Eighty-seven M-ASD, 63 PM carriers, and 43 age- and IQ-matched female controls participated in semi-structured conversations with a trained examiner. Transcripts and videos of these conversations were coded for discourse marker use including speaker markers (i.e., lexical fillers, revisions, filled pauses) and listener markers (i.e., backchanneling, such as nodding). Global pragmatic language ratings were coded from video by independent, blind raters using the Pragmatic Rating Scale (PRS; Landa et al.,1992). Pragmatic language total- and factor scores (i.e., dominant or reticent) were included in analyses.

Results: PM carriers used significantly more lexical fillers and backchannels than the M-ASD group and controls ($ps < .05$), controlling for overall word count. Groups did not differ significantly in filled pauses or revisions ($ps > .10$). M-ASD and PM carriers demonstrated higher PRS total and factor scores (i.e., more difficulty) than controls ($ps < .05$). In both M-ASD and PM carriers, but not controls, higher PRS total scores related to fewer backchannels ($r = -.36$, $p < .01$; $r = -.31$, $p< .05$); greater reticence factor scores correlated with fewer revisions ($r = -.31$, $p< .01$; $r = -.42$, $p < .05$) and filled pauses ($rs = -.31,-.36$, $ps < .01$). In the PM group, higher PRS totals and dominant factor scores related to more frequent revisions ($r = .33$, $p < .01$; $r = .23$, $p< .05$). Increased lexical fillers related to unusual rate of speech ($r = .33$, $p< .05$) in the PM group.

Conclusions: This study suggests a complex influence of discourse markers on pragmatic language. Consistent with prior literature, overall pragmatic language profiles between M-ASD and PM carriers were similar (Losh et al., 2012); however, PM carriers employed some discourse markers at increased rates compared to the M-ASD group. In spite of differences in the frequency of their use, discourse markers influenced pragmatic language in similar ways for the PM and M-ASD groups, but not controls. This suggests an important, but subtle, role in conversational management through discourse marker use, potentially indicative of subclinical profiles related to ASD.

60 **168.060** Discrepancies in Parent Vs. Clinician Reporting of Autism Specific Language Patterns across Racial and Ethnic Groups

H. V. Medeiros[1]*, E. Hanson*[2] *and J. Straus*[1]*, (1)Developmental Medicine, Boston Children's Hospital, Boston, MA, (2)Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background*:* Previous research has shown differences in parent and clinician reporting of symptoms of Autism Spectrum Disorder (ASD) (Lemler, 2012) and that symptom recognition, diagnosis, and treatment can be heavily influenced by culture (Donohue et al., 2017; Tek & Landa, 2012; Daley, 2004). In previous analyses, we found differences in non-minority parent reports compared to clinician reports of ASD complex mannerisms but not in minority parent reports compared to clinician reports.
Objectives: This study aims to examine differences in parent versus clinician reporting of language related symptoms of ASD by first analyzing discrepancy between parent and clinician ratings for two language related symptoms: stereotyped speech and echolalia (SSE). Second, we explored whether these discrepancies differed across racial and ethnic groups.

Methods: Data on individuals with ASD was used from Boston Children's Hospital and the Boston Autism Consortium Phenotypic and Genetic Factors in ASD study. 119 participants met inclusion criteria, including: 1) Demographics form, 2) Behavior and Sensory Interest Questionnaire (BSIQ, Hanson et al., 2016), and 3) Autism Diagnostic Observation Schedule-Second Edition (ADOS, Lord et al., 2012). Participants were grouped according to NIH minority status (NIH, 2017). Clinician-reported SSE (CSSE) was measured using an average of the ADOS A3 and A4 codes "Immediate Echolalia," and "Stereotyped Speech", scored 0-3. Parent-reported SSE (PSSE) was measured using BSIQ-F1 category of "Language Preservations," using an average of two individual codes: F1.a. Immediate echolalia and F1.b. delayed echolalia (i.e. stereotyped speech), scored 0-3). First, a one-way ANOVA was used to compare the CSSE and PSSE scores. Next, Tukey post-hoc tests were performed to analyze between-group comparisons for CSSECaucasian, CSSEMinority, PSSECaucasian, and PSSEMinority, to explore whether there were significant differences based on minority status of the child.

Results: Of 119 participants, 87 (73%) were identified by their parents as "White/Caucasian" and 32 (27%) as one of the listed racial and/or ethnic minority descent categories. Categories endorsed by parents included 9 (7.6%) "Asian," 4 (3.4%) "Black/African-American," 6 (5%) "More than one race," 11 (9.2%) "Hispanic," and 5 (4.2%) who identified as "Other." Due to low numbers in each minority group, these groups were combined together for the current analysis. Results from a one-way ANOVA showed significant differences in reporting between PSSE and CSSE ($p=0.005$). Tukey post-hoc contrasts showed significant differences in CSSEMinority and PSSEMinority ($p=.014$) but no significant differences in CSSECaucasian and PSSECaucasian ($p=.476$). All other findings were not significant (CSSEMinority and PSSECaucasian, CSSECaucasian and PSSMinority, PSSMinority and PSSCaucasian).

Conclusions: Preliminary analyses showed significant differences in reporting of SSE between parent and clinicians, suggesting that parents and clinicians are recognizing evidence and/or levels of echolalia and stereotyped speech differently. Between-groups analyses resulted in a statistically significant difference between parent and clinician report of SSE for the minority group, but not for any other group. Differences in the reporting of behaviors can impact diagnosis and treatment, and illuminates the need for more research in this area. Inconsistencies in reporting could possibly be attributed to parents having different knowledge about ASD symptomology across cultural groups.

61 **168.061** Do Play Contexts Impact Engagement States in Preschool Children with Autism Spectrum Disorder?

A. Binns[1]*, D. Casenhiser*[2]*, K. Forsyth*[3]*, S. Shanker*[4] *and J. Oram Cardy*[5]*, (1)Western University of Ontario, London, ON, Canada, (2)Audiology & Speech Pathology, University of Tennessee Health Science Center, Knoxville, TN, (3)SLP, Hamilton, ON, Canada, (4)York University, Toronto, ON, Canada, (5)Western University, London, ON, Canada*

Background:
A large proportion of a preschool child's day is spent in play. As a result, it is often through play that children interact with their environment. This makes play a powerful tool for clinicians to use during intervention with preschool children. Existing research has shown that many preschool children with Autism Spectrum Disorder (ASD) have challenges in social engagement, however, very little research has examined the extent to which play context affects how children with ASD engage with their environment. Discovering which play contexts are more conducive to engagement could inform the context in which clinicians conduct therapy with children with ASD and shape recommendations about play context for parents of children with ASD.

Objectives:

To explore the impact of two different play contexts (symbolic and gross motor) on the engagement states of pre-school children with ASD.

Methods:

Seventy-one children with ASD aged 25-57 months were videotaped during natural play interactions with a parent. Five minutes each of play with symbolic toys and play with gross motor toys were used to examine children's engagement states. Data used in this study were part of a larger RCT, however, only pre-treatment, parent-child play interactions were examined here. Time-tagged video coding of the children's engagement states was conducted using Datavyu software and Adamson and colleagues' (2010) engagement coding system. The 8 engagement codes were collapsed into three categories of engagement states: (1) not engaged with parent, (2) engaged with parent only, or (3) engaged in joint attention.

Results:

On average, participants spent significantly more time not engaged with their parent during play with symbolic toys than during play with gross motor toys ($t(70) = -2.65$, $p < 0.05$). During play with gross motor toys, a significantly greater amount of time was spent engaged with their parent only ($t(70) = 4.12$, $p < 0.05$), compared to when children were playing with symbolic toys. There was no significant difference in joint attention between the gross motor and symbolic play contexts ($p > 0.05$).

Conclusions:

Play contexts seem to impact how pre-school children with ASD engage with their environment. Children with ASD engage with parents for a greater proportion of time when in an environment with gross motor toys as compared to when in an environment with symbolic toys. Clinicians might benefit from using gross motor play contexts when targeting social engagement goals with preschoolers with ASD. Clinicians may be reassured that gross motor play appears to be equally useful as symbolic play for targeting engagement in joint attention.

62 **168.062** Do Predictors in Machine Learning Classification of ASD Differ for Children Vs. Adolescents?

S. Plate[1], *E. Sariyanidi*[2], *M. Cola*[1], *C. J. Zampella*[2], *L. D. Yankowitz*[1], *A. Riiff*[1], *V. Petrulla*[1], *B. Tunc*[2], *J. D. Herrington*[2], *K. Bartley*[2], *E. S. Kim*[1], *A. de Marchena*[3], *J. Pandey*[1], *R. T. Schultz*[1] *and J. Parish-Morris*[1], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)University of the Sciences, Philadelphia, PA*

Background: Autism spectrum disorder (ASD) is defined by early and persistent deficits in social communication, as well as the presence of restricted interests and repetitive behaviors. The majority of children with ASD are verbally fluent, and information gathered from brief natural language samples could facilitate remote screening while generating ecologically valid social communication profiles to inform personalized treatment planning. Prior research suggests that a variety of linguistic features produced by participants with ASD and their conversational partners are useful predictors of diagnostic status and/or symptom severity, including prosody, turn-taking rates, and word choice (Bone, 2013; Parish-Morris et al., 2016). However, few studies have harnessed the power of machine learning to predict diagnosis from short, conversational language samples with *non-expert interlocutors*, and little is known about whether prediction accuracy and specific predictive features remain consistent in childhood vs. adolescence. This study addresses these two important gaps.

Objectives: Apply machine learning to language features extracted from transcripts of naturalistic conversations, with the goals of (1) classifying participants as ASD or typically developing, and (2) comparing classification accuracy and predictive features between a child sample, an adolescent sample, and a collapsed sample that includes all participants.

Methods: Eighty-five matched participants (Table 1) participated in two 3-minute semi-structured "get to know you" conversations with two previously unknown confederates who were not autism experts (Ratto et al., 2011). In the first conversation, the confederate is trained to act interested in the conversation, and in the second, bored. Transcripts were analyzed using LIWC software (Tausczik & Pennebaker, 2010) and R's 'qdap' package (Rinker, 2017), resulting in 121 features for participants and confederates in each condition, as well as the difference between conditions. Our machine learning pipeline included a logistic regression classifier trained with participant and/or confederate features within a leave-one-out-cross-validation loop. Cross-validated classification accuracy was measured within children and adolescent samples separately, as well as across the entire age range; accuracy was compared using McNemar's test. Conversational features with non-zero coefficients in the classifier were identified as top predictors of diagnostic status.

Results: Diagnostic classification accuracy was high in both age groups: 89% in adolescents and 76% in younger children (Table 2). Accuracy dropped significantly to 66% (p<.015) when the entire age range was classified within a single model, suggesting that optimal classification models may differ by age group. The most accurate classification model was driven by participant-level features for children and by confederate-level features for adolescents. For children, top predictive features included participant pronoun use, intra-turn pause duration, and "friend"-category words. For adolescents, top predictive features in the most parsimonious model included confederate word-level "authenticity" and negations.

Conclusions: This study showed that (1) features derived from naturalistic conversations with *non-expert interlocutors* can be used for diagnostic classification, and (2) top classification features may change over the course of development. Using machine learning to extract clinically-relevant dimensions from short, naturalistic conversation samples with naïve confederates could provide a new path toward rapid improvements in remote screening, characterization, and developing yardsticks for measuring treatment response.

63 **168.063** EARLY Reading Skills in Children with ASD: Giftedness or Impairment?

ABSTRACT WITHDRAWN

Background:

7% of our clinical population with ASD in Tunisia have early reading abilities, also referred to as hyperlexia

Most of parents and some professionals often consider this skill as a gift and reinforce it, whether some others consider it as an impairment and try to reduce it.

Objectives: Our objective was to correlate early reading skills with some major traits of autism.

Methods:

61 children aged 4-11 years old with documented early reading skills through a thorough assessment of reading and developmental levels of

language and intelligence, were further assessed for systematization (Empathy Questionnaire/Systemization Questionnaire EQ-SQ), sensory abnormalities (Sensory Profile 2) and stereotyped behaviors(Repetitive Behaviour Questionnaire RBQ)

Results:

Reading scores were significantly associated with systematization quotient (p=0.003) but not with empathy quotient.

They were also significantly associated with RBQ global score, especially with the Sameness dimension ($p<10^{-3}$)

Early reading skills were associated to the 'Sensitive/Sensor' profile (0.049) according to the SP2 scores, and more specifically to visual hypersensoriality (0.04)

Conclusions:

It seems that early reading skills in ASD correspond, rather than a talent, to a stereotyped hypersystemizing behavior underpinned by sensory abnormalities.

64 **168.064** Early Sociocognitive Skills, Language and Autism Severity in Children with Autism Spectrum Disorder

L. Taylor[1], *T. Charman*[2], *V. Slonims*[3], *P. Howlin*[4] *and J. Green*[5], *(1)King's College, London, London, UNITED KINGDOM, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Guy's & St Thomas' NHS Foundation Trust (Evelina Children's Hospital), London, United Kingdom, (4)King's College London, London, United Kingdom, (5)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland*

Background:

The Early Sociocognitive Battery (ESB; Chiat & Roy, 2008) is a novel measure of early sociocognitive skills. Scores on the ESB predict language expression and comprehension and social communication skills in typically developing children and those with language impairments. Results of longitudinal studies also indicate that scores on the ESB predict long-term social communication outcomes for children with early language difficulties. Children with very low ESB scores in the early years appear to be particularly vulnerable to later social communication difficulties and possible ASD (Chiat & Roy, 2013). Early improvements in these skills, e.g., through targeted interventions, may lead to improved long-term outcomes in children with ASD.

Objectives:

Little is currently known about the profile of ESB scores in children with ASD. In this study, we investigated the profile of ESB scores in a group of children with 'core' autism. We hypothesised that children who had not yet developed early sociocognitive skills would have more severe ASD symptoms and worse language than those children who demonstrated joint attention, social responsiveness and symbolic comprehension, as measured by the ESB.

Methods:

ESB data were collected for 249 children aged 2-11 years, taking part in the Paediatric Autism Communication Trial-Generalised (PACT-G) study. PACT-G is a randomised controlled trial of a social communication intervention for children with ASD. Measures of nonverbal ability (Mullen Scales of Early Learning, or British Ability Scales), expressive and receptive language (CDI, Oneword Picture Vocabulary Tests), Communication (Vineland Communication subdomain scores) and ASD severity (ADOS-2 subdomain scores) were also available. All data were collected at the baseline assessment, prior to randomisation and delivery of any trial intervention.

Results:

We divided the PACT-G sample into quintiles based on ESB scores and investigated how membership in each quintile related to other child characteristics, such as ASD symptom severity and language. Children who had high ESB scores, i.e., better early sociocognitive skills, had significantly lower ADOS-2 Social Affect scores, $F(4, 219) = 52.52$, $p < .001$, $\eta^2 = .49$, and fewer repetitive behaviours (ADOS-2 Rigid and Repetitive Behaviour scores), $F(4, 219) = 3.37$, $p = .01$, $\eta^2 = .06$, than children who had low ESB scores. Similarly, children with better early sociocognitive skills also had better expressive and receptive language, as measured by the Vineland Adaptive Behaviour Scales (Receptive Communication, $F(4, 230) = 24.78$, $p < .001$, $\eta^2 = .30$; Expressive Communication, $F(4, 230) = 34.73$, $p < .001$, $\eta^2 = .38$) and the Receptive, $F(4, 229) = 51.43$, $p < .001$, $\eta^2 = .48$, and Expressive, $F(4, 226) = 39.27$, $p < .001$, $\eta^2 = .41$, One Word Picture Vocabulary Tests.

Conclusions:

These findings show a differential pattern of language and ASD symptoms, based on the profile of early sociocognitive skills, for children with 'core' autism. Identifying difficulties in these skills may lead to targeted interventions that could improve long-term communication outcomes for children with ASD. Early sociocognitive skills could also be used to predict differential response to social-communication interventions.

65 **168.065** Evaluating the Pragmatic Rating Scale-School Age: Robust Psychometrics and Clinical Implications

E. F. Dillon[1], *K. J. Greenslade*[2], *E. Utter*[3] *and R. Landa*[1], *(1)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (2)Kennedy Krieger Institute, Baltimore, MD, (3)Kennedy Krieger Center, Center for Autism and Related Disorders, Baltimore, MD*

Background: Pragmatic, or social communication, deficits are key characteristics of autism spectrum disorder (ASD); subclinical differences are detectable in first degree relatives of individuals with ASD (Landa, 1992; Greenslade et al., in press). Two main types of pragmatic language measures exist: parent report and standardized structured clinician-administered assessments. Both have limitations. Parent–rated may be less sensitive than clinician-rated measures (Hess & Landa, 2012) and structured measures lack ecological validity. To provide a clinician-rated measure based on ecologically valid communication samples, the Pragmatic Rating Scale-School Age (PRS-SA; Landa, unpublished) was developed. The PRS-SA enables clinicians to rate level of social difficulty (0=none, 3= severe) across 21 components of communication.
Objectives: To evaluate the internal consistency and concurrent validity of the PRS-SA in 4- to 8-year-olds with a continuum of ASD symptomatology, and preliminarily examine whether the PRS-SA is useful for detecting ASD symptoms and risk. Hypothesis: The PRS-SA will demonstrate: (1) moderate internal consistency due to the diversity of social language and communication features measured; (2) strong correlation (concurrent validity) with standard ASD measures, as pragmatic impairment is central to ASD; and (3) good sensitivity and specificity for ASD classification (positive/negative).
Methods: 136 4- to 8-year-olds (*M*=6.94 years, *SD*=1.85) (83 males; *n*=49 with ASD) at high and low risk for ASD participated in a prospective,

longitudinal study of ASD (additional data will be added by the INSAR presentation). All had complete data on the Abbreviated Stanford Binet Intelligence Scale, 5th Edition, ADOS-2, SRS-2, and PRS-SA. Cronbach's alpha examined internal consistency. Pearson's correlation coefficients assessed PRS-SA criterion validity (concurrent) with the SRS-2 and ADOS-2 (standardized ASD assessments). A receiver operating curve (ROC) analysis was conducted to examine PRS-SA sensitivity and specificity for identifying ASD+ or ASD- status (Figure 1).

Results: Cronbach's alpha (α=.635) indicated a moderate level of internal consistency, and no improvements were noted with the removal of any individual item. PRS-SA total score was significantly correlated with SRS-2 total score (r=.453, p=.002) and ADOS-2 Communication domain algorithm score (r=.424, p<.001).

ROC analysis generated an AUC of .890, indicating a good level of sensitivity and specificity for identifying ASD status. A PRS-SA cut off score of 21 is optimal for identifying ASD+/ASD- status: sensitivity=.837, specificity=.790.

Conclusions: As hypothesized, the PRS-SA demonstrated moderate internal consistency, likely reflecting the diversity of communication behavior encompasses in pragmatics and measured by the PRS-SA. Factor analysis will explore potential subscales when sample size is increased, and will be reported in this presentation. Strong correlations between PRS-SA total score and two standardized mainstream ASD measures (one a parent report and one a clinician-rated, direct observation), provide strong concurrent validity evidence, affirming the PRS-SA's use to detect ASD-related pragmatic communication behavior. Our findings suggest that PRS-SA scores of ≥21 in 4- to 8-year-olds indicate the need for ASD evaluation. Additional recruitment will allow a validation of this cut off score in an independent confirmatory sample; sensitivity and specificity results from this analysis will be reported.

66 **168.066** Evaluation of a Novel Non-Word Repetition Test As a Clinical Marker for Language Impairment in Multilingually-Exposed Children with ASD

F. Li[1], *A. M. Gonzalez Barrero*[2], *H. Goad*[3] *and A. Nadig*[1], *(1)School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada, (2)Department of Psychology, Concordia University, Montreal, QC, Canada, (3)Department of Linguistics, McGill University, Montreal, QC, Canada*

Background: Language impairment (LI) is observed in 40-60% of children with ASD (Pickles et al., 2014). Sentence Repetition tests (SR) are quick and can reliably identify LI (Archibald et al., 2009). However, SR tests involve repetition of linguistic content and as such do not work well with multilingually-exposed children, since they may appear to have LI when in fact they just have reduced exposure to the language of testing. Nonword repetition (NWR) tests can also reliably identify LI, but they employ nonwords and are less influenced by language exposure (Thordardottir & Brandeker, 2013). No NWR task exists with stimuli that are phonotactically permissible in multiple languages. In this context, we developed a Multilingual Non-Word Repetition (ML-NWR) test for administration in English, French and Spanish, and applied it to a large sample of children with ASD or typical (TYP) development.
Objectives: To examine whether 1) ML-NWR performance is comparable with different dominant languages (L1s), 2) ML-NWR performance is less affected by amount of exposure to L1, than a SR test, 3) ML-NWR is accurate in identifying children with ASD and LI from a multilingual sample, 4) ML-NWR performance correlates with performance on an established English NWR test.

Methods: Data from 88 participants (38 with ASD) were analyzed. Participants varied in age (5-10 years), L1 (English or French), amount of exposure to that L1, presence or absence of ASD, and presence or absence of LI (among the children with ASD). Participants were administered the ML-NWR test and a SR test (from the CELF-4 or French Canadian version) in their L1 and, for bilinguals, their L2. A subset of 12 participants (seven with ASD) was also administered the Children's Test of Nonword Repetition (CNRep). LI was defined as SR score less than or equal to 1 SD below the mean along with prior documentation of structural-language difficulties. In the ML-NWR test, 27 stimuli of increasing length and phonological complexity were administered live by an examiner. Examiner and participant productions were transcribed in IPA by two independent listeners who were blind to participant LI status.

Results: 1) ML-NWR performance was globally comparable across participants with English versus French as an L1; data was therefore collapsed for further analysis. 2) In the TYP group, current amount of L1 exposure was significantly correlated with SR, but not with ML-NWR performance. In the ASD group, neither correlation was significant (Figure 1). 3) The ML-NWR test achieved a good level of utility as a tool for detecting LI in a multilingual sample (Figure 2). A percent phonemes correct (PPC) cut-off of 95% yielded a sensitivity of 75% and a specificity of 77%. 4) ML-NWR performance was significantly and highly correlated with CNRep performance (r = .894, p < .001).

Conclusions: The ML-NWR test was less influenced by amount of language exposure than a SR task. It displayed a good level of utility as a screener for LI in multilingually exposed children with ASD. Ongoing analyses will compare stability of LI detection across L1 and L2 in bilingual participants.

67 **168.067** Examining the Contribution of Children's Play and Engagement to Language Development in Preschoolers with Autism Spectrum Disorder

J. M. Moffitt[1], *M. Alessandri*[2], *A. Gutierrez*[3], *D. Correa*[4], *N. Decius*[4], *G. David*[4] *and L. Nichols*[5], *(1)Psychology, University of Miami, Coral Gables, FL, (2)University of Miami, Coral Gables, FL, (3)University of Miami, Miami, FL, (4)Center for Autism and Related Disabilities, University of Miami, Coral Gables, FL, (5)University of Miami, Psychology, Miami, FL*

Background: Individuals with autism spectrum disorder (ASD) display significant heterogeneity in symptom and skill presentation across the lifespan (e.g., Georgiades et al., 2013; Howlin & Magiati, 2017). In addition, some of these individual difference factors (e.g., cognitive function, expressive language skills) present at treatment outset have been linked to treatment outcomes (Howlin & Magiati, 2017) giving rise to an interest in factors that may impact the child's participation in the learning environment. In an effort to improve outcomes, such as language development, skills such as joint attention and symbolic play are often direct targets of early intervention for children with ASD (e.g., Kasari et al., 2008) yet trajectories of language development in these children are not fully understood and further research is needed.
Objectives: The present study aimed to examine the contribution of children's engagement and symbolic play skills on later expressive language functioning. Although these data were drawn from a larger ASD preschool intervention study, the present study investigates individual differences in participating children for the sample as a whole.

Methods: The sample for this study consists of 134 preschool children (85% male, M = 4.2 years, SD = .62) diagnosed with ASD who were enrolled in

one of 78 participating classrooms in the study and present for all relevant assessments. The classrooms were located in North Carolina, Florida, Minnesota, and Oregon. Children participated in an assessment battery at the beginning of the year that included measures of general developmental level (MSEL), symbolic play (SPA), joint engagement (ICER-R) and autism symptoms (ADOS-2). At the end of the school year, expressive language was also assessed (PLS-5).

A three-level hierarchical regression was conducted with expressive language (EC standard score) as the dependent variable, child age and developmental level (MSEL Composite Standard Score) entered as predictors on the first step, joint engagement (duration of coordinated or supported joint engagement with people and objects during ICER-R) on the second step, and symbolic play (duration during the SPA) entered on the third step.

Results: The full model predicted 47.8% of the variance in expressive language scores, $F(5,128) = 25.38$, $p < .001$. The models adding joint engagement ($\beta = .148$, $p < .05$, *F change* (1,129) = 5.28, $p < .05$) and symbolic play ($\beta = 2.82$, $p < .01$, *F change* (1,128) = 4.76, $p < .05$) each explained an additional 2% of the variance beyond the lower level predictors.

Conclusions: These results show that children with higher levels of joint engagement and symbolic play at the beginning of the year demonstrate more expressive language skill at the end of the year. This suggests the importance of continuing targeted interventions and monitoring related to complex play, classroom engagement, and early language predictors in children diagnosed with and at-risk for ASD. This sample included preschool children with notable language impairment, a group for whom the sequelae of these early deficits may be particularly problematic if not adequately addressed.

68 **168.068** Exploring Problem Behavior and Language Development in Preschoolers with Autism Spectrum Disorder

J. M. Moffitt[1], *D. Correa*[2], *L. Nichols*[3], *G. David*[2], *N. Decius*[2], *A. Gutierrez*[4] *and M. Alessandri*[5], *(1)Center for Autism, California State University, Fullerton, Fullerton, CA, (2)Center for Autism and Related Disabilities, University of Miami, Coral Gables, FL, (3)University of Miami, Psychology, Miami, FL, (4)University of Miami, Miami, FL, (5)University of Miami, Coral Gables, FL*

Background: Children with autism spectrum disorder (ASD) consistently demonstrate high levels of externalizing behavior problems compared to their typically developing peers, though significant heterogeneity is present (e.g., Anderson, Maye, & Lord, 2011). Behavior problems occur in many domains of functioning for children with ASD and have the potential to interrupt learning opportunities, social interactions, and other critical points of engagement.

Objectives: The present study examined the contribution of children's problem behaviors to later expressive language functioning. These data were drawn from a larger study preschool intervention project for children with ASD, however the present focus is on individual differences.

Methods: The sample includes 137 preschool children (85% male, $M = 4.2$ years, $SD = .62$) diagnosed with ASD and enrolled in one of 78 participating classrooms across four states. Children participated in an assessment battery at the beginning of the school year targeting general developmental level (MSEL), problem behaviors (CBCL CTRF), and autism symptoms (ADOS-2). At the end of the year, problem behaviors were reassessed and expressive language was evaluated using the PLS-5. At the beginning of the year 37 children used less than 5 words during the ADOS assessment (27%), 76 regularly used single words (55.5%), and 24 were using phrase speech (17.5%).

A hierarchical regression was conducted with expressive language as the dependent variable (PLS-5 Expressive Communication Standard Score), child age and developmental level (MSEL Standard Score) entered as predictors on the first step, and problem behaviors at the beginning of the year (CBCL CTRF Total T-score) on the second step.

Results: The full model predicted 46.8% of the variance in expressive language, $F(3,133) = 40.94$, $p < .001$. Problem behaviors explained an additional 2.5% of the variance beyond the lower level predictors, $\beta = -.162$, $p < .05$, *F change*(1,133) = 6.39, $p < .05$. Even when considering only the children with minimal expressive language at the start of the year (completed ADOS Module 1, n = 113), the full model predicted 36.2% of the variance in expressive language scores, $F(3,109) = 22.19$, $p < .001$. Problem behaviors explained an additional 3.7% of the variance beyond the lower level predictors, $\beta = -.195$, $p < .05$, *F change*(1,109) = 6.56, $p < .05$. Problem behaviors at the end of the year were significantly related to problem behaviors at end of the beginning of the year, $r = .61$, $p < .001$, and to expressive language at the end of the year, $r = -.32$, $p < .001$.

Conclusions: Results show that children exhibiting more reported problem behaviors at the beginning of the year demonstrated lower expressive language skills at the end of the year. It appears that problem behaviors have a significant impact on language both concurrently and across time. Significant problem behaviors may be arising in the absence of matured expressive language, and continued communication interference may exacerbate these issues highlighting the need for early communication interventions. However, further exploration is needed around stronger predictors of language development in children with more significant language delays.

69 **168.069** Gesture Use in the Conversation of Korean Children with High-Functioning ASD: Focused on Communicative Functions and Types of Gestures

J. CHOI and ***Y. Lee****, Hallym University, Chuncheon, Korea, Republic of (South)*

Background:

Gestures play an important role in conversation by accompanying and amplifying information conveyed in speech. Deficits in using communicative gestures in ASD have been reported repeatedly. Early studies found reduced rates of gestures in children with ASD, however recent studies have reported that it is the type and function of gestures that is limited rather than a decrease in gesture frequency. Limitations in the gesture use of children with ASD can also have a negative effect on conversation.

Objectives:

This study aimed to investigate gesture use in the conversation of children with high-functioning autism spectrum disorder (HFASD) focused on communicative functions and types of gestures

Methods:

The participants were 17 HFASD children and 34 typically developing children (TD) matched on chronological age, language age, and IQ. The HFASD were diagnosed as having ASD first by a psychiatrist, and then confirmed using ADOS-2(mean=11.94, range=8-20). The mean chronological age in months of the HFASD group was 98.83±18.60, and the TD group was 99.31±20.70. The language age of the HFASD group was 88.72±22.16 and the TD

group was 92.25±23.38. The mean IQ of the children with HFASD was 99.55±9.96 and TD children was 99.28±13.62.

Behavior samples of the participants were collected during conversation with the examiner through a semi-structured procedure (Choi & Lee, 2013). The samples were recorded using two camcorders.

The gestures of the participants were analyzed according to the communicative function of the gesture, which were categorized as serving the function of responsiveness or assertiveness (Dore, 1986). Gestures were also grouped into four gesture types; deictic, iconic, markers (conventional), and speech beats (Goldin-Meadow & Mylander, 1984). The total number of gestures, and the number of gesture according to communicative function and type were measured.

Results:

The total number of gestures were not significantly different between the two groups (t=-.087, p=0.922). The HFASD group (23.13±15.40) used a similar number of gestures as the TD group (23.50±12.11).

In contrast to the similar frequency of gesture use, significant differences were observed in the communicative functions and the types of gestures. Compared to the TD group, HFASD group used responsiveness function gestures significantly less often, however, there was not a significant difference in the use of gestures that served the assertive function (t=-4.189, p<.001).

In the number of type of gesture, the HFASD group used iconic gestures the most (9.66±9.48) and beats gestures the least (2.60±3.24). In contrast, the TD group used markers gestures the most (12.56±6.15) and deictic gestures the least (1.71±2.30). A significant difference between the two groups was observed in a markers gestures only (t=-2.921, p<.01).

Conclusions:

In the results of the study, the HFASD children used a similar number of gestures during conversation; however, they showed significant differences in the communicative function and types of gestures. The HFASD children used more gestures that fulfilled the assertiveness function, and significantly more marker gestures than TD children as well. The results of the study showed that the different gesture use of the HFASD children was closely related to their limited social abilities.

70 **168.070** Grammatical Strengths of Aspect Processing in the General Population of Mandarin-Exposed Preschool Children with Autism Spectrum Disorders

Y. E. Su[1] *and L. R. Naigles*[2]*, (1)Childa Language Lab, School of Foreign Languages, Central South University, Changsha, Hunan, China, (2)Psychological Sciences, University of Connecticut, Storrs, CT*

Background:

Despite their selective impairments in producing grammatical morphemes, preschool English-exposed children with ASD have demonstrated a strength in on-line understanding of grammatical aspect (Tek et al., 2013; Tovar et al., 2015). The general population of preschool Mandarin-exposed children with ASD has similarly been observed to omit aspectual morphemes significantly more often than typical children (Su et al., 2018; Zhou et al., 2015). This study investigates whether Mandarin-exposed children with ASD's impairments in producing aspect markers stem from their grammatical deficits (i.e., utilizing aspect markers to encode temporal meaning) or their pragmatic difficulties (i.e., referring less frequently to non-present events).

Objectives:

Using Intermodal Preferential Looking (Naigles & Tovar, 2012), we assessed the online processing of aspect markers in a general group of Mandarin-exposed preschool children with ASD, investigating whether they utilize the perfective marker *le* and the progressive marker *zai* to distinguish between completed and ongoing events.

Methods:

Participants included 42 Mandarin-exposed children with ASD, MA=52.07 ± 14.89 months; *M*(vocabulary)=235.62 ± 212.17 words, and 39 TD children, MA=31.79 ± 1.34 months; *M*(vocabulary)=695.95 ± 84.11 words. The TD children were recruited to be significantly younger (p<.001) with the goal of matching the ASD group in vocabulary; however, TD vocabularies were significantly larger than ASD (p<.001). Children listened to sentences with the perfective marker *le* (e.g., *ta xi-le wawa* 'she washed the dolly') or the progressive marker *zai* (e.g., *ta zai-xi wawa* 'she is washing the dolly') paired with side-by-side completed or ongoing events, only one of which matched the test sentence.

Results:

The participants' looking behaviors while viewing the videos indicated that both groups demonstrated comprehension of the aspect markers. On the percent looking to match measure (Table 1), effects of audio, F(1, 79)= 30.77, p<.001, and trial, F(1, 79)=9.28, p=.003, and a significant interaction between audio and trial, F(1, 79)=6.57, p=.012, emerged during the total test trials relative to the control trials. Follow-up t-tests showed that both groups looked significantly longer to the match during the test relative to control trials for the 2nd half of the test trials with the perfective marker *le* and for the 1st half of the test trials with the progressive marker *zai* (all ps<.05). Timecourse data confirmed this looking pattern that hearing the perfective marker *le* triggered more eye movements to the completed event during the 2nd half of the test trials, whereas hearing the progressive marker *zai* triggered more eye movements to the ongoing event during the 1st half of those test trials, in both groups of children (Figure 1 illustrates the timecourse data of the ASD group).

Conclusions:

Mandarin-exposed preschool children with ASD demonstrated similar sensitivity to aspect markers as younger TD children, even though the expressive vocabulary levels of the ASD group were dramatically delayed. Thus despite their frequent omissions of the aspectual morphemes in language production, comprehension of grammatical aspect may be preserved in the general population of preschool children with ASD across countries.

71 **168.071** How Are Minimally Verbal Children and Adolescents with Autism Spectrum Disorder Using Pragmatic Communication in a Different Medium?

C. G. La Valle[1]*, C. Thörn*[2]*, J. Segal*[3]*, D. Plesa-Skwerer*[4] *and H. Tager-Flusberg*[4]*, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Davidson College, Davidson, NC, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Psychological and Brain Sciences,*

Boston University, Boston, MA

Background: Minimally verbal (MV) individuals with ASD demonstrate difficulties in pragmatic communication, both in the use of speech and communicative gestures, when engaging with a conversational partner (La Valle et al., in prep). Motor difficulties may contribute to reduced communicative gestures (Dewey, Cantell, & Crawford, 2007); however, no studies have assessed gestural forms in MV individuals with ASD. Further, how MV individuals are using pragmatic communication in a different medium, sign language, and how this may differ between children and adolescents, has not been studied, yet a full understanding of pragmatic communication should include both more categorical (sign) and imagistic (gestural) components (Kendon, 2014). The inclusion of sign and gesture can lend key insights into how other modalities collaborate to accomplish communicative goals (Goldin-Meadow & Brentari, 2017). This study will assess how MV children and adolescents are using sign and gesture to display communicative intent during a social interaction.

Objectives: To compare the pragmatic communication profiles of MV children and adolescents with ASD by investigating gestural form and sign language use when engaging with a conversational partner.

Methods: Twenty-five MV children with ASD (19 males; *M*age: 8.92 years) and 25 MV adolescents with ASD (19 males; *M*age: 15.89 years) were administered the ADOS (*n* = 50 Module 1). Within this sample, five children (4 males; *M*age: 9.91 years) and 8 adolescents (6 males; *M*age: 15.35 years) used sign language. Of the 13 participants who used sign language, 12 used sign language and communicative gestures. Transcripts of the first 30 minutes of the ADOS sessions were coded for gestural form: reach, point, reach approximation, point approximation, nodding, and head shaking and sign language use, including the form of the sign (clear sign vs sign approximation). Sign function was assessed in terms of communicative intent: responding to a question, request, repetition, label, comment, and to acknowledge/agree/disagree with the conversational partner.

Results: Both participant age groups, on average, produced fewer than two gestures. The primary gestural form for both groups was a reach approximation (*M* = 3.36). Adolescents nodded more (Mean rank = 30) during the conversational interaction compared to children (Mean rank = 21; *U* = 200, *p* = .001, *r* = .46). The groups did not differ in reaching, pointing, reach approximations, point approximations, and head shaking. Both participant age groups of signers, on average, produced 2.38 signs. Adolescents used more clear signs (Mean rank = 28.5) compared to children (Mean rank = 22.5; *U* = 237.5, *p* = .037, *r* = .58). The primary sign function for both groups was to request (*M* = 1.5). The groups did not differ in any of the sign functions (see Figure 1).

Conclusions: Findings highlight potential motor difficulties as evident by the use of poorly formed gestures. However, both groups showed similar patterns in the use of communicative functions when using sign language (e.g., request). Overall, use of gestures and signs were very low, suggesting that MV individuals with ASD are not compensating for decreased verbal output via other modalities when engaging with a conversational partner.

72 **168.072** Hyperlexia in ASD: First Study in an Arabic Language Context

R. Bourourou[1], *S. Bouslah*[2] *and N. Gaddour*[3], *(1)University of Monastir, Monastir, Tunisia, (2)Psychiatry, University of Monastir, Monastir, Tunisia, (3)University Hospital F. Bourguiba, Monastir, Tunisia*

Background:

While a large number of children with autism spectrum disorder (ASD) do not develop oral language or show major difficulties in basic language skills, a number of them can have spectacular early reading skills, also referred to as "hyperlexia".

This particularity has not been studied before in Arabic language context.

Objectives: We, therefore, aimed at carrying out a study on Tunisian children with ASD and hyperlexia, in order to estimate the prevalence of this association and its characteristics.

Methods:

A cross-sectional descriptive study was conducted at University Hospital of Monastir on 868 patients with ASD aged 4 to 11 years old.

First a screening checklist for early reading skills was used by clinicians to select early readers, then a battery assessing reading skills was used with the positive cases;

Evaluation also consisted in demographic, biographical and developmental data as well as individual assessment of intelligence (Leiter 3) and receptive language (Peabody 2).

Results:

We found a prevalence rate of hyperlexia in ASD of 7%.

With respect to quantitative measures of reading, all children with hyperlexia had more advanced reading abilities than their chronological age, their level of expressive language, their mental age, and the average reading abilities of their age group. They also had a level of receptive language adapted to their ages and reading levels.

Depending on the ability or inability to decode the "No-Words" and the degree of mastery of the vocalization rules, these children were divided into two groups: A group "good readers" (n = 8), who used highly developed phonological reading strategies and reached the final stage of orthographic stage and a second group of "beginners or poor readers" (n = 22), who used visual reading strategies, had low mastery of vocalization rules, and confusion of colloquial and standard Arabic.

Conclusions:

Hyperlexia seems frequent in Tunisian context and should be considered during the assessment and the follow up of patients with ASD

73 **168.073** Infant Communication Measures Predict Preschool ASD Symptom Severity and ASD Diagnosis

L. R. Watson[1], *S. Nowell*[2], *L. Turner-Brown*[3], *D. Garrido*[4], *M. DuBay*[5], *R. Grzadzinski*[6], *G. Baranek*[7] *and E. Crais*[1], *(1)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)University of North Carolina at Chapel Hill, Carrboro, NC, (3)UNC TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)University of Granada, Granada, Spain, (5)University of North Carolina, Chapel Hill, NC, (6)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (7)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA*

Background:
Recent screening tools have expanded our potential to identify infants at greater likelihood of later autism spectrum disorder diagnosis (GL-ASD), and have utility for both clinicians and researchers. However, the time lag between a positive infant screening and a conclusive ASD diagnosis presents challenges, including caregiver psychological burdens due to uncertainty about their child's diagnosis, delayed access to ASD-specific services requiring a diagnosis, and slower, more costly progress in research when study aims require knowledge of diagnostic outcomes. Thus, researchers continue to seek infant markers that more accurately predict ASD diagnostic outcomes.

Objectives:

1. Evaluate the extent to which infant communication measures are associated with severity of preschool ASD symptoms in the Social Affect (SA) and Restricted and Repetitive Behaviors (RRB) domains
2. Test the accuracy of infant communication variables in classifying preschool ASD-related diagnostic outcomes

Methods:

Preschool assessments provided diagnostic outcomes for 52 children (aged 36 – 70 months) identified through community screening at 12 months as at GL-ASD. Children were assessed initially at 13.7 months, pursuant to an intervention trial. Infant communication measures included the Communication and Symbolic Behavior Scales (CSBS) Social, Speech, and Symbolic composites; Mullen Scales of Early Learning (MSEL) Receptive and Expressive Language and Visual Reception scales; and frequencies of Canonical Vocalizations and Directed Vocalizations coded from 30 minutes of adult-infant interaction. Preschool outcomes were the Autism Diagnostic Observation Schedule (ADOS) Calibrated Severity Scores (CSS) for the SA and RRB domains (available for 45 children), and final clinical classification (ASD or non-ASD).

Results:

Associations between infant communication measures and preschool ADOS SA and RRB CSS scores were examined, controlling for MSEL Visual Reception scores and intervention group. Infant CSBS Speech and MSEL Expressive Language had significant partial correlations with preschool SA CSS (both *r*s = -.39). Three infant communication variables had significant partial correlations with RRB CSS: MSEL Receptive Language (*r* = -.31), Canonical Vocalizations (*r* = -.41), and Directed Vocalizations (*r* = -.49). Multiple other partial correlations between infant communication measures and preschool SA or RRB scores were marginally significant. We evaluated an iterative series of binomial logistic regression models, using variables significantly or marginally significantly correlated with CSS scores, to derive a parsimonious model predicting preschool diagnostic classification from infant CSBS Social, MSEL Receptive and Expressive Language, and Directed Vocalizations. The model yielded a $\chi^2$of 9.81 (p= .044) in the omnibus test. The model correctly classified 79% of the sample – 31/34 (91%) of NonASD children but only 10/18 (56%) of children with ASD.

Conclusions:

Multiple measures of infant communication correlated with preschool SA and/or RRB symptoms. Such measures may collectively support earlier "best estimate" diagnoses of infants at GL-ASD, although none of the measures we tested had significant unique discriminative power within the model. The current model requires validation with an independent sample. Further, our model misclassified 44% of the children eventually diagnosed with ASD as "NonASD," suggesting that ongoing monitoring and reassessments are warranted for screen-positive infants even when initial communication assessments do not support an ASD diagnosis.

74 **168.074** Infant Predictors of Language and Communicative Skills in School-Aged Children at Familial Risk for Autism Spectrum Disorder (ASD)

B. Milosavljevic[1], *E. Shephard*[2], *S. Delmonte*[3], *T. Gliga*[4], *M. H. Johnson*[5], *T. Charman*[6] *and &. the BASIS Team*[4], *(1)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom of Great Britain and Northern Ireland, (3)King's College London, London, United Kingdom, (4)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (5)Centre of Brain and Cognitive Development, Birkbeck College, University of London, London, United Kingdom, (6)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:
Atypicalities in language development are frequently observed among individuals with autism spectrum disorder (ASD). Evidence suggests that these language features are also present among children at familial risk for ASD, without a clinical diagnosis. Early predictors and aetiological pathways of language development in ASD and familial risk for ASD are not fully clear. Research in typically developing (TD) children suggests that early social attention facilitates both expressive and receptive language development. However, there is a scarcity in longitudinal research exploring the predictors of language development within ASD.

Objectives:

This prospective longitudinal study aims to explore the developmental trajectories and early-life predictors of language skills during mid-childhood (6-8 years) in children at increased familial risk for ASD. Specifically, we aimed to examine if 1) children at high-risk for ASD exhibit difficulties with language skills; 2) there are differences in language skills among high-risk children who meet diagnostic criteria for ASD and those who do not; and (3) language outcomes during mid-childhood are associated with social attention during infancy.

Methods:

Language ability was measured at age 6-8-years in a cohort of children at high-risk (HR) for ASD, who have been studied prospectively since infancy. Expressive (EL) and receptive (RL) language skills were assessed using the Clinical Evaluation of Language Fundamentals (CELF) and the Vineland Adaptive Behaviour Scales (VABS), which measure structural language and communicative skills, respectively. Language skills were compared between high-risk children who met DSM-5 criteria for ASD (HR-ASD; *n*=15), high-risk children without ASD (HR-non ASD; *n*=27) and low-risk controls (LR; *n*=37). Social attention was measured using a battery of eye-tracking tasks at ages 7- and 14-months. Of particular interest was the association between early gaze-following (GF; proportion of first looks to the correct object), attentional engagement (AE; proportion of time spent looking at the correct object) and Eye-Mouth Index (EMI; attention to eyes relative to the mouth) during social scenes and later language development. ASD symptoms were measured using the Social Responsiveness Scale-2 (SRS-2).

Results:

There were no significant group differences in performance on the CELF, but there were significant differences on both the EL and RL scales of the VABS. Group comparisons suggest that the HR-ASD group had significantly lower scores than the LR group. EMI at 7-months was significantly associated with expressive language scores on the CELF in both the HR ($r(21)=-.49$, $p=.004$) = and LR groups r(23)=-.57, $p=.02$), where increased attention to the mouth was associated with better language skills (Figure 1). However, increased attention to the mouth was also associated with higher ASD symptoms in the HR group ($r(26)=-.41$, $p=.03$). There were no other significant associations between the language measures and AE, GF or EMI.

Conclusions:

Children at-risk for ASD exhibited intact structural language but had difficulties with everyday communication. Increased attention to the mouth relative to the eyes in infancy was associated with better language during mid-childhood but also with higher ASD symptomatology. This suggests that attention to the mouth may facilitate language learning, but that attention to the eyes promotes better social understanding.

75 **168.075** Interference of the Communicative Profile of Children with Autism Spectrum Disorders upon the Quality of Life of Their Mothers

***A. C. Tamanaha**, J. Perissinoto and M. K. Ishihara, UNIFESP, São Paulo - SP, Brasil, Brazil*

Background: According to the World Health Organization, quality of life is defined as the perception an individual has on his/her position within the cultural context and the system of values in which he/she is contained. This perception is intrinsically related to the objectives, expectations, patterns, and concerns of such individual.We know that when a member of a family is assailed by an ailment, the quality of life of all of those who surround him/her suffer a strong impact. One of the great concerns of the families regarding the development of a child with Autism Spectrum Disorder (ASD) is the lack or impairment of the child's speech.
Objectives: The objective of this study was to analyze the interference of the communicative profile of children with ASD upon the quality of life of their mothers

Methods: This was a transversal study. The sample was obtained from 41 mothers of children diagnosed with ASD by a multi-disciplinary team: the mothers were divided in two groups: 20 mothers of non-verbal children-GASD-NV; and 21 mothers of verbal children-GASD. We applied the WHOQOL-Bref questionnaire to score and analyze the quality of life of these mothers.

Results: There was no significant difference in the maternal perception related to the domains that reflected quality of life which we compared between these two groups of mothers. In both groups we observed high indexes of insatisfaction.

Conclusions: We verified that the quality of life of the mothers of children with ASD were affected, regardless of the communicative profile of the child.

76 **168.076** Is PLAY Related to Spoken Language Development in Children with Autism: Preliminary Evidence from Project IMPACT Intervention

*K. Harper[1,2], A. B. Barber[3], C. Cook[4], V. Moore[5] and **E. Malaia**[6], (1)The University of Alabama, Tuscaloosa, AL, (2)Communicative Disorders, The University of Alabama, Tuscaloosa, AL, (3)Communicative Disorders, University of Alabama, Tuscaloosa, AL, (4)University of Alabama, Tuscaloosa, AL, (5)University of Alabama, TUSCALOOSA, AL, (6)Communicative Disorders, University of Alabama, Tuscaloosad, AL*

Background: Spoken language is a strong predictor of developmental and academic outcomes in children who have ASD (Lincoln et al., 1988; Howlin et al., 2000). In typically developing children, social experiences and play facilitate language development (Adamson et al., 2009, Dawson, 2008, & Kuhl, 2010; Carpenter et al., 1998; Toth et al., 2006). Thus, children with ASD are at risk for language delay given the social impairments characteristic of the disorder. Social communication is the most common outcome measured by early intervention programs. However, the specific dimensions of social communication as they relate to spoken language gains are not well understood.
Objectives: The primary purpose of this study is to investigate whether an evidence-based parent-mediated social communication (Project ImPACT intervention; Ingersoll & Dvortcsak, 2010) will increase social communication and spoken language in young children with ASD. The second objective is to examine the relation between three dimensions of social communication: play, social engagement, and imitation as measured by the Social Communication Checklist (SCC; Ingersoll & Dvortcsak, 2010) and spoken language as measured by the MacArthur Bates Communicative Development Inventories (MB-CDI; Fenson et al., 2007).

Methods: The data were collected as part of a larger ongoing study of the Project ImPACT intervention. Children (average age 31.63 months; 16 M; N=18) participated in Project ImPACT, where interventionists coach caregivers on strategies to support their children in the areas of social engagement, language, social imitation, and play for 12 weeks. Preceding and following therapy, each child's caregiver and clinician assessed communication, language, and social interactions through the SCC and the MB-CDI. Pre- and post-intervention assessments of language and play by parents and clinicians were analyzed using Spearman's correlation.

Results: Following intervention, 68% of the parents reported improved language, as measured by MB-CDI scores. Amount of play, as reported by the parent post-intervention, was significantly correlated with post-intervention scores on MB-CDI Vocabulary subsections: Sound Effects and Animal Sounds ($r= .63$, $p= .009$); Vehicles (Real or Toy; $r= .57$, $p = .021$); Toys ($r= .519$, $p= .039$); Furniture and Rooms ($r= .618$, $p=.014$); Small Household Items ($r= .662$, $p= .005$); Outside Things and Places ($r= .631$, p= .009); Quantifiers ($r= .519$, $p= .039$). 37% of post-intervention MB-CDI scores showed significant correlation to the amount of play reported by parents post-intervention. All Actions and Gestures subsection scores were significantly correlated with the amount of reported play (First Communicative Gesture, $r= .632$, $p=.009$; Games and Routines (Gestures), $r= .603$, $p= .015$; Actions with Objects, $r= .525$, $p= .037$; Pretending to be a Parent, $r= .593$, $p= .016$; Imitating Other Adult Actions, $r= .552$, $p= .027$).

Conclusions: Preliminary findings following twelve-week Project ImPACT intervention indicate strong correlations between play and spoken, as well as non-verbal communication for turn-taking and initiation of interaction. Play is an accessible and age-appropriate strategy that can be used by caregivers in their homes to facilitate early development of language and social skills, and this study contributes to understanding the role of play in development of communication in children on the autism spectrum.

77 **168.077** Joint Engagement in Minimal Verbal Children with Autism

Y. C. Chang[1], *S. Y. Shire*[2], *W. I. Shih*[3] *and C. Kasari*[3], *(1)Special Education and Counseling, California State University, Los Angeles, Los Angeles, CA, (2)University of Oregon, Eugene, OR, (3)University of California, Los Angeles, Los Angeles, CA*

Background:

Joint engagement (JE) is the state where children interact with an object and a social partner, providing a rich context for social communication. Children with autism have difficulties sustaining JE (Adamson et al., 2009) but can make gains through developmental interventions (e.g., Kasari et al., 2014). Therefore, this construct of JE haspreviously applied in interactions focused on spontaneous bidirectional interaction versus adult led instruction. The study will examine the proof-of concept for exploring engagement in Discrete Trial Teaching (DTT).

Objectives:

The study will examine: 1) the construct of engagement within DTT intervention, 2) whether children who participated in DTT made gains in JE at intervention weeks 3 and 6, and 3) whether JE predicts responder status at week 6.

Methods:

Participants. The sample is a from a subset of a social communication intervention trial. Children were randomized to either Joint Attention Symbolic Play Engagement Regulation (JASPER) or DTT. Twenty-seven minimally verbal (less than 20 spontaneous words) children with autism, ages 4.6-8 years (mean age=6.32; SD = 1.18) received DTT.

Intervention. Each child received 30-minute DTT sessions 5x/week (or 40-minute sessions 4x/week) conducted 1:1 at school, home, or other community locations.

*Interventionist-Child interactions (ICX).*Engagement was coded from 10-minute videos between the interventionist and child from weeks: 1 (first session), 3, and 6. Children's engagement state (Joint Engagement, Object, Person, Onlooker, and Unengaged) were coded in seconds. JE was also coded either child initiated or adult-directed. Proportion of time spent in each state was analyzed.

Clinical Global Impression-Improvement. Responder status was measured by the CGI-I, which measured children's improvement of social communication on a likert scale of 1-7. Children with a rating of a 1 (very much improved) and 2 (much improved) were categorized as responders. Children with a rating of 3 (minimally improved) to 7 (very much worse) were categorized as slow responders.

Results:

The proportion of time that children spent in adult-initiated JE significantly increased at week 3 ($F(1,52)=14.8$, $p=0.0003$) and at week 6 ($F(1,52)=14.5$, $p=0.0004$). There were 9 responders and 18 slow responders to the intervention at week 6. Changes in adult-initiated JE from baseline to week 3 ($Z=-0.646$, $p=0.52$) and to week 6 ($Z=-1.168$, $p=0.243$) did not predict response.

Conclusions:

Children in DTT increased the time spent in adult-directed JE over six weeks of intervention. However, the increase in adult-directed JE did not predict responder status which measured children's *spontaneous*use of social communication. This suggests that children in DTT were more attentive and responsive to instruction over time but did not necessarily increase their use of *spontaneous*social communication. Therefore, this result did not capture the mechanism for change in social communication that one would expect in developmental interventions. This may be due to the nature of DTT instruction, where children are expected to be more responsive to the interventionists' prompts and may have fewer opportunities to initiate. Future research should further examine the quality of joint engagement (adult versus child-led) across instructional models.

78 **168.078** Judgments of Discourse Quality and Impression Formation of Adults with Autism Spectrum Disorder

P. Geelhand *and M. Kissine, ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium*

Background: Studies of spoken discourse in Autism Spectrum Disorder (ASD) essentially rely on transcripts, and suggest less coherence relative to neuro-typicals (NT) (e.g. Baixauli, Colomer, Rosello, & Miranda, 2016; Stirling, Douglas, Leekam, & Carey, 2014). Individuals with ASD are also perceived as socially more awkward than their typical peers (Bone, Black, Ramakrishna, Grossman, & Narayanan, 2015; Grossman, 2015). Crucially, negative first impressions of adolescents with ASD have also been associated with reduced intentions to take up or maintain social interactions with these individuals (Sasson et al., 2017). However, up to date, no study has sought to directly relate the linguistic features identified in transcripts with impression formation of the speaker. Furthermore, studies have focused essentially on the impressions of typically developing individuals.

Objectives: The aim of the current study is to relate discourse features identified in transcripts with their perception by naïve listeners with and without a diagnosis of ASD as well as their contribution to impression formation of the speaker. Our research questions are threefold:1) Do naïve listeners perceive discourse features identified in transcript analyses? 2) If so, do they influence rater's impression of the speaker? 3) Are there group differences in the perception of discourse features?

Methods: To measure participants' impression of discourse abilities and the speaker, a rating scale was designed. Seven items targeted discourse quality (i.e. relevance, referential cohesion, coherence, level of detail, naturalness, fluency and perseverance) and four items targeted subjective impressions of the speaker (i.e. ease of understanding speaker, ease of being understood by speaker, likelihood of becoming friends, and typicality). Rating stimuli were 12 audio recordings of a dyadic conversation on the topic of relationships. Six audios involved an experimenter and a NT speaker (3 females, 3 males) and six audios involved the same experiment and an ASD speaker (3 females, 3 males). Raters were 16 participants with ASD (7 males), mean age = 28.98 (SD = 7.81), mean IQ = 113.01 (SD = 16.79). Testing is still on-going for 4 participants with ASD and the NT participants (matched on sex, age and IQ).

Results: There was a significant main effect of speaker's diagnostic ($\chi^2(1) = 44.926$, $p < 0.001$), with ASD speakers receiving overall lower ratings ($M=4.57$, $SD=1.78$) than NT speakers ($M=5.10$, $SD=1.55$). There was also a significant interaction between speaker's diagnostic and scale items ($\chi^2(10) = 48.889$, $p <0.001$). ASD speakers received significantly lower ratings on discourse relevance, referential cohesion, coherence, level of detail and fluency, as well as speaker's perceived typicality.

Conclusions: These preliminary results suggest that ASD participants rated ASD speakers' discourse, as well as ASD speakers themselves, as being less typical than their NT peers. Interestingly, there was no significant effect of speakers' diagnosis on perceived ease to understand the speakers and being understood by them as well as likelihood to become friends. It remains to be determined whether NT raters will perceive discourse

abilities and the speaker similarly to ASD raters, viz. whether speaker's diagnostic will have an effect on the same scale items.

79 **168.079** Language Preference & Proficiency in Sequential Bilingual Children with Autism Spectrum Disorders (ASD)

C. A. Mendez- Rossello *and R. E. Oliveras, Behavior & Brain Sciences, Ponce Health Sciences University, Ponce, PR*

Background: Children with ASD have been informally observed and have been associated with the preference of English in television programs, movies, and even as a way to learn and communicate; this being assumed by some Speech and Language Pathologists in Puerto Rico (2016). Objectives: The study titled Language preference and proficiency of sequential bilingual children with Autism Spectrum Disorders (ASD) was conducted with the purpose of investigating bilingualism in families with at least a child with ASD, and the language best dominated and preferred by the child. Also, to understand the nature of the language practices, and their limitations or constraints according to administered surveys.

Methods: The first phase of the method was the administration of instruments, which had an exploratory approach and identified the preferences of language and other types of exposure to language of these children. This was measured with the Survey for Parents, The Survey for Speech and Language Therapists and Pathologists, Special Education Teachers, Psychologists, as well as other Professionals and with the Screening Sheets of Exposure to Language for Parents. The participants or subjects on this stage had to meet the following criteria: (a) ages of 6-12 years old, (b) a documented diagnosis of ASD, (c) Puerto Rican living in Puerto Rico, and (d) being a sequential bilingual (Spanish/ English).

Results: A sample of *n=38* completed the first phase of this study. The sample of participants varied between parents of children with ASD and Professionals who give services to children with ASD. The majority of the sample was composed of women (92.1%). The results indicate that (92.1%) of the children with ASD prefer English. Also, it was reported that the frequency of English usage was *pretty much*(51-75; ¾) reflecting itself as a percentage of 51.7%. Finally, the results detected that the language used to communicate with the minors is Spanish (48.6%). Nevertheless, both languages (English/ Spanish) are used with the same frequency with a ratio of 45.7%.

Conclusions: According to the review of literature and theoretical framework, the English language is preferred by children with ASD. This language facilitates learning and communication; what is affirmed by the Speech and Language Pathologists in Puerto Rico. This may be due to the concreteness of the English language and linked to the metrical organization of speech. English is an easier language to acquire by children with autism since phonological development tends to be easier to attain because in Spanish the word length (number of syllables) tends to be significantly longer.

80 **168.080** Language Profiles of Infants Showing Early Signs of Autism Spectrum Disorder (ASD)

S. Dimov[1]*, T. Iacono*[2]*, K. J. Varcin*[3,4]*, M. Boutrus*[4,5]*, L. Chetcuti*[4,6]*, A. J. Whitehouse*[3,4] *and K. Hudry*[4,6,7]*, (1)Olga Tennison Autism Research Center, La Trobe University, Melbourne, Australia, (2)La Trobe Rural Health School, La Trobe University, Bendigo, Australia, (3)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (4)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (5)Telethon Kids Institute, University of Western Australia, Perth, Australia, (6)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (7)Victorian Autism Specific Early Learning and Care Center, Olga Tennison Autism Research Centre, Melbourne, Australia*

Background:

Impairment or delays in language acquisition are among the clearest early indicators for Autism Spectrum Disorder (ASD). Typically, children understand words before they can use them (i.e., receptive language advantage). While children on the autism spectrum may have both receptive and expressive language delays or impairments, some past research suggests *receptive* language may be relatively more impaired (e.g., Hudry et al., 2010; 2014). However, few studies have investigated receptive-expressive language profiles in infants showing early signs of ASD.

Objectives:

To investigate language profiles in a unique cohort of infants showing early signs of ASD identified via community-referral, using multiple measures.

Methods:

A cohort of 94 infants with multiple language assessment data were assessed (67.0% male) aged 9-16 months (*M* = 12.32, *SD* = 1.97). Parents/caregivers completed the Vineland Adaptive Behavior Scales (VABS) for functional receptive and expressive communication, and the MacArthur Bates Communication Development Inventory (MCDI, Words and Gestures form) for receptive and expressive vocabulary. Direct assessment included the Autism Observation Scale for Infants (AOSI), a measure of early signs of autism, and the Mullen Scales of Early Learning (MSEL), yielding a measure of child receptive and expressive ability.

Results:

Both receptive and expressive language domains were delayed in this cohort when compared to chronological age. Correlational analyses revealed only moderate to low agreement among the two parent-report and one direct assessment of language. No evidence of reduced receptive advantage was observed in this cohort, in that language profiles were indicative of a more normative profile. Regression analyses revealed that autism symptoms were not predictive of receptive advantage on any of the measures. However, MSEL receptive advantage was significantly predicted by higher nonverbal abilities, and MCDI receptive advantage by older chronological age. No predictive associations were apparent for the VABS receptive advantage.

Conclusions:

Existing research on language profiles with diagnosed children and 'high-risk' infant siblings may not generalise to community-referred samples and/or very young infants showing early signs of ASD.

81 **168.081** Language, Gesture, and Looking Patterns during Viewing of Social Interactions in Children with Autism Spectrum Disorder: Results from the ABC-CT Interim Analysis

M. L. McNair[1]*, A. Naples*[1]*, D. A. Trevisan*[2]*, R. Bernier*[3]*, C. Brandt*[4]*, K. Chawarska*[1,5]*, G. Dawson*[6]*, J. Dziura*[4]*, S. Jeste*[7]*, C. A. Nelson*[8]*, F. Shic*[9,10]*, C. Sugar*[7]*, S. J. Webb*[3] *and J. McPartland*[1]*, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Faculty of Education, Simon Fraser University, Burnaby, BC, Canada, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)Yale University, New Haven, CT,*

(5)Child Study Center, Yale School of Medicine, New Haven, CT, (6)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (7)University of California, Los Angeles, Los Angeles, CA, (8)Boston Children's Hospital, Boston, MA, (9)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (10)Pediatrics, University of Washington School of Medicine, Seattle, WA

Background: Autism spectrum disorder (ASD) is characterized by social communication difficulties, impacting both language and gesture. It is known that decreased attention to faces when viewing social interactions correlates with lower language abilities in ASD; however, it remains unclear how the presence of spoken language during viewed social interactions influences looking patterns.
Objectives: To investigate relationships among linguistic and gestural abilities with looking patterns to videos of social interactions with and without spoken language.

Methods: Eye-tracking data were collected across five sites from 161 children with ASD between the ages of 6 and 11 years (mean age=8.71 years, mean IQ=95.80) and 64 age-matched typically developing (TD) controls (mean age=8.73 years, mean IQ=114.64). Using a SR EyeLink-1000+ to collect eye-tracking data, participants viewed videos in which two people engaged in a shared activity. In one paradigm, actors spoke to each other; during a second paradigm, actors did not speak. Receptive and expressive language function was assessed by parent report on the *Vineland Adaptive Behavior Scales, 3rd Edition.* Gesture was assessed with the *Autism Diagnostic Observation Schedule, 2nd Edition* (*ADOS-2*) gesture scores. Repeated measures ANOVAs compared the log of the ratio of percent looking to activity compared to percent looking to face between eye-tracking paradigms. The relationship between the log-ratio and the *Vineland-3* Communication Scores were analyzed using Pearson's correlations, and gesture scores were analyzed using Spearman's correlations.

Results: Across both paradigms, children with ASD looked significantly less to faces compared to activity than TD children ($F(1,223)=7.625$, $p=0.006$). While there was no significant difference in looking time to faces in the TD group between speech and non-speech videos, children with ASD looked significantly less to faces compared to activity during videos with speech ($F(1,223)=32.931$, $p=0.001$). In children with ASD, higher *Vineland-3* expressive language scores significantly correlated with greater looking time to faces during the videos with speech ($r(161)=-0.203$, $p=0.010$). In TD children, greater *Vineland-3* receptive scores significantly correlated with more looking to faces compared to activity during the speech videos ($r(63)=-0.269$, $p=0.033$). There were no significant correlations between *Vineland-3* expressive or receptive scores and looking time to faces during non-speech videos in either diagnostic group, and *ADOS-2* gesture scores did not significantly correlate with looking time to faces during non-speech or speech videos in either diagnostic group.

Conclusions: In children with ASD, the presence of language in videos of social interactions was associated with decreased attention to faces; however, greater expressive language functioning in this group was related to increased attention to faces. This study highlights that speech may modulate preferential looking to faces in ASD and that eye-tracking studies should carefully consider content of stimuli. Future studies should investigate how associated features of ASD, such as social anxiety, impact attention to faces while viewing verbal and non-verbal interactions.

82 **168.082** Language, Grammar, and Nonverbal Cognitive Abilities in Adolescents and Young Adults with ASD: A Pilot Study

T. M. Girolamo *and M. L. Rice, Child Language Doctoral Program, University of Kansas, Lawrence, KS*

Background: Little is known about the language abilities of adolescents and young adults with Autism Spectrum Disorders (ASD). Even less is known about how language abilities in this age range may relate to other developmental outcomes, such as nonverbal cognitive abilities. Previous work has found that some individuals with ASD may also have language impairment. Yet there is a gap in understanding how language, grammar, and nonverbal cognitive abilities may relate to one another. This gap has direct implications for understanding the phenotypic variability in autism, as well as in meeting the needs of individuals with ASD across the life span.
Objectives: A pilot study was carried out to investigate the following research questions:

1. How do language abilities compare to grammar abilities?
2. How do language abilities relate to nonverbal cognitive abilities?
3. How do nonverbal cognitive abilities compare to grammar abilities?

Methods: The Institutional Review Boards of the University of Kansas and the New York City Department of Education approved this study. This study was a descriptive study evaluating the efficacy of individualized assessment. Participants were assessed in a single session outside of school. The assessment protocol consisted of: 1) the Clinical Evaluation of Language Fundamentals-3 (CELF-3); 2) the Test for Early Grammar Impairment (TEGI); 3) the Columbia Mental Maturity Scale (CMMS), and; 4) the WISC-III Digit Span (D-Span).

All participants (n=10) carried a diagnosis of ASD, as students in a specialized school where most students qualify for Title I funding and free/reduced lunch, and were exempt from state standardized testing. The least restrictive environment of all participants was a self-contained classroom in a ratio of 8 or 12 students to 1 classroom teacher and 1 classroom paraprofessional. All participants were male, a racial/ethnic minority, and an adolescent (M = 18.3 years, range = 15 - 21 years).

Given the exploratory nature of the study, analyses included descriptive analysis and visual inspection of the data.

Results: Results revealed that:

1. Language abilities may not straightforwardly associate with grammar abilities. While CELF-3 scores showed little variation, with 80% showing a floor effect, the TEGI showed more variability. 50% of participants demonstrated adult-like performance (i.e., 97% or above).
2. Language abilities may not straightforwardly associate with nonverbal cognitive abilities. There was greater variability in the CMMS and the WISC III D-span than the CELF-3, such that 50% of participants had a maturity index of above 9L on the CMMS and 10% had an above-average on the D-span. An additional 20% had a score one SD below the mean on the D-Span.
3. Nonverbal cognitive abilities may not straightforwardly associate with grammar abilities. Some participants had relatively high maturity indices but non-adultlike grammar abilities.

Conclusions: Preliminary findings suggest that language, grammar, and nonverbal cognitive abilities may not always positively associate with one another. To better understand the relationships between various developmental outcomes in individuals with ASD, future research should focus on expanding the sample size and on documenting outcomes over time.

83 **168.083** Local and Global Processing in Adults with Autism: Relation between Narrative and Perceptual Abilities

F. Papastamou[1], *P. Geelhand*[2] *and M. Kissine*[2], *(1)Université Libre de Bruxelles, Bruxelles, Belgium, (2)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium*

Background:

Previous studies have shown that individuals with autism spectrum disorder (ASD) tend to structure their narrative around details rather than on global events (Barnes, & Baron-Cohen, 2012; Diehl, Bennetto & Young, 2006; Jolliffe & Baron-Cohen, 2000; Rumpf *et al*., 2012). Weak Central Coherence or Enhanced Perceptual Functioning are often invoked to explain these results, the core idea being that ASD individuals display a reduced influence of global information and enhanced focus on detail (Happé & Frith, 2006; Mottron *et al*, 2006). Yet, this relationship between narrative and perceptual abilities has not been experimentally tested.

Objectives:

We explore the relation between local/global processing in narrative and perceptual tasks in adults with ASD compared to NT controls.

Methods:

We analyse the story grammar (number of gist events vs. irrelevant details) in the online storytelling, based on the picture book 'Tuesday' from the ADOS-2. Our participants are 20 adults with ASD and 20 controls matched on age (mean=28), sex (14 males, 6 females), verbal IQ (mean=111), perceptual IQ (mean=106) and total IQ (mean=108). We also measure reaction times (RTs) and accuracy on four sub-tasks of the WAIS-V battery: Block Design, Picture Completion, Similarities and on a Block Design segmented task. Finally, participants' mental inhibition is measured with the Stroop interference test.

Results:

There is a strong Group effect on gist and details enunciation in narratives, with ASD participants verbalizing less gist, and more details in their narratives than NT participants.

There are no Group effects on RTs in Block design or on the effect of stimuli segmentation. However, there is a strong effect of Block Design RT on gist enunciation (but no interaction with Group). The faster participants are on this task, the more gist they provide in their narrative.

There is a significant effect of Picture Completion RT, and a strong interaction RT X Group effect on details enunciation. The faster ASD participants are to detect missing details on a figurative picture, the more details they tended to provide in their narrative.

Interestingly, there is a significant Stroop x Group interaction effect on picture Completion RT. For NT participants, the better they score on mental inhibition, the faster they are to detect missing details on a figurative picture. And finally, there is a significant Stroop interference x Group interaction effect on details enunciation. For ASD participants, the better they score on mental inhibition, the fewer irrelevant details they provide in their narratives (see Figure 1 & Table).

Conclusions:

While NT participants showed a global bias in a detail-focused figurative task (Picture Completion), ASD participants showed a local bias in global-focused one (Narrative). Interestingly, the results reveal that those bias are linked to mental inhibition. Thus, in global focused tasks involving no local distraction and clear instructions (i.e. Block Design Task and Similarities task), ASD participants perform similarly to NT participants.

84 **168.084** Machine Learning Classification of Natural Conversational Utterances Using Acoustic Features Drawn from Children with ASD and Typical Controls

S. Cho[1], *M. Liberman*[2], *N. Ryant*[1], *K. Bartley*[3], *R. T. Schultz*[4] *and J. Parish-Morris*[4], *(1)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (2)University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA*

Background:

The earliest descriptions of autism spectrum disorder (ASD) include mention of atypical speech patterns, including unusual prosody. Although phonetic properties of speech have been explored in ASD, most prior research samples were either elicited in a highly structured context (e.g., reading sentences or word lists) or drawn from semi-structured clinical interviews with an autism expert (i.e., ADOS evaluations). While valuable, these studies produce results that may not generalize to the everyday conversations that really matter for children on the autism spectrum. In this study, we address a gap in the literature by developing and testing a machine learning (ML) classification approach to children's natural interactions with a naïve conversational partner.

Objectives:

Automatically measure phonetic features in the natural conversations of children with ASD and typically-developing controls (TD). Develop an ML classifier to predict the diagnostic category of the speaker.

Methods:

Seventy children with ASD (N=35, 13 females) or TD (N=35, 11 females), matched on IQ (ASD: 105; TD: 107; t=-.53, p=.6) and age (ASD: 11.42; TD: 10.57; t=1.33, p=.19), completed a 5-minute "get-to-know-you" conversation with a novel confederate who was not an autism expert (N=22, 19 females). At the turn level, we extracted 31 acoustic features from each participant's utterance using the RAPT algorithm (as implemented in get_f0) for pitch (Talkin, 1995), with Praat (Boersma & Weenink, 2017) and VoiceSauce (Shue et al., 2011) for other intensity and spectral features (Table). To avoid pitch-tracking errors, we ran the pitch-tracker twice, once to estimate the modal pitch range of each speaker and once to pitch-track within the obtained speaker-specific pitch range. Pitch values were normalized from Hz to semitones using the 5th percentile of each speaker as the base. We trained a support vector machine using Scikit-learn (Pedregosa et al., 2011) with a radial basis function kernel and 5-fold cross-validation. All acoustic features were scaled using MinMaxScaler in Scikit-learn. With the classification results of all turns from each child, we implemented a simple majority vote to predict the child's final diagnostic status.

Results:

Our acoustic turn-level classifier correctly identified whether an utterance came from an ASD or TD participant 60.59% of the time. A majority vote at the speaker level using turn-level results correctly distinguished ASD and TD 66.67% of the time. The accuracy of this acoustic/phonetic classifier is better than the 59% average recall reported using phonetic features at the turn level in prior research (Bone et al. 2016), and is especially promising given that current data are drawn from natural conversations with naïve interlocutors, which tend to be messier and more variable than other types of data.

Conclusions:

This preliminary exploration suggests that acoustic features of natural conversation are useful for distinguishing children's diagnostic category, and advances the goal of scaling real-world machine learning applications in ASD. Our next step is to combine multiple classifiers, using more sophisticated algorithms, feature selection methods, and an expanded feature set that includes lexical information (e.g., word choice, frequency of non-speech vocalizations, filled pauses) to predict diagnostic status and estimate symptom severity.

85 **168.085** Maternal Depressive Symptoms and Linguistic Input to Infants at High or Low Risk for Autism Spectrum Disorder

M. Lauze[1], *A. B. Choi*[2], *C. A. Nelson*[3] *and H. Tager-Flusberg*[4], *(1)Tufts University, Medford, MA, (2)Harvard University, Cambridge, MA, (3)Boston Children's Hospital, Boston, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA*

Background: Parents of children with autism spectrum disorder (ASD) experience higher levels of depressive symptoms than the general population (Bailey et al., 2007). Depression can impair parents' social skills, and studies have shown that depressed mothers use fewer overall and less varied words when speaking to their children (Rowe, Pan, & Ayoub, 2005). While this relation has been studied in typical development, it remains less clear whether it is also found among mothers of infant siblings of children with ASD.

Objectives: We aimed to determine (1) whether mothers of infant siblings of children with ASD (high-risk with eventual ASD = HRA+; high-risk with no ASD = HRA-) and mothers of infants with no family history of ASD (low-risk comparison = LRC) experience different levels of depressive symptoms and (2) the relation between maternal depressive symptoms and linguistic input to infants within the first two years of life.

Methods: Mothers completed the Center for Epidemiologic Studies Depression Scale Revised (CESD-R; Eaton et al., 2004) when infants were 6, 12, 18, and 24 months of age. To address objective 1, CESD-R scores of HRA+, HRA-, and LRC mothers were compared at each time point, using nonparametric tests (n = 166). For objective 2, measures of maternal linguistic input (word tokens = number of total words; word types = number of different words) were examined from 10-minute parent-child interactions of a subsample of participants (n = 89) at child ages 12, 18, and 24 months. Correlational analyses were then conducted between maternal depressive symptoms and linguistic input, controlling for maternal education level, for the entire sample.

Results:

(1) Using Kruskal-Wallis tests, we found no significant group difference in CESD-R scores at 6, 18, and 24 months. However, we found a significant group difference in CESD-R scores at 12 months, $\chi^2(2, N = 129) = 6.22$, $p = .045$. Post-hoc analyses using Mann-Whitney U tests revealed that HRA+ mothers' CESD-R scores were significantly higher than those of LRC mothers, $z = -2.237$, $p = .025$. Additionally, HRA- mothers' CESD-R scores were higher than those of LRC mothers, though marginally significant, $z = -1.185$, $p = .069$.

(2) Mothers' 12-month CESD-R scores were significantly, negatively correlated with word tokens and types produced at 24 months, tokens: $r = -.34$, $p = .014$; types: $r = -.33$, $p = .017$. This same relation was found between mothers' 18-month CESD-R scores and token and type production at 24 months, tokens: $r = -.37$, $p = .015$; types: $r = -.45$, $p = .002$.

Conclusions: Mothers of children at high risk of developing ASD did not, for the most part, report higher levels of depressive symptoms. Additionally, mothers who reported higher depressive symptoms tended to use fewer, less diverse words with their children. Understanding maternal linguistic input to HRA children provides insight into these children's subsequent language development.

86 **168.086** Talking Success (Pilot Program): Preparing Young Adults with ASD for Life after Undergraduate Study

ABSTRACT WITHDRAWN

Background:

While college opaquely prepares students for the work force (e.g. study skills equivalent to being prepared for the work day), this is not transparent for students with autism spectrum disorders (ASD). Taylor and Seltzer (2011) reported individuals with ASD to be gainfully employed between 4.1% and 11.8% of the general population. Adults with ASD experience difficulty maintaining jobs, and acclimating to new job settings (Hendricks & Wehman, 2009; Howlin, 2000; Hurlbutt & Chalmers, 2004; Jennes-Coussens, Magill-Evans, &Koning, 2006; Müller, Schuler, Burton, & Yates, 2003). Adult-based social skills, inclusive of performance on a job interview, must be explicitly taught to individuals with ASD, in order to facilitate gainful employment.

Objectives:

Adelphi University in New York created the Bridges to Adelphi Program, to support students who self-disclose as having ASD. Each student has individualized objectives in the areas of academic, social, and vocational skills. The objective of this work was to report on an effective vocational and communication-based intervention for college students with ASD. The focus of this project was to support *pre*-employment. That is, how can an interdisciplinary team facilitate success for students who self-identify as having ASD and who desire, and are capable of, gainful employment?

Methods:

The author developed a pilot program within the Bridges to Adelphi program, called "Talking Success." Eight students engaged in weekly discussions focused on how to communicate effectively in the workplace. Talking Success was designed as an interdisciplinary transitional program, across speech-language pathology, social work, and vocational domains. During Talking Success meetings, students identified their location of employment, and specific duties (social and vocational) required within that particular aspirational site. Sessions were focused on building specific interview skills for each student's self-identified goal (e.g., active listening, formulating alternative responses) and were directed by a social worker and two graduate students studying speech-language pathology, who were supported by weekly meetings held by the author. A vocational trainer held supplementary meetings. Student success was monitored by journal entries from students, weekly reports by student clinicians (supervised by the social worker), and ultimately, obtaining a desired externship.

Results:

Five of the eight students secured their desired internships, with two now gainfully employed post-graduation, and one showing promise for near future employment. While the 20% success rate for gainful employment may appear minimal, one must consider sample size (n=8). Further, for these two individuals, outcomes had great impact on individuals who participated in Talking Success, showing potential for growth and development of this program. Preliminary findings are practical and immediately replicable and generalizable.

Conclusions:

Explicit training on social and vocational skills related to an individual's aspirational location of employment increases the likelihood of securing an externship in young adults with ASD.

87 **168.087** A Novel Hybrid Telehealth Approach for Assessing Social Communication in at-Risk Toddlers in Rural Communities from a Distance

M. R. Talbott[1], *G. S. Young*[2], *M. E. Miller*[1], *S. B. Jackson*[1], *A. C. Stahmer*[1] *and S. Rogers*[3], *(1)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA*

Background: Despite evidence for the efficacy of ASD-specific early behavioral intervention in improving children's outcomes, there remain significant barriers to disseminating empirically-validated treatments to families and community settings (Rogers & Talbott, 2016; Stahmer, Aranbarri, Drahota, & Rieth, 2017). Effectiveness trials demonstrating positive effects of a treatment in the final community setting are needed before public early intervention programs will cover such treatments. One central challenge to the conduct of such randomized controlled effectiveness studies is the measurement of proximal social communication behavioral treatment targets, which require live, reciprocal interactions, for toddlers living in rural and geographically distributed community settings.

Objectives: Our goal is to assess the feasibility, fidelity, validity, and reliability of one approach to meeting this need: a hybrid live-distance assessment, in which professionals working within local EI systems administer a play-based interaction, which is later scored from video by highly trained expert coders blind to study group at the University site.

Methods: Data were collected as part of an ongoing community-based pilot randomized controlled trial (RCT) testing an adapted Community-Early Start Denver Model (C-ESDM) across 4 states: Alabama, California, Colorado, and Pennsylvania. University partners in each state recruited 7 assessors (all female), who were graduate students (*n=1*) and early intervention professionals (*n = 6*) working in their local communities. Assessors received training on an adapted Community-ESDM Curriculum Checklist (CC) via telehealth and received feedback on submitted training tapes before conducting independent assessments. Assessments were scheduled in families' homes, lasted approximately 1.5 hours, and were videotaped for later coding by raters trained to reliability and blind to families' study group. Analyses examined the following 4 measures: Feasibility (proportion of scheduled visits completed); Fidelity (number of administrations meeting published CC administration and scoring rules); Inter-rater reliability (agreement between assessor and coding scores); and Validity (relations between assessor-derived CC scores and standardized and normed measures of social communication).

Results: 31 children (21 male) receiving low-intensity early intervention (EI) services by participating providers, and their caregivers, enrolled and had an intake assessment scheduled. An additional 3 families enrolled but withdrew before scheduling. Families completed 97% (30 of 31) of scheduled visits, indicating high feasibility. Preliminary analyses indicate acceptable fidelity levels for community assessors. Intra-class correlation coefficients for the Curriculum Checklist Proportional Score Totals between 21 coders and assessors was .87, indicating excellent interrater reliability. There were significant positive correlations between the MacArthur Bates total vocabulary inventory for both assessor (r = .57, p = .03, n = 15) and coder (r = .56, p = .03, n = 18) total scores.

Conclusions: While this method requires substantial efforts and staff time, it provides a potential route for increasing the participation of at-risk toddlers living in rural and low-resources areas into high-quality University-based treatment studies. This increases the acceptability and validity of the interventions and procedures.

Poster Session
169 - Diagnostic, Behavioral, Sensory and Intellectual Screening and Assessment
11:30 AM - 1:30 PM - Room: 710

88 **169.088** The Autism Preschool Peer Interaction Observation Scale (APIOS): Naturalistic Observation to Assess Social-Communicative Skills during Ongoing Interaction with Peers

N. B. Bauminger-Zviely[1] *and A. Shefer*[2], *(1)School of Education, Bar Ilan University, Ramat Gan, Israel, (2)School of Education, Bar Ilan University, RAMAT GAN, Israel*

Background: Peer relations in typical development are cardinal for children's development of ample cognitive, linguistic, and social skills (e.g., Hay, Caplan, & Nask, 2009). Longitudinal evidence shows that individual variations in behavior and in responding to peers' behavior at early ages predict later social competence, even when accounting for factors such as temperament and attachment relations (e.g., Hay et al., 2009). Peer relations do not develop typically in children with autism spectrum disorder (ASD), thus limiting peer relationship experiences in young children with ASD and forming the basis for reduced peer engagement across development (Manning & Wainwright, 2010). Yet, naturalistic observation procedures to reliably evaluate spontaneous peer engagement are scarce, and those that are developmentally oriented at the preschool years are even more limited.

Objectives: The major aim of the current study was to examine the validity and reliability of a newly developed peer observation scale, the *Autism Peer Interaction Observation Scale (APIOS)*, in (a) differentiating between preschoolers with ASD and typical age-mates regarding their social functioning during real-life peer interactions in and out of natural classroom environments; and (b) linking the APIOS with frequently used standard reports to assess social-adaptive functioning (Vineland), social dysfunction (SRS-2), autism severity (ADOS), and IQ (Mullen).

Methods: Eighty-five preschoolers (age 3-6 years) participated in the study: *n*=50 individually included high-functioning children with ASD (HFASD; IQ>75) and *n*=35 typically developing age-mates matched on chronological age, IQ, and mothers' education. The theory-based APIOS (Shefer & Bauminger-Zviely, 2016) comprises a 3-hour observational procedure assessing preschoolers' social-communication abilities and difficulties during spontaneous peer interactions during various activities in and out of preschool. The APIOS includes 9 categories and 17 subcategories for *adaptive social functioning* (nonverbal communication, functional and complex social behaviors, prosocial behaviors, social and imaginary play, conversation, range and quality of facial expressions) and another 3 categories for *non-adaptive behaviors* (aggressive, stereotyped-repetitive, and irregular sensory interest), rated by the observer along a 4-point scale from 1 (typical) to 4 (very atypical behavior). APIOS inter-rater reliability, established for approximately 20% of preschool observations, ranged from 85.7% to 96.4%. To evaluate adaptive skills and social functioning, the Vineland and SRS-2 were completed by children's teachers.

Results: Main results verified the APIOS's distinctive value in differentiating HFASD from typical groups, with the latter showing more adaptive socio-communication and fewer non-adaptive behaviors. Based on the APIOS, we also clustered behaviors according to severity of socio-communicative deficit. In HFASD, the most deficient behaviors were imaginary play and conversation, and the more intact behaviors were nonverbal behavior and functional social communication. The APIOS correlated well with the Vineland, SRS-2, and IQ: Children observed to demonstrate more intact peer relations on the APIOS showed higher IQ, better adaptive skills, and fewer social atypicalities. In contrast, only a few significant correlations emerged between the APIOS and ADOS.

Conclusions: We discuss the importance of developing appropriate naturalistic peer-engagement observation procedures to obtain comprehensive assessment of social-communication in HFASD and also to provide intervention guidelines.

89 **169.089** The Playground Observation of Peer Engagement

M. Dean[1] *and Y. C. Chang*[2]*, (1)Education, California State University, Channel Islands, Camarillo, CA, (2)Special Education and Counseling, California State University, Los Angeles, Los Angeles, CA*

Background: Many children with autism spectrum disorder (ASD) have social challenges, which become increasingly apparent as children with ASD enter school. Several commonly used checklists and surveys are used to measure social behaviors of individuals with ASD (e.g., Gresham & Elliott, 2008; Constantino & Gruber, 2005), but these measures rely on reporters' perceptions of behavior, rather than objective observations of social behaviors within authentic social contexts. There is a critical need for social skills assessments that are able to measure the extent to which children with ASD utilize social skills in real life settings (Freeman & Cronin, 2017). The Playground Observation of Peer Engagement (POPE; Kasari, Rotheram-Fuller and Locke, 2005) is a 15-minute observation measure that captures discrete social behaviors by measuring the proportion of time that children spend in different engagement states and the frequency of social initiations, responses, and conversations. The POPE has been shown to detect changes in behaviors of children with ASD in naturalistic environments.
Objectives: The study purpose is to provide a systematic review of social skills intervention studies that have utilized the POPE to measure the effect of interventions on peer engagement in naturalistic environments.

Methods: A comprehensive search using three electronic databases and keyword search terms (Playground Observation of Peer Engagement, POPE, autism, ASD, playground observation, peer engagement) yielded 74 articles. Eight articles met the inclusion criteria: (a) Participants with ASD were in kindergarten through high school and were educated in a mainstream setting; (b) Social skills interventions at school in inclusive settings; (c) POPE was used to examine changes in social engagement of individuals with ASD.

Results: Selected articles include four randomized controlled trials (Kasari et al, 2016; Kasari, et al, 2012; Kretzman, et al, 2015; Shih, et al., 2018), one quasi-experimental design (Locke, et al, 2018), and three single subject experimental designs (Ezzamel & Bond, 2017; Radley et al., 2014; Radley et al., 2017). One hundred and ninety-six socio-economically and ethnically diverse children with ASD (ages 5 -11) participated in social interventions at school. POPE observations occurred before the start of the intervention (Baseline), post intervention (Exit), and four to six weeks post intervention (Follow-up). Evidence of behavior change was reported for Solitary, Joint Engagement, and Initiations and Responses. Five studies reported a significant decrease in Solitary between baseline and exit, with participants maintaining effects at follow-up (n=4). Six studies reported increase in Joint Engagement pre and post assessment, with four studies maintaining the effects at follow-up. Three studies reported an increase in positive social initiations and social responses post intervention, with two studies reporting maintenance effects at follow-up.

Conclusions: The POPE is an ecologically valid observation instrument that is able to capture discrete social behaviors of a diverse population of children with ASD at school. Currently, POPE observations have only been tested in elementary school settings. Research is needed to examine the usefulness of the POPE in secondary settings, and to examine which variables on the POPE are consistently being used to measure change.

90 **169.090** Latent Profiles of Social Interaction and Classroom Educational Experiences in Students with Autism Spectrum Disorder

N. Sparapani[1]*, V. P. Reinhardt*[2]*, J. Traser*[1]*, A. C. Stahmer*[3] *and P. Mundy*[4]*, (1)School of Education, University of California, Davis, Davis, CA, (2)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (4)University of California at Davis, Sacramento, CA*

Background: Teachers report feeling underprepared to effectively program for students with Autism Spectrum Disorder (ASD) and less able to manage social communication and behavioral concerns characteristic of ASD (Locke et al., 2015). Difficulty providing effective programming for students with ASD has been identified as a significant source of stress, leading to low self-efficacy and a higher frequency of teacher burnout (Boujut et al., 2017)—which could place students with ASD at risk for educational failure. This could, in part, relate to the notable heterogeneity in social communication skills that students with ASD present in educational settings (Fleury et al., 2014).
Objectives: The purpose of this study was to identify subgroups of students with ASD based upon a set of social interaction features and examine if and how social interaction patterns influence the nature and quality of students' classroom experiences.

Methods: Participants include 119 preschool–3rd grade students with ASD and their teachers (*n* = 65) across 16 districts who were video-recorded in their classrooms at the beginning of the school year. Research assistants coded a 10-minute sample of the video observation using an adapted version of the *Classroom Measure of Active Engagement* (Sparapani et al., 2016) and Noldus Observer® Video-Pro Software (XT 14; 2017). Inter-rater agreement between the coders indicated overall good reliability, with coefficients ranging between 82–98%. We utilized latent profile analysis (LPA) to identify subgroups of interaction among students with ASD and compared models with two, three, and four profiles based on students'

communicative intentions (protesting, regulating others' behaviors, securing attention, commenting and asking questions) and the frequency they initiated communication with their peers and looked at others' faces.

Results: Preliminary findings (*n* = 63; 74% male) indicated that four patterns of social interaction best described the sample (Entropy =0.98), showing excellent overall model fit, the best fit in comparison to competing models, and strong membership probability (0.96 to 0.99). Students in subgroup 1 (5% of the sample) showed the highest frequency of comments and questions (2 SD above the sample mean) and initiated communication with peers (1 SD above). Subgroup 2 (10%) was characterized by a high frequency of protesting (3.5 SD above). Subgroup 3, the largest group (80%), was characterized by limited communication and eye gaze overall (0.5 SD below the mean). Students in subgroup 4 frequently communicated to gain a social partner's attention (4 SD above), exhibited a higher rate of communication and eye gaze overall, and frequently communicated with peers.

Conclusions: These preliminary findings indicate that patterns of social interaction form constellations that vary among students with ASD. We will run further analyses to explore the dynamic relations among profile membership, teacher discourse moves, and the quality of instructional practices. Examining the influence that profile membership may have on the nature and quality of students' educational experiences within classroom activities will provide insight into malleable features that support student engagement and help to guide educational programming for learners with ASD.

91 **169.091** The Brief Observation of Social Communication Change (BOSCC) Using Naturalistic Social Interactions for Minimally Verbal Children with ASD

S. H. Kim[1], *R. Grzadzinski*[2] *and C. Lord*[3], *(1)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY, (2)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (3)University of California Los Angeles, Los Angeles, CA*

Background: The Brief Observation of Social Communication Change (BOSCC), a new treatment outcome measure, is designed to provide a standardized and efficient method of measuring changes in social and communicative behaviors in children with ASD over a relatively brief period of time (minimum of 8 – 12 weeks), observed in a naturalistic, play-based, semi-structured environment. The BOSCC offers the possibility of truly "blinded" scoring of videos by non-expert human coders. Much progress has been made in recent work on the BOSCC including the initial evidence of its strong reliability and validity (Grzadzinski et al., 2016; Kim, Grzadzinski, Martinez, & Lord, 2018).
Objectives: 1) We aim to synthesize the results from our recent work to demonstrate the initial validity and reliability of the BOSCC based on parent-child interactions (Grzadzinski et al., 2016)as well as examiner-child interactions using the standardized segments from the Autism Diagnostic Observation Schedule (ADOS; referred to as the ADOS-BOSCC hereafter) in minimally verbal children (Kim, Grzadzinski, Martinez, & Lord, 2018)as well as the work by other groups (Divan et al., 2018; Fletcher-Watson et al., 2016; Kitzerow, Teufel, Wilker, & Freitag, 2016; Nordahl-Hansen, Fletcher-Watson, McConachie, & Kaale, 2016). 2) We will also propose future directions to extend the usefulness of the BOSCC based on interactions across different adult social partners (e.g., parents vs. blind examiners) as well as varying contexts (e.g., lab vs. home).

Methods: Initial psychometric studies of the BOSCC and ADOS-BOSCC included 56 children with ASD ranging from 1-5 years of age. Inter-rater and test-retest reliability as well as convergent validity were examined. The feasibility of the BOSCC application across different social partners and settings were examined based on past and on-going studies of 72 young children with ASD.

Results: Initial studies of the BOSCC and the ADOS-BOSCC demonstrated high inter-rater and test-retest reliability (intra-class correlations ranging from 0.79-0.98) as well as strong convergent validity with measures of language and adaptive communication skills. Changes in social communication skills were observed in minimally verbal children using the BOSCC with parent-child and examiner-child interactions with medium effect sizes (Cohen's d= 0.3-0.6). A preliminary analysis based on 72 toddlers showed that the BOSCC scores obtained from the lab versus home environment did not differ significantly (t=.474, p=.492). Using a subset of children (n=49), the BOSCC scores based on examiner-child interactions were highly correlated with the BOSCC scores based on parent-child interactions (r=0.8, p<0.01).

Conclusions: The BOSCC could provide blinded observations of social communication changes in minimally verbal children with ASD under 5 years of age across different social partners and contexts with high reliability and validity. We hope to extend the usefulness of the BOSCC in future studies to further examine its strengths and limitations as well as the additive effects of the information gathered through different contexts on measuring treatment outcome.

92 **169.092** A 6-Year Trend Survey from a Childhood Autism Surveillance Program in Lagos, Nigeria

E. A. Campbell[1], *K. A. Ogunsola*[1], *T. Adegbite*[1], *A. E. Lamikanra*[2] *and Y. Oshodi*[3], *(1)Lagos University Teaching Hospital, Lagos, Nigeria, (2)Blazing Trails International, Frisco, TX, (3)University of Lagos College of Medicine, Lagos, Nigeria*

Background:
The increased need for research to determine the burden of Autism in Africa also draws attention to the need to address the service gap and related challenges in autism care in many African countries. Stakeholder Collaboration can play roles at varying levels, a strategy which may herald the discovery of sustainable solutions which will evolve to address this challenge.

Objectives:

The report aims to describe some of the findings, processes and strengths of a stakeholder driven, community surveillance program over a period of 6 years (2013 to 2018).

Methods:

Clinical evaluation sessions held over 4-5 day periods each year. The evaluations were conducted by a multidisciplinary team of volunteers from different agencies/sectors. Assessments were made based on the DSM 5 Criteria for Autism.

Results:

The collaborative team drawn from the private sector (GTBank & NGO's), public sector and educational sector (University and other skilled volunteers) comprised multidisciplinary professionals committed to autism care. The 6-year experience had over 1050 attendees in total with varied neurodevelopmental disorders. Majorities were males with age range between 1 and 40 years

About a third were clearly not ASD (who were referred out) or had incomplete data. More than half proceeded for further evaluations each year

being: 58, 94, 134, 101, 72 & 104 consecutively.

For Majority this consultation was their first contact with formal orthodox care. Repeat attendees were noted from 2014 to 2018. This ranged between 7 and 35%. Caregiver burden was clearly evident each year amongst caregivers.

Conclusions:

This program highlights that much can be achieved through team work. In the face of scarce resources, a collaborative effort is a useful strategy to ensuring service delivery in Africa where there are little or no ASD relevant services. Monitoring, evaluation and quality assurance processes need to be continually included and reviewed in such programs going forward.

93 **169.093** A Comparison of Parent-Reported and Clinician-Reported Measures of Autistic Traits in Bilingual and Monolingual Autistic Children

J. J. Finnemann[1], *S. Crockford*[2], *N. Katsos*[2] *and J. L. Gibson*[2], *(1)Psychiatry, University of Cambridge, Cambridge, United Kingdom of Great Britain and Northern Ireland, (2)University of Cambridge, Cambridge, United Kingdom*

Background: There is a growing literature on the cognitive profile of bilingual speakers and its unique advantages and disadvantages. Current evidence suggests that bilingualism confers advantages in the area of executive function, specifically attention control, inhibitory control and cognitive flexibility (Bialystok & Majumder, 1998; Bialystok, 1999; Bialystok, 2003; Bialystok & Viswanathan 2009; Kovacs & Mehler, 2009; Carlson & Meltzoff, 2013). However, evidence from the language development of bilingual children suggests that exposure to more than one language may results in delays in first word acquisitions, compared to monolingual children, (Meisel, 2004) and smaller overall vocabulary size (Ben-Zeev, 1977). In light of the latter evidence, parents of children with primary language impairment or other communication difficulties such as autism have historically often been advised to restrict the language input to one language (Juarez, 1983; Thordardottir, 2002; Kremer-Sadlik, 2005). While evidence is converging that multilingual environments are not detrimental to development in ASD (Uljarevic et al, 2017), it is poorly understand how the convergence between differences in bilingual and autistic language development may impact assessments and interventions for autistic bilingual children.

Objectives: To perform an explorative investigation of parent-reported and clinician measures of autistic symptomatology in bilingual and monolingual children with ASD.

Methods: ADOS and parental SRS data were collected as part of a multi-centre intervention study (Bieleninik et al 2017; TIME-A consortium) and included 45 children with autism raised in a multilingual environment and 319 (314 for the SRS) monolingual children with autism. All children were between the ages of 4 and 7 (mean age = 5.4 years, sd ± 0.99). Multilingualism was identified by the researcher working with the particular child and based on whether the child was exposed to more than one language in their home environment.

Results: Preliminary analyses show that the mean SRS scores for bilingual children were marginally lower (152.31) than for monolingual children (160.53) (p=0.074), indicating less pronounced parent-reported autistic symptoms. On the other hand, ADOS Social Affect scores in the bilingual children were higher (15.84), compared to the monolingual children (13.49) (p=0.001). The differences were primarily the language and communication items (A1-A8) and a few social items (smiling, facial expressions and requesting). Advanced statistical analyses will be reported by the time of the conference.

Conclusions: While the severity of symptoms reported by parents on the SRS was not significantly different between the groups, the ADOS results from the clinicians suggested a higher level of autistic symptoms in the multilingual group. Importantly, the differences seem to arise from items measuring the language and communication of the child, suggesting that additional factors might have to be taken into consideration when clinicians do not have access to all of the languages spoken or comprehended by the children. Further understanding of how the interaction between bilingualism and autism may impact parent reporting and clinical assessments of autism should be our next research priority, to ensure that the currently available tools are appropriate for autistic bilingual individuals.

94 **169.094** A Comprehensive Psychometric Analysis of Factor Models of the Autism-Spectrum Quotient Using Two Large Samples: Model Recommendations and the Influence of Divergent Traits on Total-Scale Scores

M. C. English[1], *G. E. Gignac*[1], *T. A. Visser*[1], *A. J. Whitehouse*[2] *and M. T. Maybery*[1], *(1)School of Psychological Science, University of Western Australia, Perth, Australia, (2)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia*

Background: Similar to clinically-diagnosed autism, autistic traits observed in the neurotypical population are heterogeneous. Psychometric measures of autistic traits, like the 50-item Autism-spectrum Quotient (AQ; Baron-Cohen et al., 2001), take this into account by providing scores on individual trait dimensions in addition to total-scale scores.

However, currently the factor models used for the AQ are diverse. This is an issue for researchers who use the AQ on two levels. First, inconsistencies are created as notionally similar dimensions have been defined in different ways. For example, there are at least ten different ways in which a 'social ability' factor has been defined using the AQ. Second, differences in the models also result in differences in the relationships between factors. Critically, a psychometrically sound model could contain some factors with low inter-correlations, suggesting significant heterogeneity between trait dimensions which would question the interpretability of total-scale scores.

Objectives: Our aim was to conduct a comprehensive large scale psychometric review of existing factor models of the AQ. This would serve to 1) provide guidance as to which models are and are not viable for research purposes, and 2) provide evidence as to whether total-scale scores are adequately interpretable for research purposes, or whether researchers should restrict themselves to observing and comparing individual differences on specific dimensions.

Methods: A series of confirmatory factor analyses were conducted on ten competing AQ factor models. We fitted each model separately to large samples of English-speaking undergraduate students (n = 1702) and individuals from the general population (n = 1280) to obtain indices of psychometric fit. Inter-factor correlations were also calculated for each model to assess the heterogeneity of the factors. Finally, the model that demonstrated the best fit indices was subject to a multi-group factorial invariance analysis, to determine if it showed comparable fit between the undergraduate and general population samples, and an analysis of internal consistency that accounts for inter-factor correlations.

Results: The 28-item three-factor model proposed by Russell-Smith et al. (2001) demonstrated superior fit indices across both samples.

Furthermore, the multi-group factorial invariance analysis indicated that the model fit both samples comparably, suggesting that it is appropriate for use in both samples. Inter-factor correlations for the model varied from weak-negative to moderate-positive. Whilst internal consistency of each of the factors was adequate, internal consistency for the full 28-item scale estimated using coefficient omega hierarchical was poor.

Conclusions: Based on our comprehensive analysis of the existing AQ factor models, we recommend that researchers interested in using the AQ to examine individual trait dimensions use the Russell-Smith et al. (2001) three-factor model, as this model showed the best psychometric fit and internal consistency of the individual factors.

Given that this model excludes a substantial proportion of items on the AQ (indicative of the heterogeneity of these particular items), that some of the inter-factor correlations of this model are low, and that internal consistency of full 28-item scale is relatively poor, we caution researchers against using total-scale AQ scores and instead encourage the use of individual factor scores.

95 **169.095** A Computer Administered Autism and Developmental Disorder Screen for Toddlers (CAADST) Efficiently Improves Identification at the 18-Month Pediatric Visit

P. E. Bergmann[1], *R. A. Sturner*[2,3], *B. J. Howard*[4,5], *L. Stewart*[6,7], *S. M. Attar*[4] *and K. Bet*[4], *(1)ForesightLogic, Shoreview, MN, (2)Pediatrics, Center for Promotion of Child Development through Primary Care, Baltimore, MD, (3)Pediatrics, Johns Hopkins U School of Medicine, Baltimore, MD, (4)Total Child Health, Baltimore, MD, (5)Pediatrics, The Johns Hopkins U Sch. of Medicine, Baltimore, MD, (6)Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (7)Center for Promotion of Child Development through Primary Care, Baltimore, MD*

Background:

To achieve early identification, “autism specific” screening is recommended by the American Academy of Pediatrics (AAP) at both 18 and 24-month visits. The Modified Checklist for Autism in Toddlers- Revised (M-CHAT-R) screen has been shown to require a follow-up interview (M-CHAT-R/F) (Kleinman, 2008) and may be less accurate at the 18-month visit than 24-months (Pandey, 2008) (Sturner, 2017). Preliminary data suggested that algorithms of individualized item presentation with computer assisted administration and scoring may improve accuracy for younger toddlers. The AAP also recommends screening for other developmental disabilities at the 18-month visit using a “broadband developmental screen”. It has been suggested that “autism specific” and “broad band” items may have overlapping clinical value when considered together. Yet the predictive performance of combined screening has not been examined when screen positive cases as well as screen negative children are considered.

Objectives:

To develop optimal decision trees of parent administered items to improve the accuracy of detecting autism and other developmental disorders at the pediatric 18-month visit.

Methods:

Parents of 11,878 children 16-20 months old completed the M-CHAT-R before 18-month pediatric visits via an online system (CHADIS). Positive screens (96) and practice matched controls (314) were recruited and parents completed additional items derived from prospective studies of autism outcomes that showed promise for identification of autism (First Years Inventory (FYI); Parents Observation Checklist [POC]; MacArthur-Bates Communicative Development Inventory; Parent Observation of Social Interaction (POSI)). The children had diagnostic autism evaluations using the Autism Diagnostic Observation Schedule- Toddler version and Mullen Scale of Early Development with clinical impression of autism considered to be a positive for autism. Developmental disorder (DD) was defined as the typical entry criteria for early intervention services (score >1½ SD below the mean on >=2 subscales or >2 SD on 1 subscale). Optimized decision trees for predicting autism and DD diagnoses were created through application of recursive partition models (CART) of the potential predictor variables using a random selected subset of the dataset and tested with the holdback sample resulting in decision rules (Computer Assisted Autism and Developmental Screen for Toddlers or CAADST) for presenting varying numbers (7 to 21) of items to subgroups of parents.

Results:

ROC analyses of CAADST showed improved sensitivity (0.92) compared to both M-CHAT-R/F (0.27); M-CHAT-R (0.62) and M-CHAT-R + ASQ (0.75) and higher Negative Predictive Values (NPV; 0.92 compared to M-CHAT-R (0.76); M-CHAT-R/F (0.68); or M-CHAT-R + ASQ (0.81); with lower rates of specificity (0.60 vs 0.93) and PPV (0.56 vs 0.70) compared to M-CHAT-R/F but similar specificity and Positive Predictive Value (PPV) to both M-CHAT-R and M-CHAT-R + ASQ.

Conclusions:

An algorithm for computer administered parent report items correctly identified more toddlers with autism and/or developmental disorder with greater certainty that a child with a negative screen does not have a problem than the standard combination of broadband and autism specific tools in a community sample using fewer items and no follow up interview.

96 **169.096** A New Adult Screening Measure for Autism, an International Collaborative Project and Initial Results

E. Diamond[1], *A. Rediker*[2], *P. Dwyer*[3] *and J. M. Diamond*[4], *(1)The Wright Institute, Berkeley, CA, (2)Clinical Psychology, The Wright Institute, Berkeley, CA, (3)Department of Psychology, University of California, Davis, Davis, CA, (4)Pediatrics, Kaiser Permanente Hospital, South San Francisco, CA*

Background:

Despite increasing rates of autism diagnoses among children, evidence suggests that many adults with autism remain undiagnosed. Internationally, adults seeking diagnostic evaluations are sometimes screened with tools originally designed for children or adolescents, or that were designed as measures of autistic traits in the general population. Due to the proprietary nature of some tools, assessments can also be expensive, even in places with universal healthcare.

Objectives:

The aim was to make a free adult autism screening measure with collaboration from those with autism and other stakeholders. All participants took a preliminary version of the questionnaire and could offer feedback on items and wording.

Methods:

An English language questionnaire was made, based on the type of difficulties commonly experienced by autistic adults. As the autism spectrum

includes those who may not use spoken language or may have intellectual challenges, adult siblings, parents, care workers and others with extended close contact with an autistic person were invited to participate. To increase participation from several countries, social networking was used. There were 32 items focusing on typical areas of struggle for autistic adults. For most questions, the participant was given age ranges to indicate when the difficulty was first noticed: 2-5, 6-12, or 13 and older; never; or that the difficulty was no longer an issue. There were four open ended questions addressing difficulties with language, other medical diagnoses, mental health diagnoses and whether additional questionnaire items might be needed.

Results:

Participants were 780 adults (81% autistic). By age, 42% were between the ages of 18-24, 28% were 25-33, 19% were 34-45, and 9.5% were 46-60. Participants were from 25 countries, including all predominately English-speaking countries, several EU countries, India, Pakistan, Japan, Israel, South Africa and Brazil. Each open-ended question received several hundred responses.

For 27% of respondents, recognizing people by face was noticed as a struggle, and somewhat of a struggle for 40%. Anxiety or worry emerged as a struggle for 35.4% between ages 2-5; only for 2.5% was it never an issue. For 2.3%, suicidality began between the ages of 2-5, and for 21.4% it began between 6-12. Feelings of isolation for 23.5% began between the ages of 2-5, and for 40% of participants, it began between the ages of 6-12. Post-traumatic stress disorder was reported by 207 participants.

Full measure and responses with gender breakdown for male, female and non-binary will be presented, as well as analysis of qualitative responses.

Conclusions:

We believe this measure can aid with the differential diagnosis in autistic adults. The items together have the ability to characterize clinically important difficulties beyond DSM diagnostic criteria, such as isolation, anxiety, suicidality, prosopagnosia, academic issues, sensory issues and more. In our sample, autism in adults coincides with prosopagnosia in two-thirds of respondents, and with self-report of suicidality in almost a quarter in the teen years. The adult perspective on autism herein provided may also aid in guiding treatment plans for a younger cohort with this diagnosis.

97 **169.097** A Practical Model for ASD Screening By Eye Tracking: Combined Fixation on Human Faces and Pupillary Light Responses (PLR)

X. He[1], *L. Shen*[1], *D. Li*[2] *and X. Gao*[1], *(1)School of Medicine, Tsinghua University, Beijing, China, (2)Tsinghua University, Beijing, China*

Background: As a country with huge population and limited experienced pediatric psychiatrists on ASD, China has the need for auxiliary diagnostic technique on ASD to do large scale screening. In the field of early ASD detection, there are some prominent achievements in research, but few of them are turned into practicing, especially in China.
A.Klin and W. Jones who were the first using eye tracking for ASD research found 12-month high-risk ASD babies showed different interests on eyes and mouths. Pupillary Light Response (PLR) was another biomarker that was proved to be efficient in identifying ASD and TD.

Objectives: The goal is to design a practical model for ASD screening on children of 3-6 years old by eye tracking technique, the model features come from two experiments with different paradigms of fixation on human faces and pupillary light response (PLR).

Methods: The experiments use SMI desktop eye tracking system with frequency 250Hz. Experiment I consist of 12 pictures of human faces in same size and luminance with different gender and age. Starting with a 10 second black picture, 12 pictures were showed continuously with 5 seconds on each. Fixation time on Area of Interest (AOI) of eyes, mouths, and faces were collected, as well as pupillary data. Experiment II also consists of 12 pictures, but with 6 black and 6 white pictures. Starting with a 10 second grey picture, one black and one white picture were showed alternately. Pupillary data were collected. Data were analyzed later in SPSS and MATLAB.

53 ASD and 51 TD children of 3-6 years old were recruited. 34 ASD children passed the test on calibration of Eye Tracker and double checked by CARS (Child Autism Rate Scale). After deleting invalid data, 73 subjects with 26 ASD and 47 TD were left. Data from the 73 subjects were split into two sets of train and test. The train set has 36 subjects with 13 ASD and 23 TD, while the test set has 37 subjects with 13 ASD and 24 TD. The train set was used to train the model, and the test set was used to evaluate the performance of the model.

Based on the data of experiment I and experiment II, feature extraction and selection were carried out respectively. Two independent classifiers were constructed, whose outputs were combined for final results. ASD/TD decision was made only if output I and output II both gave ASD/TD judgement, otherwise no decision was made. Please refer to attached flow chart.

Results:

By applying the data of test set to the model, it showed a ratio of 73% on valid prediction for the 37 subjects, while no decision for the remaining 27% of the subjects. Among the valid predictions, the precision rate on ASD is 100%, and the precision rate on TD is 94.73%.

Conclusions: The model can be used for ASD screening on 3-6 years old children.

98 **169.098** A Six-Minute Measure of Canonical Babbling Status to Identify ASD in Toddlers

E. Tenenbaum[1], *K. L. Carpenter*[2], *M. Sabatos-DeVito*[3] *and G. Dawson*[4], *(1)Duke Center for Autism and Brain Development, Durham, NC, (2)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (3)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (4)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC*

Background: To improve our ability to identify autism spectrum disorder (ASD) early in development, we need objective, reliable, and accessible measures. Previous work by Patten and colleagues (2014) suggests that early vocal patterns may provide a window into diagnostic status as early as 9-12 months. Patten and colleagues used retrospective home-videos to look at canonical babbling ratios (CBR), or speech-like utterances relative to all vocalizations. Here we investigated whether CBR as measured during a standardized six-minute presentation of videos on a tablet in primary care settings can be used to identify ASD status.
Objectives: (1) To determine whether CBR can be assessed during a short video presentation, and (2) To assess whether CBR can be used to discriminate diagnostic status for ASD.

Methods: Typically developing children (TD), children with language or developmental delays (DLD), and children with ASD were recorded using the camera in a tablet while they watched six minutes of videos selected to elicit behaviors associated with ASD during their 18- or 24-month well-child visits. Videos from thirty-nine children (ASD: *n* = 16, 3 male, *M* = 26.4 months, *SD* = 4.2; TD: *n* = 16, 3 male, *M* = 26.1 months, *SD* = 2.6; DLD: *n* = 7, 4 male, *M* = 24.9, *SD* = 2.6) were coded offline in realtime for canonical babbling based on the methods and canonical babbling status of CBR >.15 used by Patten et al. (2014).

Results: All but three participants (2 TD, 1 DLD) vocalized during this procedure, allowing for calculation of CBR for 36 children. A one-way ANOVA showed a significant effect of diagnostic status on CBR, F(2,33) = 6.96, p = .003, driven by the difference between ASD and TD participants (*p* = .002). Whereas 86% of TD and 83% of DLD children had achieved canonical babbling status, only 44% of children with ASD had CBR > .15. Odds ratio for the likelihood of ASD diagnosis given canonical babbling status for ASD and TD participants was 7.71, *p* = .002 (95% CI: 1.28 to 46.36). See Figure 1.

Conclusions: These results suggest that canonical babbling status can be measured in a short period of time in the context of a video presentation in a routine clinical setting. Further, they lend support to previous findings that CBR can help identify diagnostic status of children with ASD early in development. Given the small sample, replication will be necessary to confirm the generalizability of these findings. Future efforts will explore automatization of coding of vocalizations for increased accessibility.

99 **169.099** A Social Motivation and Competency Scale for ASD: Confirmatory Factor Analytic Structure and Measurement Invariance of Quantitative Socialization Traits

D. Tagavi[1] *and T. W. Vernon*[2]*, (1)University of California, Santa Barbara, Santa Barbara, CA, (2)University of California Santa Barbara, Santa Barbara, CA*

Background: The constructs of social motivation and competency are primary considerations when attempting to understand and target the interpersonal vulnerabilities inherent in autism spectrum disorder (ASD). Social motivation is particularly pivotal, as the desire to engage provides the experience necessary to increase social competencies and can yield favorable social experiences to further increase motivation (Chevallier et al., 2012). To successfully implement social intervention efforts, it is critical to understand each participant's unique profile of social motivation and associated competencies (Vernon et al., 2016). To date, qualitative judgements of these constructs have been the default strategy for individualizing autism intervention approaches; no measurement scale currently exists that attempts to quantify these attributes in a single instrument.

Objectives: The objective of the current study is to provide initial validation of a Social Motivation and Competency Scale (SMCS) as a parent- and self-report measure designed for youth and young adults with ASD through the use of confirmatory factor analysis.

Methods: The Social Motivation and Competency Scale (SMCS) is a 26-item measure that assesses an individual's motivation and competency in social communication situations. Separate parent- and self-report versions were developed with identical item content. Items pertaining to comfort in social interaction, conversation skill use, empathy, friendships, appropriate behavior, social contact, and social interest are rated on 1-5 Likert scales. A sample of 200 participants (108 teens and adults with ASD and 92 parents) completed the SMCS as part of a larger intervention study. Confirmatory factor analysis, internal consistency, model fit indices, factor loadings, and between-factor correlation matrix were conducted to determine construct validity.

Results: Results of the CFA on the total sample indicated that the two-factor model showed adequate fit across indices with the exception of CFI where fit was approaching adequacy (CFI=.896). Factor loadings for both factors were adequate and statistically significant (p < .001) with all loadings >.48. Comparing the configural confirmatory factor analysis model to the model with metric invariance across groups, there was a significant increase in model misfit ($\Delta\chi2$ (474, *N*=200)=928.12, *p*<.001) based on chi-square difference test, suggesting that the factor loadings are not equivalent across groups. We did not establish invariance across the child and parent groups.

Conclusions: We found that the two-factor structure of the SMCS proposed by the creators had adequate fit for the overall sample and child group. Being able to easily measure these two constructs has important future implications, as being able to understand baseline levels of these characteristics can help inform which specific areas of social skill to target for optimal outcomes. Although we failed to establish invariance between child- and parent-reports, these results are not surprising when theoretically examining why individuals with ASD and their caregivers might view these constructs differently. Future directions will examine the factor structure of the SMCS in a larger population and can also serve to collaborate with other researchers to identify indicators that more sensitively measure motivation and competency across raters so that accurate measures of these domains can be established and compared.

100 **169.100** A Systematic Review of Research Involving ASD Screening Tools: A Roadmap for Modelling Progress from Basic Research to Population Impact

P. Doehring*, ASD Roadmap, Chadds Ford, PA*

Background: Concerns about ASD's prevalence and delays in diagnosis mobilized $2.5 billion in research funding in the United States between 2008 and 2015. Yet recent reports indicate persistent and significant gaps in timely and accurate identification. We recently reviewed all projects funded through the National Institutes of Health from 2008 to 2013 focused on ASD identification. Only 9 projects (or 1% of total NIH funding for ASD research) focused on improving ASD identification among community providers. Do these apparent gaps in research funding in the United States reflect broader gaps in translating research into community practice? To understand these gaps, we have piloted a research roadmap for improved ASD identification that tracks progress from knowledge gained through basic research to demonstrated impact across large, diverse populations. Other presentations submitted to IMFAR demonstrate patterns of funding over time that are consistent with the roadmap.
Objectives: To further define a research roadmap for achieving large scale improvements in ASD identification, by evaluating its utility in capturing publication gaps and trends over time for one specific body of work: clinical and implementation research on ASD screening using the Checklist for Autism in Toddlers (CHAT) and its variants.

Methods: We defined the major categories of the roadmap (Basic and Applied Research) and sequentially-related subcategories of the latter (Clinical, Implementation, and Other Applied Research). We further defined each subcategory with respect to specific sub-types, objectives, and milestones for research. We conducted electronic database searches for all peer-reviewed publications involving the the development, validation,

or implementation of the CHAT or its variants. In Phase 1, we reviewed abstracts to eliminate articles that are not relevant, and assigned those remaining to subcategories of the roadmap. Full-text reviews currently underway in Phase II will involve more detailed coding of sub-types, objectives, and milestones.

Results: An initial review of almost 200 abstracts from 1992 to 2018 yielded more than 110 relevant research studies involving the CHAT and its variants. More than 80% were classified in Phase I as clinical research studies (e.g., exploring the tool's usefulness with different populations, evaluating a new variant or translation, and so on). Fewer than 20% were classified as implementation or other applied research, with most assessing potential barriers rather than seeking to overcome them. Few studies explored the tool's utility outside of medical settings, or its potential to improve rates of timely and accurate ASD identification across a designated region. Trends over time in publications of clinical and implementation research are consistent with the roadmap.

Conclusions: A systematic review of 25 years of clinical and implementation research involving the CHAT and its variants demonstrates the utility of the research roadmap in charting progress. The relative lack of emphasis on implementation research - especially research addressing implementation barriers - may begin to explain persistent gaps in timely and accurate identification, and help to reshape research priorities.

101 **169.101** Implementation Research Designed to Improve ASD Identification: A Comprehensive Review of Projects Funded in the US from 2008 to 2015

***P. Doehring**, ASD Roadmap, Chadds Ford, PA*

Background: Concerns about ASD's prevalence and delays in diagnosis mobilized $2.5 billion in research funding in the United States between 2008 and 2015. Yet recent reports indicate persistent and significant gaps in timely and accurate identification. We recently reviewed all projects funded through the National Institutes of Health from 2008 to 2013 and focused on ASD identification. We found only 9 projects (totaling $10 million, or 1% of total NIH funding for ASD research) focused on improving ASD identification among community providers, and few Principal Investigators (PIs) with extensive community experience. How could research lead to widespread improvements in identification? Have funders prioritized the implementation research needed to translate recommendations from research into community practice? Have the resulting projects achieved their stated goals?

Objectives: To review the level of funding and progress evident with respect to implementation research designed to improve ASD identification among community providers across the US between 2008 and 2015, and any possible relationship to the training and experience of the PIs. This review utilizes a new research roadmap (submitted separately to IMFAR) for improved ASD identification that tracks progress from basic research to population outcomes, with Implementation Research as one distinct stage.

Methods: We downloaded information on all research projects addressing ASD identification between 2008 and 2015 in the Autism Research Database (ARD). We identified projects focused on Implementation Research (i.e., seeking to demonstrate effective training of community practitioners, to identify and close gaps in community implementation, or to scale up programs of implementation) by reviewing principal aims of all projects not assigned in the ARD to categories clearly associated with basic research. We are also classifying the principal outcomes of the resulting publications on the research roadmap, and reviewing the resumes of PIs for evidence of clinical training and experience.

Results: Of 399 research projects focused on ASD identification funded for $278 million between 2008 and 2015, the majority (220) were assigned to categories in the ARD associated with Basic Research. Project summaries were available for 156 of the remaining 179 projects. A detailed review of the principal aims revealed 14 projects potentially involving Implementation Research, totaling $9 million (or 3% of all funds allocated to improve ASD identification). Allocations over time supported the research roadmap, with increasing emphasis on implementation research in later years. Analyses of the associated publications, training, and background of the 14 PIs are underway. Preliminary results suggest that most PIs have little or no experience delivering services in community settings.

Conclusions: Little research funded between 2008 and 2015 to improve ASD identification appears to have focused on improving implementation in community settings, and additional analyses underway will clarify whether the projects funded actually achieved their stated aims. The relative lack of focus on implementation research, compounded by the limited experience of project PIs, may begin to explain how gaps in identification have persisted despite significant investments in ASD research. Progress captured by the research roadmap suggests, however, an increasing focus on implementation research in future years.

102 **169.102** Research Grants to Develop Tools to Improve ASD Identification: A Comprehensive Review of Projects Funded in the US from 2008 to 2015

***P. Doehring**, ASD Roadmap, Chadds Ford, PA*

Background: Concerns about ASD's prevalence and delays in diagnosis mobilized $2.5 billion in research funding in the United States between 2008 and 2015. Yet recent reports indicate persistent and significant gaps in timely and accurate identification. We recently reviewed all projects funded through the National Institutes of Health from 2008 to 2013 and focused on ASD identification. We found only 9 projects (totaling $10 million, or 1% of total NIH funding for ASD research) focused on improving ASD identification among community providers, and few Principal Investigators (PIs) with extensive community experience. How could research lead to widespread improvements in identification? Have funders prioritized the development of clinical tools for identification, and have the resulting projects achieved their stated goals?

Objectives: To review the level of funding and progress evident with respect to clinical research designed to improve tools for ASD identification across the US between 2008 and 2015, and any possible relationship to the training and experience of the PIs. This review utilizes a new research roadmap (submitted separately to IMFAR) for improved ASD identification that tracks progress from basic research to population outcomes, with Clinical Research as one distinct stage.

Methods: We downloaded information on all research projects addressing ASD identification between 2008 and 2015 in the Autism Research Database (ARD). We identified projects focused on Clinical Research (i.e., seeking to develop, validate, improve, or extend tools or protocols for ASD screening or diagnosis) by reviewing principal aims of all projects not assigned in the ARD to categories clearly associated with basic research. We are also classifying the principal outcomes of the resulting publications on the research roadmap, and reviewing the resumes of PIs for evidence of clinical training and experience.

Results: Of 399 research projects focused on ASD identification funded for $278 million between 2008 and 2015, the majority (220) were assigned

to categories in the ARD associated with Basic Research. Project summaries were available for 156 of the remaining 179 projects. A detailed review of the principal aims revealed 32 projects potentially involving Clinical Research, totaling $34 million (or 12% of all funds allocated to improve ASD identification). Allocations over time supported the research roadmap, with increasing emphasis on more advanced clinical research in later years. Analyses of the associated publications, training, and background of the 28 PIs are underway. Preliminary results suggest that most PIs have little or no experience supervising the delivery of clinical services outside of specialized university or hospital settings.

Conclusions: Little research funded between 2008 and 2015 to improve ASD identification appears to have focused on improving tools for ASD identification, and additional analyses underway will clarify whether the projects funded actually achieved their stated aims. The relative lack of focus on clinical research, compounded by the limited experience of project PIs, may begin to explain how gaps in identification have persisted despite significant investments in ASD research. Progress captured by the research roadmap suggests, however, an increasing focus on clinical research in future years.

103 **169.103** An Item Response Theory Evaluation of the Autism Diagnostic Interview-Revised (ADI-R)

K. Sterrett[1], *M. Pizzano*[2], *L. M. Chiang*[3], *A. Sturm*[4] *and M. Kuhfeld*[5], *(1)University of California Los Angeles, Los Angeles, CA, (2)Education, University of California, Los Angeles, Los Angeles, CA, (3)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (4)UCLA, Los Angeles, CA, (5)Northwest Evaluation Association, Portland, OR*

Background: Early and accurate diagnosis of autism spectrum disorder (ASD) is essential for access to interventions and subsequent improvement in children's outcomes (Itzchak & Zachor, 2011; Stone & Yoder, 2001). Yet, the Autism Diagnostic Interview- Revised (ADI-R; Rutter, Couteur & Lord, 2003), one component of the gold standard assessment, has been shown to have reduced diagnostic agreement with clinical impressions across contexts (de Bildt et al., 2015; Zander, Sturm, and Bolte, 2015). There is additional evidence that parental factors such as level of ASD concern can may be related to the sensitivity of the ADI-R (Havdahl et al., 2017).

Objectives: This study aims to determine if the age at which parents were first concerned about their child's development influences their report of their child's ASD symptoms on the ADI-R.

Methods: A sample of 3557 individuals with ASD (Mage= 101.15(46.25), 79% Caucasian), was culled from two large national data repositories (NDAR and Simons Simplex Collection). A categorical variable representing parental concern was created: early (first concern before 12 months of age), average (first concern between 12 and 36 months) and late (first concern after 36 months). Differences between the three time of concern groups on ADOS severity scores and age were tested using a one-way analysis of variance (ANOVA). Factor structure of the ADI-R was evaluated using exploratory factor analysis with half the sample, followed by confirmatory analyses to cross-validate findings with the second half. To compare groups on the latent variables, multiple group models were tested including non-verbal IQ as a covariate to identify items that showed statistical redundancy and confirm the overall similarity of the groups across latent traits. Differential item functioning using item response theory was then applied to examine ADI-R item bias between the three timing of concern groups following procedures of Hansen et al (2014).

Results: There were minimal group differences on ADOS severity and age between concern groups (h^2 = .004; h^2 = .02 respectively). A two-factor structure representing social communication (SC) and restricted and repetitive behavior (RRB) domains was found to best fit the data (RMSEA= .056, CFI= .958, TLI= .955).

Six items demonstrated substantial statistical redundancy (i.e., local dependence) with other items and were excluded from evaluation of factor mean differences. These items were adjacent to each other on the test form (e.g. items 30 and 31). The latent variable means for the SC and RRB factors were higher in the early concern group compared to the late concern groups (.69 and 1.22 SD higher, respectively). The same pattern was observed when NVIQ was included as covariate (.37 and 1.05 SD higher), despite no group differences on ADOS scores. Eleven SC domain items and three RRB domain items were biased (i.e., DIF) based on parental concern group.

Conclusions: This study demonstrates that the timing of initial parent concern about their child's development influences parents' item-level responses on the ADI-R. This suggests that excluding items with item bias by age of concern may strengthen the independent diagnostic accuracy and precision of the ADI-R.

104 **169.104** Application of the Brief Observation of Social and Communication Change (BOSCC) to ADOS Assessments in the Preschool Autism Communication Trial

S. Carruthers[1], *T. Charman*[2], *H. McConachie*[3], *J. Green*[4], *A. Pickles*[5] *and P. Consortium*[4], *(1)King's College London, London, United Kingdom of Great Britain and Northern Ireland, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Institute of Health and Society, Newcastle University, Newcastle upon Tyne, United Kingdom, (4)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (5)Biostatistics and Health Informatics, King's College London, Institute of Psychiatry, Psychology and Neuroscience, London, United Kingdom*

Background:

Commonly used outcome measures in autism intervention trials are often insensitive to subtle, yet meaningful, changes in the child's social and communication behaviours. The BOSCC has been recently developed with the aim of providing a more sensitive tool. This study is among the first to retrospectively apply the adapted BOSCC-for-ADOS scheme to ADOS assessments from a previously conducted trial. The Preschool Autism Communication Trial (PACT) is the largest trial the BOSCC has yet been reported on.

Objectives:

To explore the psychometric properties of the BOSCC as applied to ADOS assessments in the Preschool Autism Communication Trial.

Methods:

The study included 152 children (aged 2-4 years 11 months) with a diagnosis of core autism. 117 children (77.0%) were ADOS module 1 and 35 children (23.0%) were module 2. The BOSCC was scored from recordings of the ADOS assessments from the PACT study. The BOSCC module 1 scheme was applied to all children.

Results:

Item distributions

Most social and communication items had a good spread of scores with some skew observed on items related to vocalisations, most likely on account of the characteristics necessary for eligibility. Restricted and repetitive behaviours (RRB), mannerisms and unusual sensory interests were skewed items, in line with previous research. The spread and overall pattern of distribution did not change when module 2 children were removed.

Inter-rater reliability

Four coders scored 15 videos. Intra-class correlations demonstrated high reliability across total scores: total score 0.93 (95% CI: 0.85-0.97), social and communication subscale 0.93 (0.84-0.97) and RRB subscales 0.82 (0.66-0.92).

Correlations – cross-sectional (baseline)

The BOSCC social communication subscale score strongly positively correlated with the ADOS communication and social score (r = 0.72, p <.001). The BOSCC RRB subscale was more moderately positively correlated with the ADOS RRB subscale (r = 0.46, p < .001). The BOSCC total score was weakly correlated with the ADOS CSS score (r = 0.33, p <.001).

Factor analysis

We conducted a confirmatory factor analysis using all Core items (Items 1-13) to test the two-factor model (SC and RRB) identified in previous literature. Our model fit was poor with root mean square error approximation (RMSEA) of 0.130 and comparative fit index (CFI) of 0.85. In line with previous literature, RRB items had lower factor loadings.

Correlations – change (TAU group only)

BOSCC total score change weakly correlated with ADOS CSS change (r = 0.35, p<.004). This is in line with previous research.

Sensitivity analyses

Analyses with module 2 participants removed did not change the interpretation of results.

Conclusions:

The BOSCC-for-ADOS when applied to a large group of children with core autism with minimal language, provides a good spread of scores across items, reliable coding and correlates in the expected directions with the ADOS in line with previous research. Potential reasons for the poor fitting factor analysis will be discussed.

105 **169.105** Are Visuospatial Strengths Observable in Autistic Preschoolers with Aggravating Symptoms?

V. Langlois[1,2], *V. Larose*[1], *G. Thermidor*[2], *L. Mottron, M.D.*[2] *and C. Jacques*[1,2], *(1)University of Quebec in Outaouais, Gatineau, QC, Canada, (2)University of Montreal Center of Excellence for Pervasive Developmental Disorders (CETEDUM), Montreal, QC, Canada*

Background: Adult autistic people (Caron, Mottron, Berthiaume, & Dawson, 2006) and school-age children (Van der Hallen, Chamberlain, de-Wit, & Wagemans, 2018) present strengths in various visuospatial tasks. Courchesne et al. (2015) demonstrated a similar profile in minimally verbal preschool children. However, no studies have examined the presence of visuospatial strengths in minimally verbal preschool children with behavioral difficulties that negatively impacting their adaptation to their physical and social environment. As a result, specialized services for this population do not use the strengths of these children in intervention.

Objectives: To document the presence of visuospatial strengths in autistic preschool children with associated conditions aggravating their adaptation. An exploratory study.

Methods: Ten autistic children (31 to 51 months of age) admitted in Day Hospital Services for major food selectivity, sleep difficulties, aggressivity or self-injury participated in the present study. The severity level according to the DSM-5 was established between 2 and 3 for all children by a child psychiatrist. Verbal language level was measured by Mc Arthur, Reynell or CELF according to their chronologic age and ADOS-2 module used in the diagnostic evaluation process. Non-verbal intelligence was assessed with the Preschool Embedded Figure Test (*PEFT*; Witkin, Oltman, Raskin, & Karp, 1971). A descriptive statistical analysis provided a group portrait of the participants regarding their performance on the PEFT and their developmental age in terms of oral language.

Results: All but one child presented a major speech onset delay (developmental speech level: 16.5 months (SD=11.2). Six children could complete the PEFT. The average number of successful items was 16.75 on 24 (SD=2.99) for four 3 years old children and 16.5 on 24 (SD=3.54) for two 4 years old children. This performance outranged that of the normative sample (10.58, SD=4.93 and 12.87, SD= 3.43 respectively). A t-test revealed a significant difference between groups at 3 years old (t=2.41; p=0.02), while it was not significant at 4 years old (t=1.47; p=0.15).

Conclusions: Non-verbal autistic children with major aggravating symptoms present a superior performance in target detection in the same extent as those without such symptoms. The next step of the present study will consist in testing interventions addressing these symptoms using their specific strengths.

106 **169.106** Does the Factor Structure of IQ Differ between the DAS-II Normative Sample and Autistic Children?

C. C. Clements[1], *J. R. Bertollo*[1,2], *L. D. Yankowitz*[1], *M. W. Watkins*[3], *B. E. Yerys*[1] *and R. T. Schultz*[1], *(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Virginia Polytechnic Institute & State University, Blacksburg, VA, (3)Educational Psychology, Baylor University, Waco, TX*

Background: Intellectual disability commonly co-occurs with ASD, and the DAS-II (Differential Ability Scales, 2nd Edition) is frequently used as part of an intellectual disability assessment in school-age children with ASD. Like most IQ assessments, the DAS-II was developed with a nationally representative normative sample. Despite widespread use, it remains unknown whether the normative DAS-II measurement model (e.g., factor structure, loadings) holds for the autistic population (Wicherts, 2016). In other words, it is not known if the DAS-II measures the same construct in the same way for autistic and neurotypical children. If not, then the often discussed "IQ splits" in ASD (e.g., high matrix but low verbal similarities subtest scores, Nowell et al., 2015; Klin et al., 2005; Seigel et al., 1996) might be due to measurement bias and artifacts rather than intelligence (Thompson, 2016). Thus, measurement invariance requires that the relationship between DAS-II scores and the latent construct of intelligence should not be affected by autism (Thompson, 2016; Wicherts & Dolan, 2010).

Objectives: To determine whether the normative structure of the DAS-II, which influences score calculation and interpretation, holds in individuals

with ASD.

Methods: We obtained the raw DAS-II normative data for 2,400 individuals, as well as the raw DAS-II data from the Simons Simplex Consortium (SSC) for 1,317 autistic individuals and a replication sample of 416 autistic individuals from The Children's Hospital of Philadelphia's Center for Autism Research (CAR). Using the three-factor structure specified in the DAS-II technical manual as a baseline model, we combined normative and SSC datasets for multigroup confirmatory factor analyses to assess how well that measurement model fit both samples (Chen, Sousa, & West, 2005). We analyzed configural invariance (subtests loading on the same factors for each group), metric invariance (subtests loading at equal levels between groups), and scalar invariance (mean subtest scores equal across groups). Additional analyses including subtest correlations, exploratory structural equation modeling, and replication with the CAR ASD sample will be completed by May 2019.

Results: Both normative and ASD sample data showed excellent fit with the 3-factor model (normative: CFI=1.000; TLI=1.000; RMSEA=0.000; ASD: CFI=0.998; TLI=0.995; RMSEA=0.034). The configural and metric models showed excellent fit (CFI>0.995, TLI>0.995, RMSEA<0.025), but the scalar model showed a decrease in fit statistics (ΔCFI=0.010; ΔTLI=0.016; ΔRMSEA=0.038) that exceeded recommended thresholds (ΔCFI<0.010 or ΔRMSEA>0.010; Chen, 2007), suggesting measurement bias. A likelihood ratio test confirmed significantly worse fit of the scalar model compared to metric and configural models (metric: $\chi^2(5)=107.7$, $p<0.00$).

Conclusions: Preliminary analyses suggest only weak factorial invariance (i.e., configural and metric, not scalar invariance) and measurement bias in autistic DAS-II scores. Although the factor structure and loadings do not vary significantly between groups, the pattern of subtest means does; consequently, the lower mean DAS-II subtest scores of the autistic population cannot be attributed only to lower levels on the latent constructs of verbal, nonverbal, or spatial intelligence. These results have important clinical implications, namely that artifacts may influence DAS-II scores for autistic patients. Recommendations for appropriate interpretation of DAS-II scores from children with ASD will be discussed.

107 **169.107** Gender Differences in Vineland Domain Scores in ASD

***C. Shulman**, Z. Nir and O. Bing, The School of Social Work, The Hebrew University of Jerusalem, Jerusalem, Israel*

Background:

An understanding of gender differences in the presentation of ASD has important implications for tailoring assessment measures to the potentially unique presentations and needs of males and females. Adaptive behavior, which was incorporated into DSM5 criteria for the establishment of an ASD diagnosis, is a crucial area of assessment for individuals with autism spectrum disorder (ASD). Saulnier and Klin (2007) found no relationship between verbal IQ scores, severity of autism and adaptive functioning in older higher functioning children with ASD, supporting the necessity for including the assessment of adaptive functioning when evaluating ASD, as higher cognitive ability is not always related to real-life adaption. Paul et al. (2004) and Szatmari et al. (2015) found discrete correlations among Vineland domain scores and autism symptomatology by analyzing Vineland age equivalent scores rather than standard scores. Hartley and Sikora (2009) investigated gender differences in the presentation of ASD and found no differences in adaptive functioning in toddlerhood. The present study extends these studies by assessing older, newly-diagnosed ASD and IQ matched school-aged boys and girls using age equivalent domain scores as a method of identifying gender differences in adaptive functioning in ASD.

Objectives:

The aims of this study are (1) to examine similarities and differences in adaptive functioning in school-aged, newly-diagnosed boys and girls; (2) to investigate relationships between domain scores, autism severity, and behavior profiles in later diagnosed boys and girls with ASD.

Methods:

Participants included 30 newly-diagnosed school-aged children (M=9.378; SD=2.4; boys M=9.04; SD=1.83; girls M=9.53; SD=2.22) who are part of a larger study focused on comparing gender differences among children who receive a diagnosis of ASD for the first time when they are school-aged and those diagnosed as toddlers/preschoolers. A complete diagnostic evaluation included assessing intellectual and adaptive functioning, characterization of autism symptomatology and behavioral profiles. For the present study, the male and female participants were matched on chronological age and IQ functioning.

Results:

Significant gender differences were found in Vineland domain age equivalents only. Boys performed significantly better than girls overall (VABS composite: t(27)=1.738; p<0.05) and in activities of daily living (t(27)=2.677; p<0.01). Specifically, boys' age equivalent scores were higher in domestic skills (t(24)=3.420; p<0.05), personal skills (t(24)=1.684; p<05), and the socialization domain in play skills (t(24)=2.438; p<0.05).

Distinct behavior profiles emerged for boys and girls, with the male profile revealing significant correlations among Vineland domain scores and severity of repetitive and restrictive behaviors. Behavior problems were significantly related to severity of symptoms on the ADOS social and affective scale for boys, while behavior problems were associated with Vineland scores for the girls.

Conclusions:

This research emphasizes the importance of adaptive functioning as an additional element in understanding the differences between boys and girls with ASD. Distinctive adaptive profiles emerge by focusing on school-aged children who receive an initial ASD diagnosis, pointing to the need to individualize interventions to the unique needs of males and females with ASD at this age.

108 **169.108** Accumulated Experiences of a Dutch Autism Expert Team for Toddlers & Pre-Schoolers

*M. Buruma and **E. M. Blijd-Hoogewys**, INTER-PSY, Groningen, Netherlands*

Background:

Although diagnosing a child with ASD is possible at a young age, the diagnostic process is complex. For, the child is subject to rapid behavioral developmental changes and potential regressions, and is very sensitive to changes in its immediate environment. Therefore, it is important to do an extensive and thorough assessment.

International guidelines for ASD diagnosis in young children recommend: 1) a multidisciplinary specialist autism team, preferably consisting of a pediatrician/clinical psychiatrist, a psychologist, and a speech therapist, 2) working with experts in autism diagnostics and young children, 3) a

case coordinator, 4) start assessment within 3 months after referral, 5) using different information sources (home life, nursery/playground/school, ...), 6) mapping physical health and medical history, and 7) consideration of co-morbidity and differential diagnostics.

Diagnostic assessment exists of questioning parental concerns (based on child behavior in various environments), a developmental history (specifically aimed at joint attention skills, executive functioning and sensory information processing), skill observation(s), details on day-to-day functioning (home life and day care/education), a medical history and a profile of strengths and weaknesses (including cognition and language) (Dutch clinical best estimate, 2017).

Objectives:

Sharing clinical experience in diagnosing ASD in young children.

Methods:

Our team exists of 18 professionals: 1 child psychiatrist, 1 pediatrician, 1 clinical psychologist, 4 health care psychologists, 5 (educational) psychologists, 1 speech/language therapist, 3 home treatment specialists, 1 play therapist, and 1 case coordinator.

From April 2013 until May 2018, we assessed 360 children, following the above mentioned guidelines for autism diagnostics in young children, also using the ADOS-2, language and intelligence tests. Observations were done both at our center (structured play), at home (free play) and at day care or school.

Results:

Of the 360 children, 72% were boys and 28% girls. We regularly see children from other cultures (e.g. African, Antillean, South American, Eastern European, Filipino, Indian, Pakistani and Russian).

The first assessment occurred on average 2 weeks after referral. In 58%, an ASD diagnosis was confirmed. In the youngest children, often a DC0-5 diagnosis was made, which at a later age, after reassessment, was often changed into ASD. In 14% of the cases, no diagnosis was made. These children were kept under review. Reassessment occurred in 34% of the children, which occurred 1-2 years later, when new concerns were raised.

Co-morbidity was often present, such as a developmental delay (45%) or language deficits (55%). Often, there were additional problems concerning sleeping, eating, potty training, motor skills and/or parent-child interaction. Children were regularly referred to clinical genetics, to look into underlying genetic causes.

Over the years, we came to see more girls with ASD. Their profile seems somewhat different.

Conclusions:

Despite the good reliability of ASD classifications at a young age, it is important to keep track of children in their development and to evaluate them regularly. Re-assessment is strongly recommended in young children (<4 years), because the development of young children is rapid. Cognitive and language skills are still developing strongly and there is a great intertwining with the environment.

109 **169.109** Measures of Effectiveness for Single-Question Sleep Problem Screeners in Children with ASD

A. R. Marvin[1], *D. Coury*[2], *B. A. Malow*[3], *J. K. Law*[1], *P. H. Lipkin*[1] *and A. Bennett*[4], *(1)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (2)Nationwide Children's Hospital, Columbus, OH, (3)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN, (4)Children's Hospital of Philadelphia, Philadelphia, PA*

Background:

50-80% of children with ASD have sleep problems, which are associated behavioral issues and negatively affect well-being in both children and parents. Given this high prevalence and impact on child and family functioning, developing brief and rapid screeners for parents of children with ASD for sleep problems is important.

Objectives:

To evaluate the effectiveness of two single-question sleep issue screeners compared to the Composite Sleep Disturbance Index (CSDI).

Methods:

U.S.-based primary parents of children with ASD were recruited from a validated/verified national autism registry. Parents completed an online survey on co-occurring conditions that incorporated:

- The CSDI, a validated tool that scores the frequency/duration of six sleep habits (scored 0-2) over the previous month; total score range=0-12; score≥4 indicates a severe sleep problem.
- A seventh, non-scored, question on the CSDI asks how satisfied/dissatisfied the parent is with their child's current sleep pattern (5-category Likert scale).
- A question about the degree to which the child had experienced sleep problems during the past 30 days (4-category Likert scale).

Results:

Demographics

610 parent/child dyads were analyzed. Responding parents were primarily female (94%), white (89%), and non-Hispanic (92%); mean age of 43.3 (*SD* 7.2; range 25-65) years. Children were primarily male (81%), white (84%), and non-Hispanic (88%); mean age of 12.1 (*SD* 3.6; range 3-17) years.

Distribution of Scores and Responses (See Table and Figure)

- CSDI scores, parental dissatisfaction, and severity of sleep problems were highly correlated, n=610, p=.000; CSDI-dissatisfaction: r=0.783; CSDI-degree sleep problems: r=0.734; dissatisfaction-degree sleep problems, r=0.750.
- 377 (62%) children had a CSDI score≥4.
- CSDI scores differed between age groups, $\chi^2(2) = 12.292$, $p = 0.0021$. Young children had higher CSDI scores than both school-age children (p=0.0033) and teens (p=0.0002); however, there was no difference between school-age children and teens (p=0.1571).
- 116 (19%) of parents were completely satisfied with their child's current sleep pattern; of these, 109 (94%) had CSDI score<4. 246 (40%) were neither-satisfied-nor-dissatisfied or dissatisfied; of these, 235 (96%) had CSDI score≥4.

- 181 (30%) of parents indicated their child had no sleep problems; of these, 153 (85%) had CSDI score<4. 229 (38%) had moderate or severe sleep problems; of these, 215 (94%) had CSDI score≥4.

Evaluation

When intermediate categories (parent satisfaction/dissatisfaction="mostly satisfied" and degree sleep problems="mild") *were excluded,* parent satisfaction/dissatisfaction compared to degree sleep problems proved to be a superior predictor of CSDI severe vs. non-severe sleep problems (satisfaction/dissatisfaction: PPV=96%, NPV=94%, LR+=10.59, LR-=0.03, J=88%; degree sleep problems: PPV=94%, NPV=85%, LR+=10.55, LR-=0.13, J=80%). It is notable that 54% of children whose parents are "mostly satisfied" with their child's current sleep pattern have a severe sleep problem, and that 67% of children whose parents rate their child's degree of sleep problems as "mild" have a severe sleep problem.

Conclusions:

Single-question sleep-issue screeners are useful as a preliminary screener for sleep problems. Children with ASD can generally be correctly categorized as having a severe vs. non-severe classification *unless they have an intermediate response*, such "mostly satisfied" or "mild" degree sleep of problems. Parents may benefit from education relating to recognition of sleep problems.

110 **169.110** Next-Generation Emotion Recognition Markers for Autism Spectrum Disorder

C. H. Chatham[1], *J. F. Hipp*[2], *D. Nobbs*[3], *T. Kilchenmann*[3], *F. Lipsmeier*[3], *L. Murtagh*[1], *K. Sanders*[4], *J. W. Smith*[5], *D. Umbricht*[1], *C. Gossens*[3] *and M. Lindemann*[3], *(1)Neuroscience, Ophthalmology, and Rare Diseases (NORD) Roche Pharma Research and Early Development. Roche Innovation Center Basel, Hoffmann La Roche, Basel, Switzerland, (2)Neuroscience and Rare Diseases (NRD), Roche Pharma Research and Early Development, Roche Innovation Center, Basel, Switzerland, (3)Roche Pharma Research and Early Development. Roche Innovation Center Basel, Hoffmann-La Roche, Basel, Switzerland, (4)Product Development Neuroscience, F. Hoffmann-La Roche Ltd., Basel, Switzerland, (5)Product Development Neuroscience, F. Hoffmann-La Roche Ltd., Welwyn Garden City, United Kingdom*

Background: The factors driving recognition of facial emotion, and the impairment of this ability in some autistic individuals, are poorly understood. This lack of understanding may partially reflect psychometric challenges associated with static faces. Static faces are heterogeneous, have potentially limited dynamic range, and have an underexplored relationship to real, dynamic facial expressions. Each of these challenges motivates innovations in the development of more sensitive, generalizable, and clinically-useful markers of non-verbal receptive communication for autistic people.

Objectives: This work addressed the above challenges by designing a next-generation emotion recognition task (ERT) for use in clinical trials with autistic participants, leveraging computational and "participatory design" methods alike.

Methods: Starting with systematic review of the ERT literature, a candidate task was designed according to those task features most commonly associated with significant individual differences in real-world functioning (as quantified by adaptive behaviour) or with pharmacological effects (focusing on oxytocin/vasopressin manipulations in particular). Optimal stimuli for the task were selected using a Bayesian item-response theory (IRT) model of "norming" data from typically-developing volunteers. A series of focus groups were then conducted with the task, in two different countries, to directly incorporate feedback from individuals with Autism Spectrum Disorder. Finally, adaptive psychophysical algorithms were constructed to address the focus group feedback, and the algorithm's performance characteristics were confirmed through Monte Carlo simulation.

Results: Our systematic review revealed that the majority of tasks eliciting either an association between ERT performance and a pharmacological intervention or individual differences in real-world functioning (as quantified by adaptive behaviour skills) occupy a relatively restricted design space. A task was proposed on this basis, with adaptations for frequent, low-burden administration on smartphones in a home-based setting. Specifically, individuals are asked to classify non-masked, static faces displaying 7 emotions (including a "neutral" emotion) of varying intensity in a self-paced manner. A Bayesian IRT was developed which correctly predicts static ERT performance from dynamic ERT training data, and further revealed psychometric advantages to using Emotient FACET coding (as compared to nominal emotional intensity ratings) for calibration of individual stimuli. Based on qualitative feedback collected from autistic individuals the task length was shortened by introducing an adaptive psychophysical staircase algorithm for determining the optimal intensity of the displayed emotion stimuli based on individuals' previous responses, without losses to estimation accuracy (Monte Carlo simulations). The final assessment, involving all of these features, is now deployed to autistic individuals enrolled in two clinical trials (one interventional, one observational).

Conclusions: A combination of modelling methods and participatory design is needed to create next-generation marker tasks which are both powerful and feasible for high-frequency, at-home testing in clinical trials. Our application of these methods has yielded a promising assessment of non-verbal receptive communication, currently being validated in two deployments. Ultimately, we plan to make this assessment available to the field at large.

111 **169.111** No Gender Differences in Cognitive or Adaptive Functioning Abilities for Toddlers Diagnosed with DSM-5 ASD

H. Hodges*, C. Lee, W. Barbaresi, G. Sideridis and E. Harstad, Developmental Medicine, Boston Children's Hospital/Harvard Medical School, Boston, MA*

Background: Prior studies indicate that females are less likely to have autism spectrum disorder (ASD), but when affected tend to have more severe impairment than males with ASD. Limited, if any, studies currently exist comparing functioning between male and female toddlers with a Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) ASD diagnosis.

Objectives: To compare cognitive, adaptive, and language functioning in male versus female toddlers at time of diagnosis of DSM-5 ASD.

Methods: We conducted a retrospective chart review of toddlers (18-36 months) diagnosed with DSM-5 ASD via a standardized assessment at Boston Children's Hospital from July 2013-July 2015. Children were included if they were seen by both a developmental-behavioral pediatrician and a psychologist for developmental testing and if they met DSM-5 diagnostic criteria for ASD. The primary outcomes were standard scores from cognitive, adaptive, and language measures, specifically the Bayley Scales of Infant and Toddler Development, Third Edition, and the Vineland Adaptive Behavior Scales, Second Edition. Due to provider preference, rather than specific patient characteristics at presentation, a subset of patients (N = 99) received an additional language measure, the Receptive-Expressive Emergent Language Test, Third Edition. We conducted

statistical comparison of scores between genders via independent two-sample t-tests.

Results: We abstracted data for 500 subjects; 21% were female (N = 104) and 79% were male (N = 386). There was no statistical difference in the average age at diagnosis for males versus females (26.1 versus 25.5 months, respectively; p = 0.211), the Bayley Scales of Infant and Toddler Development cognitive standard score (80.8 versus 80.0, respectively; p = 0.585) or the Vineland adaptive behavior composite standard score (75.0 versus 73.8, respectively; p = 0.283). There were no gender differences in the Bayley Scales of Infant and Toddler Development language standard score (63.8 for males versus 60.7 for females; p = 0.108), although in the subset of patients who had the Receptive-Expressive Emergent Language Test administered (N=99), males had higher receptive language scores (65.2 versus 59.5 respectively; p= 0.023) and higher expressive language scores (65 versus 59.7 respectively; p = 0.045) compared to females.

Conclusions: We found no significant gender difference in cognitive or adaptive functioning of toddlers at time of DSM-5 ASD diagnosis. This is in contrast to prior studies suggesting lower cognitive and adaptive functioning in female patients when compared to males. We did find lower receptive and expressive language scores among females in a subset of toddlers who received a separate language measure, suggesting that gender differences may exist in some developmental domains.

112 **169.112** Predictive Effect of Handwriting Impairments and Adaptive Function on Autism Diagnosis

A. Y. Herstic[1], *R. N. Rochowiak*[1], *A. Tiedemann*[1], *C. A. Koch*[2], *R. Nicholas*[3], *M. B. Nebel*[1] *and S. H. Mostofsky*[4], *(1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Developmental Cognitive Neurology, Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (3)University of Nottingham, Nottingham, United Kingdom, (4)Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD*

Background: Children with Autism Spectrum Disorder (ASD) frequently exhibit impairments in handwritten letter formation. Why are these deficits potentially relevant in the current age of digital literacies? Research suggests that writing letters by hand helps typically developing children learn to build stable representations in memory and conceptualize information. Children with ASD often exhibit deficits in conceptual adaptive behavior relative to their cognitive skill level, and these deficits may provide important clinical prognostic information. Thus, investigating the interplay of handwriting and conceptual adaptive skills may benefit researchers and clinicians in assessing autistic symptom severity.
Objectives: To determine if handwriting letter formation moderates the relationship between adaptive functioning and ASD diagnosis.

Methods: Participants included 159 children aged 8-16 years (85 ASD; 119 male; M_{age}=10.43). Three conditions of the Minnesota Handwriting Assessment (MHA) were completed on a digital tablet: participants were presented with one sentence that would be copied (copy), traced (trace), and traced as quickly as possible (fast-trace). Handwriting data was analyzed using Large Deformation Diffeomorphic Metric Mapping (LDDMM) and a letter-form score was given to quantify the participant's deviation from a template for each condition. Higher scores indicate poor performance. Caregivers of participants completed the Adaptive Behavior Assessment System, Second Edition (ABAS-II). The Conceptual domain of the ABAS-II (ABAS-c) was used for analysis, consisting of three sub-categories: communication, functional academics, and self-direction. Lower scores indicate poor adaptive functioning.

A multiple regression analysis was used to determine how each MHA condition predicted diagnosis. The best predictor was then used in a two-step moderated regression analysis to first examine the effect of the ABAS-c and this predictor separately, and then to measure the combined effect of those predictors on diagnosis.

Results: Multiple regression indicated that, among the three handwriting conditions, fast-trace (FT) letter-form score was the best predictor of ASD diagnosis (see Table 1). A regression model including ABAS-c and FT letter-form scores was significant, with the ABAS-c being a slightly better predictor of ASD diagnosis than FT (see Table 2). Given these results, a moderated regression was used to determine the effect of FT letter-form on the relationship between adaptive functioning and ASD. We observed that the combined effect (i.e, product) of FT letter-form and ABAS-c accounted for significantly more variance in ASD diagnosis than just ABAS-c or FT letter-form alone (see Table 2), suggesting that FT letter-formation moderated the relationship between adaptive functioning and ASD.

Conclusions: Children with ASD struggle with letter formation even when the visual-spatial transformation demands of printing are minimized, as in the FT condition. The moderation analysis further suggests that considering poor adaptive functioning and poor FT letter-formation together was more informative of ASD diagnosis than considering only adaptive functioning or FT letter-formation alone. Therefore, it may be useful to collect handwriting measures as part of an ASD diagnostic evaluation. Handwriting assessments are easy and quick to administer, and as opposed to most parent-report adaptive function measures, are direct measures from the child. Thus, they could provide for a more complete diagnostic picture.

113 **169.113** Replication and Validation of the Brief Autism Detection in Early Childhood (BADEC) in a Clinical Sample

R. E. Nevill[1], *D. Hedley*[2] *and M. Uljarevic*[3], *(1)University of Virginia, Charlottesville, VA, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (3)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA*

Background: Because ASD can be reliably diagnosed as early as 18 months, pediatricians are recommended to use ASD screeners during 18 and 24 month wellness checks. Despite this, most children are not diagnosed until after age four, which is partially due to the inconsistent use of screeners. Reasons for this include short appointment times and clinicians' limited knowledge of available screeners. One screener, the Autism Detection in Early Childhood (ADEC) is a 16-item, play based screener for 12-36 month olds. It has good reliability and validity, requires minimal training, and can be administered in 10-15 minutes. Despite these strengths, the ADEC has not been widely implemented. Since tools such as this it would still consume most of a standard 9-16 minute visit, there is a need to abbreviate it further. The BADEC, a five-minute version of the ADEC was therefore developed using a research sample (Nah et al., 2018).
Objectives: To evaluate the BADEC in a clinical sample by a) calculating the Nah et al. BADEC's sensitivity and specificity b) replicating their procedures to determine if the same five items from the original ADEC are identified as best predictors, and c) evaluating the screening ability and validity of abbreviated version we identified.

Methods: Participants were 107 children aged 14-36 months (*M* = 28.70 months, *SD* = 5.40) with confirmed final diagnosis of ASD (n = 48) or who had ASD ruled out (NASD; n = 59), and had complete ADEC data. Participants were screened and evaluated at a pediatric hospital. Screening ability of the Nah et al. (2018) BADEC was assessed in the current sample. Following Nah et al. (2018), Receiver Operating Characteristic analysis was

performed on all 16 ADEC items to identify five items associated with best area under the curve (AUC) values. These were then combined into one overall current BADEC score, and sensitivity, specificity, and concurrent, predictive, and diagnostic validity were calculated.

Results: The following items emerged with highest AUC values: Gaze Monitoring (.82), Task Switching (.75), Response to Name (.74), Reciprocity of a Smile (.74), and Following Verbal Commands (.73). Our findings are in agreement with Nah et al. (2018) on the inclusion of three items. While Nah et al (2018)'s data supported a cutoff of 4, our data supported a cutoff of 5 (Se = .77, Sp = .86, PPV = .82, NPV = .82, AUC = .82). Both versions of the BADEC had strong concurrent, predictive, and diagnostic validity.

Conclusions: An abbreviated version of the ADEC can effectively screen for ASD in children under age three. Short tools such as these are particularly amenable for inclusion in wellness checks given that they are easy to use. This can facilitate timely access to supports for those who go on to receive a diagnosis. There is value in evaluating screening tools in clinical contexts given that the majority of available screeners are developed using research samples. Future research evaluating brief screeners should evaluate whether adherence to screening guidelines increases after pediatricians are trained in its use.

114 **169.114** Age-Based Diagnostic Tracks Are Effective in Interdisciplinary Team Evaluation for Autism Spectrum Disorder

J. Gerdts[1]*, J. Mancini*[2] *and R. Bernier*[1]*, (1)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (2)Seattle Children's Autism Center, Seattle, WA*

Background: Diagnostic evaluations for autism spectrum disorder (ASD) follow a range of processes that can be lengthy and contribute to long wait times. At Seattle Children's Autism Center (SCAC), we utilize an interdisciplinary team evaluation model with two providers of different disciplines after an initial neurodevelopmental intake. This model has high provider satisfaction, maintains consistency in ASD diagnostic rates, and results in significantly fewer billed hours than a traditional psychology-only evaluation (Gerdts, et al., 2018). SCAC provider feedback in working in teams has centered on two themes for improved processes: streamlining evaluations for younger children, and identifying different approaches for patients with clinically complex diagnostic profiles.

Objectives: We will explore the effectiveness of a single day team evaluation model for patients 5 years, foregoing the initial neurodevelopmental intake; and determine whether intake providers can reliably predict the length of time needed for evaluation of children 6+ (regular versus "complex").

Methods: Two diagnostic tracks are being piloted: 1) Patients 5 years, who generally have less history and fewer records to review. Patients are sent directly to an interdisciplinary team evaluation involving an assessment of adaptive functioning, record review, and developmental/ASD-related history, as well as a direct assessment with feedback provided to families on the same day. For this track, outcome variable of interest is the ratio of incoming:outgoing referrals.

2) Patients 6+ years receive an initial clinical intake to obtain developmental history and collect records, and subsequent referral to an interdisciplinary team evaluation (Gerdts et al., 2018). In our pilot, intake providers indicated whether they anticipate the patient could participate in a regular team evaluation or whether the evaluation would need to be longer. Data from 27 patients 6+ years seen thus far in our pilot were tracked. Blind ratings from intake providers (*n*=10) were compared to evaluation outcomes from interdisciplinary teams (*n*=19 teams). Patients ranged in age from 6-18 years (*Mean*=10.55 years, 67% male).

Results: The ratio of incoming:outgoing referrals for children 5 years over the past 4 months has been decreasing despite an increase in the number of diagnostic referrals coming into SCAC (Figure 1: Aug=1.58, Sept=1.99, Oct=1.21, Nov=0.70). In the 6+ year track, there was 70.3% agreement between intake provider rating and ultimate team process. Mismatches were often when intake provider rated a patient as needing a lengthier evaluation, when teams were actually able to complete their evaluation in standard time. Patients with mismatched provider ratings were older than those with matched (13.1 years v 9.8 years).

Conclusions: Efficiency in evaluating children 5 years at SCAC has been improving since the pilot launch. Expediting young children is particularly important for accessing early intervention services. Referral for patients 6+ into two tracks based on clinical impressions at intake is 70% accurate. Further information and pilot data are necessary, but outcomes thus far suggest that specialized evaluations completed by appropriate providers (e.g., a psychiatrist/psychologist, developmental pediatrician/speech-language pathologist) could be helpful in optimizing clinical time and provider expertise. We plan to analyze full pilot data and efficiency data over time.

115 **169.115** The Reliability of Computerized Neurocognitive Assessments in Autism Spectrum Disorder

J. Weissman[1]*, I. Giserman-Kiss*[1]*, H. Grosman*[1]*, K. Meyering*[1]*, D. Halpern*[1]*, J. Buxbaum*[2]*, A. Kolevzon*[1] *and P. M. Siper*[1]*, (1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: The administration and implementation of computerized neurocognitive assessments is emerging, however, the reliability of such assessments remains in question (Vrana & Vrana, 2017). The feasibility of computerized assessments has been demonstrated in typically developing populations, although its use is not considered a substitute for clinician-administered assessments (Butcher, Perry, & Atlis, 2000; Gualtieri & Johnson, 2006). The reliability of computerized neurocognitive assessments in comparison to clinician-administered assessments has yet to be studied in individuals with autism spectrum disorder (ASD).

Objectives: This study explores the performance of children with ASD and their unaffected siblings on both computerized and clinician-administered measures of intellectual functioning.

Methods: Thirty-six individuals participated in this study, including 17 individuals with ASD (ages 6-24 years) and 19 unaffected siblings (ages 6-27 years). ASD diagnoses were confirmed via gold-standard tools and expert clinical judgement. Computerized administrations of the Peabody Picture Vocabulary Test-4 (PPVT-4) and a Visual Reasoning (VR) (testmybrain.org) task were completed on a laptop in the clinic. All participants were administered the Wechsler Abbreviated Scale of Intelligence-II (WASI-II). Probands also completed a comprehensive developmentally-appropriate test of cognitive functioning (Wechsler Adult Intelligence Scale-IV, Wechsler Intelligence Scales for Children-5, Stanford Binet-5, Mullen Scales of Early Learning). Developmental quotients were calculated for participants who completed the Mullen.

Results: T-tests were run between clinician-administered and computerized measures. Results revealed that probands' performance did not differ significantly between assessment modality (i.e., clinician-administered versus computerized) across domains, except for one comparison (WASI-II

Perceptual Reasoning Index standard score (SS) vs. VR SS), with significantly stronger performance on the clinician-administered WASI-II (p=.04). In contrast, unaffected siblings performed significantly better on all clinician-administered assessments compared to computerized assessments (p<.01).

Conclusions: This study demonstrated that children with ASD performed similarly on computerized- and clinician-administered assessments, whereas their unaffected siblings performed significantly better on clinician-administered assessments. Results suggest that individuals without ASD may respond better to human social interaction and prompting. Future directions include further examination of the reliability of computerized cognitive assessments in larger and more homogenous subgroups of individuals with ASD.

116 **169.116** Validity of the Aberrant Behavior Checklist

***L. Swineford**, Speech and Hearing Sciences, Washington State University, Spokane, WA*

Background: Autism spectrum disorder (ASD) is considered a life-long disorder with incredibly heterogeneous symptom presentation. The prevalence of ASD is estimated at 1 in 68 in the United States as identified in 2010, and the World Health Organization has listed ASD as one of three top priorities. Further, the socioeconomic burden of this developmental disorder to the U.S. economy is estimated at $126 billion. Given the individual and societal impact of this disorder, an increased effort has been placed on developing interventions to lessen the severity of the core symptoms of ASD. To date, there is no agreed upon outcome measure for measuring change in core autism symptoms in response to clinical trials. Objectives: One measure that has been proposed as an outcome measure is the Aberrant Behavior Checklist (ABC; Aman et al., 1985a), specifically the Social Withdrawal scale to measure core symptoms of ASD. However, it is unclear if and how well this subscale truly measures core symptoms of autism. Thus, the purpose of this project is to expand upon existing psychometric work on the ABC and examine the validity of the ABC subscales in relation to other measures designed to assess core symptoms of autism.

Methods: Participants were drawn from a sample of children with an ASD diagnosis who participated in the Simons Simplex Collection. The primary measure of interest for this project is the Aberrant Behavior Checklist (ABC; Aman et al., 1985a) which contains 58 items that comprise five subscales: Irritability, Social Withdrawal, Stereotypic Behavior, Hyperactivity/Noncompliance, and Inappropriate Speech. A total of 2709 participants have a completed ABC and were included in this project. Preliminary analyses included correlations between the subscales of the ABC and other measures of core symptoms of autism including the Autism Diagnostic Observation Schedule, Repetitive Behavior Scale Revised, and the Social Communication Questionnaire.

Results: Small to medium significant correlations were observed between the five subscales of the ABC and all measures of core autism symptoms listed above. To examine the validity of the ABC using multiple methods of assessment and multiple constructs, additional analyses will be conducted using confirmatory factor analysis and exploratory structural equation modeling. Further, measures expected to diverge, or measure constructs other than core autism symptoms will be included in the final analyses.

Conclusions: Several studies have examined the factor structure of the ABC; however, the methodology and statistics used have been limited. The current project extends upon previous work by examining the construct, convergent, and divergent validity of the ABC in a large sample of individuals with ASD using more sophisticated statistical techniques. This approach allows for examination of possible relationships between scores on the ABC and measures expected to converge and diverge with the ABC whereas traditional correlational methods cannot examine underlying constructs which assessment tools are designed to measure. Better understanding what constructs the subscales of the ABC measures, with an emphasis on the Social Withdrawal scale, is imperative as it is being used as an outcome measure in treatment trials.

Poster Session
170 - Epigenetics
11:30 AM - 1:30 PM - Room: 710

117 **170.117** Autism Spectrum Disorder Associated with Mutations in Srcap Upstream of Those Associated with Floating-Harbor Syndrome Generate Overlapping Yet Distinct Functional DNA Methylation Signatures

ABSTRACT WITHDRAWN

Background: Autism spectrum disorder (ASD) is an etiologically and phenotypically heterogeneous neurodevelopmental disorder. Genetic causes have been identified (>200 ASD-risk genes), but no single gene mutation accounts for >1% of all ASD cases. A role for epigenetic mechanisms in ASD etiology is supported by the many ASD-risk genes that function as epigenetic regulators and evidence that epigenetic dysregulation can interrupt normal brain development. We have identified two individuals with ASD who carry variants of unknown significance (VUS) in the Snf2 Related CREBBP Activator Protein gene (*SRCAP*). *SRCAP* encodes the core catalytic component of the SRCAP complex, which is involved in chromatin remodelling and acts in the Notch signalling pathway, important during development. Heterozygous variants in exons 33 and 34 of *SRCAP* are known to cause a rare genetic disorder, Floating-Harbor Syndrome (FHS; OMIM #136140), although not all FHS cases have an identifiable genetic cause. FHS is characterized by distinctive facial features, short stature, intellectual and speech impairments, and delayed bone age. ASD is not commonly comorbid with FHS, but the two disorders share some overlapping physical, cognitive and behavioural features.
Objectives: Given that SRCAP functions as an epigenetic regulator within important developmental pathways, we investigated whether aberrant epigenetic marks, specifically DNA methylation (DNAm), contribute to the molecular pathophysiology of FHS and if such specific DNAm patterns will distinguish between the two phenotypes observed in individuals with independent variants in the same gene.

Methods: To test this, we assessed for genome-wide DNAm patterns using the Illumina MethylationEPIC array in whole blood DNA from patients with a clinical diagnosis of ASD and *SRCAP* VUS (n=2) or FHS and pathogenic *SRCAP* variants (n=3).

Results: Despite a small number of cases, we identified an FHS-specific DNAm signature comprised of >2,000 CpG sites (FDR corrected p-value<0.001) that distinctly separated FHS cases from age- and sex-matched neurotypical controls (n=59). Pathway analysis performed on the differentially methylated genes in this signature revealed enrichment in neuronal differentiation and fibronectin production, biological pathways relevant to the pathophysiology of FHS. The FHS DNAm signature was used to classify the two individuals with ASD in order to better interpret the

pathogenicity of the *SRCAP* VUS, classifying them as intermediate between FHS signature cases and controls, reflecting the partially overlapping phenotypic features described.

Conclusions: In summary, we have demonstrated functional and biological utility of the FHS DNAm signature: it can be used as a molecular biomarker to inform pathogenicity of VUS and thus FHS diagnosis, and to elucidate the underlying biological mechanisms that will help us to better understand, diagnose and treat FHS and other disorders with overlapping features, such as ASD.

118 **170.118** Correlations between Psychological Assessments and RNA Concentrations in Saliva of Adolescents and Adults with ASD

D. Levitskiy[1], *K. E. Wagner*[2], *A. Rajan*[1], *R. Ericson*[1], *N. Shea*[2], *E. P. McKernan*[3], *J. Kopec*[3], *S. D. Hicks*[4], *N. Russo*[3] *and F. A. Middleton*[5], *(1)Quadrant Biosciences Inc, Syracuse, NY, (2)Syracuse University, Syracuse, NY, (3)Psychology, Syracuse University, Syracuse, NY, (4)Penn State Milton S. Hershey Medical Center, Penn State College of Medicine, Hershey, PA, (5)SUNY Upstate Medical University, Syracuse, NY*

Background: The prevalence rates of autism spectrum disorder (ASD) have steadily increased over the past two decades, nearly tripling since 2002. Current assessment procedures rely on behavioral assessments and parent-report surveys that can be influenced by situational variables. An objective molecular indicator of ASD symptom severity could inform treatment plans. Recent literature suggests that epigenetic factors, such as poly-omic RNA levels in saliva, can accurately distinguish school-aged children with ASD from their peers. We examined concentrations of salivary RNAs in a cohort of adolescents and young adults with ASD and compared RNA patterns with non-ASD peers to determine whether saliva RNA markers informed symptom severity and adaptive functioning.

Objectives: The current study compared ASD symptom severity and adaptive functioning to concentrations of human saliva RNAs, including mature/precursor microRNA (miRNA), piwi-interacting RNA (piRNA), long intergenic non-coding RNA (lincRNA), and ribosomal RNA (rRNA), to identify saliva RNA markers that correlate with behavioral phenotypes.

Methods: 53 individuals (26 ASD, 26 non-ASD; M = 12 yrs) were assessed using the Autism Diagnostic Observation Schedule (ADOS) and the Vineland Adaptive Behavior Scales 2nd Edition (VABS-II). Approximately 3 mLs of saliva were collected during a non-fasting state via expectoration into an Oragene RNA collection kit (DNA Genotek, Ottawa Canada). RNA was sequenced using an Illumina TruSeq Small RNA Prep protocol and a NextSeq500 instrument (Illumina; San Diego, CA, United States). Quantification of RNA reads were determined using the SHRiMP2 and Bowtie aligners in Partek Flow (Partek; St. Louis, MO, United States). Reference databases used for transcript assignment included miRBase version 21, RefSeq Transcripts 84, and the Human piRNA sequence v1.0 reference index. After alignment, a data transformation was applied to reduce batch effects and to study the full expression range of the RNAs. Sequencing data was transformed by applying an inverse hyperbolic sine transformation followed by cumulative sum scaling normalization. Associations between behavioral assessment scores and miRNA concentrations were performed using Spearman's Rank Correlation. In total, about 200 transcripts per RNA category were compared to 9 independent behavioral scores derived from the ADOS and VABS-II assessments.

Results: Results show significant correlations ($p < .05$) between sequencing data and both the VABS-II Socialization score and the ADOS-2 composite score. Spearman correlation coefficients ranged from +/- 0.5, suggesting relationships of weak to moderate strengths. Statistically significant correlations were found in each RNA category investigated (miRNA, piRNA, lincRNA, and rRNA), with mature/precursor microRNAs containing the strongest relationships between transcript counts and behavioral scores. Some of these microRNAs were the same as those identified in our previous pilot study of salivary microRNAs from an independent cohort of ASD and control subjects.

Conclusions: Poly-omic RNA levels are associated with both symptom severity and adaptive functioning in adolescents and young adults with ASD. This finding suggests that RNA profiles are a promising molecular marker with the potential to provide useful clinical data informing patient management and treatment plans.

119 **170.119** Epigenetic Changes Are Associated with Prenatal Air Pollution Exposure and Autism-Related Quantitative Traits

C. Ladd-Acosta[1], *J. I. Feinberg*[1], *F. Lurmann*[2], *L. A. Croen*[3], *I. Hertz-Picciotto*[4], *C. J. Newschaffer*[5], *A. P. Feinberg*[6], *M. D. Fallin*[1] *and H. E. Volk*[1], *(1)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Sonoma Technology, Inc., Petaluma, CA, (3)Division of Research, Kaiser Permanente, Oakland, CA, (4)University of California at Davis, Davis, CA, (5)AJ Drexel Autism Institute, Philadelphia, PA, (6)Johns Hopkins University, Baltimore, MD*

Background: Prenatal exposure to air pollution has been associated with increased risk of autism spectrum disorder (ASD). Identification of biologic mechanisms of this association can provide molecular targets for intervention. Evidence from the fields of environmental and autism epidemiology supports DNA methylation as a plausible biologic mechanism linking air pollution exposure with ASD risk.

Objectives: The main goal of this study was to identify DNA methylation changes, in two developmentally relevant tissue types, associated with prenatal exposure to air pollution and with autism-related quantitative traits. Secondary objectives included identifying sex-specific DNA methylation changes related to prenatal air pollution exposure and evaluate whether air pollutant related methylation changes show tissue-specificity or not.

Methods: Early Autism Risk Longitudinal Investigation (EARLI) is a US multi-site enriched-familial risk pregnancy cohort study. Genome-scale DNA methylation measurements for 133 placenta and 175 cord blood samples were obtained using the Infinium HumanMethylation450k platform. Ambient nitrogen dioxide (NO_2) and ozone (O_3) air pollutant exposure levels were estimated from prenatal address locations of EARLI mothers using inverse distance weighting via measurements from the Environmental Protection Agency's monitoring network. ASD-related quantitative traits include the Social Responsiveness Scale (SRS), Vineland Adaptive Behavior Scales (VABS)-2 composite, and the Mullen Scales of Early Learning (MSEL) composite scores at 36 months. Bumphunting was performed to identify differentially methylated regions (DMRs) associated with prenatal O_3 and NO_2 exposures in each tissue and by sex, adjusting for technical and biological sources of variation. Permutation testing was applied and a family wise error rate (FWER) statistic was used to assess statistical significance. Exposure-associated DMRs were then examined for associations with 36 month outcomes.

Results: We identified 9 DMRs in either cord blood or placenta, including 6 sex-specific, associated with prenatal O_3 or NO_2 exposures. Among these 9 air pollution associated DMRs, 2 also showed a significant (FDR < 0.05) and 1 showed a suggestive (FDR < 0.10) difference in methylation associated with a poorer 36-month outcome and in a direction that is consistent with air pollution – outcome main effects. For example, increased prenatal exposure to NO_2 and low VABS scores are both associated with a 9% loss of methylation in placenta, on average, at the *ZNF442*

locus. Formal mediation analyses are underway and will also be presented.

Conclusions: We observed locus and sex-specific methylation changes associated with prenatal NO_2 and O_3 exposures, providing potential biologic targets for a wide range of child health outcomes, including ASD. Associations, in the same direction, of some DMRs with both prenatal air pollutant exposure and quantitative traits, suggest DNA methylation may mediate the effects of prenatal air pollution exposure on child developmental function.

120 **170.120** Impact of Endocrine Disruptors on Mirna Expression in Sperm: A Risk Factor for Autism?

*V. W. Hu[1], **J. Debski**[1], H. T. Shu[1] and Y. Lai[2], (1)Biochemistry and Molecular Medicine, The George Washington University, Washington, DC, (2)Statistics, The George Washington University, Washington, DC*

Background: The rapidly rising prevalence of autism spectrum disorders (ASD) in the U.S., now as high as 1 in 40 individuals, suggests that environmental factors may be increasing risk for ASD. However, there is a critical gap in our knowledge regarding the nature of environmental factors and the biological mechanisms through which they may influence susceptibility to ASD. Recent studies by our group and others suggest that endocrine disrupting compounds (EDCs), many of which are ubiquitous in our environment, may be contributing to the rising prevalence of ASD. Moreover, germline exposures to EDCs in animal models have been reported to induce lasting phenotypic changes in offspring which are, in some cases, transmitted transgenerationally and potentially through epigenetic mechanisms.

Objectives: The overarching goal of this study is to test the hypothesis that miRNA expression in sperm is associated with measured levels of 1,1-dichloro-2,2-bis(p-chlorophenyl) ethylene (p,p'-DDE) in the serum of young sperm donors from the Faroe Islands, whose diet includes pilot whale meat and blubber which predisposes them to higher than average levels of long-lived environmental EDCs, which accumulate in fatty tissues. Specifically, we investigated differences in the expression of miRNAs in sperm from men with the highest (third tertile) and lowest (first tertile) exposures with respect to blood p,p'-DDE levels, and performed bioinformatics analyses on the differentially expressed miRNAs to identify target genes and pathways that may predispose offspring to ASD.

Methods: Sperm from men with the highest and lowest levels of DDE exposure (8 samples per group) was isolated from whole semen using a density gradient protocol. Total RNA was obtained from cell lysates (after DNA extraction) using Ribozol followed by chloroform extraction. The isolated RNA was submitted for small RNAseq analysis. RNAseq data was analyzed using the MicroRNA Analysis app within Illumina's BaseSpace Sequence Hub. Ingenuity Pathways Analysis (IPA) software was used to identify the potential target genes of differentially expressed miRNAs, which were then analyzed for pathways and functions using the Core Analysis feature of IPA.

Results: Fifty-five and 132 differentially expressed miRNAs were identified by the DESeq2 and RankProd software packages, respectively, in the MicroRNA Analysis app, with 25 miRNAs represented in both datasets. Approximately 6300 potential target genes were identified for the 25 overlapping miRNAs, of which 347 were represented in SFARI Autism Gene Database (hypergeometric distribution p-value ≤ 0.015 for enrichment in autism risk genes). Network prediction analysis of the 347 overlapping genes revealed GABA receptor signaling (p-val: 5.5E-06) and PTEN signaling (p-val: 1.1E-05) as the top canonical pathways represented within the gene set, with an overabundance of genes involved in developmental disorder (100 genes, p-val: 4.8E-05 – 1.2E-39), neurological disease (211, p-val: 6.2E-05 – 5.4E-35), and nervous system development and function (50, p-val: 1.7E-05 – 1.8E-13). Seventy of these genes are directly linked to autism/intellectual disability (p-val: 1.2E-39).

Conclusions: The results of this pilot study show that higher levels of exposure to p,p'-DDE are associated with differentially expressed microRNAs in sperm. These miRNAs potentially target genes involved in pathways and functions implicated in ASD.

121 **170.121** Impact of Endocrine Disruptors on the Sperm Methylome: A Risk Factor for Autism?

*V. W. Hu[1], **A. Maggio**[1], H. T. Shu[1], B. Laufer[2], J. LaSalle[2] and Y. Lai[3], (1)Biochemistry and Molecular Medicine, The George Washington University, Washington, DC, (2)University of California at Davis, Davis, CA, (3)Statistics, The George Washington University, Washington, DC*

Background: Although autism spectrum disorders (ASDs) are among the most heritable of neurodevelopmental disorders, the rapidly rising prevalence of ASDs worldwide suggests that environmental factors may interact with genetic risk for ASD. Environmental factors may impact the expression of genes associated with ASD through epigenetic mechanisms which could lead to intergenerational effects influencing risk for ASDs. This study addresses environmentally associated epigenetic modifications in spermatocytes as a result of exposure to a class of ubiquitous endocrine disrupting compounds (EDCs), the organochlorines. EDCs are of particular interest with respect to risk for autism because of their ability to interfere with hormonal signaling, which has been implicated in the regulation of *RORA*, a gene that our laboratory has previously shown to be differentially methylated in ASD and a master regulator of many other ASD risk genes.

Objectives: Here, we examine DNA methylation patterns in sperm from young men in the Faroe Islands (Denmark) with higher than average exposure to environmental organochlorines as a result of a diet that includes pilot whale meat and blubber. Organochlorine compounds, with long half-lives both in the environment and bodily tissues, have been associated with methylomic modifications. Specifically, we investigated differences in DNA methylation in sperm from men with the highest (third tertile) and lowest (first tertile) exposures with respect to blood levels of 1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene (p,p'-DDE), a stable breakdown product of the pesticide DDT. We then performed bioinformatics analyses on the genes associated with the differentially methylated regions (DMRs) to identify genes and pathways that may predispose offspring to ASD.

Methods: Sperm cells were purified from semen by density gradient centrifugation, and DNA was extracted from lysates using a Qiagen AllPrep DNA kit. Whole genome bisulfite sequencing (WGBS) was performed on 32 samples (16 samples from the first and third tertiles of DDE exposure) on the Illumina HiSeqX sequencer giving roughly 4x coverage after stringent quality control and quality analysis. A bioinformatics pipeline fine-tuned for low-coverage WGBS data (<https://github.com/ben-laufer>) was used to determine differential methylation between low and high DDE exposure groups. Gene ontology and pathway analyses were performed using GREAT and Ingenuity Pathway Analysis (IPA) software, respectively.

Results: Preliminary analyses revealed 674 differentially methylated regions (DMRs, permutation p ≤ 0.05) distributed across all genomic annotations. The most significant DMR was located in exon 7 of *PTPRN2* (p=7.7E-05), a diabetes-associated gene whose DNA methylation status in blood has been linked to pesticide exposure and to smoking in sperm. Moreover, gene ontology analyses implicate significant localization of genes at the terminal bouton and axon terminus of nerve cells (Adj p £ 5.2E-06). Pathway analyses further support the over-representation of nervous system genes (*ANKLE2, CNTNAP2, MBP, MYO16, PAX6, SPATA5*, and *TRAPPC9*) in the DMRs (Fisher's Exact p=3.9E-03). The top developmental

disorders revealed by IPA include autosomal dominant mental retardation (Fisher's Exact p=1.9E-04) and autism (Fisher's Exact p=5.2E-04).

Conclusions: Elevated exposure to certain organochlorines is associated with differential genome-wide DNA methylation patterns in sperm. The DMRs are enriched for genes involved in neurological functions and developmental disorders, including ASD.

122 **170.122** Parental Occupational Exposure to Solvents and Autism Spectrum Disorder: An Exploratory Look at Gene-Environment Interactions

E. C. McCanlies[1], *J. K. Gu*[1], *M. Shi*[1], *M. L. Kashon*[1], *C. C. Ma*[2], *W. T. Sanderson*[3], *I. Hertz-Picciotto*[4] *and B. Yucesoy*[5], *(1)HELD/BB, NIOSH, Morgantown, WV, (2)BB, NIOSH, Morgantown, WV, (3)College of Public Health, University of Kentucky, Lexington, KY, (4)University of California at Davis, Davis, CA, (5)CTP, FDA, Beltsville, MD*

Background: There is some evidence that parental occupational exposure to solvents may be associated with autism spectrum disorder (ASD). Similarly, there are a number of genetic factors that are associated with ASD. However, little research has evaluated potential gene-solvent interactions in the etiology of ASD.

Objectives: To investigate the joint effect of genetic variants and parental occupational solvent exposure in ASD.

Methods: Demographic, health, genetic microarray analysis, and parental occupational history information were collected for 416 children with ASD, 298 typically developing (TD) children and their parents as part of the CHildhood Autism Risks from Genetics and Environment study. Solvent exposure was assessed by two industrial hygienists. For each job, the frequency and intensity of potential solvent exposure was estimated and a binary and semi-quantitative cumulative exposure variable was determined. To assess gene-solvent interaction, the total number of minor alleles at each locus was fit in a model that contained the single nucleotide polymorphism (SNP) alone, solvent alone, and a SNP x solvent interaction term. The ratio of odds ratios (ROR) and 95% confidence interval were used to assess the effect of gene-solvent interaction on a multiplicative scale on the risk of ASD. The relative excess risk for interaction (RERI) was used to estimate interactions on an additive scale. In this model, the dominant model was used to create binary genotype variables that were put into the logistic model described above.

Results: Statistically significant ($p \leq 0.05$) interactions were found for both the additive and multiplicative models. Multiplicative interactions were found between solvents and a number of serotonin, major histocompatibility complex, inflammatory, and metabolism gene variants in the risk of ASD (n = 35 variants; ROR > 2; $p \leq .01$). Similarly, there were a number of superadditive interactions between solvents and serotonin, major histocompatibility, inflammatory, and metabolism gene variants (n = 23 variants; RERI > 0). Monotonic superadditive interactions were found between solvents and two *HTR1A* serotonin gene variants and two *RORA* gene variant (RERI > 1; $p \leq 0.05$). There were also a number of subadditive interactions between solvents and antioxidant metabolism genes, major histocompatibility complex, inflammatory, and metabolism gene variants (*GLRX3, HLA-C*HLA-B, HTR2A, HTR7, TGFB2, TNXB, VEGFA*; RERI < 0, $p \leq 0.05$).

Conclusions: This study indicates that the joint effects of certain antioxidant metabolism, major histocompatibility complex, inflammatory, and serotonin gene variants and parental occupational exposure to solvents may be associated with ASD. This is one of the first studies to evaluate potential gene-environment interactions in the risk of ASD. Additional studies with a larger sample size to confirm and extend these findings are needed.

123 **170.123** Paternal Sperm DNA Methylation and Offspring 36-Month Outcomes from an Autism-Enriched Cohort

J. I. Feinberg[1], *H. E. Volk*[1], *C. Ladd-Acosta*[1], *A. E. Jaffe*[2], *C. J. Newschaffer*[3,4], *I. Hertz-Picciotto*[5], *L. A. Croen*[6], *A. P. Feinberg*[7] *and M. D. Fallin*[1], *(1)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Lieber Institute for Brain Development, Baltimore, MD, (3)AJ Drexel Autism Institute, Philadelphia, PA, (4)A.J. Drexel Autism Institute, Philadelphia, PA, (5)MIND Institute, University of California, Davis, Sacramento, CA, (6)Division of Research, Kaiser Permanente, Oakland, CA, (7)Johns Hopkins University, Baltimore, MD*

Background: There is growing evidence supporting the contributions of both genetic and environmental risk factors for autism spectrum disorder (ASD). Epigenetic marks can reflect both genetic and environmental variation and have been implicated in ASD via multiple lines of evidence. We, and others, have reported DNA methylation associations with ASD and related traits, although the specificity of timing and tissue type (brain, blood, cord blood, placenta, sperm) is still unclear. Sperm is an important tissue for inquiry given its direct connection to germline DNA of the offspring and recent reports on relationships between genetic and paternal environmental experiences and sperm methylation. We previously reported associations between paternal sperm DNA methylation and 12-month ASD-related outcomes (AOSI) in the ASD-enriched risk Early Autism Risk Longitudinal Investigation (EARLI) cohort.

Objectives: We have now examined the associations between paternal sperm DNA methylation and three ASD-related quantitative outcomes at 36 months in the same EARLI sample.

Methods: We performed comprehensive genome-scale methylation analyses on DNA derived from semen samples contributed by 50 fathers enrolled in EARLI. Methylation was measured via the CHARM 3.0 array, which contains over 4 million probes and covers over 7 million CpG sites. We used a region-based approach to identify differentially methylated regions (DMRs) in paternal sperm genomes sampled prior to birth that associated with 36-month offspring scores on: the Mullen Scales of Early Learning (MSEL; 40 subjects), the Social Responsiveness Scale (SRS; 32 subjects), and the Vineland Adaptive Behavior Scales (VABS; 36 subjects). In addition to exploring relevant gene ontology for the associated regions, we identify regions that overlap across each of the 36-month assessments and also across the 193 DMRs previously associated with the Autism Observation Scale for Infants (AOSI) at 12-months in the same cohort.

Results: We identified 50 DMRs in the paternal sperm genome associated with MSEL, 154 sperm DMRs for SRS, and 67 sperm DMRs for the VABS at genome-wide significance (FWER $p < 0.05$); 25 DMRs overlap across at least two outcomes. Developmental outcome-associated DMRs include genes previously associated with ASD (e.g. *WWOX, SALL3*) and also overlap with DMRs previously reported to be associated with 12-month AOSI scores in the same EARLI sample.

Conclusions: These findings suggest paternal germ-line methylation around the time of pregnancy is associated with offspring cognitive and adaptive functioning in early development up to 3 years later. These prospective results for autism-associated traits, in an enriched familial risk sample, highlight the potential importance of sperm-based epigenetic mechanisms in ASD and neurodevelopment.

124 **170.124** Rare Epigenic Variations in Autism Spectrum Disorder

M. Janecka[1], *E. Hannon*[2], *P. Garg*[3], *A. Starnawska*[4], *N. H. Staunstrup*[4], *D. Schendel*[4], *J. Mill*[5], *A. Reichenberg*[1], *A. Sharp*[3] *and J. Buxbaum*[6], *(1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Exeter Medical School, University of Exeter, Exeter, United Kingdom, (3)Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Aarhus University, Aarhus, Denmark, (5)University of Exeter Medical School, University of Exeter, Exeter, United Kingdom, (6)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

Background: To date, epigenome-wide association studies have found few significant associations between the levels of DNA methylation and autism spectrum disorder (ASD). Identifying further case-control differences could be challenging in an etiologically heterogeneous disorder. Objectives: Our study tests if ASD is associated with loci showing extreme DNA methylation levels in a small fraction of cases, akin to the observations of the role of rare genetic mutations in ASD etiology.

Methods: As described in our previous work, DNA was isolated from dried blood spot samples (Guthrie cards) collected early postnatally from all newborns in Denmark, and archived in the Danish Neonatal Screening Biobank. The DNA extraction and subsequent DNA methylation profiling was performed at Statens Serum Institut, using a previously established method. Quality control steps included removal of samples with low signal intensities, low bisulfite conversion, or low detection P value, and probes within 5bp of known single nucleotide polymorphism. We also excluded all probes on the sex chromosomes. Data were normalized using the wateRmelon package.

Subsequently, a sliding-window approach was used to identify “epivariation”, i.e. regions where DNA methylation levels in cases or controls were outside the 99% confidence intervals in the set of independent, reference control samples, at a minimum of 3 consecutive probes within 1kb, with at least one of those probes deviating a minimum of 10% from the most extreme reference control.

Using permutation testing, we investigated the overall enrichment of such regions in cases compared to controls, as well as the differences in the characteristics of the underlying genomic regions (i.e., enrichment of either ASD-associated genes derived from the Autism Sequencing Consortium) or genes intolerant to mutation, defined as pLI >0.9.

Results: After quality control, there were 629 ASD and 634 control samples (both ~50% female) used in the analyses, with 456,725 autosomal probes analyzed. There were no significant differences in the rates of epivariation between cases and controls (p=0.084). However, cases had significantly more instances of epivariation in ASD FDR 0.1 genes (respectively, 0.003 and 0.001 per individual, p=0.015) and FDR 0.5 genes (respectively, 0.020 and 0.004, $p=2.3x10^{-8}$), and genes intolerant to mutation (0.074 and 0.059, p=0.035).

Conclusions: Our data indicate that ASD cases show a significant enrichment of epivariations in both genes previously linked with ASD, and genes intolerant to mutation, when compared to controls. Future studies will establish whether such epivariations could be causal in some cases of ASD, rather than marking other genomic alterations, e.g. copy number variations or aberrations of imprinting.

125 **170.125** Targeted Next-Generation Bisulfite Sequencing Identifies Differential Methylation in a South African ASD Cohort

C. O'Ryan, S. Stathopoulos and ***R. Van der Colff****, Molecular and Cell Biology, University of Cape Town, Cape Town, South Africa*

Background: DNA methylation is a well-recognised epigenetic modifier of gene expression that mediate transcription via conformational chromatin changes. DNA methylation is implicated in various biological processes, and has been investigated in the aetiology of disease, including Autistic Spectrum Disorders (ASD). A recent study done by our group, using a whole-genome bead-chip approach, identified over 800 genes to be differentially methylated between ASD and controls in a South African cohort, with many of these genes in canonical pathways involved in mitochondrial function. Mitochondrial homeostasis is fundamental and has been associated with numerous neurological disorders. A 50-fold increase in mitochondrial disease in children with ASD compared to the general population has been reported, implicating mitochondrial dysfunction in the pathophysiology of ASD.
Objectives: Firstly, to set up targeted Next-Generation Bisulfite Sequencing (tNGBS) for 30 to 40 loci using buccal cells, to identify assays that can accurately measure methylation at high quantitative resolution. Secondly, to confirm DNA methylation observed in our earlier whole-genome methylation screen in a locus-specific manner using pyrosequencing for the loci optimised using tNGBS. Lastly, this study aims to examine methylation of genes implicated in mitochondrial dysfunction in ASD.

Methods: The 898 genes from our methylation screen were compared with genes from the SFARI database and we identified 59 common genes. These included seven high confidence genes based on SFARI rankings, as well as genes involved in mitochondrial function and ubiquitination pathways, and these were selected for tNGBS. Only loci that passed assay validation QC criteria (e.g. r^2 >0.9) and minimal PCR bias were carried through for subsequent locus-specific pyrosequencing analysis. DNA samples were collected from the buccal cells of a homogenous, mixed race cohort of South African boys, aged 6 to 12, with 46 ASD cases, and 46 neurotypical controls.

Results: From the 59 common genes in the methylation screen -SFARI overlay, 40 met criteria to be selected for tNGBS and four loci were pyrosequenced. We confirmed differential methylation between ASD and controls, highlighting the importance of epigenetic changes. These results accentuate the role of mitochondrial and ubiquitination pathways in ASD.

Conclusions: This study showed that pyrosequencing is a cost- and labour-effective way to identify loci that show differential methylation of the promotor regions of genes. It demonstrates the importance of epigenetics in ASD and the dysfunction in pathways maintaining mitochondrial homeostasis.

126 **170.126** The Potential Role of a Retrotransposed Gene and a Long Non-Coding RNA in Regulating an X-Linked Chromatin Gene (KDM5C): Novel Epigenetic Mechanism in Autism

Z. Talebizadeh[1], *A. Shah*[1] *and L. DiTacchio*[2], *(1)Children's Mercy Hospital, Kansas City, MO, (2)University of Kansas Medical Center, Kansas City, KS*

Background: A growing body of evidence supports the potential role of the circadian system and chromatin remodeling genes in autism. Considering the heterogeneity in autism, and the complex nature of the epigenetic landscape, identification of biologically relevant epigenetic factors requires reducing heterogeneity using proper subtyping. Previously, we have reported that members of the KDM5 family of genes are involved in the circadian machinery. X chromosome inactivation (XCI) is one of the biological processes highly dependent on epigenetic steps. There is also a crosstalk between DNA methylation and gene regulatory processes, including alternative splicing. We have previously shown the trend of a higher degree of XCI skewness (XIS) in autistic females compared to controls.

Objectives: To investigate the role of circadian genes and their potential mis-splicing in autism.

Methods: In the present study, we used human blood samples (n=39) and a combination of whole genome (Exon array) and gene-targeted assays (PCR, TaqMan, Sanger sequencing) to characterize alternatively spliced KDM5 isoforms in controls and autism, stratified by XCI profiles (with or without XIS). Mouse brain samples were used to study isoforms circadian dependency.

Results: Several isoforms, including previously uncharacterized microexons and intron-retained variants, were identified for each gene. Overall, we found that the X-linked gene (*KDM5C)* undergoes a more complex splicing process than the autosomal genes (*KDM5A* and *KDM5B*). We also identified a *KDM5C* isoform (*KDM5C*-3'UTR-lncRNA) containing a novel 3'UTR originated from a retrotransposed gene of an autosomal methyltransferase (*SUV39H2*). This 3'UTR shows 83% sequence homology with lncRNAs and is located 32kb downstream of *KDM5C*. The *KDM5C*-3'UTR-lncRNA isoform was differentially expressed in autistic females with XIS compared with controls (Figure.1). Intriguingly, the XIS and noXIS autistic females presented different expression profiles, which indicates that such differences would have remained undetected without the subtyping. Since no differences were seen between the XIS and noXIS controls, the detected expression differences for *KCM5C*-3'UTR-lncRNA may be related to the underlying mechanism of autism, and not XIS itself.

This finding would ideally need to be studied in human brain samples collected at different circadian time-points, but it was impossible to do so. Therefore, we attempted to gather basic information about circadian dependent expression fluctuation of Kdm5 isoforms in wild type mouse brain samples (n=27). We characterized alternatively spliced isoforms of the Kdm5 genes and assessed their expression level in samples collected at different circadian time-points. In doing so, we showed that some Kdm5 isoforms follow a circadian oscillation pattern of expression (Figure.2).

KDM5C plays a crucial role in balancing histone H3K4 methylation states. The identified retro-*SUV39H2* originated lncRNA also shows H3K4 marks. LncRNA RNA-seq data from UCSC browser confirmed the expression of lncRNA from the region encompassing the retro-*SUV39H2* gene abundantly, in multiple tissues, including brain and blood.

Conclusions: This study provides the first evidence and a suggestive model for the potential role of retrotransposed elements in autism through linking methylases and demethylases, two functionally complementary components of chromatin remodeling, which may collectively contribute to disease etiology through lncRNAs.

127 **170.127** Use of Electronic Devices and Screen Exposure in a Population of Preschoolers with ASD

*G. Garrido[1], **C. Amigo**[2], N. Orrico[3], A. Zulberti[4], G. Lamas[4], F. Cardoso[4] and M. Castillo[4], (1)Universidad de la República, Montevideo, Uruguay, (2)Clinica de psiquiatria pediátrica Facultad de medicina, UDELAR, Montevideo, Uruguay, (3)Montevideo, Centro Hospitalario Pereira Rossell Asociación Española, Montevideo, Uruguay, (4)Centro Hospitalario Pereira Rossell, Montevideo, Uruguay*

Background: There is general concern in the pediatric medical community, about early screen exposure in children and its possible consequences in health. To date, literature considering the use of electronic devices and screen exposure in children with ASD is very limited. However, many studies suggest that early screen exposure has a negative impact in different areas of development, including language and social interaction. Given that the first years of live constitute a period of great cerebral plasticity, we consider for this study the hypothesis that early intensive screen exposure could have a negative impact in development and in susceptible individuals could condition the severity of ASD symptoms. The intervention in this variable could help modify developmental pathways.

Objectives: to describe the use of electronic devices and screen exposure in a population of preeschoolers with ASD diagnosis.

Methods: Descriptive, observational, trasversal study. The sample consists of 30 preeschoolers who have received attention in the outpatient clinic which specializes on ASD at Centro Hospitalario Pereira Rossell, Montevideo, Uruguay, in the period june 2017- june 2018. A questionnaire specially designed for this study was administered as well as CBCL 1 ½-5. ADOS 2 was administered to all patients above 30 months of age.

Results:

The whole sample was exposed to more than one electronic device. Exposure started before 6 months of age in 35% of patients, and between 6-12 months in 25%. Daily time of exposure is variable, with 28% of the sample watching more than 5 hours a day. 57% of the parents had recently reduced screen exposure in their children.

Conclusions:

There is an early exposure to screens in a large number of the subjects. Special care should be taken in exposure before six months of age. 81% of the subjects exceeded the American Academy of Pediatrics recommendation regarding screen exposure.

128 **171.128** Improvements in Motor Skills, Play, and Socialization in Young Children with Autism Spectrum Disorder Following a Motor Skill Intervention: Preliminary Results

***T. Runge**[1], A. T. Ibbitson[1] and M. Lloyd[2], (1)Faculty of Health Science, University of Ontario Institute of Technology, Oshawa, ON, Canada, (2)Kinesiology, University of Ontario Institute of Technology, Oshawa, ON, Canada*

Background: Children with Autism Spectrum Disorder (ASD) experience challenges in social communicative skills and repetitive behaviours along with delays in motor skills. These challenges can act a barrier to participation in unstructured active play and organized sport; yet, there are few programs available to that focus on development of skills in multiple domains. Fundamental motor skill (FMS) interventions have been shown to improve motor skills as well as social and behavioural skills in children with ASD. Furthermore, motor skills may provide the foundation to lead to increased time in active play ultimately facilitating improvements in social skills.

Objectives: To determine whether improvements in motor skills are associated with increased socialization following a 12-week FMS intervention.

Methods: Participants with ASD (n = 14, 11 male, 3 female, Mage = 3.51, SD ± 0.52) were randomly assigned to an intervention group (n = 7, Mage = 3.64, SD ± 0.69) or waitlist control group (n = 7, Mage = 3.38, SD ± 0.13) prior to participating in the 12-week FMS intervention. The intervention ran

for 1 hour, 2 times per week for 12 weeks. The Vineland Adaptive Behaviour Scale: 2nd Edition and Test of Gross Motor Development-2 (TGMD-2) were completed before and after the intervention. The Vineland-II measures overall adaptive functioning across 4 domains; Communication, Daily Living Skills, Socialization (SOC), and Motor Skills. Play and Leisure Time (PLT) is a sub-domain of the SOC domain. The TGMD-2 measures fundamental motor skills and produces a Gross Motor Quotient (GMQ).

Results: Prior to the intervention, the intervention group had a GMQ mean of 81.57 (SD ± 19.09), SOC standard score mean of 73.86 (SD ± 9.86) and PLT V-scale score mean of 9.71 (SD ± 1.38) whereas the control group showed GMQ mean of 69.14 (SD ± 14.04), SOC standard score mean of 77.43 (SD ± 8.4) and PLT V-scale score mean of 10.57 (SD ± 16.18). There were no significant differences between the groups at the pre-test. Following the intervention, the intervention group displayed GMQ mean of 91.86 (SD ± 20.91), SOC standard score mean of 86.14 (SD ± 17.19), and PLT V-scale score mean of 12.71 (SD ± 3.59) while the control group presented GMQ mean of 76.86 (SD ± 12.93), SOC standard score mean of 76.14 (SD ± 9.17) and PLT V-scale score mean of 10.43 (SD ± 1.51). The intervention group showed significant change from the pre-test to post-test for GMQ ($p = 0.045$) and PLT V-scale score ($p = 0.022$). There were significant results of time by group for SOC ($p = 0.046$) and PLT ($p = 0.019$) as well as time for GMQ ($p = 0.028$) and PLT ($p = 0.03$).

Conclusions: According to the preliminary results, the intervention targeting fundamental motor skills also has a positive impact on socialization and play and leisure time in 3-5 year olds with ASD. Furthermore, early FMS interventions are important in providing opportunities for motor and social skills to develop in hopes of increasing participation in active play.

129 **171.129** Individual Differences in Developmental Gains across One Year of Early Intervention for Pre-Schoolers with Autism.

C. A. Bent[1], *M. Yaari*[2], *C. C. Green*[3], *J. A. Smith*[4], *C. Dissanayake*[5] *and K. Hudry*[6], *(1)Victorian Autism Specific Early Learning and Care Centre, La Trobe University, Melbourne, Australia, (2)Department of Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel, (3)Olga Tennison Autism Research Centre, La Trobe University, Bundoora, VIC, Australia, (4)School of Psychology and Public Health, Olga Tennison Autism Research Centre (OTARC), Melbourne, Australia, (5)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (6)Victorian Autism Specific Early Learning and Care Center, Olga Tennison Autism Research Centre, Melbourne, Australia*

Background: Many children with autism benefit from intensive early intervention. However, individual responses vary greatly and little is known about the profile of skills associated with more favourable outcomes. Age at intake and amount of intervention received are commonly identified as contributing to positive outcomes, as are symptom severity and developmental level. However, these factors have rarely been examined together, and among child characteristics, total scores are often used to measure skills, which may mask information about specific behavioural predictors.

Objectives: We aimed to identify specific behaviours associated with developmental gains across one year of intervention, and further examine the role of intervention dose and child age at intake, in a large sample. In this cohort, while we can control for the influence of intervention type, as all children received the same program - participant characteristics and intervention dose naturally vary, enabling us to examine the association of this variation on outcomes.

Methods: Participants were a cohort of 110 children (*M* age = 2.7 years at intake; range 1 to 4.8 years) who received approximately 1-year of Group-Early Start Denver Model (Vivanti et al., 2017) between 2015 and 2017. The Autism Diagnostic Observation Schedule (ADOS-2) was conducted at intake, and single items representing key foundational skills were examined as potential predictors (e.g., Pointing, Response to Joint Attention, etc.) of outcome. The primary outcome of interest was change in Mullen Scales of Early Learning (MSEL) Verbal and Non-Verbal age equivalent (V/NVAE) scores; administered at intake (T1) and exit (T2). Earlier cohorts have shown improvement on the MSEL through this program (Vivanti et al., 2014). Intervention dose was estimated as days/week*months enrolled.

Results: Large variability was evident in developmental gains on the MSEL (see Figure 1). Controlling for T1 AE scores, correlations were evident between younger age at intake and higher T2 NVAE ($r=21$, $p<.05$), and between higher intervention dose and T2 VAE ($r=.24$, $p<.05$). Hierarchical regressions examining the *unique* role of potential predictors, controlling for T1 AE scores, revealed higher T2 NVAE was predicted by ADOS Pointing and intervention dose and (less) ADOS Overactivity ($F(1,83)=54.53$, $p<.001$, $R^2=.72$). ADOS Response to Joint Attention was associated with higher T2 VAE ($F(1,88)=220.82$ $p<.001$, $R^2=.83$). Whilst correlated with outcomes, age at intake was not a significant *unique* predictor of T2 V/NVAE, nor were other ADOS social-communication skills (e.g., Play, Eye Contact and Language) when entered alongside the aforementioned significant unique predictors.

Conclusions: Identifying specific skills/behaviours associated with more favourable developmental outcomes can help inform future individualised treatment decisions. *Developmental* age may play a greater role in predicting gains than *chronological* age. Nevertheless, these data reinforce the importance of early intervention to ensure learning supports are in place to minimise the extent of the gap between chronological and developmental age over time. While examination of associated factors in a large cohort receiving a common intervention informs our understanding of predictors of outcome, replication of findings within a comparative study is required to disentangle genuine predictors of intervention outcome from broad indicators of good prognosis.

130 **171.130** Individual Treatment Change during the Early Social Interaction (ESI) Project Predicts Long-Term Behavioral Outcomes

T. N. Day[1], *W. Guthrie*[2], *A. Wetherby*[1] *and C. Lord*[3], *(1)Florida State University Autism Institute, Tallahassee, FL, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)University of California Los Angeles, Los Angeles, CA*

Background: Early intervention has been shown to improve language, cognitive, and/or social outcomes for toddlers diagnosed with ASD (Dawson et al.,2010; Kasari et al.,2010; Wetherby et al.,2014), as well as reductions in autism symptoms and adaptive behavior at school-age (Estes et al.,2015; Pickles et al.,2016). However, given substantial variability in children's responses to early intervention (Guthrie et al.,2016), it is also important to examine individual treatment change to elucidate maintenance of improvements and impact on long-term outcome.
Objectives: To examine how *individual-level* change in social interaction skills during treatment predicted child functioning at follow-up. Specifically, this study investigated the relationship between individual trajectories of children who received 18-months of parent-implemented early intervention and outcomes at school-age.

Methods: Toddlers with ASD (*N*=82) participated in a crossover RCT design in which they were randomized to receive either Individual-ESI or Group-ESI for 9-months (Condition I, ~18-27-months of age) and then crossed over to receive the other treatment for an additional 9-months

(Condition II, ~27-36-months of age). The CSBS was administered at baseline and every other month until the end of treatment. Sixty-five children returned for a long-term follow-up assessment between 5-8-years (*M*=6.79y), which included the ADOS-2, ADI-R, DAS-II (*Differential Ability Scales-II*), WJ (*Woodcock-Johnson Achievement*), Vineland-II, and BASC-3 (*Behavior Assessment System for Children*).

Results: At follow-up, children demonstrated average IQ, academic achievement, and behavioral functioning, with mild impairment in adaptive behavior and autism symptoms.

A piecewise hierarchical linear model was fit to model change during treatment; the final model included random intercepts, random slopes, fixed quadratic terms, and condition-by-slopes interactions. The resulting slopes were then used to predict school-aged outcomes via linear regression. Greater increases (i.e., steeper slope) in CSBS-Social composite scores during Condition I, but not Condition II, predicted *lower* ADOS-Social Affect scores at follow-up (*t*=-2.33, *p*.=.02). In contrast, greater increases in CSBS-Social during Condition II predicted *higher* ADOS-RRB scores at follow-up (*t*=3.11, *p*=.003). Finally, greater increases in CSBS-Social during Condition I, but not Condition II, predicted *moderately fewer* externalizing symptoms on the BASC at follow-up (*t*=-1.93, *p*=.06). Changes in CSBS-Social during treatment were not significant predictors of intellectual or academic functioning (DAS-II, WJ), adaptive behavior (Vineland-II), or parent-reported social interaction symptoms (ADI-R).

Conclusions: On average, children who participated in early ESI treatment as toddlers demonstrated age-appropriate intellectual and academic functioning at school-age follow-up. The degree of change in social interaction skills during treatment was a significant predictor of behavioral outcomes (i.e., autism symptoms, externalizing symptoms) approximately 3.5-years after treatment ended, but not of intellectual, academic, or adaptive functioning. While change during Condition I predicted ADOS and BASC scores, change during Condition II was generally not predictive of outcomes, likely due to the more limited gains observed in Condition II. The exception to this was the unexpected finding regarding the negative relationship between change in social skills during Condition II and school-age RRBs; we plan to examine this relationship further via parent-report (i.e., RBS-R). In sum, this study demonstrates the importance of examining individual changes during early treatment in predicting long-term outcomes.

131 **171.131** Informing an Early Intervention Model for Children at Risk of Autism Spectrum Disorder and Other Developmental Disabilities

J. Armstrong[1], *C. Elliott*[2], *J. Wray*[3], *E. Davidson*[4], *J. Mizen*[5] *and S. J. Girdler*[6], *(1)Curtin University, Bayswater, Australia, (2)Child and Adolescent Health Services and School of Occupational Therapy and Social Work, Health Department and Curtin University, SUBIACO, Australia, (3)State Child Development Service, Western Australia Department of Health, Perth, Western Australia, Australia, (4)Child and Adolescent Community Health, Health Department, Perth, Australia, (5)Child Development Service, Health Department, Perth, Australia, (6)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia*

Background: Therapeutic playgroups are increasingly recognised as an important engagement point for vulnerable families accessing early intervention services for their children at risk of Autism Spectrum Disorder and other developmental disabilities. However, there is currently no clear description and specification for best practice in playgroup intervention which impedes effective playgroup implementation and evaluation. Researchers state inconsistent playgroup definitions, models and practice principles have hindered playgroup implementation and evaluation, calling for a common definition of playgroups components and identify the "active ingredients of playgroups to strengthen the evidence base for playgroup effectiveness. Therefore, the systematic development and evaluation of playgroups is novel and important to establish evidence based practice with findings being directly beneficial to children at risk of Autism Spectrum Disorder and other developmental disabilities.
Objectives: This study aimed to address a substantial evidence gap by providing a clear definition of therapeutic playgroups and playgroup practice principles that produce the most efficacious outcomes for children at risk of developmental disabilities and their families.

Methods: Using the Medical Research Council Framework for the Development and Evaluation of Complex Interventions this study identified the "active ingredients" of therapeutic playgroups. Initially, a scoping review was conducted to identify the evidence base for therapeutic playgroups. Secondly, parents (n=23) and health professionals (n=40) were consulted as stakeholders, and defined the "active ingredients" of playgroup intervention and theory. Finally, findings were triangulated to identify an overarching theoretical framework, modelling therapeutic playgroup process and evaluation.

Results: Therapeutic playgroups require a complex interplay of service provider (facilitator qualities), participant (shared experiences and social networking) and intervention characteristics (format, physical resources and information provision). The overarching frameworks that defined therapeutic playgroup intervention was family centred practice, self-efficacy theory and peer support theory.

Conclusions: These findings provide a definition of evidence based therapeutic playgroups with a clear description of the program, including theoretical frameworks, essential functions of the program and performance assessment. The program description enables the active ingredients to be taught, learned and implemented with good outcomes. Findings also contribute to our understanding about the role playgroups have in facilitating child and parent outcomes in children at risk of Autism Spectrum Disorder, whilst providing a protocol for how to develop and deliver effective playgroups which has implications nationally and international.

This study is the first to develop a therapeutic playgroup intervention framework using the Medical Research Council Framework, a critical step in establishing evidence based therapeutic playgroups for children and their families at risk of Autism Spectrum Disorder and other developmental disabilities.

132 **171.132** Intervention in the Assessment Clinic: Feasibility and Efficacy of an Abbreviated Group-Based Intervention Model for Toddlers

K. Bernardi[1], *A. Solish*[2], *E. M. Dowds*[3], *K. Perry*[2], *I. Roth*[4], *M. Pilkington*[2], *L. Zwaigenbaum*[5], *S. E. Bryson*[6] *and J. A. Brian*[2], *(1)Holland Bloorview Kids Rehab, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Autism Research Centre, Holland Bloorview Kids Rehabilitation Hospital-Autism Research Centre, Burlington, ON, Canada, (4)Autism Research Centre, Holland Bloorview Kids Rehab, Toronto, ON, Canada, (5)University of Alberta, Edmonton, AB, Canada, (6)Dalhousie University, Halifax, NS, Canada*

Background: Recent evidence from parent-mediated early intervention models for toddlers with ASD has demonstrated child- and parent-level gains following 3-12 months of intervention. These models are relatively resource-efficient, but demand continues to grow and is outpacing capacity such that toddlers may be missing out on intervention at a key time in development when neuroplasticity is optimal. In response to this

increasing demand, our team developed an abbreviated, group-based version of our 12-week, in-home parent-mediated Social ABCs intervention. The Social ABCs parent-mediated intervention (standard model) is a 12-week in-home model, with demonstrated efficacy based on a cross-site RCT.

Objectives: To develop, pilot, and evaluate an abbreviated group-based model of an evidence-based parent-mediated intervention for toddlers with ASD or related social-communication challenges. The motivation for this work was to increase access to intervention, at the earliest signs of concern, for toddlers within the course of their clinical diagnostic care pathway, including before a diagnosis may be confirmed.

Methods: We adapted the original 12-week, one-on-one model to be delivered in a small-group format over six weeks (5 group-based didactics and 9 one-on-one parent coaching sessions in the clinic). Referrals were received from diagnosing clinicians (Psychologists or Developmental Paediatricians) or Social Workers within the clinical assessment service (Child Development Program) at Holland Bloorview Kids Rehab Hospital in Toronto, Ontario. To date, we have completed 4 groups (n = 12 toddler-parent dyads). Data from the first 3 groups were coded from video tape and analyzed, including measures of parent implementation fidelity (% correct use of strategies) and child responsivity (rate of responding to parent-provided language opportunities). Data from 20 dyads (6 groups) will be included for presentation at INSAR in May 2019.

Results: Interim analyses of group 1 led to program modifications which have been maintained for subsequent groups. Parents achieved implementation fidelity at a mean rate of 75% by the end of the program (week 6), increasing significantly from baseline, $t = 7.98$, $p < .001$. Child Responsivity increased by 43% from baseline to week 6 ($t = 6.32$, $p < .001$), at a pace commensurate with that reported in our previous RCT based on the original, 12-week one-to-one home-based model. Within the clinic-delivery model, our team has trained two Speech-Language Pathologists to provide parent-coaching. Parents and clinical staff have reported high levels of satisfaction with the program.

Conclusions: Findings reveal the feasibility and acceptability of our abbreviated group-based intervention model for toddlers with ASD and related social-communication concerns. Results demonstrate that the abbreviated model can be implemented in a clinical setting for toddlers within the context of a diagnostic assessment service. This abbreviated, group-based approach adds to the suite of services that can be offered to families very early in their diagnostic assessment journey, in many cases before a definitive diagnosis may be confirmed, and/or while awaiting more intensive intervention services. Weaving a brief intervention program into a clinical assessment pathway has the added value of providing clinicians with information about a child's response-to-treatment in cases of diagnostic uncertainty.

133 **171.133** Measure of Interactive Strategy Implementation – Caregivers (MISI-C): Preliminary Validity and Reliability

B. Vibert[1], *S. Dufek*[2], *C. B. Klein*[3], *Y. B. Choi*[3], *J. Winter*[4], *C. Lord*[5] *and S. H. Kim*[6], *(1)Psychiatry, Center for Autism and the Developing Brain, Weill Cornell Medical College, White Plains, NY, (2)Psychiatry, University of California, Davis, Sacramento, CA, (3)Psychiatry, Weill Cornell Medical College, White Plains, NY, (4)Center for Autism & the Developing Brain, NYP, White Plains, NY, (5)University of California Los Angeles, Los Angeles, CA, (6)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY*

Background: Early interventions for ASD use Parent Mediated Intervention (PMI) to teach parents interactive strategies targeting social communication in their children with ASD (Kasari et al., 2014; Pickles et al., 2016; Wetherby et al., 2014). Although individual treatments have attempted to use specific fidelity ratings to measure caregiver strategy implementation (Gulsrud et al., 2016; Rogers et al., 2018), there is no uniform measurement that can be used to examine caregiver strategies *across* different PMIs. This study provides initial validity and reliability of the Measure of Interactive Strategy Implementation-Caregivers (MISI-C), a novel outcome measure designed to capture changes in caregiver implementation of interactive strategies for toddlers with ASD over the course of various early interventions.

Objectives: We aim to (1) determine items for inclusion in the final MISI-C coding scheme, (2) explore the factor structure of the MISI-C items, (3) examine inter-rater (IRR) and test-retest (TRT) reliability, and (4) provide initial evidence for validity of the MISI-C in capturing changes in caregivers' strategy implementation during intervention and how those changes are associated with changes in children's social communication.

Methods: The MISI-C was applied to 116 observations of 43 caregiver-child dyads with minimally verbal children ranging from 1-5 years of age with varying language, cognitive, and ASD symptoms. All caregiver-child dyads participated in various PMIs (Kasari et al., 2010; Rogers et al., 2012; Wetherby et al., 2014) and were observed at two time points, on average 6 months apart. We constructed items in the MISI-C based on the interactive strategies commonly taught across different Naturalistic Developmental Behavioral Intervention ([NDBIs]; Schreibman et al., 2015). An Exploratory Factor Analysis (EFA) was conducted to determine statistically related domains of core strategies. Intraclass correlations (ICCs) were used for IRR and TRT reliability. Paired sample t-tests were used to assess changes in caregiver implementation of strategies over time quantified by the MISI-C domain and total scores. Correlations between changes in caregiver strategies (MISI-C) and changes in child social communication (Brief Observation of Social Communication [BOSCC]; Grzadzinski et al., 2016) were observed using Pearson's r.

Results: EFA results supported a five-factor model (CFI=0.09, RMSEA=0.59) (Table 1). Total score ICCs for IRR and TRT reliability were 0.80 and 0.92, respectively. Significant changes over time were observed for all five domains and total MISI-C scores ($p<0.01$), with medium to large effect sizes ranging from 0.5-0.9 (Figure 1). Statistically significant associations between changes in caregivers' implementation of interactive strategies (MISI-C) and changes in children's social communication (BOSCC) were found ranging from $r= -.33$ to $-.49$ ($p<.05$).

Conclusions: Results show promising, initial evidence for strong reliability and validity of the MISI-C as an outcome measure that captures changes in caregiver implementation of interactive strategies. Additionally, changes in caregivers' implementation of strategies were significantly associated with changes in children's social communication over the course of varying treatment models. This novel outcome measure could allow a uniform measurement approach to assessing treatment effects on caregivers, and thus enabling replications and the aggregation of samples across different intervention trials to increase statistical power.

134 **171.134** Parent Well-Being over 6 Months in a Randomized, Controlled Caregiver Mediated Intervention Study for Toddlers with Autism

M. Pizzano[1], ***L. M. Chiang***[2], *T. L. Cohenour*[3], *E. P. Pak*[3], *A. Gulsrud*[2] *and C. Kasari*[3], *(1)Education, University of California, Los Angeles, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience & Human Behavior, Los Angeles, CA, (3)University of California, Los Angeles, Los Angeles, CA*

Background: Converging evidence suggests caregivers of children with ASD experience more stress than caregivers of typically-developing children or children with other disabilities (e.g. Hayes & Watson, 2013). Parenting stress potentially counteracts the effectiveness of early interventions, negatively impacting parental and child outcomes (Osborne et al., 2008). Kasari et al., (2015) examined differences in parental stress

between caregiver-mediated (JASPER) and parent education interventions (PEI) and found a reduction in child-related stress for the PEI group, and no change in parent-related stress for either group from entry to 10-week exit. Examining longitudinal follow-up data and specific subscales of parental stress will aide in better understanding of specific stress factors and their maintenance after an active treatment concludes.
Objectives: This study aims to extend previous work by Kasari et al., (2015) by exploring parent-subdomain scores as measured by the Parenting Stress Index (PSI; Loyd & Abdin, 1985) during the active treatment and follow-up phase of a randomized, controlled intervention study for toddlers with ASD and their caregivers.

Methods: Participants (n=86) were from a larger research study comparing effects of two treatment conditions on joint attention outcomes of toddlers with ASD (Kasari et al., 2015). The toddlers and their primary caregivers were randomized to one of the two treatment groups: parent psychoeducation (PEI) or 1:1 caregiver-mediated social communication intervention (JASPER). The present study examines Competence, Isolation, Health, Attachment, Role Restriction, Depression, and Spouse Relationship subscales of the parent-related stress domain of the PSI by treatment group at entry, 10-week exit, and 6-month follow-up. Generalized linear models were used to analyze changes in parent-subscale scores across the three timepoints. ADOS Calibrated Severity Score (CSS) was used to account for autism symptom severity.

Results: Significant time-by-group interaction effects were present for three of the parent-subscales: Isolation (b= 0.153, X^2= 6.89, p= 0.030); Attachment (b= -0.3083, X^2= 6.72, p= 0.034); Depression (b= -0.77, X^2= 6.87, p= 0.032). These effects were only present when analyzing across all three timepoints. No group-by-time interaction effects were found for the other four parent-related stress subscales.

Conclusions: Although Kasari et al., (2015) found overall reduction of parental stress in the child-related domain in PEI group with no change in the parent-related domain from entry to exit in either group, our analysis indicates that over a longer period of time (6 months), changes are present in sub-scales of the parent domain of PSI. JASPER parents reported higher scores for the Isolation subscale and lower scores for Attachment and Depression subscales when compared to the PEI group over time. This translates to JASPER parents reporting lower levels of depression and improved feelings of closeness (attachment) with their toddlers in comparison to PEI group. However, parents who received JASPER also experienced higher levels of isolation at follow-up. JASPER caregivers might have felt more isolated and less supported to independently implement intervention strategies without active coaching after exiting the study. Psychoeducation and booster sessions may help mitigate such perceived isolation after the active treatment period ends.

135 **171.135** Parent-Child Group Intervention Based on Esdm for Young Children with ASD

C. Colombi[1], *A. M. Fish*[1], *A. Capuano*[2] *and J. Judge*[2], *(1)Psychiatry, University of Michigan, Ann Arbor, MI, (2)University of Michigan, Ann Arbor, MI*

Background: Despite strong evidence for the positive impact of early intervention that begins immediately following diagnosis (Koegel et al., 2014), access to high quality treatment is quite limited, and this is particularly true for very young children with ASD. One way of increasing access to intervention is to teach intervention strategies to parents immediately after diagnosis.
Objectives: The first aim of this project was to adapt an existing evidence based intervention, the Early Start Denver Model (ESDM) (Rogers and Dawson, 2010), to a parent-child group delivery in order to increase access to treatment in the period immediately following diagnosis, and thereby improve child outcomes. The second aim was to examine the progress of the children enrolled in the study. The third aim was to evaluate whether parents learned intervention strategies.

Methods: The Parent-Child group ESDM was delivered to 19 young children with ASD, between 24 and 51 months of age, and their caregivers. Each family participating in the study received one 1-hour session per week of the treatment, delivered in a group of 3-5 child-caregiver dyads, for 12 weeks. Social-communication behaviors were measured by the Brief Observation of Social Communication Change (BOSCC) (Lord et al., 2016). Parent learning of the therapy strategies was measured by the ESDM Parent Fidelity Measure (Rogers et al., 2012).

Results: Preliminary data indicated gains in social-communication behaviors in children as measured by the BOSCC. After 12 weeks of intervention the children demonstrated a decrease of 4 points in the BOSCC (t=7.9; p<.01). Changes in the BOSCC scores were negatively correlated to age (r= -.53; p<.05), indicating that the youngest children made the most gains in social communication. Parents improved in their therapy strategies as demonstrated by improved scores in the fidelity measure at the end of the intervention. Acceptability of the program was very good as indicated by retention of all participants. Moreover, results from a five-point Likert-based scale survey indicated that the caregivers agreed or strongly agreed that the program was useful and satisfying.

Conclusions: Our preliminary results suggest that the ESDM delivered in a parent-child group context may be useful to teach intervention skills to parents and to increase social communication in young children with ASD. Additionally, our results suggest that early intervention is most efficacious when started as early as possible in development.

136 **171.136** Predicting Differences in Age of ASD Diagnosis within a Multi-Stage Screening Protocol

S. M. Brunt[1], *A. S. Carter*[2], *A. Eisenhower*[3] *and R. C. Sheldrick*[4], *(1)Psychology Department, University of Massachusetts Boston, Boston, MA, (2)University of Massachusetts Boston, Boston, MA, (3)Psychology, University of Massachusetts Boston, Boston, MA, (4)Boston University School of Public Health, Boston, MA*

Background: Early detection of ASD is thought to promote better long-term outcomes, by enabling earlier uptake of ASD intervention; however, a roughly 1.5-year gap persists between the age at which ASD can typically be diagnosed (< age 2) and the national median diagnostic age (3 years, 10 months; Baio et al., 2014). Moreover, children of racial or ethnic minorities are diagnosed significantly later than White children (Mandell et al., 2009).
Objectives: The aim of the present study is to determine factors that distinguish children who receive an ASD diagnosis before 2 years of age from those who receive a later diagnosis.

Methods: This study occurs within the context of a multi-stage screening and assessment protocol aimed at decreasing disparities in ASD diagnosis and service receipt. The project partners with local Early Intervention (EI) agencies to identify children at risk for ASD by disseminating a two stage screening process. Partnering EI agencies administer Stage 1 parent-reported questionnaires of child functioning. Children who obtain scores above cut-offs or have a parent or EI provider express concern regarding ASD, were referred to Stage 2, a play-based observational assessment. Children who screened positive at Stage 2 were referred to a research-based diagnostic evaluation prior to 36-months of age, when children transition out of EI services.

The majority of the 395 (16.2% female) participants received a diagnosis between the age of 2 and 3 (mean: 28 months, range: 16-38 months). Participants were divided into three age groups: 14-23 months; 24-30 months; and 31-36 months at ASD diagnosis. The sample was diverse with respect to race/ethnicity (76 White non-Hispanic, 98 Black, 224 Latinx, and 25 Asian participants), immigration status (53.7%), English learner status (35.8%), and poverty status (58.7%). Performance on screening measures, level of parental concern, and family demographic factors were compared among age groups.

Results: Children diagnosed under 24 months were more likely to be White non-Hispanic than Black, Latinx, or Asian, $x^2(6)=17.27$, $p=.008$. However, groups did not differ by English language learner status, immigration status, household income, or parental education. A series of one-way ANOVAs indicated that diagnostic-age groups did not differ in Stage 1 scores of ASD-specific problems or competencies, nor did they differ in the presence of parental concerns about a) ASD, b) child language, or c) child behavior, emotions, and relationships.

Conclusions: Because the current study took place within the context of a screening protocol that is specifically designed to address and reduce health disparities in rates and age of diagnosis, we expected to see no differences in age of diagnosis. The fact that only race, but not other known social determinants of health such as income, English learner status, or parent education, related to diagnostic age, suggests that racial discrimination, race-related systemic factors, and/or ethnically and culturally-relevant barriers may be at play. Next steps include incorporating Department of Public Health data on EI referral reason and age of entry to further understand the sources of these age-related disparities.

137 **171.137** Predictors of Response to Early Parent-Mediated Interventions for Young Children with Autism: A Systematic Review

*M. Yaari[1], **J. A. Smith**[2], C. A. Bent[3], C. Dissanayake[4] and K. Hudry[5], (1)Department of Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel, (2)School of Psychology and Public Health, Olga Tennison Autism Research Centre (OTARC), Melbourne, Australia, (3)Victorian Autism Specific Early Learning and Care Centre, La Trobe University, Melbourne, Australia, (4)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (5)Victorian Autism Specific Early Learning and Care Center, Olga Tennison Autism Research Centre, Melbourne, Australia*

Background: Autism is characterised by marked heterogeneity, with substantial individual variability evident in presentation and outcomes. There is a growing body of evidence supporting the effectiveness of early parent-mediated interventions for young children with autism. However, individual responses vary, with little known about child and familial characteristics predictive of outcomes.
Objectives: We conducted a systematic review to identify child and family characteristics associated with developmental outcomes for young children with/at risk of autism receiving parent-mediated early intervention.

Methods: Following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines and Covidence software platform, we identified relevant literature using Psych INFO, Medline, Pubmed, CINAHL and ERIC databases and manual review of reference lists from key papers. Eligibility for inclusion in the systematic review was the paper: (1) examined the efficacy/effectiveness of early parent-mediated behavioural interventions; (2) utilised a comparative design (e.g., RCT); (3) included participants with/or having high likelihood of developing autism, aged 0-6 years; and, (4) reported a statistical moderation between a child/family characteristic and a quantitative, established outcome measure of child development. Two independent reviewers screened titles and abstracts of all identified papers. Full-texts were accessed to confirm eligibility for papers meeting inclusion criteria. Relevant data were extracted for each paper by two independent reviewers. Discrepancies were identified and resolved through discussion and with the aid of an additional reviewer where necessary.

Results: Ten papers from eight individual studies met inclusion criteria. Each varied in the predictors, outcomes and interventions explored. There was some evidence that children who commenced interventions with lower skills made greater gains in language, adaptive behaviour and social communication, but not for all children. Two papers reported that higher parental stress and higher family income were associated with larger gains in child outcomes for the intervention group. Two papers (reporting on the same intervention study) also found associations between features related to higher quality parent-child interactions and better child outcomes following the intervention. However, a key drawback of the identified studies is the heterogeneity of predictors, outcomes and interventions, making it difficult to synthesise findings and draw strong conclusions. Additionally, risk of bias – particularly around lack of blinded outcome assessment – was an issue in some identified papers.

Conclusions: Identifying child and family characteristics that predict favourable intervention outcomes may help further our understanding of which children with autism may benefit most from which intervention. More tailored interventions could help optimise short and longer terms outcomes. Further well-designed studies, including larger sample sizes, are needed to identify differential predictors of intervention outcomes. Inclusion of additional parent-related predictors of parent-mediated interventions in future studies would also strengthen the literature

138 **171.138** Preliminary Outcome of the Early Start Denver Model for Young Children with Autism Spectrum Disorder in a Clinical Setting in Taiwan

***T. L. Lin**[1], C. H. Chiang[1], S. Y. Ho[2], H. C. Wu[3] and C. C. Wong[2], (1)Department of Psychology, National Chengchi University, Taipei City, Taiwan, (2)Child Developmental Assessment & Intervention Center, Zhongxing Branch of Taipei City Hospital, Taipei City, Taiwan, (3)Department of Rehabilitation, Taipei Tzu Chi Hospital, Buddhist Tzu Chi Medical Foundation, New Taipei City, Taiwan*

Background: The Early Start Denver Model (ESDM) is a comprehensive and naturalistic behavioral development early intervention program that has been shown to positively affect key outcomes for toddlers and young children with Autism Spectrum Disorder (ASD) following over 12 months of high-intensity intervention. However, most studies have been conducted in Western countries, with few conducted in East Asian settings, such as Taiwan. In Taiwan, clinical settings are the main resources of intervention services for young children with ASD. Public health policy regarding early intervention in Taiwan stipulates that there should be a multidisciplinary team in the clinical setting and encourages team members to work collaboratively. Team members should include clinical psychologists, occupational therapists and speech-language pathologists. This policy's focus on an interdisciplinary approach aligns with that of intervention programs such as the ESDM. Therefore, implementing the ESDM in clinical settings in Taiwan is pragmatic and important for young children with ASD.
Objectives: The purpose of this study was to preliminarily evaluate the effectiveness of an ESDM intervention based on Taiwanese public health policy for young children with ASD in the Greater Taipei area in Taiwan.

Methods: A total of 16 children with a DSM-5 diagnosis of ASD aged between 25 and 46 months (mean = 33.5 months) were recruited. Children received 9 hours per week of one-to-one ESDM intervention in clinical settings for 6 months. Interventions were delivered by clinical psychologists, occupational therapists, and speech-language pathologists trained by an ESDM accredited trainer. Outcome measures were

administered pre- and post-intervention, comprising the Mullen Scales of Early Learning (MSEL) and Autism Diagnostic Observation Schedule (ADOS). The MSEL was used to measure nonverbal (visual reception and fine motor), verbal (receptive and expressive language) and overall cognitive performance assessed by standardized developmental quotients (DQ), and ADOS was used to measure the severity of ASD symptoms.

Results: The average overall cognitive performance at entry of children with ASD was moderately delayed (mean DQ = 53.6). However, after receiving 6-months of the one-to-one ESDM intervention, children made significant improvements in nonverbal, verbal and overall cognitive performance, and the developmental gains were 6.9, 10.0, and 8.5 months, respectively, which were in excess of what may have been expected due to maturation. The effect sizes of improvement in receptive language and overall cognitive performance were large (>.80). Moreover, children's symptom severity of communication and play in ADOS were decreased significantly post-intervention, and the effect sizes were both nearly large (>.75).

Conclusions: This study provides preliminary findings on the implementation of ESDM in Taiwan. The results indicate that a low-intensity and short-term ESDM intervention directly delivered by a multidisciplinary team in a clinical setting may be a promising treatment for young children with ASD. The following steps in Taiwan are to incorporate a control group for comparison and follow up the 2 matched groups to determine the long-term effects.

139 **171.139** Preliminary Results of a 12 Week Motor Skill Intervention on Motor Skills for 3-5 Year Old Children with ASD

M. Lloyd[1]*, A. T. Ibbitson*[2] *and T. Runge*[2]*, (1)Kinesiology, University of Ontario Institute of Technology, Oshawa, ON, Canada, (2)Faculty of Health Science, University of Ontario Institute of Technology, Oshawa, ON, Canada*

Background:

Fundamental motor skills are the foundation skills required for children to engage in more complex games and activities; they include running, throwing, catching, kicking, etc. Fundamental motor skills are also critical to engagement in active play in early childhood. Active play is a critical venue where social, communication and even behavioural skills are developed in addition to engagement in age appropriate physical activity. Evidence indicates that children with ASD experience delays in fundamental motor skills. Well-controlled intervention studies that target fundamental motor skills are scarce.

Objectives:

The purpose of this study was to conduct a 12 week, 2x/week fundamental motor skill intervention for 3-5 year old children with ASD to examine if motor skills improve.

Methods:

14 children with ASD (11 male, 3 female, Mean age = 3.51 ± .52) were recruited for a 12 week, 2 hours/week, wait-list controlled fundamental motor skill intervention. Participants were randomly assigned to the intervention (n = 7, Mean age = 3.74 ± 0.69) or control group (n = 7, Mean age = 3.38 ± 0.13). As part of a larger ongoing study motor skills were measured 3 ways at pre-test and post-test. The Test of Gross Motor Development-2 (TGMD-2), the Peabody Developmental Motor Scales-2 (PDMS-2), and lastly the Vineland Adaptive Behavior Scales, 2nd Edition (VABS-2) parent/caregiver form (motor subscale) were used to triangulate the motor assessments of the participants and provide a comprehensive picture of skill. A 2x2 repeated measures analysis was conducted on each of the assessments.

Results:

At the pre-test assessment, all children with ASD were significantly delayed in their motor skills as measured by each of the TGMD-2, the PDMS-2 and the VABS-2 motor subscale with most scoring at or below the 1st percentile. There were no significant differences between the groups at the pre-test. For the gross motor quotient of the TGMD-2, there was a significant effect for time ($p = 0.002$) but the group by time interaction was not significant. For the PDMS-2 gross motor quotient there was a significant effect for time ($p = 0.03$) but no effect for the group x time interaction. For the VABS-2 motor scale the effect for time was approaching significance ($p=.09$) but again no effect for group x time.

Conclusions:

All the children demonstrated significant delays in motor skills at the baseline assessment. The delays were so significant that challenges in age appropriate active play would be impeded. This finding indicates that early intervention on gross motor skills in addition to traditional interventions (e.g. behavioural, speech and language) is warranted for 3-5 year old children with ASD. These preliminary results of the 12 week, 2 hours/week motor intervention indicate an overall positive effect but a much larger sample size is needed due to high variability in the performance of the participants.

140 **171.140** Psychiatric Live Animotion Intervention (PLAI) - Virtual Training for Preschool Children with Autism Spectrum Disorder

N. R. Nørgaard*, C. Cantio and N. Bilenberg, University of Southern Denmark, Odense C, Denmark*

Background: Autism Spectrum Disorders (ASD) are considered incurable. Studies have found that early intervention is crucial for the development and prognosis, and the existing early interventions are often extensive and costly, or in-effective. Therefore, there is an urgent need for the development and application of efficacious and cost-effective interventions. Virtual reality (VR) paradigms can be empowering for children with ASD, because it may overcome some of the barriers experienced in face-to-face interaction with humans. However, the effect of VR is still sparsely explored in children with ASD.

Objectives: The objectives are to explore the feasibility and effect of the newly developed Psychiatric Live Animotion Intervention (PLAI) for preschool children with ASD.

Methods: A therapist puts on a motion-capture suit (Smartsuit Pro©, Rokoko) that registers every movement of his/her body and transfers them to an animated character on a computer. The animated character is streamed through the Internet to the child's device at home and a live recording of the child is projected back to the therapist (Figure 1). It is hypothesized that the simplified and interesting playful universe may induce a greater level of social behavior and communication in children with ASD. Two boys with ASD, age 4 and 5, received 8 weeks of intervention with sessions twice a week (duration of 12-18 minutes). The treatment manual was developed with inspiration from Applied Behavior Analysis (ABA) and the Early Start Denver Model and consisted of eight activities that attempted to strengthen and encourage the use of both verbal and non-verbal communication, motor skills, social skills, and pretend play. The authors used a case study-design including both

qualitative and quantitative data. The study explored the effectiveness of PLAI in improving behavioral, social and communicative outcomes in preschool children with ASD.

Results: The participants showed a significant improvement in therapist rated problem behavior (Test Observation Form, TOF) and vocalization after participating in PLAI (Table 1). Furthermore, the children's vocabulary increased respectively with 5.5 % and 7.7 %. Significant improvements were seen in subscales on both parent and daycare rated problem behaviors (CBCL 1½-5 and C-TRF). No significant effects were found on ASD symptomatology (Social Responsiveness Scale 2nd edition, SRS-2). Parents expressed great satisfaction with the intervention and reported improvements in their offspring's greeting behavior, concentration level and communication skills. One of the parents stated "He has learned a simple thing such as how to wave goodbye. It is such a small thing, but still very important". The other family emphasized the effect on communication skills "We think he has become much better at answering our requests. Previously we could ask him about the same thing five times and he would not respond. We think that could be a result of this intervention".

Conclusions: These case studies support the feasibility of PLAI. The families had positive views on the intervention. Likewise, PLAI seems to have a potential impact on several verbal and behavioural measures both in and outside the intervention.

141 **171.141** Quality and Duration of P-Esdm Intervention Mediates the Developmental Outcomes of Toddlers with ASD

ABSTRACT WITHDRAWN

Background:

A clinical trial previously published our team indicated that Chinese ASD toddlers receiving 26 weeks of P-ESDM via regular coaching sessions significantly improved their developmental outcomes including social communications than those receiving community interventions.

Objectives:

To further explore how parents' duration and mastery of P-ESDM could influence the developmental outcomes of toddlers with ASD.

Methods:

We calculated the durations of P-ESDM (≥20hrs/week or ＜20hrs/week) according to the Intervention Record Sheet completed by parents and evaluated their mastery of P-ESDM (master-fidelity score≥3 or loose-fidelity score ＜3) based on their fidelity and their self-assessment. Considering the parents who mastered the techniques of ESDM well tended to implement the intervention more frequently, we performed repeated measure ANOVA and post-hoc t-tests comparing the developmental outcomes of ASD toddlers receiving P-ESDM intervention for more or less than 20 hours a week at home, and receiving the intervention by more or less skilled parents.

Results:

1. We perform 2 (Mastery: master, loose)*2 (Duration: ≥20hrs/week, <20hrs/week) repeated measure ANOVA. The results indicated that the interaction between the 2 factors is significant (F=21.135, P=0.019). Then post-hoc t-tests were applied and the results are listed as follows.
2. ASD toddlers receiving P-ESDM intervention for more than 20 hours(n=15) demonstrated greater improvement in general development than those for less than 20(n=8)(ΔGQ: 10.78±12.22 vs. 2.95±4.24， P=0.037), especially in Language domain.
3. ASD toddlers with relatively more-skilled parents(n=14) showed significant improvement in general development than those with less-skilled parents(n=9)(ΔGQ: 11.41±12.43 vs. 2.84±3.97， P=0.029) , especially in Language and Eye-hand coordination domains.

Conclusions:

Our results demonstrated that higher intensity of P-ESDM intervention with more-skilled parents would effectively improve developmental outcomes of toddlers with ASD, even with low-intensity professional coaching. We underscore the importance of regular parent training and actively participating in the early intervention for ASD toddlers in daily life.

142 **171.142** Randomized Clinical Trial of an Online Pivotal Response Treatment Training Program: Parent and Child Outcomes

***E. McGarry**, A. Baktha and T. W. Vernon, University of California Santa Barbara, Santa Barbara, CA*

Background:

Despite advances in early interventions for autism spectrum disorder (ASD), disparities in access to contemporary evidence-based treatments remain a serious concern (Thomas et al., 2007; Liptak et al., 2008). Numerous barriers, including delays in translating research to community practice, cost of services, extensive time commitments, and geographical distance to trained providers limit the ability for families to take advantage of the latest scientifically based autism interventions (Johnson & Hastings, 2002; McIntyre & Barton, 2010). To address this, recent studies have begun to explore parent-implemented interventions via an online format. These approaches improve access to training for families, can fit into busy family schedules, and lower the cost of treatment (Nelson, Bui, & Velasquez, 2011; Ritterband et al., 2003). The current project examined the feasibility, utility, and preliminary efficacy of a newly developed online course designed to help parents implement an evidence-based natural developmental behavioral intervention, Pivotal Response Treatment (PRT), with young children with ASD. This new program was examined using a randomized clinical trial design.

Objectives:

This study's objective was to investigate the impact of an online course of PRT early intervention strategies on parent and child outcomes.

Methods:

Participants were 24 parent-child dyads with ASD, ages 12-56 months. PRT presentations consisting of informational slides, video examples, and brief quizzes were delivered through a Qualtrics-based digital platform each week. Topics focused on core intervention strategies to elicit communication and social engagement through playful interactions, motivational elements, natural environments, and behavior principles. Parents submitted weekly videos capturing their use of these treatment strategies, which were coded for PRT fidelity of implementation (FOI) and child social-communicative behaviors. FOI was defined as the parent properly demonstrating all PRT components with competency at least 80% of the time. Social validity measures were also obtained following course participation.

Results:

Preliminary data from families who have completed the course were analyzed. Analysis revealed that parent's treatment fidelity improved significantly from baseline (M= 65.40%, SD= 19.02) to Week 5 (M= 90.18%, SD= 7.59); *t* (9)= -5.57, *p*= .01. By the end of the program, 90% of parents met fidelity of implementation (80% or higher fidelity score). These results were supported by social validity data from families indicating high satisfaction with the course. On a 0-5 scale (0= Strongly Disagree, 5= Strongly Agree), all families reported that the course was clearly written and well organized (M= 4.5, SD=0.53), that they would recommend the course to a friend (M=4.5, SD=0.53), and that the course provided them with a clear understanding of Pivotal Response Treatment (M= 4.2, SD=0.42). Coding and analysis of child social-communication outcome measures is currently underway, with preliminary data indicative of increases in social engagement, prompted language, and spontaneous language use.

Conclusions:

The data indicate that parent fidelity significantly improved following participation in the online course. These results suggest that an online intervention may be a feasible approach to disseminating PRT strategies. This innovative format has the potential to reduce disparities in access to evidence-based intervention.

143 **171.143** Short-Term Outcomes for Pre-Schoolers with ASD Receiving Group-Based and One-on-One Early Start Denver Model (EDSM) Intervention

C. C. Green[1], *C. A. Bent*[2], *J. A. Smith*[3], *K. Pye*[4], *K. Hudry*[5] *and T. Victorian ASELCC Team*[4], *(1)Olga Tennison Autism Research Centre, La Trobe University, Bundoora, VIC, Australia, (2)Victorian Autism Specific Early Learning and Care Centre, La Trobe University, Melbourne, Australia, (3)School of Psychology and Public Health, Olga Tennison Autism Research Centre (OTARC), Melbourne, Australia, (4)Victorian Autism Specific Early Learning and Care Center, La Trobe University, Melbourne, Australia, (5)Victorian Autism Specific Early Learning and Care Center, Olga Tennison Autism Research Centre, Melbourne, Australia*

Background:

The Early Start Denver Model (ESDM) is an intensive intervention for young children with Autism Spectrum Disorder (ASD). The individually delivered approach (i.e., one-on-one) has evidence of efficacy – from a published randomised controlled trial (Dawson et al., 2010) – for accelerating children's cognitive development and building adaptive behaviours. A group-delivery approach has also been developed for implementation within educational settings (G-ESDM; Vivanti et al., 2017), which has some published evidence of effectiveness via evaluation of pre-and post-treatment outcomes in a non-randomised design (Vivanti et al., 2014). Child gains from one or other format have not been directly compared, nor have G-ESDM gains been evaluated in the short-term (i.e., following 5-months).

Objectives:

In the context of an ongoing study comparing child outcomes following various approaches to ESDM delivery, we are comparing the short- and medium-term gains made by children within around 6- and 12-months of participation in either group- or individually-delivered ESDM.

Methods:

We are assessing developmental gains made by children receiving one of two ESDM programs – both provided by the same team – in either an autism-specific group setting, or delivered one-on-one in children's homes/local childcare. Developmental abilities are assessed using the Mullen Scales of Early Learning (MSEL) and adaptive behaviours using the Vineland Adaptive Behaviour Scales (parent interview; VABS) administered pre-treatment and again after around 6- and 12-months.

Results:

To date, 21 pre-schoolers (M=34 months, SD=5.4; 18 boys, 5 girls) are enrolled in the study (G-ESDM N=14; individual ESDM N=7). All have completed a 5-month mid-point assessment and two have completed 10-month end-point. By the time of INSAR, we will have 10-month end-point data for all. On average, children receiving G-ESDM and individual ESDM *appear to have* made similar age-equivalence gains within the first 6-months of their program for MSEL Visual Reception (respectively; M=3.9m gains, SD=6.5; M=3.6m, SD=5.3). By contrast, average gains for the individual ESDM group seem more substantial than those for the G-ESDM group for MSEL Fine Motor skills (respectively, M=7.8, SD=11.4; M=2.8, SD=4.9) and Receptive Language (M=13, SD=10.8; M=3.1, SD=10.1) and slightly so for Expressive Language (M=4.6, SD=4.7; M=2.9, SD=6.9). However, MSEL age equivalent gains were highly variable *within* each group (Figure 1). Children receiving G-ESDM group made substantial age-equivalence gains for VABS Personal skills (Figure 2a) such as feeding and dressing themselves (M=6.6m gains, SD=5.1) as well as VABS Domestic skills (Figure 2b) including cleaning up and safety awareness (M=8.4, SD=12.0). Children in the individual ESDM group made similar gains for VABS Personal skills (M=9, SD= 7.6) and Domestic skills (M=7.3, SD=8.0).

Conclusions:

Children receiving both types of intervention – G-ESDM in specialised playrooms or individual ESDM in the home/community – made gains in verbal and non-verbal development and adaptive behaviour within the initial 6-months of intervention. While preliminary results seem to slightly favour individual ESDM delivery, outcomes were highly variable within each group. Additional, and longer-term developmental and behavioural outcome data (i.e., at 10-month program exit) will be available by INSAR 2019.

144 **171.144** Social Communication Skills As a Possible Driver of General Developmental of Pre-Schoolers with ASD Who Received Esdm in a Community Setting in Austria

D. Laister[1], *D. Holzinger*[2] *and J. Fellinger*[2], *(1)Autismuskompetenzzentrum - Hospital of St. John of God, Linz, Austria, (2)Hospital of St. John of God, Institute for Neurology and Senses, Linz, Austria*

Background: The Early Start Denver Modell (ESDM) seeks to focus on core-symptoms of ASD by social communication intervention to improve social engagement in young children with ASD. The main goal is to increase the social attitude and interest so that the child can use natural social environments for further development. Importance of parent reported outcomes is rising in the literature. The Pervasive Developmental Disorder Behaviour Inventory (PDDBI) is a widely used questionnaire to measure ASD related symptoms in children with ASD. Social communication skills are well described as crucial skills to be taught in early intervention programs.

Objectives: Investigation of the impact of social communication core skills on developmental trajectories and parental related stress. ESDM was

delivered in an Austrian community setting with weekly three appointments for 1.5 hrs in the centre, at home and in the kindergarten over a period of one year.

Methods: Subjects were children (n = 43, ages 28 to 54 months, mean age 42.4 months) consecutively diagnosed with ASD in a regional autism centre in Austria. Developmental status was assessed with standardized instruments (Mullen Scales-MSEL, PDDBI, Vineland Adaptive Behaviour Scales-VABS 2 and Parental Stress Inventory-PSI) at baseline and after intervention.

Results: The Intervention-Group showed improved language skills (t-tests) in the MSEL (Expressive Language: T(41)=-2.02, p=.05, ES=.34; and Receptive Language: T(39)=-3.24, p=.002, ES=.59) and highly significant general MSEL-Total-Score improvement (T(37)=-2.92, p=.006, ES=.62). Furthermore, highly significant reduction in parent-reported core autism symptoms (PDDBI-Autism Composite Score: T(42)=5.31, p<.001, ES=-.98) and gains in Social Communication skills (PDDBI-Social Approach (SOCAPP): T(42)=-3.82, p<.001, ES=.65) could be found. The SOCAPP gains significantly correlated with all MSEL-domain-gains (r's from .32 to .45; p's from .005-.046), VABS-Daily Living skills gain (r=.36; p=.017) and PSI-Children-scale gain (r=-.40; p=.016). Regression analyses were used to test if the SOCAPP-skills before intervention significantly predicted children's developmental gains. Two of the four MSEL-developmental gains (Visual Reception: β=.30, p=.049 and Expressive Language: β=.37, p=.015) were predicted by the SOCAPP-scale. No such prediction was found for PSI-Children-scale- or VABS-Daily Living skills-gains. Dividing the group in two samples with median split into a low-SOCAPP- and high-SOCAPP-gain-group and analysing for trajectory-differences led to one significant interaction effect of MSEL-Receptive Language (F(1,38)=4.85, p=.034).The high-SOCAPP-gain-group showed significant more Receptive Language improvements. No such group-effect was found for any other MSEL-scale-gain.

Conclusions: ESDM reduces reported ASD-symptoms and also showed strong effects on family reported social communication skills. Social Communication skills highly correlated with developmental domains and with parental stress level. Furthermore, Social Communication skills might be predictive for child's development. The SOCAPP scale of the PDDBI seems to be a highly relevant set of questions which reflect crucial information of children's development. Developmental gains seem promising, although further research with a control group design is needed. Further studies are needed to assess the predictive value of the SOCAPP scale and to evaluate the possibility of using a set of questions in screening procedures.

145 **171.145** Super Responders: Predicting Expressive Language Gains Among Minimally Verbal Children with Autism Spectrum Disorder

J. Panganiban[1] *and C. Kasari*[2]*, (1)Semel Institute, University of California Los Angeles, Los Angeles, CA, (2)University of California, Los Angeles, Los Angeles, CA*

Background: Research in autism spectrum disorders (ASD) has focused on developing efficacious interventions addressing core deficits of ASD. However, the heterogeneous nature of ASD complicates the development of such interventions. Due to this heterogeneity, it is unlikely that there is a one size fits all intervention. It is important to understand for whom an intervention works. Advancements in data analytics, in particular machine learning, provide new methods to identify subgroups among a given population, and can potentially help to identify for whom intervention works best. Of particular interest are minimally verbal individuals. A targeted social communication intervention known as JASPER (Joint Attention, Symbolic Play, Engagement, and Regulation) has shown promise for improving language outcomes among minimally verbal children with ASD and may provide the context to examine the question of for whom an intervention benefits.
Objectives: This study aims to develop a model predicting expressive language gains among minimally verbal, preschool aged children with ASD that received JASPER. This study also explores the utility of classification and regression tree (CART) analysis to identify relationships between child characteristics and gains in expressive language.

Methods: Secondary data analysis was conducted on a sample of 99 minimally verbal, preschool age children with ASD, collected from participants across five previous intervention studies. Expressive language gains were calculated using expressive language age equivalents from the Mullen Scales for Early Learning. Predictors for the analyses were taken from demographic and behavioral assessments completed prior to intervention. Using expressive language age equivalent change scores, 47% (n = 47) of the sample were identified as "super responders," children that exceeded expressive language gains expected through maturation. To predict responder status, all initial predictors were used to generate conditional inference forests, a machine learning process for variable selection.

Results: Conditional inference forest results identified three variables to be fitted into the final model; play diversity, requesting gestures, and fine motor age equivalent. A final conditional inference tree was created, with play diversity being the only significant predictor of responder status. Participants with higher entry play diversity scores (above 23) predicted super response while lower scores (23 or below) predicted slow response. Overall model accuracy was 67%, with a specificity of 55% and sensitivity of 78%. For comparison, stepwise logistic regression was run, and play diversity significantly predicted responder status (χ^2 (1) = 10.686, p = .001). Receiver operating characteristic curves were generated to compare model performance, and comparison of area under the curves for the two models showed no statistical difference (p = .82).

Conclusions: Overall accuracy of the conditional inference tree was moderate, and performed similarly to the more traditional logistic regression analysis. However, the conditional inference tree provides a cutoff point that may provide clinical utility over the regression results. Both models identify play diversity as an important predictor of expressive language gains from JASPER, a play based social communication intervention. Additionally, the model appears to be more sensitive to identifying slow responders. The role of play diversity and expressive language gains in JASPER is discussed.

146 **171.146** Targeted Parent Support of Social Behavior Among Toddlers with Autism

D. M. Moore[1]*, B. Barger*[1]*, B. DiPetrillo*[1] *and K. Baggett*[2]*, (1)Georgia State University, Atlanta, GA, (2)Mark Chaffin Center for Healthy Development, School of Public Health, Georgia State University, Atlanta, GA*

Background: Autism spectrum disorder (ASD) affects 1 in 59 children in the United States (Centers for Disease Control and Prevention [CDC], 2018). Parent-mediated early interventions, which aim to support parent facilitation of toddler social communication, are a major focus of research (Green et al., 2017). Systematic review of the experimental literature revealed that out of 25 studies of parent-mediated interventions to improve toddler social communication outcomes, only seven (28%) used a measure designed to assess both parent and toddler behavior during observed parent-child interaction (Moore, Barger, Baggett, 2018). Measures reported in this literature tend to require high levels of training, are time burdensome to administer and score, and are not designed for repeated measurement. Consequently, they are of limited utility for community

early childhood practitioners in monitoring progress of parent support of toddler social communication within early intervention programs. To address this limitation, a progress monitoring measure designed for practitioners, was used for secondary coding and analysis of parent-child interaction video data from a recently published study of a parent-mediated intervention program (Schertz, Odom, Baggett, & Sideris, 2017).
Objectives: The aim was to examine whether or not a practical and psychometrically sound practitioner progress monitoring measure was useful for examining relationships between targeted parent support and toddler social communication among dyads enrolled in a parent-mediated intervention study. The following research questions were addressed: Is parent positive support behavior significantly and positively related toddler social behavior? Do toddlers whose parents engage in high levels of targeted support demonstrate more positive social behavior compared to toddlers whose parents engage in low levels of targeted support?

Methods: The sample consisted of 131 toddlers and their parents enrolled in a parent-mediated RCT (Schertz et al., 2017). Direct observation of 10-minute video recorded parent-child interactions at home were conducted using the Indicator of Parent Child Interaction-2 (IPCI-2; Baggett et al., 2011). Interobserver agreement was examined for 20% of coded videos. Mean percent agreement was 92.5%, Analyses were conducted to examine parent support of toddler social behavior at the time of enrollment. Descriptive statistics are provided for parent targeted support (Facilitators) and toddler Engagement with parents. Bivariate regression analyses were conducted to examine parent Facilitators and toddler Engagement with parents.

Results: Parents obtained a mean Facilitator score of 217.9 (SD= 59.8, range=285) and children obtained a mean engagement score of 126.37 (SD= 40.0, range= 190). Parent Facilitators and child Engagement were highly and significantly correlated, r=.747, p<.0001. Toddler engagement differed significantly depending upon whether their caregivers engaged in low, medium, or high levels of targeted support (facilitators), F (2, 128) = 47.72, p < .0001.

Conclusions: This study highlights the relevance of a practitioner monitoring measure to assess parent-child interaction. Results demonstrate that a practitioner observation measure, with high interobserver agreement, can be used to capture targeted parent support, crucial to promoting social engagement among toddlers with ASD.

147 **171.147** The Challenges of Individualizing Early Intervention in a Context of Large-Scale Services

A. Paquet[1], *C. Dionne*[2] *and S. McKinnon*[3], *(1)Psychoéducation, Université du Québec à Trois-RIvières, Trois-Rivières, QC, Canada, (2)Psychoéducation, Université du Québec à Trois-Rivières, Trois-RIvières, QC, Canada, (3)CIUSSS Saguenay-Lac-St-Jean, CISSS Bas-St-Laurent et Côte-Nord, Sept-Îles, QC, Canada*

Background: For more than 15 years, the Quebec government, through health and social services organizations, has offered early behavioral intervention (EBI) to young children with autism. These services were organized on the basis of scientific knowledge, but also on the particular realities and challenges of each of the regions concerned. A provincial study has documented the different choices that institutions have made across the province, including the choice to offers EBI in inclusive child care settings for a majority of children (Dionne et al., 2016). However, to date, a limited number of studies have focused on large-scale community-based EBI services (Eikeseth, Långh, Hammar, Klintwall, & Bölte, 2018, Eikeseth, Klintwall, Jahr, & Karlsson, 2012). In a collaborative research perspective, studies conducted over the last few years with skateholders that are implementing EBI in context of large-scale public services in Quebec. One of the aspects of the intervention addressed in these studies is the individualization of practices in order to consider the unique needs of each child, the realities of his family and his living environment, as well as the resources available.
Objectives: General objective is to document the practices of clinical team members with respect to intervention planning in the context of EBI in the context of large-scale public services. More specifically, the following objectives will be addressed: 1) describe the level of individualization of EBI programs by analyzing intervention plans and evaluating their quality, 2) describe the variables considered by professionals when choosing strategies for intervention, 3) describe the decision-making process with respect to these choices.

Methods: A mixed method, combining data from various sources (interviews, questionnaires, intervention plans analysis) was used. A total of 23 participants (supervisors and practitioners) from 3 rehabilitation centers participated in the project. In addition, a total of 37 intervention plans were analyzed.

Results: Most frequently targeted areas of development for intervention plans are communication, followed by cognitive skills. A variety of evidence-based intervention strategies are implemented (eg, discrete trial teaching, reinforcement, visual support). When it comes to choosing these strategies, according to the results to the questionnaire, respondents consider child characteristics (m = 4.35), family characteristics (M = 4.31), as well as those of the child care setting (M = 4.17) as very important. All the supervisors interviewed mentioned the need to consider a set of child characteristics. Among those mentioned by a majority : level of language and communication (100%), the progression of the child (100%), impairments or associated health problems (88.9%), level of development (88.9%), but also, sensory characteristics (66.7%), chronological age (66.7%), interactions and social skills (66.7%), attention span (55.6%), ASD severity (55.6%) and child interests (55.6%).

Conclusions: The choice of intervention strategies is a complex process based on the analysis of a large number of factors. The absence of a clear protocol to frame EBI services certainly contributes to complicate this process. The clinical support offered by the organizations is therefore essential, although very variable across organization. Different clinical supports should be developed to support teams implementing EBI within community services.

148 **171.148** The Effect of “the Transporters” Intervention Program on the Expression of Empathy during Social Interaction in Children with ASD

T. Gev[1,2], *M. Saban*[1], *I. Gordon*[1] *and O. Golan*[1], *(1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Association for Children at Risk, Givat-Shmuel, Israel*

Background: Children with ASD often struggle to express concern towards others’ distress and to provide instrumental support to others’ need. However, the behavioral examination of these abilities in children with ASD during social interaction has been limited.
Various intervention programs attempted to target cognitive empathy deficits in children with ASD. *The Transporters* (TT) animated series is such an intervention that was found to be effective in several controlled trials. However, the generalization of its taught skills and their expression in social interactions were not studied.

Objectives: (1) to examine the differences between children with ASD and their typically developing (TD) peers on empathic concern and provision of support during social interaction; (2) to examine the effects using TT intervention has on the empathic and pro-social behaviors during social interaction in children with ASD.

Methods: To examine question (1), two groups of 4-7 years-old children, 37 (9 girls) with ASD and 28 (5 girls) TD children, matched on age, gender and cognitive abilities, were recruited. Question (2) was examined with twenty 4-7 year olds (2 girls) with ASD who watched TT daily for 8 weeks. They were compared to a matched group of 22 participants (6 girls) with ASD, who watched a control series. Children were presented with two empathy prompts during a 20-minute play schedule: a pain paradigm (e.g., the experimenter allegedly bit by a mosquito); and a help paradigm (e.g., the experimenter allegedly fails to find the toys for the next activity). For the examination of the second research question, participants undertook similar activities before and after 8 weeks of watching the series. Interactions were video-recorded and micro-analytically coded for children's affect, gaze direction, verbal response, assistive behaviors, as well as ignoring and freezing.

Results: Children with ASD exhibited less adaptive empathic responses, compared to their TD peers. During the pain paradigm, as a reaction to the experimenter's distress, participants in the ASD group expressed positive affect for a longer duration, compared to the TD group. In addition, the ASD group exhibited freezing or ignoring behaviors for longer duration, compared to the TD group. In both pain and help paradigms, The TD group exhibited more adaptive assistance behaviors that the ASD group.

An examination of the effect of TT intervention on the pain paradigm, revealed that following the intervention, children from TT group increased their verbal responses to the experimenter and decreased their ignoring and freezing behaviors. No such change was observed in the control group. In addition, following the intervention, children from TT group increased the time they spent looking at their interaction peer, and effect that was not found in participants who watched the control series.

Conclusions: Our findings show children with ASD demonstrate empathic response deficits in an ecological social scenario. In addition, the study provides support for the effectiveness of TT in promoting pro-social behaviors in children with ASD, including a shift from a passive to a more active stance, an enhanced search for social cues in others' faces.

149 **171.149** The Effectiveness of Brief Community-Based Parent Coaching in Pivotal Response Treatment

H. E. Flanagan[1], *T. Hamodat*[1], *L. Williams*[2], *D. J. Chitty*[1] *and I. M. Smith*[1,2], *(1)IWK Health Centre, Halifax, NS, Canada, (2)Dalhousie University, Halifax, NS, Canada*

Background: Parent coaching is a cost effective and important element of early autism intervention. We examined the effectiveness of brief parent coaching in Pivotal Response Treatment (PRT) for 4-5 year-old early communicators. Coaching was provided by community clinicians at the beginning of a publicly funded intervention program in Nova Scotia, Canada. Parents received four, two-hour coaching sessions within the same week. Trainers reviewed a handout with parents that described PRT principles and provided 10-minute blocks of individualized coaching using strategies such as suggestive prompting, reinforcing parent initiations, and providing frequent, specific, positive feedback.
Objectives: *1)* Our primary objective was to determine if training led to increases in parents' skills providing clear, developmentally appropriate language opportunities. This was defined as gaining shared control of preferred objects or activities and providing either model prompts (e.g., "spin"), leading prompts ("e.g., ready, set..."), choice questions (e.g., "milk or juice?"), or time delays (e.g., holding onto a bubble wand and giving an expectant look). 2) We also examined changes in parents' fidelity using the following PRT techniques: following child lead, ensuring child attention, and being contingent on reasonable attempts at correct responding.

Methods: Parents of 27 children were included in analyses. Children were 4 to 5 years old (M = 4.78, SD = 0.14) and were included if they were non-verbal (48%), used single words (22%) or used 2-word combinations (30%). If more than one caregiver from a family participated in training, a single caregiver was randomly selected. Participants were 17 mothers, 8 fathers, 1 aunt and 1 grandfather. Ten-minute videos of parent-child interaction were obtained pre- and post- training (at each, parents were asked to encourage communication through play). Inter-rater reliability of video coding was moderate to strong (ICC = .90 for objective 1; κ = .59-.77 for objective 2).

Results: 1) Prior to coaching, parents presented a mean of 4.3 clear, developmentally appropriate language opportunities in 10 minutes (40% presented none, 19% presented one). A large increase in frequency was seen after coaching, to a mean of 15.2 clear opportunities (all but one parent presented at least two). 2) Parent fidelity improved for attaining child attention, demonstrated in 15% of intervals prior to coaching and 59% of intervals four days later, $t(26) = 5.47$, $p<.001$. Fidelity for contingency also improved, from 11% to 66%, $t(26) = 7.61$, $p<.001$. Following child lead was high at baseline and did not change (85% to 91%; $t(26) = 1.00$, $p=.327$).

Conclusions: Brief parent coaching in PRT by trained community clinicians led to substantial changes in parents' interactions with their children with ASD. In four days, parents learned to present frequent, clear, developmentally appropriate language opportunities. Parents also demonstrated the PRT techniques of attaining child attention and contingency much more frequently following coaching. These findings support PRT as an intervention model readily implemented by parents. They add to a growing body of research supporting parent coaching in natural developmental behavioral interventions as a cost-effective approach to improving outcomes for children with ASD.

150 **171.150** The Efficacy of "Play-Based Communication and Behavior Intervention" Very Early Intervention Model on Toddlers with Autism Spectrum Disorder

X. Ke[1], *M. Fen*[2], *X. Xiao*[3], *J. Weng*[4] *and T. Xiao*[5], *(1)Child Mental Health Research Center for Nanjing Brain Hospital Affilated to Nanjing Medical Universi, Nanjing, China, (2)Child mental health center, Nanjing Brain Hsopital, Nanjing, China, (3)child mental Health center, Nanjing Brain hospital, Nanjing, China, (4)Child mental health research, Nanjing Brain Hospital, Nanjing, China, (5)nanjing Brain Hospital, Nanjing, China*

Background: Children with autism spectrum disorder(ASD) who participated in the "Play-based Communication and Behavior Intervention(PCBI)" were studied explore the efficacy of the PCBI very early intervention model.
Objectives: To investigate the short-term efficacy and the caregiver factors of the PCBI model on toddlers with autism spectrum disorder.

Methods: Seventy-four ASD toddlers aged from 19 to 30 months were recruit in this study. Toddlers who participate in this study were randomly assigned to PCBI group and ABA group, then intervened weekly by PCBI or ABA in total 12 weeks. The Autism Treatment Evaluation Checklist, Gesell Developmental Schedules and Portage Early Development Checklist were used to evaluate the efficacy of the PCBI. Parenting Stress Index Short

Form, General Self-Efficacy Scale, and the self-developed Caregiver Training Course Evaluation Scale and the Homework Completion Level Scale were used to assess the level of parental stress, self-efficacy, curriculum satisfaction and acceptance. The t-test was used to reveal whether there was significant difference between two groups before and after interventions. A pair of sample t-test was used to analyze the ASD symptoms, developmental level and caregiver factors of ASD children before and after intervention. Multivariate regression analysis was used to analyze the caregiver factors and the effects of PCBI.

Results:

- Compared to the ABA group, there was a significant increase in cognitive scores (D_{PCBI}=9.03, D_{ABA}=4.27, t=3.997) and a significant decrease in social behavior scores (D_{ABA}=16.91, D_{PCBI}=8.87, t=-4.022) of the Portage Early Development Checklist after 12 weeks of intervention in the PCBI group (P<0.001); While the total score and the scores of language, movement, and self-care subscale of Portage Early Development Checklist were also increased after PCBI intervention but not significant (P>0.05).
- Compared to the ABA group, after 12 weeks of PCBI intervention, the scores of social, perception, behavior of ATEC was decreased, but difference was not significant (P>0.05); while the total score of ATEC scale ($D_{ABA\ total}$=22.22, $D_{PCBI\ total}$=14.89, t=2.209) and the scores of language subscale ($D_{ABA\ language}$=6.43, $D_{PCBI\ language}$=2.89, t=2.515) was decreased significantly (P<0.05).
- After the end of PCBI, there was a significant decrease in the scores of Parenting Stress Index Short Form (P < 0.05). There was a significant positive correlation between the effect of PCBI and acceptance of the intervention model, and mastery of the skills in the caregiver factors (P < 0.05).

Conclusions: After 12 weeks PCBI very early intervention, the ASD toddlers all improved in clinical symptoms and developmental level. Compared with ABA intervention, the treatment efficacy of parenting-direct PCBI was comparable and used less medical rehabilitation resources. PCBI could reduce the parenting pressure of the caregiver; and the better the mastery of skills and the completion of homework the better the efficacy of intervention.

151 **171.151** Change in Family Empowerment Following ABA Early Intervention Associated with Changes in Practical Adaptive Skills

J. Martini[1], *F. Shic*[2,3], *J. Sigesmund*[4] *and M. A. Minjarez*[5], *(1)Center for Child Health, Behavior and Development, Seattle Children's Research Institute/University of Washington, Seattle, WA, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)Pediatrics, University of Washington School of Medicine, Seattle, WA, (4)Seattle Children's Hospital, Seattle, WA, (5)Seattle Children's Autism Center/University of WA, Seattle, WA*

Background: Applied Behavior Analysis (ABA) therapy is the standard of care for children with Autism Spectrum Disorder (ASD). The ABA Early Intervention Program (ABA EI) at Seattle Children's Autism Center is a 12-week, multidisciplinary, classroom-based program that includes 12 hours per week of center-based, 1-1 ABA therapy, weekly SLP services, and a parent education/support package including didactics, coaching in ABA methods, and case management. Naturalistic Developmental Behavioral Intervention (NDBI) is the primary ABA methodology being used (Schreibeman et al., 2015). Previous research supports the efficacy of ABA interventions in increasing adaptive skills in children with ASD (Smith & Iadarola, 2015) and emerging research supports associated improvements in family empowerment and stress (Minjarez, et al., 2012). However, research is limited regarding the relationship between child improvements in adaptive functioning and parent functioning.

Objectives: To investigate how changes in adaptive skills relate to changes in family empowerment following participation in behavioral intervention.

Methods: Participants included parents and their children diagnosed with ASD (n=32) aged 19 to 65 months (M=40.69, SD=12.26) that completed the ABA EI program. Paired sample t-tests were used to compare baseline and post-intervention ratings of adaptive skills (Adaptive Behavior Assessment System (ABAS-3): General Adaptive Composite (GAC), and Conceptual, Social, and Practical composites) and sense of family empowerment (Family Empowerment Scale (FES)). Backwards stepwise linear regression (p=0.05 entry, p=0.10 removal) was used to investigate how changes in adaptive skills (conceptual, social, practical), combined with baseline characteristics (GAC, FES), predicted changes in sense of family empowerment.

Results: Paired sample t-tests revealed improvements in FES scores from baseline (M=3.79, SD=0.54) to post-intervention (M=3.98, S=0.57); t(31)=2.16, p=0.039. Similarly, there were improvements in GAC: baseline (M=68.50, S =18.10), post-intervention (M=73.96, SD=21.24), t(23)=2.73, p=0.012. All ABAS-3 composite scores were also significant. The backwards regression model with the most parsimonious predictor variables excluded change in the social composite: FES change=1.84 – 0.31 conceptual change + 0.33 practical change + 0.12 baseline GAC – 0.668 baseline FES + e, F(4, 17)=4.441, p=0.012, adjusted R^2=.396, with practical change (t=2.279, p=0.036), baseline GAC (t=2.334, p=0.032), and baseline FES (t =-3.311, p=0.004) significant. Conceptual change (t=-1.836, p=0.084) was marginally negatively related to FES change.

Conclusions: These results are consistent with prior work showing improvements in adaptive skills following ABA intervention. Change in practical skills, but not conceptual skills, was positively associated with family empowerment. This may be due in part to ABAS-3 items at this age which inquire about skills explicitly taught in the intervention program (e.g., community use, health/safety, self-care) that could lead families to feel more able to manage daily routines. These findings are consistent with previous work (e.g., Noh, 1989) which found an association between child inability to interact with the environment and parental stress. Surprisingly, conceptual skills showed a marginally negative association with family empowerment, suggesting empowerment is more closely associated with daily living and community-related skills than communication and task management skills. This is a preliminary investigation and the study is ongoing.

Poster Session
172 - Family Issues and Stakeholder Experiences
11:30 AM - 1:30 PM - Room: 710

175 **172.175** Development of a Brief, Family-Centered Transition Intervention Using Caregiver Input

K. M. Rispoli[1], *S. L. Curtiss*[1] *and S. Naguib*[2], *(1)Michigan State University, East Lansing, MI, (2)Sunfield Center for Autism, ADHD and Behavioral*

Health, Ann Arbor, MI

Background:
Despite the influx of students with Autism Spectrum Disorder (ASD) into postsecondary transition (Smith & Lugas, 2010), supports are limited, lack cohesion, and do not sufficiently address the population's broad and complex needs (Wehman et al., 2014). Increased availability of feasible, low-cost, evidence-based parent education targeting postsecondary transition for individuals with ASD is essential. Some extant programs (e.g., Transitioning Together, SPECS) demonstrated significant improvements in parent and child attitudes and problem-solving (Hagner et al., 2012; Szidon & Kraemer, 2015). However, these programs require a significant time commitment and material and personnel resources that may limit their uptake in community settings. Moreover, evidence supporting the success of these programs is largely the result of standardized, researcher-controlled investigations. Adoption and sustainment of evidence-based practices in community settings requires understanding of stakeholder perspectives and real-world conditions that support or impede intervention implementation (Owens et al., 2014).

Objectives:

Describe findings from a pilot investigation of a brief, family-centered transition program, Planning for your Loved One's Future (PLOF).

Methods:

Participants. Seven caregivers of adolescents with ASD participated in the program.

Design. A single group, pre-post mixed methods design was used.

Procedure. PLOF was implemented in a single, 4-hour session by a licensed psychologist, who developed the program. Information was provided to caregivers on several transition-related topics, including school transition planning, parent and child advocacy, adult housing, recreation, employment and college/technical school, and legal/guardianship issues. Information was conveyed through discussion and visual supports (i.e., Power Point, handouts).

Measures. Quantitative and qualitative data were collected to measure parent transition knowledge (Transition Knowledge Scale) and empowerment (Family Empowerment Scale), as well as transition planning efforts and program acceptability (caregiver interviews).

Data Analysis. Quantitative data (n = 5) was analyzed descriptively and with paired samples t-tests. Caregiver interview data (n = 7) will undergo systematic thematic analysis.

Results:

Descriptive statics indicated an increase in means for all items related to transition knowledge. There were statistically significant increases in parents' knowledge of employment options (t (4) = .374, p<.05) as well as college and technical school options (t (4) = .316, p<.05). Parent advocacy and community transportation were approaching significance. There were no significant changes on the Family Empowerment Scale.

Preliminary qualitative analysis indicated parents were satisfied with the intervention and valued the opportunity to connect with other parents. Interview data inform further program development, such as increasing opportunities for parents to exchange knowledge. Parents also commented on the importance of introducing transition-related knowledge early, "making it part of a conversation with any age" (Parent 2). Parents noted a sense of empowerment in sharing information from the workshop with other parents, and efforts to advocate for school services for which they previously did not know their child was entitled.

Conclusions:

Despite the brief, low-intensity nature of PLOF, findings suggest gains in caregiver transition knowledge and advocacy efforts following their participation.

PLOF may have utility as a supplement to current transition services for students with ASD.

Parent feedback provides avenues for increasing the potential effectiveness of PLOF.

176 **172.176** Differences between Mothers and Fathers in Parent-Child Free-Play Interactions with Preschoolers

***C. K. Toolan**, A. Holbrook, C. Ngo and C. Kasari, University of California, Los Angeles, Los Angeles, CA*

Background:
Fathers are the primary caregivers for 21% of preschoolers in the US (US Census Bureau, 2013). Although this number has increased over the past 30 years, fathers of children with ASD remain underrepresented in early intervention research. Research comparing mothers and fathers of children with ASD tends to focus on differences in stress and coping strategies; few studies have examined differences in intervention strategies and language use. Fathers tend to be more directive in language and play (Elder et al, 2003), but our understanding of father-child interactions is still relatively limited. Understanding baseline differences between mothers and fathers may help inform parent training in interventions for young children with ASD.

Objectives:

To determine if parent strategies and parent language use differs in parent-child free-play interactions based on parent gender.

Methods:

This study uses baseline data from a social communication intervention RCT. Participants included 53 primary caregivers (38 mothers, 15 fathers) and their preschoolers with ASD (*Mage*=45.13 months, *SD*=5.37). Children used <30 spontaneous words at baseline.

Each parent-child dyad completed a videotaped 10-minute free play assessment (PCX). PCXs were coded (ICCs=.75-.88) for parents' use of strategies common across ABA-based interventions, namely:

1. Responsiveness: Supportively responding to child's verbal and nonverbal cues
2. Pacing: Timing and appropriateness of actions and language
3. Prompting: Quality and appropriateness of prompt usage (e.g., prompt hierarchy)
4. Environmental arrangement: Placement of body and materials in relation to child

Items were rated on a 5-point Likert scale; higher ratings indicated more fluent and more appropriate use of strategies. PCXs were also transcribed and analyzed for parent language (total utterances, MLU, number of different words).

One-way ANCOVAs were conducted to determine the effect of parent gender on parent strategies and parent language, controlling for child age, non-verbal IQ, and number of different words. Bonferroni post-hoc tests were conducted as needed.

Results:

Estimated marginal means for parent outcomes are reported in Table 1. There was a main effect of parent gender on pacing, $F(1,48)=7.12$, $p=.008$. Mothers ($M=3.55$, $SE=.17$) were significantly more likely to appropriately pace interactions compared to fathers ($M=2.61$, $SE=.28$). Parent gender was also associated with prompting, $F(1,48)=5.09$, $p=.029$. Mothers ($M=3.35$, $SE=.15$) were significantly more likely to prompt appropriately compared to fathers ($M=2.71$, $SE=.24$). Parent gender was not associated with responsiveness, environmental arrangement, or parent language.

Conclusions:

Mothers and fathers did not differ in the amount of language they used; however, when compared to mothers, fathers' pacing and prompting tended to be less appropriate within the context of free play. These findings are practically significant, given the importance of parents' appropriate pacing (e.g., Gulsrud et al, 2016) and prompting (e.g., Hardan et al, 2015) in facilitating children's social communication. Understanding these baseline differences between mothers' and fathers' interactions provides valuable information for parent training, highlighting areas where fathers may need additional support to facilitate their children's social communication skills.

177 **172.177** Differences in Parenting Stress between Mothers and Fathers Following an Autism Diagnosis

A. Milgramm *and K. V. Christodulu, Center for Autism and Related Disabilities, Albany, NY*

Background: Incorporating fathers into parenting research is a recent and important development (Flippin & Crais, 2011). Results of studies comparing stress levels of mothers and fathers of children with autism are mixed, with some evidence supporting similar levels of stress (e.g., Hastings, Kovshoff, Ward, et al., 2005), and other data supporting higher maternal stress (e.g., Dabrowska & Pisula, 2010). Only one study has specifically compared levels of stress in parents newly adjusting to the diagnosis (Davis & Carter, 2008). Clearly, additional research on the topic is needed. Furthermore, it is important to better understand sources of parenting stress in order to tailor autism intervention to meet the needs of both parents (Flippin & Crais, 2011). Given that social interaction deficits are a core, underlying feature of the disorder, child social impairment may be one particularly salient source of stress.

Objectives: (1) To compare parenting stress in mothers and fathers of children newly diagnosed with ASD. (2) To examine associations between child social impairment and parenting stress for both parent genders.

Methods: Participants included 29 mother-father pairs who enrolled in a parent education program designed to teach families about ASD. The children of enrolled parents ranged in age from 2-10 years ($M=4.5$ years). Parents completed the Parenting Stress Index–Short Form (PSI-4-SF; Abidin, 2012), comprised of three subscales: Parental Distress (PD), Parent-Child Dysfunctional Interaction (P-CDI), and Difficult Child (DC). Parents also completed the Social Responsiveness Scale, 2nd Edition (Constantino, 2012), comprised of five subscales: Social Awareness (Awr), Social Cognition (Cog), Social Communication (Com), Social Motivation (Mot), and Restricted Interests and Repetitive Behavior (RRB). Paired samples t-tests were conducted to examine differences in stress between mothers and fathers. Pearson correlations were conducted separately for mothers and fathers to examine associations between child social impairment and parenting stress.

Results: The current sample revealed that 41.4% of mothers and 20.7% of fathers had a Total Stress score within the clinically significant range. There was a significant difference between mothers and fathers on the DC subscale ($t(28)=2.552$, $p<.05$, Mother>Father). There were no group differences on PD ($p=.17$) or P-CDI ($p=.17$) subscales. For mothers, P-CDI scores correlated significantly with Com ($r=.42$, $p<.05$), and DC scores correlated significantly with Cog ($r=.55$, $p<.01$), Com ($r=.60$, $p<.01$), and RRB ($r=.42$, $p<.05$). For fathers, there were no significant correlations between child social impairment and parenting stress (p's=.07-.94; see Table 1).

Conclusions: Following a child's diagnosis of autism, mothers and fathers experience comparable levels of stress with regard to personal factors (e.g., social support, spousal conflict) and the parent-child relationship. However, as compared to fathers, mothers perceive the child's behavioral characteristics to be more difficult. Moreover, maternal stress was related to several aspects of child social impairment, including cognition, communication, and restricted interests and repetitive behavior, while no significant associations were found for fathers. Additional research on the mechanisms underlying these differences is critical and may be related to mothers' increased involvement in the care of the child with autism, more adaptive coping strategies utilized by fathers, or different parental expectations.

178 **172.178** Division of Caregiving Responsibilities Among Caregivers of Children with and without ASD

C. A. Paisley[1]*, J. A. Rankin*[1]*, K. K. Baker*[2] *and T. Tomeny*[1]*, (1)The University of Alabama, Tuscaloosa, AL, (2)University of Alabama, Tuscaloosa, AL*

Background:

Parenting children with ASD requires greater demands relative to parenting typically developing children (TD; Ingersoll & Hambrick, 2011) and mothers report increased need for support from family relationships and outside sources compared to normative data (Johnson, Frett, Feetham, & Simpson, 2011). However, literature suggests that parents of children with ASD who are primary caregivers may receive less support from their spouses compared to parents of TD children, even though parenting demands may be greater (Bristol, Gallagher, & Schopler, 1988). Furthermore, Johnson et al. (2011) demonstrated that when mothers and fathers feel their family social support needs do not match their support received, their stress levels increase and mental health worsens in both parents. Social norms around parenting continue to shift, and it is becoming more common for both parents to take equal share of parenting responsibilities.

Objectives:

The current study sought to explore whether primary caregivers of children with ASD receive less support from secondary caregivers compared to primary caregivers of TD children, and whether disagreement exists between primary and secondary caregivers in how often the secondary caregiver is involved in caregiving.

Methods:

The current online study included 67 mother-father dyads of a child with ASD and 48 mother-father dyads of TD children. The Child Caregiving Involvement Scale (CCIS; Wood & Repetti, 2004) is a 10-item questionnaire that assesses perceptions of caregiver responsibility for specific child-care activities. Secondary caregivers were asked to report on their own responsibility and primary caregivers were asked to report on the

secondary caregiver's responsibility. Correlations and paired sample t-tests were conducted to compare the involvement of secondary caregivers reported by primary and secondary caregivers and between ASD and TD groups. Discrepancies were determined as mean differences that exceeded one half standard deviation (as in Tomeny et al., 2018).

Results:

In the ASD group, 15% of secondary caregivers reported they spend less time caregiving relative to their spouse's report, while 25% reported they did more than their spouse reported. In the TD group, 13% of secondary caregivers reported they spend less time caregiving relative to their spouses' report, while 18% reported they did more than their spouse reported. There was no significant difference between primary (M=22.78, SD=9.28) and secondary (M=22.25, SD=8.03) caregiver's report of how much the secondary caregiver shared responsibilities in the ASD group, $t(66)$=.69, p=.506. Additionally, there was no significant difference in share of responsibilities reported by primary caregivers of children with ASD and primary caregivers of TD children, $t(113)$=.665, p=.508. Secondary caregivers of children with ASD and TD children also did not differ on their report of shared responsibilities, $t(113)$=1.476, p=.143.

Conclusions:

Overall, analyses illustrated that secondary caregivers and their spouses were generally in agreement about levels of involvement of secondary caregivers. ASD and control groups did not differ in the amount of caregiving provided by secondary caregivers, regardless of reporter. Although past research has shown negative effects on stress and mental health when caregivers do not agree on shared responsibilities, our results show promise of perceived equality of childcare responsibilities.

179 **172.179** Effects of Caregiver-Focused Programs on Psychosocial Outcomes in Caregivers of Individuals with ASD: A Meta-Analysis

Y. Yu[1], *J. H. McGrew*[2] *and J. Boloor*[3], *(1)Indiana University - Purdue University Indianapolis, Indianapolis, IN, (2)Psychology, Indiana University - Purdue University Indianapolis, Indianapolis, IN, (3)Educational, School and Counseling Psychology, University of Kentucky, Lexington, KY*

Background: Caregivers of individuals with autism spectrum disorder (ASD) experience greater negative psychosocial outcomes than caregivers of individuals with other developmental disabilities. The majority of interventions for this population have focused exclusively on the offspring with ASD. Few studies have specifically targeted the caregivers of individuals with ASD, and the effectiveness of these interventions is not clear. Objectives: To fill the gap, the current study used meta-analytic techniques to comprehensively review interventions that directly target psychosocial outcomes in caregivers of those with ASD and to explore potential moderators of effectiveness.

Methods: The initial literature search was conducted in September 2017 in multiple sources (e.g., ERIC, MEDLINE, PubMed). Backward and forward searches and e-alerts were conducted for additional relevant studies. Articles generated from e-alerts were screened for inclusion criteria until July 2018. The search encompassed published and unpublished empirical studies, systematic reviews, and conference proceedings. A random-effects model was used to calculate the mean effect size, Hedges' g. The mean effect sizes from both pre-post intervention comparisons and group comparisons between treatment and control groups were calculated. Subgroup analyses and meta-regressions were conducted to examine potential moderators.

Results: A total of 41 unique studies met the inclusion criteria, targeting 1771 caregivers. Overall, the interventions had a small positive effect on improving psychosocial outcomes in caregivers of individuals with ASD (within-subjects: Hedges' g = .44; between-subjects: Hedges' g = .28). A variety of intervention approaches were identified: cognitive behavioral therapy (CBT), acceptance and commitment therapy (ACT), mindfulness-based intervention, psychoeducational intervention, social support, positive psychotherapy, written emotional disclosure, and multicomponent interventions. Intervention impact was associated with type of intervention. Specifically, CBT and ACT/mindfulness-based interventions were more consistently effective in improving caregivers' overall psychosocial outcomes. The strongest pre- to post-treatment effect size impacts were noted for decreased perceived stress/distress (Hedges' g = .56) and parenting stress (Hedges' g = .55) and improved general well-being (Hedges' g = .54). The largest between group caregiver effect sizes were for decreased parenting stress (Hedges' g = .49), reduced depressive symptoms (Hedges' g = .32) and anxiety level (Hedges' g = .42), and improved general well-being (Hedges' g = .65).

Conclusions: Overall, interventions were effective in improving caregivers' psychosocial outcomes with a small, significant effect size. Most of the intervention approaches demonstrated some evidence of effectiveness although there was inconsistency in demonstrating significance for both within- and between-subjects analyses. The most consistent evidence was for ACT and mindfulness-based interventions which were moderately effective in improving caregiver psychosocial outcomes in both pre-post and group comparisons. The results indicate some evidence for the effectiveness of caregiver-focused interventions, however more studies with larger sample size, rigorous research design, and long-term follow-up assessments are needed.

180 **172.180** Emotional Experience and Perception of Immigrant Families through Their Diagnosis Trajectory and Anticipation for the Future

C. Magnan-Tremblay[1], *M. Rivard*[2], *M. Millau*[3], *M. Boulé*[4] *and C. Rochefort*[5], *(1)Institut de recherche en santé mentale de Montréal, Montréal, QC, Canada, (2)Psychology, Universite du Quebec a Montreal, Montréal, QC, Canada, (3)UQAM, Montréal, QC, Canada, (4)Psychology, UQAM, Montreal, QC, Canada, (5)Psychologie, Université du Québec à Montréal, Montréal, QC, Canada*

Background: Immigrant families having a child with autism spectrum disorder (ASD) face multiple challenges associated not only with their diagnosis, but also with cultural differences (e.g., in communication, values, perceived needs; Dyches, Wilder, Sudweeks, Obiakor & Algozzine, 2004; Millau, Rivard & Mello, 2018). Literature indicates that challenges encountered by theses families are mostly related to accessing services, joining services and poor quality of life (Mandell & Novak 2005; Millau, Rivard & Mello, 2018; Roth 2016). However, little information exists about emotional experience and perceptions of immigrant families having a child with ASD during their diagnosis trajectory.
Objectives: The present study aims to document the subjective experience of immigrant families in getting access to an ASD diagnosis for their child, in the area of Montréal (Québec, Canada).

Methods: Twenty-four families having a child with an ASD diagnosis completed a socio-demographic questionnaire and a questionnaire evaluating their trajectory. They also participated in semi-structured interviews in which they talked about their experience and perception through their trajectory in the health services to obtain a diagnosis for their child.

Results: This poster will present results from semi-structured interviews documenting families emotional experience and perception relating to the diagnosis process, relating to their child and the progress achieved, their apprehension for the future and the presence of social support and family members when they arrived in the province of Quebec.

Conclusions: These results help us to better understand the particularities experienced by immigrant families and gives us pathways for improvement to adapt the type of support offered to immigrant families and to better accompany them in the critical periods of their trajectory.

181 **172.181** Enhancing the Parent Experience While Waiting for an Autism Spectrum Disorder (ASD) Evaluation

R. Lieb *and S. Delahanty, NeuroDevelopmental Science Center, Akron Children's Hospital, Akron, OH*

Background: The Autism Spectrum Disorder (ASD) diagnostic process is lengthy and anxiety-provoking for many families. Retrospective research has focused on families' experiences including satisfaction during the evaluation process (e.g., Howlin & Moore, 1997, Crane et al, 2016). However, none have assessed caregiver experiences while actively going through the assessment process.
Objectives: This two-phase project surveyed caregivers during their child's ASD assessment. The objective was to evaluate caregiver experiences prior to their child's appointment and test whether providing education prior to the appointment impacts thoughts, knowledge, and emotions compared to the control group.

Methods: Participants included caregivers of children being evaluated in an interdisciplinary ASD clinic at a Midwestern children's hospital (typical clinic age 2-6 years). Participants completed a voluntary, anonymous survey during their child's diagnostic appointment. In Phase 1 (N=42), participants were asked questions including age of first concern, awareness of ASD resources, resources they wished for before the appointment, and emotions felt while waiting. In Phase 2 (N=26), caregivers received a one-page "fact sheet" prior to their appointment including ASD symptoms and testing-day information (including testing rooms visuals). They received the same survey as Phase 1; with additional questions on the helpfulness of the fact sheet.

Results: See Table 1 for demographic information. There were no significant group differences between the current age of the child or caregiver, age of first concern for overall development, or age of first concern for ASD ($p>.05$ for all). Both groups reported similar familiarity with a national and local ASD resource ($p=.496$). Twenty-two caregivers reported receiving the fact sheet prior to their appointment. The majority of them reported the fact sheet as very helpful (mean=4.09 on a 5-point Likert scale). Analyses were conducted to compare Phase 1 and 2 group differences on requests for information and feelings experienced while waiting (see Table 2 for frequencies). Surprisingly, despite finding the fact sheet very helpful, Phase 2 caregivers reported wanting significantly *more* information about child development, ASD information, ASD resources, the appointment, treatments, school connections, cost, and connection to other families ($p<.01$ for all) than Phase 1 caregivers. Phase 2 caregivers also reported being significantly more anxious, sad, confused, alone, scared, stressed, and frustrated ($p<.03$ for all) but interestingly also reported being significantly more relieved and hopeful ($p<.03$ for each).

Conclusions: Research has demonstrated the stressful nature of the diagnostic process (Crane et al, 2016). Surprisingly, even though this study provided (caregiver-reported) helpful information in advance, caregivers still reported wanting more. They also reported significantly more negative emotions than those that did not receive the fact sheet. Findings suggest that perhaps the stress and active challenges families experience while waiting may not be allayed by providing standardized information. Encouragingly, caregivers also reported positive feelings, suggesting that there are opportunities to continue to support and encourage families. To date, research has neglected to examine caregiver emotions, particularly positive emotions, during the ASD evaluation waiting period. Additional research is needed to enhance our understanding of these experiences to help improve caregiver and child outcomes.

182 **172.182** Examining Differences in Family Impact Among a Racially and Ethnically Diverse Population of Parents of Children with Autism Spectrum Disorder

N. A. Nwosu[1]*, T. Benevides*[2]*, J. Lee*[3] *and J. Franks*[4]*, (1)Department of Psychology, Georgia State University, Atlanta, GA, (2)Augusta University, Martinez, GA, (3)School of Nursing, Georgia State University, Atlanta, GA, (4)Center for Leadership and Disability, Atlanta, GA*

Background: Raising a child with autism spectrum disorder (ASD) has a substantial influence on family caregivers' emotional and physical health and wellbeing. A recent meta-analysis reported that parents of children with ASD experienced significantly higher levels of parenting stress compared to parents of children with other and without developmental disabilities. Existing literature rarely addresses culture and the possible role that race and/or ethnicity (as a proxy for culture) might contribute towards family impact. Little is known about how families from different racial and ethnic backgrounds report family impact beyond individual stressors associated with caregiving.
Objectives: The purpose of this study was to examine a following research question: What differences in family impact exist among a racially and ethnically diverse population-based sample of caregivers of children with ASD? Additionally, we explored differences between English- and Spanish-speaking Hispanics.

Methods: Using publicly-available data from the 2005-2006 and 2009-2010 National Survey of Children with Special Health Care Needs (NS-CSHCN; CDC, 2005, 2009), this retrospective, cross-sectional study examined family impact among caregivers (N= 5,178) of children with ASD. Family impact was defined by the financial impact, time spent caregiving, and work impact variables, and evaluated in five racial and ethnic groups: 1) white, non-Hispanic; 2) any race, English-speaking Hispanic; 3) any race, Spanish-speaking Hispanic; 4) black, non-Hispanic; and 5) other race, non-Hispanic. Multivariate logistic regression in Stata 14.1 was used to analyze the association of race and ethnicity with family impact variables, while controlling for child and family covariates.

Results: In logistic regression models adjusted for characteristics of the child and family, English-speaking Hispanic caregivers were 2.0 times more likely (95% CI: 1.14-3.55) to report spending 11+ hours caring for their child as compared to white, non-Hispanic caregivers. Examination of time spent caregiving revealed that white non-Hispanic caregivers were significantly more likely to spend $500 or more on their child's care than black (OR=1.8, 95%CI: 1.18-2.80), Spanish-speaking Hispanic caregivers (OR=3.60, CI: 1.69-7.64), and caregivers of other racial/ethnic backgrounds (OR=2.32, CI: 1.55-3.49). No significant differences were observed in job impact variables between racial/ethnic groups.

Conclusions: The unique contribution of this study is that financial and time spent caregiving impacts differed between racial/ethnic groups within this U.S. population-based sample. Further investigation into caregiver preferences for spending on services and supports between caregivers of different racial and ethnic backgrounds can clarify how and why caregivers make decisions about care. Additional research is needed

to determine whether caregivers who reported spending greater than 11 hours a week were compelled to engage in this level of caregiving due to lack of finances or lack of other support, or whether the caregiver chose to engage in caregiving based on preference, cultural expectations, or family norms. Racial and ethnic differences exist in providing and spending more for direct care, but they do not necessarily represent disparities. With other demographic variables controlled for, these findings suggest the need to support caregivers in the most meaningful way in their preferred methods of providing care.

183 **172.183** Examining Potential Developmental Consequences of Parental Decisions to Disclose Their Child's Autism Diagnosis to Their Child

A. Riccio[1], *A. Jordan*[2], *S. K. Kapp*[3], *A. M. Dorelien*[4] *and K. Gillespie-Lynch*[5], *(1)Department of Psychology, The Graduate Center, City University of New York (CUNY), New York, NY, (2)CUNY, Staten Island, NY, (3)University of Exeter, Exeter, United Kingdom, (4)A Friendly Face, Staten Island, NY, (5)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY*

Background: A large body of literature examines effects of parenting an autistic child, often focusing on parental interpretations of the diagnosis. Initially, research focused on the difficulties, stress, and conflict that can accompany parenting an autistic child (e.g., Dumas et al., 1991), with more recent works focusing on positive outcomes and perspectives offered by families (e.g., Hastings & Taunt, 2002). Positive interpretations of autism by parents have been found to lead to desirable parent (e.g., self-efficacy) and child outcomes (e.g., reciprocal play, attention, and affect; Pakenham et al., 2004; Wachtel & Carter, 2008). However, research linking parents' descriptions of autism with their children's understanding of autism and autistic identity development has not been conducted.
Objectives:

1. Analyze if parental decisions to disclose/withhold their child's autism diagnosis influence adolescents' perceptions of autism
2. Evaluate how autistic young adults reflect on and learn from parental disclosure.

Methods: Adolescent participants (n = 15, M_{age}= 16.2) and their mothers were recruited from an informal educational program in New York City. Adolescent participants completed in-person, semi-structured interviews; mothers completed online questionnaires containing identical questions. A second sample of autistic college students (n=19, M_{age} = 20.9) recruited from a mentorship program answered semi-structured interviews and online surveys. Qualitative analyses of adult data focus on these interview questions: "How old were you when your parents first told you about autism? What did they tell you?" and "If you had a child with autism, when would you tell them about autism and what would you tell them?"

Results: Only participants whose parents disclosed their diagnosis voluntarily (n=6) described strengths (n=3) or neutral differences (n=3) when asked to define autism. Participants (100%) who were told about their diagnosis by a parent involuntarily (n=6) or not yet been informed of their diagnosis (n=3) focused solely on challenges associated with autism, compared with a third (n=2) of those whose parents voluntarily disclosed (Table 1).

Most (14; 73.7%) autistic college student participants were told about their diagnosis by a parent; three (16%) reported that they sought their own diagnosis or discovered their diagnosis within paperwork. When asked how they would tell their own child about an autism diagnosis, many described sharing challenges associated with autism (n=7; 36.8%), telling their child about autism in the same way they had been told (n=5; 26.3%) and self-disclosing (n=4; 21.1%). Only three (16%) planned to tell their child at a *younger* age than they were told.

Conclusions: Data suggest that parental decisions to disclose their child's autism diagnosis to their child impact their children's perceptions of autism and anticipated parenting decisions. Although benefits of parents choosing to disclose their child's diagnosis to their child were observed, autistic young adults often planned to inform their own children about their potential autism diagnosis similarly to how they themselves had been informed. Future longitudinal research should examine how parental disclosure decisions contribute to autistic identity development over time.

184 **172.184** Examining Primary Care Experiences for Adults with Autism Spectrum Disorder

L. I. Duker (Stein)[1] *and B. Pfeiffer*[2], *(1)Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)Rehabilitation Sciences, Temple University, Philadelphia, PA*

Background: Primary care is associated with positive outcomes for society, including improved access to health care services, health outcomes, and cost savings. However, few studies have documented the experiences of adults with autism spectrum disorder (ASD) in the primary care system. Of those, adults with ASD report multiple challenges with the receipt of primary care, decreased satisfaction, and increased unmet physical and mental healthcare needs. As adults with ASD represent a growing segment of society, the number who require primary care is expected to increase over the next decade. Consequently, there is a pressing need to improve the quality of primary health care for adults with ASD with empirically validated, client-centered strategies and tools.
Objectives: To identify perceived barriers and strategies to facilitate successful primary healthcare encounters for adults with ASD, as reported by adults with ASD, caregivers of adults with ASD, and primary care providers (PCPs) treating adults with ASD. These findings will identify potential areas to address obstacles to the provision of successful primary healthcare services for adults with ASD.

Methods: As part of a larger mixed methods design, adults with ASD (n=34), caregivers of adults with ASD (n=31), and PCPs treating adults with ASD (n=13) completed surveys. Survey topics included barriers to care as well as strategies previously utilized by the adult with ASD, caregiver, or PCP; the success of those strategies; and the potential of those strategies to improve care in the future. Participants were primarily located in Los Angeles, CA and Philadelphia, PA; this dual location enabled the collection of information from two underserved minority populations, Latinos and African Americans. For descriptive purposes, frequencies and percentages were calculated for all survey items.

Results: Multiple barriers to primary care were reported by adults with ASD and caregivers, including communication and sensory challenges. Adults with ASD and caregivers reported minimal use of strategies during primary care visits, but that those used were helpful to improve care (e.g., social story, environmental adaptations, practice visits). Expert PCPs reported utilizing strategies more frequently than novice PCPs. All consumer and provider respondent groups endorsed that multiple strategies had the potential to improve care in the future for adults with ASD

(e.g., list of patient needs, visual schedule, environmental adaptations).
Conclusions: Adults with ASD experience challenges in the access to and provision of primary care, but believe multiple strategies have the potential to improve this care. These findings help identify priorities for intervention development in order to improve patient-centered care for this population.

185 **172.185** Exploring Well-Being in Young Adults with Autism Using Photovoice

G. Y. H. Lam[1], *E. Holden*[2] *and M. Fitzpatrick*[2], *(1)Department of Educational and Psychological Studies, University of South Florida, Tampa, FL, (2)The Learning Academy, University of South Florida, Tampa, FL*

Background: Much of the literature has focused on the challenges faced young adults with autism during post-school transition. However, little is known about how this population defines a good life and what they desire for themselves. Research taking into considerations the perspectives of individuals with autism and recruiting their meaningful participation is essential for the autism community and different stakeholders to understand the wants and needs of this population (Pellicano, Dinsmore, & Charman, 2014).
Objectives: The current study used a participatory action research (PAR) approach to explore how young adults with autism perceive and define their own well-being during school-to-adulthood transition.
Methods:
This project took place within the context of a year-long community-based transition program that aims to support post-school outcomes in young adults with autism. Thirteen young adults with autism between 19 and 25 years of age volunteered to participate. All participants had adequate verbal and communication abilities to participate in the project. This project took a participatory action research (PAR) approach to support participants' active participation and to allow meaningful expression of their first-person perspectives. Specifically, the author approached the group of young adults expressing an interest in using a photography-based methodology, Photovoice (Wang & Burris, 1997), to explore how participants understand and describe their own "well-being." Throughout the research processes, participants provided input into decisions about the research questions, design of activities, and their own level of commitment to the project. After an initial training about the ethics and instructions of camera use and photography, participants took pictures during their daily lives for two months to capture and express their ideas about well-being. Weekly group discussions and individual interviews were conducted to review participants' photographs and discuss their views of well-being. Researcher and participants conducted a thematic analysis to identify themes and patterns from the photographs and discussions. On-going data analysis and feedback from the participants are still in progress.
Results:
Preliminary findings suggested an overarching theme of "connections" with family, friends, and animals. Specifically, participants displayed a sense of connectedness with their family members through their everyday encounters with them. Through the photo-taking activities, participants acknowledged the opportunities to meet up with current friends and mentors and to review past friendships in adolescence. Citing their stories with pets, stray animals, and cartoon characters, participants also expressed their love of animals and how much they enjoyed caring for them as they found them loyal, respectful, and non-judgmental. Lastly, participants identified action plans to help the local community understand the perspectives of people with autism, including presentations to parents and other stakeholders, photo exhibitions, and advocacy campaigns.
Conclusions:
Findings from this Photovoice project reveal an autism-sensitive conceptualization of well-being informed by the participants' active participation and multimodal input (visual, verbal, and written). Results help identify resources and barriers in community settings that could improve well-being in young adults with autism during post-school transition. Practical strategies for future research to encourage meaningful participation of the autism community will be discussed.

186 **172.186** Exploring the Impact of Selective Eating on Key Life Domains Among Transition-Age Youth with Autism Spectrum Disorder

S. C. Folta[1], *C. Curtin*[2], *A. Must*[3] *and L. G. Bandini*[4], *(1)Tufts University, Boston, MA, (2)University of Massachusetts Medical School, Waltham, MA, (3)Tufts University School of Medicine, Boston, MA, (4)Eunice Kennedy Shriver Center, University of Massachusetts Medical School, Worcester, MA*

Background: Eating can be a way to establish and build social connections and a means of expressing affection, sociability, and hospitality. However, it is not understood how selective eating, common among youth with autism spectrum disorder (ASD), may impact their mealtime experiences, social opportunities and general well being. Transition to adulthood has emerged as an important focus for supporting youth with

ASD, particularly since relatively few ongoing supports and services exist for this population after they age out of school. Despite the high level of parental concern about selective eating and a growing literature that suggests that proxy reporting misses important information that only individuals themselves can report, no systematic studies to date have queried youths themselves about their experiences with selective eating. Objectives: The objective of this qualitative study was to explore the impact of selective eating on key life domains of transition-age youth with ASD who self-identified as being food selective. One key goal of the study was to inform the development of supportive strategies to address food selectivity and navigating social and other opportunities that involve eating.

Methods: We conducted 19 in-depth interviews with transition-age youth with ASD. Recruitment occurred through schools, listservs, and organizations that serve youth with ASD and their families. A semi-structured interview guide was developed with questions about selective eating and its impact on mealtimes with family, activities with peers that involve food, and other social situations. Participants were also asked about their feelings about their selective eating and their interest in support. Data were analyzed using descriptive thematic coding.

Results: The mean age of participants was 21 years (SD 1.67 years). Fourteen were male, three were female, one was transgender, and one identified as non-binary. Twelve lived at home with their parents, five lived at school, and two lived with a roommate. A major theme that emerged was that the impact of selective eating on participants' lives diminished with age. Participants' perceived that this resulted from gentle pressure from parents, internal pressure, or just the passage of time. Participants described common strategies for coping with their selective eating in social situations, including picking out disliked foods, learning about the menu prior to an occasion, focusing on the foods they do like, eating ahead of time, carrying snacks, eating enough of disliked foods to avoid hunger, and occasionally going hungry. Many participants described family and peers as accommodating, but not necessarily understanding, their food selectivity. Most participants said that they were able to manage social situations that involved eating well enough and most youth were not especially interested in receiving help.

Conclusions: The transition-age youth interviewed indicated that they have developed coping strategies to manage social situations involving food. A responsive approach to supporting such youth would likely involve recognizing the effort and skills that the youth have already developed around this issue, respect for their growing autonomy, and could potentially involve a peer support network with other youth with ASD who understand the challenges and can share helpful strategies.

187 **172.187** Seeking Information and Support Online: The Development of an Online Resource 'Pathways Beyond Diagnosis' for Parents of Children Diagnosed with Autism Spectrum Disorder

A. S. Rabba[1,2]*, C. Dissanayake*[1,2] *and J. Barbaro*[1,2]*, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Long Pocket, Brisbane, Australia*

Background: The world wide web provides an ideal avenue to share information, advice, and support about an autism diagnosis. However, many websites lack quality control and do not provide a one-stop resource for families to access necessary information.
Objectives: The aim in this study was to use participatory action research (PAR) with end users (parents, clinicians) and our research team to develop an online resource to improve timely access to, and better quality, information and support for families post-diagnosis.

Methods: The PAR approach has been successful in generating research evidence to address community-based challenges. It involves four major phases: (1) cooperative researcher-stakeholder planning, (2) stakeholder-based action, (3) stakeholder-observation, and (4) cooperative researcher-stakeholder reflection. In the present study, each phase included Participatory Design (PD) workshops, where participants attended individual and/or group meetings; this was followed by translation of knowledge and ideas generated during workshops to produce mock-ups of webpages and content; rapid prototyping; and one-on-one consultations with end users to assess usability of the website.

Results: Three PD workshops were held with 15 end users (parents of children with autism n=3, health professionals and researchers n=12). Each workshop was followed by a knowledge translation session. At the conclusion of this PAR cycle, the alpha prototype of the website was built, and one round of one-on-one end user consultation sessions was conducted. The PAR cycle revealed the importance of six key topic areas (e.g., understanding autism, accessing services, support, gaining funding, putting it all together, looking into the future) associated with the time of diagnosis.

Conclusions: The development of this website using PAR presents a promising approach to assure that families receive practical and evidence-based information about the steps to take following a child's diagnosis. Without re-inventing what already exists, 'Pathways Beyond Diagnosis' seeks to inform families of where they can access relevant and reputable information but also summarises important challenges encountered post-diagnosis (i.e., grief, sharing the diagnosis).

188 **172.188** How My Life Is Different: Sibling Perspectives of ASD

P. Burnham Riosa, ***B. Davy****, R. Ensor and B. Jichici, Brock University, St. Catharines, ON, Canada*

Background: The impact of autism spectrum disorder (ASD) on the family is a growing area of research interest. Studies have primarily focused on family impact from a parental perspective, with much less emphasis on other family members' experiences. Existing research on the sibling perspective, specifically, is relatively limited and mixed. Some studies have demonstrated that neurotypically developing siblings have positive experiences toward their siblings with ASD (e.g., Rivers & Stoneman, 2003), whereas other studies have revealed disparate findings, particularly when siblings with ASD exhibit challenging behaviour (e.g., Mascha & Boucher, 2006). Further research on the sibling experience is warranted.
Objectives: The purpose of the current study was to understand the lived experiences of a sample of typically developing siblings of children with ASD.

Methods: Nine typically developing siblings (5 male, 4 female) of children with ASD (8- to 17-years old, mean age = 12.2 years, SD = 3.4 years) participated in the study. Siblings with ASD were 9- to 17-years old (mean age = 13.2 years, SD = 2.2 years) and were predominantly male (1 female). Open-ended questions were used to flexibly guide the interviews, which took place at participant homes. Initial interview questions were strategically broad (i.e., "What is it like to be (child with ASD)'s brother/sister?") as a means of allowing each participant to start at his or her own place of lived experience. Additional questions were used to gather a descriptive perspective of each sibling's experience (e.g., "How do you and your brother/sister get along?"). Thematic analysis (Braun & Clarke, 2006) was used to analyse the interview data.

Results: Preliminary results yielded three major themes: (1) "My family is different", (2) "I am a caregiver", and (3) "I accept that my sibling has ASD

but sometimes I wish they didn't". The first theme encompasses participants' understanding that having a child with ASD in the family made their family unique. Participants acknowledged that they needed to make adjustments as a result of having a family member with ASD. They also described how role expectations were different compared to families that did not have family members with ASD. The second theme highlighted the protective role that participants assumed over their siblings. Many participants described a sense of responsibility toward their family member with ASD. The third theme revealed an array of positive (e.g., love, amazement, pride) as well as negative feelings (e.g., frustration toward challenging behaviour) surrounding the experience of being a brother or sister to a sibling with ASD.

Conclusions: The current findings highlight a sample of neurotypically developing siblings' perspectives regarding their siblings with ASD and the family dynamic. Participants described rich perspectives surrounding their experiences. Further research examining sibling relationships may have important implications on the development of supports for siblings of children with ASD.

189 **172.189** Identifying Health Disparities in Young Women with Autism Spectrum Disorder through Patient-Centered Research

S. Woodmansee *and S. N. Brasher, Nursing, Emory University, Atlanta, GA*

Background: Autism spectrum disorder (ASD) currently impacts 1 in 59 youth. Within this population, an estimated 450,000 youth with ASD ages 16-24 in the United States transition to adulthood. While ASD is thought to be more common in males than females, emerging literature shows that females with ASD may be under-diagnosed and receive much later diagnoses. This absence or delay in diagnosis can potentially result in severe consequences to health outcomes of females with ASD. Further impacting their health outcomes are the limited resources and treatments available upon transitioning to adulthood. Few studies have examined gender differences during transition to adulthood. Moreover, the existing studies predominately utilize quantitative methods. Thus, young women with ASD and their experiences are often unheard.
Objectives: The purpose of this study was to engage young women with ASD, caregivers, and stakeholders to identify health disparities encountered during the transition to adulthood.

Methods: A Patient-Centered Outcomes Research (PCOR) design was used to develop research capacity and build the infrastructure necessary to conduct future research responsive to the needs of females with ASD. Caregivers and females with ASD ages 15-32 were identified using purposive sampling to participate in monthly engagement groups over 12 months. Each engagement session included 8-14 females with ASD. Discussions centered on the unique challenges to females with ASD during the transition phase. Researchers collected field notes during engagement groups to capture the young women's perspectives. An advisory board of patients and stakeholders met monthly to provide project guidance. Advisory board members included females with ASD, psychologists, healthcare providers, educators, caregivers, and researchers.

Results: Results of this study highlight the process of engaging young women with ASD, caregivers, and stakeholders to identify health disparities. Findings indicate disparities in the following domains for females with ASD transitioning to adulthood: mental health, LGBT, and gender-based healthcare differences. Participants also identified several patient-centered comparative effectiveness research proposals to address these domains, including better screening tools, peer navigators, and mentor models.

Conclusions: Healthcare transition from childhood to adulthood can be difficult for most, but especially for females with ASD. Little is known on gender-related differences during transition to adulthood and subsequent impacts on health outcomes. Findings from this patient engagement study are an initial step towards better understanding these disparities and overcoming them from a patient-centered outcomes research perspective. Results of this study have the potential to create change for young women with ASD within the healthcare field through patient-informed care. These findings are expected to form the basis for future research aimed to improve health outcomes of young women with ASD.

190 **172.190** In-Home Oral Care Habits in Latino Children with Autism: An in-Depth Look

L. I. Florindez[1]*, D. H. Como*[1] *and D. C. Florindez*[2]*, (1)Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)University of Southern California, Los Angeles, CA*

Background:
Dental care is the most prevalent unmet health need in US children. Children from underrepresented and underserved groups (i.e., Latinos, those with Autism (ASD)) are at increased risk for experiencing oral health disparities. When intersected, Latino children with ASD face unique, unresearched oral care challenges. Literature discussing these disparities recognizes a need for further research, but little centers on promoting successful home-based oral care strategies, nor focuses on other factors (i.e., diet, culture, systemic barriers) that may impede oral health.

Objectives:

The purpose of this study was to explore the factors that affect oral care routines and impede overall oral health in Latino children with ASD using data collected via videos, visual food journals, and narrative interviews.

Methods:

This study employed a qualitative approach. Ten Latino families with a child with ASD aged 6-12 were interviewed to identify the factors that impact their oral health, including how the presence of ASD may alter their child's habits. Each parent/caregiver completed two interviews, and each child completed one interview (n=30 interviews). All interviews were audio recorded and transcribed verbatim, and thematically analyzed by the researchers. Additionally, each family video recorded their child performing typical oral care routines for 3 days. Two research assistants blindly coded 37 videos using a checklist of dental behaviors, noting unique aspects of the routines. Lastly, families submitted photos of their child's meals as part of a visual food journal (n=95 photos). One research assistant documented content of photos and noted overlapping food patterns.

Results:

The interviews yielded three themes related to factors impacting overall oral care and routines. *"Estoy sóla"* described how parents of children with ASD felt isolated. From finding an appropriate dental provider to getting their child to complete oral care activities, parents felt like they were the only ones who could ultimately help their child. "*Wait, there's more"* portrayed tooth-brushing as the only routine often performed by the child; parents labeled activities such as flossing and mouthwash as too difficult to incorporate. "*It's a Battle"* described how parents had a precarious relationship with their child's oral care habits, and forcing self-care activities led to disagreements. From the videos, two themes pertaining to oral care practices were observed. *Parent Involvement* identifies parents as partners in the oral care process, helping facilitate the

activity physically or with verbal cues. *Sensory modifications* describes being aware of the sensory needs of the child, and modifying the activity to meet those needs, including altering the activity environment. Lastly, from the photos, the lack of water consumption was noteworthy, as none of the families submitted any pictures where their child drank water. Instead, children drank more cariogenic beverages (i.e., soda, juice).

Conclusions:

Together, these data provide rich content regarding the factors impacting oral care routines and overall oral health in Latino children with ASD. This research is novel in addressing the occupation of oral care itself, while also considering the influence of cultural contexts, diet, family and child descriptors, performance patterns, and systemic restrictions on the activity.

191 **172.191** Interventions to Improve Outcomes for Parents of Individuals with Autism Spectrum Disorder: A Meta-Analysis

K. T. MacKenzie *and S. Eack, University of Pittsburgh School of Social Work, Pittsburgh, PA*

Background: Parents of children with autism spectrum disorders (ASD) tend to experience greater psychological and emotional distress than parents of typically developing children. Interventions directed toward parents and caregivers have traditionally consisted of skills training and/or knowledge building interventions designed to ultimately improve child outcomes. More recently, researchers have begun to recognize the needs of parents and the importance of developing interventions to support them directly in addition to their children. However, the extent to which parent outcomes are improved by existing parent interventions is unknown.

Objectives: The purpose of this study was to conduct a meta-analytic review of existing interventions for parents of children with ASD in an effort to examine the degree to which they improve parental outcomes.

Methods: A total of 24 peer-reviewed, empirical studies containing 81 effect sizes published between January 1946 and November 2018 were identified from literature searches in relevant databases. Included studies were randomized controlled trials of interventions for parents of children with ASD in which one or more parental psychological outcomes were quantified. Studies were standardized to a common effect size (Cohen's *d*) and then subjected to a random-effects multilevel meta-analysis using inverse variance weighting. Meta-regression was conducted to examine potential study-level moderators of intervention efficacy.

Results: Analyses revealed that participation in parent interventions led to small but significant improvements in parent outcomes (d = .26 [95% CI = .08 - .43], p = .004). There was significant heterogeneity in effect sizes, suggesting wide variability in efficacy between studies, Q = 294.53, p < .001. When analyzed by outcome type, the overall effect was driven primarily by improvements in parenting confidence (d = .57, p = .000) and mental health symptoms (d = .30, p = .018). There were no significant effects of parent interventions on stress, caregiving burden, family adjustment, or physical health. When analyzed by intervention type, both parent implementation interventions (d = .20, p = .007) and parent support interventions (d = .29, p = .033) had significant effects on parental outcomes. Moderator analysis indicated that the efficacy of parent interventions was not significantly moderated by child age, parent age, intervention format (i.e. group/individual), or treatment duration.

Conclusions: The impact of existing parent interventions on the psychological and emotional outcomes of parents caring for individuals with ASD was modest and heterogeneous. Existing interventions had the greatest impact on caregiver confidence and mental health symptoms, yet had no consistent effect on stress, caregiving burden, family adjustment, or physical health. Both parent implementation and parent support interventions led to small but significant improvements in parental outcomes. While these results suggest promise in assisting parents, more work is needed to develop interventions that have a greater impact on parental outcomes.

192 **172.192** Job Burnout and Work Engagement in Registered Behavior Technicians

A. Holbrook*, C. K. Toolan and C. Kasari, University of California, Los Angeles, Los Angeles, CA*

Background:

Increases in the prevalence of ASD have resulted in a dramatic increase in the number of individuals receiving services (California Department of Developmental Services, 2007), leading to an increased demand for ASD service providers. One of the largest certified occupational groups providing intervention services to individuals with ASD are Registered Behavior Technicians (RBTs). RBTs are classified as human service professionals (Freudenberger, 1974). As such, RBTs face significant stressors that can be challenging and reduce occupational well-being (Maslach & Jackson, 1981). Although there is great need for training and retaining high-quality RBTs in the workforce, few studies have examined the unique factors that contribute to occupational well-being (i.e., job burnout, work engagement) in RBTs for individuals with ASD.

Objectives:

1) To determine which job demands and resources are significant concurrent predictors of job burnout category in RBTs. 2) To determine which job demands and resources are significant concurrent predictors work engagement in RBTs.

Methods:

The sample includes 311 RBTs (M_{age}= 27.71 years, SD=7.29) with diverse ethnic/racial backgrounds. Participants were primarily female and held a college degree or higher. Job demands examined included challenging behaviors and low client skill level. Job resources included social resources (i.e., supervision, role clarity), training satisfaction, and training methods. Burnout (i.e., negative emotional response to work-related stress) was measured using the Maslach Burnout Inventory, comprised of three subscales: emotional exhaustion (EE), depersonalization (DP), and personal accomplishment (PA). Work engagement (i.e., positive, fulfilling work-related state of mind) was measured by the short version of the Utrecht Work Engagement Scale. Multiple ordinal regressions were conducted to examine the relation between job demands, resources, and burnout. Multiple linear regression analysis was conducted to examine the relation between job demands, resources, and work engagement.

Results:

Nearly 45% of RBTs reported levels of EE that identified them as employees with high burnout. Increases in stress from challenging behaviors resulted in greater odds of burnout (high vs. low/moderate EE: OR=1.04, p<.001; (high vs. low/moderate DP: OR=1.04, p<.001). RBTs employed full-time had greater odds of burnout (high vs. low/moderate EE: OR=2.90, p<.001) compared to RBTs employed part-time. Conversely, increases in social support resulted in lower odds of burnout (high vs. low/moderate EE: OR=.98, p=.001). RBTs with matched training styles had lower odds of burnout (high vs. low/moderate EE: OR=.525, p=.012; (high vs. low/moderate DP: OR=.50, p=.027) compared to those with mismatched training styles. Increases in social support (b=.18, p=.001) and training satisfaction (b=.20, p=.001) scores were associated with increases in work

engagement scores.

Conclusions:

Findings illustrate that social and training resources are central factors associated with both burnout and work engagement. Companies may reduce the impact of job demands by providing more of these resources, such as through supervision support. Taking these steps may improve occupational well-being not only by preventing and alleviating burnout, but also increasing work engagement in RBTs – ultimately helping to ensure that individuals with ASD consistently receive the services they need.

193 **172.193** Lessons Learned from Adapting a Peer-to-Peer Parenting Program for Urban Black Families Raising Children with Autism

S. Dababnah[1]*, W. E. Shaia*[2]*, I. Kim*[3] *and S. Magaña*[4]*, (1)University of Maryland, Baltimore, Baltimore, MD, (2)Social Work Community Outreach Service, University of Maryland Baltimore, Baltimore, MD, (3)School of Social Work, University of Maryland, Baltimore, Baltimore, MD, (4)University of Texas, Austin, Austin, TX*

Background:

Very little intervention research has focused specifically on low-income Black families raising young children with autism, despite documented racial disparities in autism diagnosis and treatment. While early intervention significantly improves child and family outcomes across the lifespan (Koegel, Koegel, Ashbaugh, & Bradshaw, 2014; Warren et al., 2011), low-income children with autism are less likely to access such services (Carr & Lord, 2016; Nguyen, Krakowiak, Hansen, Hertz-Picciotto, & Angkustsiri, 2016). Although Black caregivers across socioeconomic strata experience racial discrimination and poor parent-provider relationships, low-income Black caregivers also report limited autism knowledge and suboptimal access to care for their children (Dababnah, Shaia, Campion & Nichols, 2018).

Objectives:

We will report on the process of designing and initiating a feasibility trial of an adapted version of a peer-led, in-home, 14-week manualized program, *Parents Taking Action*, among low-income urban Black families raising children with autism. The presentation will focus on the first two aims of the project: 1) Engage key stakeholders in the local implementation of *Parents Taking Action*; and 2) Adapt *Parents Taking Action* for low-income caregivers of Black children with autism.

Methods:

Using the World Health Organization's ExpandNet implementation science framework (Simmons, Fajans, & Ghiron, 2011), we used a mixed-methods approach to adapt, implement and evaluate *Parents Taking Action*. The intervention uses videos, activities, and discussion to cover topics on autism therapies, advocacy skills, behavior management strategies, and social support. Unlike group-based or clinical interventions, *Parents Taking Action* offers flexibility to participants, as meetings are set around caregivers' schedules, and in-home meetings reduce travel time and costs. To accomplish Aims 1-2, we formed an advisory group composed of individuals with autism, parents, service providers, and advocates of children with autism. The group developed recommendations on adapting the program, identifying Parent Leaders (parents of older children or adults with autism from the local community) and recruiting participants (parents of young children with or at-risk for autism). We recruited both the Parent Leaders and the intervention participants from low-income neighborhoods in a large mid-Atlantic US city.

Results:

The advisory group met quarterly in person and consulted with the research team regularly between meetings to recommend actions related to intervention adaptation and implementation. The advisors' primary recommendations included adding culturally relevant pictures and videos, addressing potential police interactions, modifying the language to be more strengths-focused, supplementing the manual with local resources, and reordering the weekly topics. After we summarized our advisors' perspectives, the research team discussed recommended changes and modified the manual. We then identified, hired, and extensively trained four Parent Leaders to deliver the in-home program to a pilot group of 15-20 local parents of young children ages eight and younger with or at-risk for autism. We will discuss various challenges we encountered during the hiring and training processes, as well as the ways in which we addressed these obstacles.

Conclusions:

The "lessons learned" from developing and implementing a peer-led intervention with significant input from community stakeholders can be used to inform future studies targeting communities experiencing the multiple effects of poverty.

194 **172.194** Listening to Parents to Inform Autism Research

M. Clark *and D. Adams, Graduate Institute of Educational Research, Griffith University, Brisbane, Australia*

Background:

Most studies setting the priorities for autism research have focused on the early intervention years (Ghanadzade et al. 2018; Pitchet et al. 2011; Rodger, Braithwaite & Keen, 2004), or the daily priorities for adults on the spectrum (Gotham et al., 2015). Therefore, we do not have a good understanding of what the priorities should be for autism research in the school years. With an increase in prevalence of Autism Spectrum Disorders (ASD), now affecting 3% of school children aged between 7 and 17-years (Blumberg et al. 2013), establishing research needs and priorities is important to inform future autism research, that can best support the learning outcomes of school aged children with ASD.

Objectives:

Researchers are beginning to understand the benefits of involving members of the autism community in setting priorities for autism research. This study aimed to investigate parents' priorities for the future focus of autism research to support their school age child with ASD across the home, school and community environments.

Methods:

A sample of 116 parents of school age children with ASD responded to an online questionnaire which included general demographics and more specific questions to determine parent's research priorities. Parents were asked to nominate their top three priorities or research areas that they wanted to see as the focus of future autism research in the home, school and community settings, from most to least important.

Results:

The data was analysed using thematic analysis. Parent priorities for autism research in the home were explored first, where *family support, daily living skills* and *behavioural difficulties* emerged as the three most prevalent priority themes for future research in the home. Parents identified that *teacher knowledge and experience with disability,* research exploring *social relationships* and research into *academic and learning outcomes* as the areas of priority for future school-based research. Within the community setting, research to promote *awareness and understanding* within the community and greater *inclusion* were of the highest priority for many parents. In addition, many parents wanted to prioritise research exploring ways of adapting the community environment and community activities to better support the needs of individuals on the spectrum.

Conclusions:

Involving members of the autism community in priority setting for autism research increases community engagement and can improve the translation of autism research to maximise the impact of future autism research where it is needed most.

195 **172.195** Mechanisms of Parental Stress Associated with Emotional and Behavioral Problems in Children with Autism Spectrum Disorder

K. G. Stephenson[1], *R. M. Fenning*[2,3], *E. Macklin*[4], *F. Lu*[4], *K. Crow*[1], *T. Pifher*[1], *M. Norris*[1], *R. steinberg Epstein*[5] *and E. Butter*[1], *(1)Nationwide Children's Hospital, Columbus, OH, (2)Center for Autism, Child and Adolescent Studies, California State University, Fullerton, Fullerton, CA, (3)Pediatrics, The Center for Autism and Neurodevelopmental Disorders, University of California, Irvine, Santa Ana, CA, (4)Massachusetts General Hospital, Boston, MA, (5)The Center for Autism & Neurodevelopmental Disorder, University of California, Irvine, Santa Ana, CA*

Background: Emotional and behavioral problems (EBP) are common in autism spectrum disorder (ASD). There is ample research to show that EBP, particularly externalizing behaviors, are associated with negative impacts on the family system. Additional research is needed to clarify the underlying mechanisms of this relationship. Studies have shown that parental self-efficacy (PSE) is an important variable in terms of parental stress and has been hypothesized as a potential mediator between EBP and family distress. A limitation to extant research is the infrequent focus on underserved populations. Further investigation into how family resources affect PSE and family distress is needed.

Objectives: The purpose of the current study was to investigate the role of PSE as a mediator of the relationship between EBP and family distress in an underserved sample of children with ASD. We hypothesized that the mediation effect would be greater for externalizing (EBP-E) versus internalizing (EBP-I) behaviors. Additionally, we hypothesized that the amount of family resources would moderate the degree of mediation such that lower family resources would be associated with a stronger relationship between lower PSE and increased family distress. We predicted no significant differences after controlling for autism symptom severity and intellectual ability.

Methods: Participants included (98) families of children with ASD between the ages of 3 and 13 who were recruited as part of a larger study of improving dental care. Families exhibited racial (45% Non-Caucasian) and ethnic (41% Hispanic) diversity, and all were underserved as defined by Medicaid-eligibility. Children completed the Autism Diagnostic Observation Schedule–2nd Edition (ADOS-2) and Stanford-Binet–5th Edition, abbreviated battery (ABIQ). Parents completed questionnaire ratings of PSE, Family Resources, Family Distress, and Child EBP. We used the PROCESS macro (Hayes, 2018) to assess for the degree of moderated mediation of the hypothesized model for both EBP-E and EBP-I (see Fig. 1).

Results: All associations were in the hypothesized directions. Both EBP-E and EBP-I models were significant and accounted for 58% and 44% of the variance, respectively. There was a significant direct effect of EBP-E on parent stress (β=.48, p<.001) and PSE mediated this relationship. The index of moderated mediation was significant (β = -.07, CI = -.14 – -.008) indicating that fewer resources was associated with greater mediation by PSE. Results for EBP-I were similar, albeit not as pronounced, as hypothesized (see Fig. 1). Results were unchanged after controlling for autism symptom severity and intellectual ability.

Conclusions: Our data suggest that EBP increase parent stress through a mechanism of decreased PSE, particularly when resources are limited. Increasing parents' sense of self-efficacy, especially in underserved populations, may be a critical focus of interventions to decrease stress associated with emotional and behavioral problems in children with ASD. These results highlight the need to support families with limited resources including providing parents with tailored interventions and novel skills that can target specific areas of concern that they may not otherwise be able to address on their own.

196 **172.196** Monitoring Electronic Communication of Autism Support Teams through Hover Reporting

C. Friedman[1], *E. McGhee Hassrick*[1], *S. F. Vejnoska*[2], *A. C. Stahmer*[3], *D. S. Mandell*[4], *P. Mundy*[5] *and C. Kasari*[6], *(1)Drexel University A.J. Drexel Autism Institute, Philadelphia, PA, (2)University of California, Davis, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, University of California at Davis MIND Institute, Sacramento, CA, (4)Center for Mental Health, University of Pennsylvania, Philadelphia, PA, (5)University of California at Davis, Sacramento, CA, (6)University of California, Los Angeles, Los Angeles, CA*

Background: A few online tools to facilitate communication and resource sharing among treatment and education team members working with children with autism have been developed. To date, no studies have investigated how these interfaces affect collaboration among users. There are no standard ways of measuring team interaction on digital interfaces. Rigorous measurement of these interactions will provide new knowledge about the impact that digital interfaces have on care coordination and outcomes. We developed, using R programming, a method to map digital social networks as a promising approach for studying team dynamics on digital interfaces for individuals with autism.

Objectives: To demonstrate how networks of communication and resource sharing can be inferred from measurements of electronic activity of team members, and how reports about that communication can be built to support team interactions.

Methods: As part of the pilot of a larger, multi-site HRSA study, we asked autism support teams to use a social networking application designed to facilitate communication between teachers and parents. We asked teams to use the tool during the implementation of two interventions: 1) a school transition support intervention implemented before, during, and after the child's transition between schools and 2) diagnosis to treatment intervention, implemented post diagnosis for families without services. Data was collected from the application and then, using R, transformed to describe activity and communication on each of the teams. These variables were then built into reports delivered to study coordinators.

Results: By using the application, members of the support teams were able to create and share calendar events, links, documents, pictures, and resources that work for the child. We experienced some challenges getting the data out of the application but once we did, the data provided a clear picture of real time, actual communication of teams. Using R, data from these teams were used to build hover reports, describing communication and activity of those teams. These reports were then given to site administrators to help them understand what team members at

their sites were doing. For the pilot, we successfully extracted the data from the app and computed average counts of different types of interaction (e.g. posting a link to the team), as well as the average number of roles present on each team.

Conclusions: Online tools present an opportunity for teams providing support to children with autism spectrum disorder to communicate and share resources and knowledge. Researchers and other entities can hover over communication in these online tools to measure actual collaboration within these teams to both measure them and to provide feedback that can better focus or guide future intervention.

197 **172.197** Parent Coaching of Music Interventions for Children with ASD: A Limited-Efficacy Study

***E. Hernández Ruiz**, School of Music, Arizona State University, Tempe, AZ*

Background: *Parent-mediated interventions* are specific interventions where parents collaborate in goal setting and implement evidence-based strategies with their children with disabilities (Steiner, Koegel, Koegle, & Ence, 2012; Zwaigenbaum et al, 2015). These models have responded to the need of early intervention services, especially in areas where professional services are scarce (Oono, Honey, & Mcconachie, 2013). Concurrently, *parent coaching* is the professional service provided to train parents in those strategies (Steiner et al, 2012). Parent coaching is currently researched as a very cost-effective and useful strategy in the ASD field (Oono et al, 2013). In music therapy, parent participation studies are emerging in the research literature, particularly in the last 5 years (2012-2017). However, parent-mediated interventions and their coaching are very limited (Blind Review, 2018a). For this study, a parent coaching model based on the Parent-Early Start Denver Model was developed (Rogers et al., 2012). The theoretical framework conceptualizes music as a mediator of parent coaching through optimization of psychophysiological arousal of both child and parent, and through synchronization of their social communication (Blind Review, 2018b). Such optimization would increase parental responsiveness, and child attention and motivation (Baker et al, 2015; Feldman et al., 2012; Trainor & Cirelli, 2015).
Objectives: The purpose of this exploratory study was to test the limited-efficacy of parent coaching of music interventions on parental responsiveness and child communicative behaviors.

Methods: An alternating treatments design for three parent-child dyads was implemented. Parents received ten 1-hour coaching sessions based on the Parent-ESDM manual (Rogers & Vismara, 2015). Music and non-music conditions were offered in each session, counterbalancing to avoid order effects. Two trained observers coded parental and child behaviors in three baseline and ten treatment sessions.

Results: Only one parent-child dyad completed the treatment and was analyzed. Behavioral video analysis of parental verbal and nonverbal responsiveness, child joint attention and verbal behaviors, and parent and therapist fidelity provided quantitative data. A semi-structured follow-up interview with the parent addressed concerns, preferences, and suggestions for improvement. Parental verbal responsiveness seemed lower during the music condition, but non-verbal responsiveness increased notably during the music condition. Importantly, parental responses changed from directive instructions to responsive comments to child communication, but this fact was not reflected in quantitative data. Parent fidelity was achieved in the 6th session. As theorized, parental fatigue due to personal circumstances impacted results in the last two sessions. Child receptive joint attention increased in the music condition only, and initiating joint attention was higher in most sessions during the music condition. Parental comfort with the music did not seem ideal with the brief time allotted to training despite familiarity with the music used.

Conclusions: Parent coaching of music interventions to enhance social communication of preschoolers with ASD seems feasible and potentially efficacious. Further research should investigate other approaches to teach the music, alternative schedules, and more precise measures of parental responsiveness, such as a ratio of directive vs. responsive parental communication.

The present manuscript is part of the author's dissertation presented in partial fulfillment of a PhD degree.

198 **172.198** Parent Education and Communal Experience (PEaCE): Results from Self-Report Questionnaires

***J. Hai**[1], S. J. Cohen[2], A. Krasno[2] and T. W. Vernon[2], (1)Education, UC Santa Barbara, Santa Barbara, CA, (2)University of California Santa Barbara, Santa Barbara, CA*

Background:

Parents of children with Autism Spectrum Disorder (ASD) report greater parenting stress, marital distress, and mental health symptomatology than parents of typically developing children, as well as parents of children with other types of disabilities. Social support, parenting self-efficacy, and coping styles moderate the association between autism and parenting stress. Parent support groups have been shown to raise awareness, decrease stress, and increase empowerment among participants. Little research exists on the mental health outcomes of support groups for parents of children with ASD.

Objectives:

The present study focused on determining the impact of a Parent Education and Communal Experience group on the mental health and life satisfaction of parents of children with ASD.

Methods:

Participants: 34 Parents, four consecutive groups

19 biological mothers, 13 biological fathers, one adoptive mother, and one step-father

19 Caucasian, 3 Asian/Pacific Islander, 6 Hispanic/Latinx, 5 Middle Eastern

Children ages 2-17 with an ASD diagnosis

Design:

Quasi-experimental, pre-post, descriptive study. To determine the acceptability and utility of a 7-week education and support group for parents of children with ASD. Parents completed self-report measures of parenting stress, anxiety, depression, life satisfaction, and empowerment.

Overview of PEaCE program:

Seven sessions, each lasting 1.5 hours, offered once per week

Week 1: Introductions

Week 2: ASD Psycho-Education

Week 3: Community Resources
Week 4: IEP/504, Parents' rights
Week 5: Self-Care, Coping Skills
Week 6: Date Night / Self-Care Night
(respite care provided, but no group meeting)
Week 7: Wrap-up
Results:
Preliminary results show paired samples T-Tests revealed a significant increase in the Service System subscale of the Family Empowerment Scale, and trends for increases on the Family and Community/ Political subscales. Analyses also revealed trends for decreased pessimism as measured by the Questionnaire on Resources and Stress, as well as a trend for increased Satisfaction with Life
after participation in the Parent Education and Support Group. Final results will be completed by early March.
Conclusions:
Despite the brief nature of this program and very small sample size, trends in the parenting stress, family empowerment, and life satisfaction measures were promising and support the utility of this parenting education and support program. The researchers intend to conduct a randomized control trial, and may consider extending the length of the program. Additionally, parents who have participated in these groups frequently request ongoing support group meetings. Therefore we would like to offer ongoing support to parents who have completed this initial program. It may also be of interest to collect qualitative data from future participants to better understand the impact of participation in this group.

199 **172.199** Parent Understanding of EEG Study Procedures for Culturally and Linguistically Diverse Children with ASD: Impact of a Social Story

***A. Losh**, L. A. Alba, K. K. Stavropoulos and J. Blacher, Graduate School of Education, University of California Riverside, Riverside, CA*

Background: The successful inclusion of children with autism spectrum disorder (ASD) in neuroimaging research poses unique challenges due to associated behavioral and communication deficits [1-3]. Children from linguistically and culturally diverse backgrounds face additional barriers to participation, one of which may be parent understanding of research procedures, a critical aspect of informed consent and assent processes [4-10]. Although limited, some research supports multimedia approaches to improving parent and child understanding of study participation [11]. Here, we assessed the effectiveness of social stories, visual aids frequently employed to support learning and understanding for children with ASD [12-14], for improving parent understanding of EEG procedures for culturally and linguistically inclusive research targeting children with ASD.
Objectives: The research questions are as follows:

1. Do parents have a better understanding of EEG study procedures after viewing a social story than after reading a traditional explanation in text format?
2. Does the social story impact parent understanding differently for English and Spanish speakers?

Methods: Participants were 83 English- or Spanish-speaking parents of children with ASD (see Table 1) who completed an anonymous online survey. Participants were randomly assigned to either (a) social story condition (photographs of a child volunteer completing the EEG study procedures accompanied by short text explanations) or (b) written condition (written explanation of study procedures intended to mirror what would typically be provided verbally and/or in writing during consent). Parents' measured understanding (two multiple choice questions about study procedures) and *perceived* understanding ("After what you just read/saw, did it increase or decrease your understanding of brain research?") were then assessed.

Results: Independent samples T-Tests revealed significant differences between groups in both measured understanding ($p < .001$) and perceived understanding ($p = .024$). A 2 (condition) x 2 (language) ANOVA revealed a significant interaction between condition and language ($p < .001$) for *perceived* understanding, but no significant interaction ($p = .220$) between condition and language for measured understanding (see Table 2). Findings suggest that only Spanish speakers perceived their understanding to be better in the social story condition versus the control condition. However, both language groups' *measured* understanding was better in the social story condition.

Conclusions: Both English- and Spanish-speaking parents of children with ASD who saw a social story demonstrated better understanding of the EEG study procedures than parents who read a written explanation. Further, Spanish-speaking parents' perception of their understanding was significantly higher in the social story condition. These results have implications for the informed consent process and recruitment, suggesting that social stories may be a feasible, cost-effective method for promoting parent understanding of child EEG research study procedures across culturally and linguistically diverse populations. If parents have a better understanding of children's neuroimaging studies, they may feel more comfortable participating, asking questions, and answering their child's questions, which could result in both parents and children having a more positive, successful experience with neuroimaging research studies.

200 **172.200** Parent-Child Interaction in Families of Children with Autism: Analysis across Mealtime and Play Contexts

***B. St John**, S. Kant and K. K. Ausderau, University of Wisconsin-Madison, Madison, WI*

Background: Children with autism spectrum disorder (ASD) often display behaviors such as food selectivity, mealtime rigidity, food refusal, and disruptive mealtime behaviors that can significantly disrupt family mealtime. These behaviors and the ways in which caregivers respond to them have been shown to greatly influence the quality of the parent-child interaction and the overall mealtime experience for families. The playtime experience is also influenced by symptoms of ASD. Specifically, children with ASD are less likely to participate in pretend play and demonstrate decreased social engagement during play. As dyadic interaction is a central component to playtime and mealtime experiences for young children, it is important to examine the impact of these contexts on the dyad and on each individual.
Objectives: The purpose of this study was to compare the differences of parent-child interaction during the mealtime and playtime contexts.

Methods: A repeated measures design was used to identify and compare the characteristics of the parent-child interaction in parent-child dyads across two contexts: playtime and mealtime. Seventeen children with ASD ages 2-7 years participated in a playtime and mealtime observation using preferred food with their primary caregiver. The interactions were video recorded and coded using the Parent-Child Early Relational Assessment. The Parent-Child Early Relational Assessment is designed to measure quality of affect and behavior during a five-minute face-to-face parent-child interaction. The parent, child, dyad, and total scores were compared across playtime and mealtime contexts using related samples t-tests.

Results: Parent and dyad scores were significantly higher ($p<.05$) in the playtime context compared to mealtime with a large effect size, indicating more positive interactions during playtime and more negative interactions during mealtime. Child scores were not significantly different across contexts.

Conclusions: Children with ASD display consistent behaviors across the playtime and mealtime contexts. However, parents displayed significantly more positive affect and behavior during playtime as compared to more negative affect and behavior during the mealtime context. This difference in parent scores suggests that context influences parent affect and behavior, thereby impacting their overall interaction with their child. The majority of previous research and interventions has focused on the behavior of children with ASD during mealtime, however our results suggest that the parents' behavior and affect also contributes to the difficult mealtime experience. Interventions focused on mealtime for children with ASD should include the parent as well as the child, as context influences this dyadic interaction and mealtime context. When designing interventions focusing on improving the mealtime experience for children with ASD, providing parent support and strategies are important methods to improve the overall family experience and potentially child eating behaviors.

201 **172.201** Parent-Child Interactions in Families of Preadolescent Children with Autism Spectrum Disorder

J. B. McCauley[1,2], *P. Mundy*[3] *and M. Solomon*[4], *(1)UC Davis MIND Institute, Sacramento, CA, (2)UCLA Semel Institute, Los Angeles, CA, (3)University of California at Davis, Sacramento, CA, (4)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA*

Background: Relationships between children with autism spectrum disorder (ASD) and their parents constitute fundamental sources of support for children as they transition into adolescence, yet little attention has been devoted to characterizing these relationships or their associations with child outcomes.

Objectives: The aims of the current study are to 1) characterize parent-child interactions in families of children with ASD using two well-validated, observer-based, family research measures to establish whether the relationships of parents and children with ASD differ from those found in families of typically developing (TD) children, 2) test within-dyad associations of family interaction characteristics, and 3) examine the associations between family interaction characteristics (child and parent positivity; parent control) with child characteristics, including temperament, mental health problems, and autism symptoms.

Methods: Families of children with ASD (n = 21) and families of typically developing children (n = 21), matched on age and intellectual abilities were recruited into the current study. Children received diagnostic and intellectual assessments. Parents were administered the Five Minute Speech Sample (Magaña et al., 1986) to measure aspects of the family environment and reported on their child's mental health problems via the Child Behavior Checklist (Achenbach & Rescorla, 2001) and regulation via the Temperament in Middle Childhood Questionnaire (Simonds & Rothbart, 2005). The child and one parent were observed engaging in a standardized discussion task. These interactions were coded for the levels of parent and child positivity (e.g., behaviors that served to show support, warmth, and responsiveness) and control (e.g., behaviors that served to control, influence, or dominate the opinions, actions, or points of view of others during the interactions) with the Iowa Family Rating Scales (Melby et al., 1998). Group differences were tested using multilevel modeling, and Spearman's correlations were used to test associations between family interaction characteristics and child functioning.

Results: Results showed no diagnostic group differences in the observed levels of positivity exhibited by parents, but significantly less positivity in children with ASD compared to TD children (See Table 1). In addition, parents of children with ASD had higher levels of observed control compared to parents of TD children. Child ADHD symptoms were negatively associated with levels of positivity in parents $rs(18) = -.45$, $p = .04$) and children ($rs(18) = -.47$, $p = .04$) in the ASD group. Also in the ASD group, child positivity was positively associated with child effortful control ($rs(18) = .52$, $p = .02$). Finally, levels of control in parents were positively associated with child anxiety in the ASD group ($rs(18) = .49$, $p = .03$).

Conclusions: Findings highlight both the positive characteristics of parents of children with ASD, and the potential impact of family processes in the development of comorbid mental health problems for youth with ASD. Parent-child relationships may be an important cornerstone of positive development during the transition to adolescence, especially in consideration that peer relationships become increasingly complex and difficult to navigate for individuals with ASD in middle-school and high-school.

202 **172.202** Parenting Needs of Chinese Parents of Children with Autism in America, Macau, and Taiwan

H. M. Chiang*, University of Macau, Taipa, Macao*

Background: Many studies have focused on parenting stress in parents of children with autism spectrum disorder (ASD) and high parenting stress is commonly reported. However, limited studies have focused on parenting needs of parents of children with ASD and few studies have focused on Chinese parents of children with ASD.

Objectives: This study was conducted to understand (a) the needs of Chinese parents of children with ASD in the United States, Macau, and Taiwan in the support services to help them decrease their parenting stress and (b) the differences in parenting needs between Chinese-American parents and non-American Chines parents.

Methods: A parenting needs survey was developed for the purpose of this study. This survey included questions about parents' characteristics, children's characteristics, and parenting needs. A total of 94 parents of children with ASD participated in this study, including 57 Chinese-American parents and 37 Non-American Chinese parents (35 Macanese and 2 Taiwanese). The mean age of their children with ASD is 9 years.

Results: 85 % of the parents indicated that they needed support services to help them decrease their parenting stress and these parents preferred attending a parent support group (42%) to receive the services over visiting a clinical professional (32%) or asking help from family and friends (27%). The non-American Chinese parents were more likely than the Chinese-American parents in getting the support services they need

through attending a parent support group (X^2 (1, N = 94) = 6.86, p < .01). The parents who needed support services showed significantly lower quality of life than those who did not (t(93) = 2.05, p < .05). 89% of the parents reported needing support services to help them improve their parenting skills. The top one support service they need is training to teach them how to teach their child/children with ASD. The top one skill that these parents wanted to learn is to manage their child's/children's behaviors. Chinese-American parents were more likely to need support services to improve their parenting skills (X^2 (1, N = 94) = 4.34, p < .05) and training for teaching their child/children with ASD than non-American Chinese parents (X^2 (1, N = 94) = 5.84, p < .05). 62 % of the parents needed financial support to help them raise their child/children with ASD. But, the relation between financial support and country (America vs. Non-America) was not significant. Not every parent reported that their child/children with ASD has/have ever received the supports and benefits from the government where they reside. Only 72% of the parents reported their child/children with ASD did. 79% of the parents reported that their child/children with ASD have afterschool program needs. The top one skill that these parents wanted their child/children to learn is social and communication skills. The relation between afterschool program needs and country was not significant.

Conclusions: Parents of children with ASD need support services to help them decrease their parenting stress. The needs of Chinese-American parents may be different from those of non-American Chinese parents.

203 **172.203** Parents' Attitudes Toward the Process of Attaining a Diagnosis of Autism Spectrum Disorder for Their Children

C. Montiel-Nava[1], *Z. Gonzalez*[2] *and I. Vargas*[3], *(1)Psychological Sciences, University of Texas Rio Grande Valley, Edinburg, TX, (2)Universidad del Zulia, Maracaibo, Venezuela (Bolivarian Republic of), (3)Psychology, Universidad Rafael Urdaneta, Maracaibo, Venezuela (Bolivarian Republic of)*

Background: Research does not have enough data about the parent's attitudes and responses to having a child diagnosed with ASD. This knowledge is crucial in the design and development of public policies for screening, diagnosis and general access to services.
Objectives: Explore parents' attitudes toward the process of attaining a diagnosis of autism spectrum disorder for their children in a sample of Venezuelan caregivers.

Methods: Parents were recruited via key informants at special schools, child development centers, and health clinics. 20 Venezuelan parents of children between 5 and 10 years of age with a diagnosis of ASD were interviewed. The instrument was a semi-structured qualitative interview which was validated by experts. Sessions were audio recorded and transcribed. Two researchers coded transcripts, and data were analyzed using thematic analysis.

Results: Three central themes were constructed following data analysis: 1.) parents' thoughts about diagnostic and the professionals involved in the diagnosis, 2.) parents' behaviors related to diagnostic, family and self, and 3.) parents' emotions about diagnostic and self. Parents expressed ambivalent attitudes with both positive and negative thoughts, emotions and behaviors related to acceptance, decision making, searching professional help for the mental health of their children. Concerns about the costs of services, availability of services, the organization of time, and the future of their child were common expressions from parents. Reports about acceptance and support from extended family were also frequent in this sample

Conclusions: Results contribute to understanding how parents' attitudes toward the process of attaining a diagnosis of ASD for their children are related to the availability of services, financial burden, and support from family. Their lived experiences about knowing of their child's autism, identify it as a defeat, uncertain and something unfortunate. These results have important implications for future work with Hispanic families and supporting them in the process of identification and diagnosis of ASD of one of their members.

204 **172.204** Participant Characteristics Predicting Response to New Research Opportunities Offered By SPARK Research Match

C. W. Lehman[1], *J. K. Law*[2], *A. R. Marvin*[2], *J. Toroney*[2], *B. Vernoia*[1], *P. Feliciano*[1] *and W. K. Chung*[1,3], *(1)Simons Foundation, New York, NY, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (3)Pediatrics, Columbia University, New York, NY*

Background: Simons Foundation Powering Autism Research for Knowledge (SPARK) is a collaborative, online study that enrolls individuals with a professional diagnosis of autism spectrum disorder (ASD) and their family members into an autism research cohort. One of SPARK's central features is "research match" (RM), a research platform that enables researchers to recruit, cost-free, potential study participants from the SPARK cohort. Participants are notified about studies by email and can indicate interest in the study by clicking a weblink. To date, 20+ studies have used RM and 20,000+ SPARK participants have responded to at least one study invitation. It is unknown how individual participant characteristics, such as demographics and prior engagement in SPARK, impact these response rates.
Objectives: Evaluate response rates by demographic and enrollment factors

Methods: Eleven studies (5 online and 6 in-clinic) that used RM during 06/2017-11/2018 were selected for analysis. All studies recruited children and/or dependent-adults with ASD. Participants who received at least one invitation for the studies were included in the sample. For families invited to more than one study, each study was considered as a separate opportunity to respond. Participants who clicked on either the "interested" or "not interested" weblink were classified as responders, while participants who selected neither were non-responders. Demographic characteristics and other SPARK-related factors were indexed to the dependent with ASD.

Results:

- There were 34,823 recruitment opportunities for the eleven selected studies
- Online studies: 33,477 recruitment opportunities; 16,102 (48.1%) response rate
- In-clinic studies: 1,346 recruitment opportunities; 423 (31.4%) response rate
- Saliva kit return and previous SPARK study protocol survey completion predicted response for both study types
- Participants were more likely to respond to either type of study if their time since enrollment was <9 months
- Clinical site affiliation was associated with higher response to in-clinic studies; however, non-affiliated participants were more likely to respond to online studies
- Age of the child with ASD was not associated with response for in-clinic studies, but parents of children <10 years were more likely to respond to online research opportunities
- No difference in response rate for child/dependent-adult gender

- See Table 1 for participant characteristics and response rates, and Table 2 for results of multiple logistic regressions

Conclusions: SPARK research match has been successful in engaging a range of SPARK participants in new research studies. Certain participant characteristics predict response to invitations about new research in general, such as previous engagement with SPARK (e.g. saliva kit return). These participants have already demonstrated willingness to engage with SPARK after registration. We also identified differences between online and in-clinic studies. Clinical site-affiliated-participants may be more likely to respond to in-clinic studies due to the pre-existing relationship with the local site. Non-affiliated participants' sole method of interaction with SPARK is online, and may indicate a general preference for how to participate in research. Participants with ASD of all ages may be seeking direct benefit from in-clinic studies, while parents of younger children may be more willing to participate in a broader range of autism research due to recency of diagnosis.

205 **172.205** Participation in Mainstream Versus Disability-Specific Community Programs for Children and Youth with Autism Spectrum Disorder

S. Thompson-Hodgetts[1]*, C. Dubland*[2]*, A. McKillop*[1]*, N. Mack-Peterson*[1] *and D. Visscher*[2]*, (1)University of Alberta, Edmonton, AB, Canada, (2)The King's University, Edmonton, AB, Canada*

Background: The World Health Organization has identified social inclusion and participation as a vital part of health, development and quality of life. In line with a philosophy of social inclusion and participation, the ratification of the United Nations Convention on the Rights of Persons with Disabilities obligates countries to take action to ensure that "community services and facilities [...] are available on an equal basis to persons with disabilities" (Article 19). However, research shows that children with autism spectrum disorder (ASD) participate in significantly fewer mainstream (inclusive) community-based programs than their neuro-typical peers.

Objectives: This study aims to (1) identify factors associated with a child's participation in community-based programs, and (2) explore parents' reasons for choosing mainstream versus disability-specific community programs.

Methods: Parents of children with ASD from Canada and the United States completed an online survey hosted through REDCap. The survey included child and family demographics (e.g., child age, communication ability, presence of disruptive behaviours, size of community, identified culture, etc.), the number and types of mainstream community programs in which the child with ASD participated (past and present), what information was provided about a child's ASD diagnosis and by whom, and open-ended questions, including, "What led you to put your child in a mainstream community program(s) versus a disability-specific program(s)?". Multivariable regression analyses will be conducted to identify child, family and/or program factors associated with the number and types of mainstream community programs in which a child participates. Qualitative responses to the open-ended question will be thematically analyzed.

Results: To date, n=82 parents, with n=92 children with ASD (mean = 8.97 years, range 2-20 years) have completed the survey (survey closes December 31, 2018). Children participated in an average of 1.22 mainstream community programs. Twenty-eight (31%) of children with ASD had never participated in mainstream community programs, whereas 22 (24%) participated in five or more.

Conclusions: Research on inclusion and participation in community programs for children with ASD is limited. Findings from this study can start to fill this gap by increasing our understanding of the types of community programs in which children with ASD participate, and factors associated with, and parents' reasons for choosing, mainstream versus specialized community programs for children with ASD.

206 **172.206** Participatory Action Research Project on Family Needs: Experiences of Professionals in Providing Support Services to Zambian Parents of Children with Autism.

J. Nyoni*, Education, Lusaka, Zambia*

Background: The role of professionals in the attainment of sustainable development of quality health for families of children with Autism Spectrum Disorders (ASD) is critical mainly in the Lower - and Middle-income nations where ASD is hardly known. Parents of children with ASD experience higher stress levels to care for these children. The stress levels are further compounded when there is inadequate support services provision from professionals. There is limited publication in Zambia on the barriers and challenges that professionals face in providing support services to these families.

Objectives: The aim of the study was to determine professional experiences in providing formal support services currently available to families of children (ASD) in Zambia and explore how the use of advocacy, professional-parent collaboration could be used to empower families, meet their support needs through Participatory Action Research (PAR) approach.

Methods:

A qualitative, Participatory Action Research (PAR) design was employed to generate data. Purposeful sampling was used to recruit 21 professionals from the Lusaka Province of Zambia under the Ministries of Health, General Education, Community Development and Social Welfare, Zambia Agency for Persons with Disabilities and Teaching Council of Zambia. Participants had more than three years working experience with ASD families. They were drawn from both the private and public sectors and rural and urban settings. Semi-structured interviews, document analysis conference proceedings, participant observations and field notes were employed to collect data. Data was analysed using thematic analysis and Dedoose (ongoing).

Results: Preliminary results indicate that professionals face barriers to provide services which included; lack of standardised and cultural friendly instruments for diagnosis. Lack of a National Policy Framework that support autism services. Some professionals faced discrimination fellow workers at working places. There was pressure from parents for immediate results about child's condition. The existing professional groups in line Ministries are uncoordinated, fragmented and operate through social media as opposed to Continuous Professional Development meetings. This has led to internal and external conflicts amongst the professionals on the type of treatment and intervention to provide to families

Conclusions:

There is a need to establish a national policy on ASD. Further training is needed amongst professionals to avoid wrong diagnosis and wrong labelling of the child. Currently, Zambia has less than 10 occupation therapists and less than 50 speech therapists against 17million people. Professionals that have set up private institutions such as hospitals, schools and assessment centres need government financial support to

reduce the costs of services provision to families. Public employees needs an extra duty stipend as a motivation.

207 **172.207** Pathologizing Among Romantic Partners of Autistics Who Use Online Support Groups: An Emergent Theory

***L. Lewis**, University of Vermont, Burlington, VT*

Background:

As many as 25% of autistic adults report they have been in intimate relationships, and few studies have explored these relationships from the perspectives of neurotypical (NT) partners. Studies that exist have indicated patterns of miscommunication, unmet need, and abusive behaviors, and NT partners are increasingly using peer-mediated online support groups to manage these challenges. Anecdotal evidence and informal review of public online forums suggest that NT partners using online support groups have symptoms of depression, anxiety, and dissatisfaction in their relationships, warranting further investigation.

Objectives:

The purpose of this study was to capture a theory that reflects the basic social experience of partners of autistics who use online support groups and the basic social process they use to navigate that experience.

Methods:

A classic Glasieran grounded theory was used to allow a theory to emerge from data. Participants were recruited via online support groups and participated in asynchronous online interviews and telephone interviews. Theoretical sampling was used and interview questions evolved throughout the study based on emergent findings. Data were concurrently collected and analyzed using constant comparative analysis. The sample included 162 NT individuals who used online support groups and believed their partners had autism.

Results:

A basic social problem was identified as an imbalance in the need for emotional intimacy between NT and autistic partners. NTs attempted to resolve this problem through pathologizing, or attributing negative aspects of their relationships to autism rather than to their partners as individuals. The degree of pathologizing resulted in five behavioral profiles of the NT partner that created relationship contexts. In order of increasing pathologizing, contexts included: mutual partnership, in which partners were viewed as equals and NTs showed respect and gratitude for autistic partners' contributions; companionship, where NTs viewed autistic partners positively but believed symptoms of autism prevented them from forming a deep connection; caregiving, in which NTs viewed autistic partners as dependent and compared their relationships to parent-child dyads; detachment, in which NTs believed their relationships were broken beyond repair due to the effects of autism and viewed giving up as a means of self-protection; and abusive context, where NT partners made negative generalizations about autism beyond their relationships and felt compelled to warn others about the perceived dangers of neuromixed relationships.

Conclusions:

While some partners used pathologizing as a coping mechanism to maintain a positive view of their partners, others used it to relieve themselves of internal pressure to invest in their relationships or to justify detachment or abuse towards autistic partners. This study highlights the need to explore risks versus benefits of unmoderated online support groups, as pathologizing is common in these groups and may perpetuate negative views of autism that create toxicity within relationships. Professionals must monitor for patterns of abuse of the autistic partner and assist both partners in creating balance in their needs for emotional intimacy while minimizing pathologizing. Future studies should explore the presence of pathologizing in neuromixed relationships outside of support group users and in couples affected by conditions other than autism.

208 **172.208** Performance of the Olson Circumplex Family Model in Families with a Child with ASD

***G. M. Tiede**[1] and K. M. Walton[2], (1)Psychology, The Ohio State University, Columbus, OH, (2)Nisonger Center, The Ohio State University, Columbus, OH*

Background:

For families of typically developing children, extremes of family cohesion (enmeshed and disengaged) and flexibility (rigid and chaotic) are associated with negative outcomes (Olson 2011). Although, some work has suggested that this may not be the case for families of children with autism (Altiere & von Kluge 2008). Specifically, regimented daily routines (increased rigidity) and highly involved caregivers (increased enmeshment) may be associated with positive outcomes (Altiere & von Kluge 2008).

Objectives:

1. Examine if families with children with autism reported more enmeshed and rigid family dynamics relative to families with typically developing children.
2. Examine if the relationship between reported enmeshment and rigidity was equally predictive of family outcomes for families with typically developing children and families with children with autism

Methods:

This data comes from a larger research effort examining leisure satisfaction and participation in families with and without a child with autism. As a part of the present analysis, 233 parents (111 with a child with autism, 122 with a typically developing child) responded to an online Qualtrics survey providing data on the following variables: Family Adaptability and Cohesion Scales (FACES-IV)(Olson, Gorall, &Tiesel 2004), The Depression-Short Form from the Neuro-QOL Item Bank v1.0 (Cella et al. 2012), and Neuro-QOL Item Bank v1.0 – Positive Affect and Well-Being – Short Form (Cella et al. 2012). Regression-based moderation analyses were used to examine if group (parent with or without a child with ASD) moderated the relationships between reported enmeshment and rigidity, and outcomes (reported happiness and depression).

Results:

Parents of children with ASD reported more enmeshment (t[233]=4.2, p<.01), and comparable rigidity (t[233]=1.0, p=.30) relative to families with typically developing children. Results from a moderation analysis found that parent reported family rigidity did not perform differently for families with typically developing children versus children with ASD for either parent reported symptoms of depression or positive affect and

well-being. However, family enmeshment performed differently in families with and without a child with ASD ($F[1,231]=7.1$, $p<.01$). Increased enmeshment was associated with decreased parental happiness in families with typically developing children ($\beta=-.31$, $p<.01$). For these families, for every one SD increase in reported enmeshment, there was a corresponding .31 SD reduction in reported positive affect and well-being. Contrastingly, increased enmeshment did not affect parent reported happiness ($\beta=.04$, $p=.63$) in families with a child with ASD.

Conclusions:

It may be that high levels of enmeshment are necessary for supporting a child with ASD (e.g., increased time spent in attendance and coordination of therapeutic appointments, learning child's specific likes and dislikes, time spent supporting child during daily life) and are not signs of dysfunction in this population. This finding dovetails with previous work, and suggests that ideal family dynamics may be different for typically developing children versus families with a child with ASD.

209 **172.209** Protecting Myself and My Child: A Grounded Theory of Parents' Journey through Diagnostic Feedback for Autism

E. Drumm[1]*, D. B. Nicholas*[2] *and J. A. Brian*[3]*, (1)University of Toronto, Toronto, ON, Canada, (2)University of Calgary, Edmonton, AB, Canada, (3)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

Background: The diagnostic feedback meeting represents the first time that parents hear the news that their child has autism. Given the essentially unanimous agreement around the significance of this event, surprisingly little of substance has been said about it in the clinical and empirical literature.

Objectives: In this project, we developed a social-psychological conceptualization of parents' journey through this pivotal period. This conceptualization addressed three interrelated questions: How are parents responding? Why are they responding this way? When do they respond differently?

Methods: Our work was guided by the methodology of grounded theory and the onto-epistemological lens of critical realism. We generated data from in-depth interviews with 27 parents of children (ages 1-10) who were recently diagnosed with autism at a clinic in Ontario, Canada.

Results: The central process, labelled *protecting myself and my child,* indicated that parents rapidly make meaning of, feel, think, and respond to the delivery of the diagnosis as signalling a hazard from which they must protect their family. Primary categories of action-interaction consisted of an *undercurrent of anticipating* in the lead-up to the feedback meeting, *sounding the alarm* when hearing the official pronouncement, followed by *swelling distress and uncertainty*. Depending on a complex interplay of conditions, parents dealt with their situation in three ways: *protective maneuvering, instrumental responding,* and/or *processing-oriented advancing,* which, in turn, affected their swell of distress and uncertainty.

Conclusions: These findings can help clinicians and service providers to think deeply about their role and how they can best use their expertise to facilitate parents' journey through what is, primarily, an emotional process.

210 **172.210** Public Health, School, and Recreational Barriers That Parents Have to Face in Rosario, Argentina

R. E. Mitre*, CND Rosario, Rosario, Argentina; Universidad Abierta Interamericana, Rosario, Argentina*

Background: Research in the field of Autism Spectrum Disorder (ASD) is not vast in Argentina, and among the available investigations, very few consider parents perspectives. However, during consultations it is very common to hear about the issues that caregivers have to struggle with. Some of the most common complaints are related to complications accessing public health services, difficulties with schools, and the pediatricians' responses when they first consulted about diagnostic concerns.

Objectives: To gather information about the barriers that parents of people with ASD have to face concerning public health, educational and recreational services. In addition, to identify the knowledge that pediatricians have regarding autism, and diagnostic tools.

Methods: Two exploratory studies were conducted in Rosario, Argentina. In the first one, 97 parents of people with ASD (ages between 22 and 56; 70.1% female, and 29.9% male) were consulted about the barriers they had to face regarding public health, schools, and leisure and recreational spaces. In the second one, 20 pediatricians (ages between 28 and 62; 85% male, and 15% female) were asked about the screening and diagnostic tools they know and/or they use in their practices, diagnostic criteria, causes, and characteristic symptoms of ASD.

Results: More than half of the parents had to go through some difficulties. Almost 60% stated that they had issues at some point: the main problem (over 50% of the cases) seems to be related to schools; the most significant findings after that were problems with hospitals and public health care centers (41.5%), issues with the public disability evaluation boards (22%), and conflicts at municipal recreational spaces (9.8%). Additionally, a low level of ASD-related-knowledge was found among pediatricians. Most of the consulted doctors (80%) were not familiar with the diagnostic criteria, and/or the screening and diagnostic assessments, and only 5% think an interconsultation is necessary in case of diagnostic suspicion.

Conclusions: As a first approach to the subject, it is possible to state that aside from the difficulties of raising a child with ASD, parents also have to overcome other barriers, including the lack of knowledge pediatricians have (that leads to wasting valuable time), and struggling with public health services and schools. Although the reaches of these studies are limited, and they should be replicated with more meaningful samples, the results allow us to consider the situation, and the need of public policies regarding autism.

211 **172.211** Qualitative Parent Outcomes of an Introductory Pivotal Response Treatment Parent Education Program for ASD

K. Oliver*, Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA*

Background: Families whose child has recently received a diagnosis of autism spectrum disorder (ASD) are a unique population in need of specialized support and guidance. These parents frequently experience feelings of stress, fear, and uncertainty, which are often related to concerns about how to address their child's social communication and behavioral needs. Further, parent goals and values are not often solicited and incorporated into early intervention programs. Pivotal Response Treatment (PRT) is a widely used evidence-based practice for ASD that parents are often taught to implement with their child. However, PRT education alone may not be enough to address the complex needs and multiple areas of concern these parents tend to report. Positive Behavior Support (PBS) is another gold standard for how to support families of children with ASD. What is not evident in the literature, however, is a clearly delineated process for how PRT parent education could be

implemented within the context of a PBS plan to address social communication and behavioral goals in a comprehensive way. Further, there is limited information on the outcomes and experiences of parents receiving these types of early intervention services.
Objectives: The aim of the current study was to provide an in-depth understanding of parent experiences participating in a brief PRT education program delivered within the context of an individualized PBS plan. The objective was to collect qualitative interview data to supplement, triangulate, and elaborate upon quantitative measures.

Methods: Four parents whose young child had recently received a diagnosis of ASD received 20 hours across five days of PRT education within the context of an individualized PBS program. Parents received instruction in PRT and specific evidence-based strategies for addressing their reported goals for themselves and their child. Parents completed semi-structured interviews following the completion of the program. Using open-coding thematic analysis, interview transcripts were coded to identify commons themes and patterns in responses.

Results: Five main themes emerged from the interviews: 1) increase in parent self-efficacy, 2) effectiveness of approaches, 3) ease of implementation, 4) reduction (but not amelioration) of stress, and 5) minimal changes to the program. Following the parent education program, all parents reported an increase in confidence and competence with interacting with their child, which was conceptualized as 'self-efficacy'. All parents reported that intervention strategies were effective and easy to implement. Parents reported reduced stress following the program but also reported concerns about future stressors, such as transitions in schooling. Further, parents reported minimal and superficial changes to the program.

Conclusions: The current study addresses an important issue in early intervention by providing a thorough examination of treatment outcomes for parents whose child has a recent ASD diagnosis. It appears that a short-term parent education program in PRT individualized to reflect parent goals and values can promote well-being for families. This study also provides detailed evidence that parents find this type of program to be helpful for improving their self-efficacy and empowering them to support their child.

212 **172.212** Developing a Participatory Mentorship Program for and with Autistic College Students: Project Reach@CSI

K. Gillespie-Lynch[1], *D. DeNigris*[2], *A. Riccio*[3], *N. Hadi*[4], *B. Kofner*[5], *A. Jordan*[6], *N. Tricarico*[7], *J. Delos Santos*[8], *M. Hossain*[9] *and S. K. Kapp*[10], *(1)Department of Psychology, College of Staten Island; CUNY Graduate Center, Brooklyn, NY, (2)Psychology & Counseling, Fairleigh Dickinson University, Madison, NJ, (3)Department of Psychology, The Graduate Center, City University of New York (CUNY), New York, NY, (4)College of Staten Island, Staten Island, NY, (5)CUNY, NY, NY, (6)CUNY, Staten Island, NY, (7)College of Staten Island, City University of New York, Staten Island, NY, (8)Hunter College, City University of New York, New York, NY, (9)Hunter College, CUNY, New York, NY, (10)University of Exeter, Exeter, United Kingdom*

Background: Autistic students are increasingly entering college, where they face difficulties self-advocating, self-regulating, developing social relationships, and managing time (Gelbar et al., 2014; Elias & White, 2017). Autistic students often have strengths they can use to overcome challenges, including systemizing skills, detail orientation, sincerity, and focus (Gobbo & Shmulsky, 2015). While autistic students are *less* likely to enroll in college than students with most other disabilities (Shattuck et al., 2017), they may be *more* likely to *persist* in college (Wei et al., 2013). However, very little remains known about factors that support their *success* in college. Supports for autistic college students are often neither evidence-based nor informed by their perspectives (Barnhill, 2016). Although promising reports about programs for autistic students have emerged (Kudder & Accardo, 2018), prior research, including our work examining earlier iterations of our program (Gillespie-Lynch et al., 2017), has *not* examined academic improvements associated with programming or provided sufficient opportunities for autistic students to develop self-advocacy skills by guiding program development.
Objectives: Evaluate a *participatory* mentorship program in which neurodivergent students play leadership roles in developing, delivering, and evaluating programming.

Methods: Our program is designed for autistic students but open to other neurodiverse students. Programming is free for students who can consent to complete assessments (e.g., interviews, standardized assessments and writing activities) for gift cards, but are under no obligation to provide data to participate. Students choose to attend an hour per week of one-on-one mentorship, structured group meetings, or both (recommended). Although our goal since program inception in 2013 was for it to be participatory, becoming truly participatory took time. The current study focuses on data collected *after* our most recent program evaluation in Summer 2015 (Hotez et al., 2018). Thirteen students with disabilities (11 autistic) have become mentors thus far. In Fall 2016, we formed a participatory research group to guide assessment/curriculum development.

Results: Of the 46 students who signed consents since Fall 2015, 38 were autistic (the focus of analyses; 92% Male; 61% White; *M* NVIQ = 96; *M* SRS-A = 69.87). Two autistic students did not continue past pre-tests. Students averaged 20.4 years when joining REACH; 93% continued for a year or more. Group curriculum is selected/developed based on individual computerized needs assessments and group discussions at the beginning of each term (see Table 1 for student-identified needs). Analysis of GPA changes associated with joining REACH revealed that the GPA of students who had been in college before joining REACH improved from the semester before (*M*=2.80) to the semester they joined (*M* = 3.10; *p* = .02); students enrolled in REACH attained higher GPAs than college norms their first semester in REACH (*p* = .04). Qualitative analysis of interviews and weekly mentor logs highlight empowering aspects of our participatory model.

Conclusions: By collaborating with autistic students, we have developed increasingly socially valid and engaging programming; students have gained valuable skills as mentors, researchers, and speakers on campus and at local and international conferences. Programming for autistic college students should build from their strengths.

213 **172.213** Determining Impact of Fellowship Grants in Autism Research

A. Halladay[1,2], *A. Karpur*[3], *J. L. New*[3], *C. L. Gold-Casey*[1], *A. T. Singer*[1] *and T. W. Frazier*[4], *(1)Autism Science Foundation, New York, NY, (2)Rutgers University, Piscataway, NJ, (3)Autism Speaks, Princeton, NJ, (4)Autism Speaks, New York, NY*

Background:
Autism advocacy organizations have funded millions of dollars in pre- and post-doctoral fellowship programs that train emerging talents in autism science. Yet, there is little data on the short and long-term impact of these investments. Utilizing a logic-model framework two non-profit organizations separately examined the impact of their funding on a range of indicators relevant to scientific output, innovation, and career trajectory.

Objectives:

We conducted the first multi-year follow-up analysis of pre-doctoral and post-doctoral fellowship funding two autism research funding advocacy organizations to identify scientific and career impact of specific autism funding.

Methods:

Guided by a logic model approach to understanding impact of grant funding, the organizations implemented slightly different evaluation methodologies. Organization A tracked pre- and post-doctoral fellows and unfunded applicants outputs for a 4-year period and impact was measured through qualitative and quantitative metrics, and bibliometric analyses. Organization B assessed outcome of pre-doctoral fellowships for up to 9 years following funding. Both organizations utilized HRA reporter, powered by UberResearch's flagship offering 'Dimensions', to track bibliometric impact and altimetric data. Other resources like PubMed data base, as well as professional networking data such as LinkedIn, ResearchGate, telephone interviews and other queries were used to document career trajectories of the funded fellows. Multiple outcomes were assessed related to scientific productivity, impact, and career trajectory, including reporting of retention in autism research, collaborations, careers in science, as well as quantitative measures of productivity including number of publications, citation index, collaborators, altimetric scores and attainment of additional funding.

Results:

Both organizations showed a similar 80% retention in autism research from funded fellows. Organization A estimated the impact of its fellowship by comparing data for funded fellows to those of fellows that were rejected. The retention rate in autism research for fellows funded was 80% whereas only 30% of non-funded fellows. Most funded pre-doctoral fellows were pursuing post-doctoral studies. Post-doctoral fellows had higher number of publications compared to pre-doctoral fellows. Both funded and unfunded fellows showed similar numbers of publications and impact factors for those publications, indicating that success in autism research, not scientific endeavors in general, were improved by autism-specific funding. For Organization B, the funded fellows brought $4 in form of funding from federal, state, and non-profit funding for every $1 invested towards fellowship support. Further the publications from fellows had an average citation rate of 27 per paper with a relative citation ratio of 2.6.

Conclusions:

Advocacy organizations should continue to support early career investigators, as the return on investment is high and most fellows remain engaged in autism research with a high volume of quality output. This combined analysis provides objective evidence of the value of fellowships on retention in autism research, and further demonstrates the utility of different outputs in determining the effectiveness of fellowship mechanisms.

214 **172.214** "Our Relationship Has Matured": Improving Parental Relationships through Specialist Peer Mentoring for Autistic University Students

C. Thompson[1,2], *T. Falkmer*[1,2], *S. Bolte*[1,2,3] *and S. J. Girdler*[2,4], *(1)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, Australia, (3)Center for Neurodevelopmental Disorders (KIND), Center for Psychiatry Research, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (4)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Perth, Western Australia, Australia*

Background:

The lifelong nature of autism spectrum disorders has implications for autistic people and their families, with many parents continuing to support to their children well into adulthood. Transitioning to adult roles, such as that of a university student, can be challenging for both autistic young adults and their parents. Specialist peer mentoring (SPM) has been proposed as one approach, which may be effective in mitigating the challenges of transitioning to university for autistic young adults.

Objectives:

This study aimed to explore the experiences and perceptions of parents of autistic young adults who participated in a SPM designed to support the transition to university.

Methods:

A total of 13 semi-structured interviews (11 mothers and two fathers) were completed. Parents were discussing the experiences of 12 specialist peer mentored autistic university students (average age=21.2; SD=1.94; 2 female). The interviews were transcribed verbatim and analysed in three stages commencing with identification of meaning units, followed by thematic analysis and directed content analysis, which linked data to the International Classification of Functioning, Disability and Health comprehensive core set for autism spectrum disorder (ICF core set for ASD).

Results:

A total of 284 meaning units were identified from the data. Five inter-related themes emerged; *the mentoring relationship is a facilitator*, *developing skills for university*, *mentoring changes lives*, *mentoring is not a substitute for other supports* and *'university' is an emotional rollercoaster*. *The mentoring relationship is a facilitator* articulated the interaction within the mentor-mentee dyad, which served as the key mechanism supporting outcomes. *Developing skills for university* captured the emergence of autistic students study skills including improvements in planning and completing tasks. *Mentoring changes lives* described parents' experience of the SPM as a transformative intervention, which resulted in improvements in the parent-child relationship. While parents valued the SPM the theme, *Mentoring is not a substitute for other supports* captured parents view that mentoring did not solve everything. *University is an emotional rollercoaster* highlighted that for parents supporting their autistic young adults was a challenging and emotional journey.

The 284 meaning units were linked with Body Function (18%), Activity and Participation (43%), Environment (31%) and Personal Factors (6%) domains within the ICF core set for ASD (2% not coded).

Conclusions:

SPM was valued by parents who attributed their improving relationship with their autistic young adult to the intervention. Linking to the ICF core set for ASD revealed that from the parents' perspective the SPM program worked to target 'the fit' between participation in university and the environment for autistic young adults. This study highlights the importance of considering and developing intervention, which target aspects of the environment in improving the life outcome of autistic young adults.

215 **172.215** Reliability and Factor Structure of the Parent Effort Scale Home Version (PES-H)

B. Pfeiffer *and K. Bevans, Rehabilitation Sciences, Temple University, Philadelphia, PA*

Background: The ability to participate in common daily activities can have a profound impact on the development of young children. Participation occurs most extensively within the context of the family. Both the child and family respond to participation restrictions through an interactional relationship in which parents provide supports to facilitate participation resulting in various amounts of parental effort. Although all parents describe effort required to support participation, research with families of children with Autism Spectrum Disorders (ASD) have described high levels of parental effort to accommodate their child's special needs[1-2]. There are few if any instruments that consider the impact of parent effort on child participation and none specifically for parents of children with ASD. The Parent Effort Scale – Home Version (PES-H) was developed to fill this need, although requires further psychometric examination.

Objectives: The purpose of this study was to examine internal consistency, factor structure, test-retest reliability, and scale distribution of the PES-H in children between the ages of 3 and 5. Additionally, this study examined differences in parental effort between children with and without Autism Spectrum Disorders.

Methods: A cross sectional design was used to collect data for psychometric analyses. Participants were 304 parents of children with and without ASD between the ages of 3 and 5 years old. Recruitment occurred nationally through social media, ASD community groups, private preschools, and school districts. Participants completed the PES-H, the Gilliam Autism Rating Scale to confirm ASD diagnosis, and a demographic questionnaire either through Qualtrics Survey software. All data was downloaded or inputted into excel and converted for STATA prior to analysis. One hundred and twenty-eight of the participants completed the PES-H two weeks later to evaluate test re-test reliability. Cronbach's alpha was used to calculate internal consistency and intraclass correlation coefficients to calculate test re-test reliability (n=304)[3]. A confirmatory factor analysis to evaluate the model fit was completed using Stata software. The frequency of response options was calculated to examine scale distribution. A Cohen's d effect size estimate was used to examine known group comparisons between scores of parent's rating of children with (n=176) and without ASD (n=137)[3].

Results: Confirmatory factor analysis identified the best fit as a four-factor model (CFI = 0.99, TLI = 0.99, RMSEA = 0.09). The four factors represented dressing, hygiene, sleep and social scales based on item content. Internal consistency was high for all four scales with Cronbach's alpha ranging between .61 to .73 and very high for the total scale at .78. Total test-retest reliability was moderate for all items and scales (*ICC* = .51-.71). The PES-H had reasonable distributions for the whole sample. Negative effect sizes on Cohen's d also indicated that parents of children with ASD when compared to children without ASD had higher effort scores on all subscales and the total scale.

Conclusions: The results of this study identify the underlying factor structure and provide initial reliability for a unique measure to assess parent effort to support participation in the community for young children with and without ASD.

173 - Molecular Neuroscience
11:30 AM - 1:30 PM - Room: 710

216 **173.216** Alteration of Mitochondrial Morphology and Function in Juvenile Rats Exposed to Maternal Immune Activation

M. Cieslik[1]*, A. Zawadzka*[1]*, A. Wilkaniec*[1]*, M. Gewartowska*[2]*, M. Frontczak-Baniewicz*[2]*, D. Q. Beversdorf*[3] *and A. Adamczyk*[1]*, (1)Department of Cellular Signalling, Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland, (2)Electron Microscopy Platform, Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland, (3)University of Missouri, Columbia, Columbia, MO*

Background: Maternal infection is a profound risk factor for neuropsychiatric disorders, including autism, schizophrenia and bipolar disorder. Studies on animal models indicate that maternal immune activation (MIA) may lead to neurochemical and behavioral abnormalities in the offspring. Additionally, mitochondrial dysfunction has been proposed as a major consequence of MIA, and may represent a critical link between neuronal dysfunction and behavioral phenotypes observed in the adult offspring.

Objectives: Here, we analyze the effect of MIA on the morphological abnormalities and alteration of mitochondrial function in rat offspring.

Methods: MIA was evoked by single intraperitoneal (i.p.) injection of lipopolysaccharide (LPS) (100 µg/kg) to pregnant rats at embryonic day 9.5. Hippocampus and brain cortex of juvenile (on 52-53 post-natal day) male rat offspring were analyzed. Molecular biology, biochemistry and transmission electron microscopy were used in the research

Results: We demonstrated that MIA evoked changes in brain morphology, especially in ultrastructure of mitochondria: we observed fragmented cristae with evidence of an expanded matrix compartment or disrupted membrane in both cerebral cortex and hippocampus of juvenile rat offspring. These alterations were accompanied by reduced mitochondrial membrane potentials and enhanced oxidative stress, measured by glutathione levels. The data presented changes in expression of electron transport chain (ETC) complexes. In the cerebral cortex of MIA rats the expression of complex I subunit (*mt-Nd1*), complex III subunit (*mt-Cyb*) and complex IV subunit (*mt-Co1*) was decreased, however in hippocampus only *mt-Co1* was reduced. We also demonstrated that MIA altered transcription of proteins regulating mitochondrial fusion-fission. The reduced level of mitofusin 1 (*Mfn1*) and mitofusin 2 (*Mfn2*), with concomitant elevation of dynamin related protein 1 (*Drp1*) was observed in the cortex, whereas the mitochondrial fission 1 (*Fis1*) expression was altered only in hippocampus of MIA rats. Moreover, we showed down-regulation of transcription factors responsible for mitochondrial biogenesis: Pgc1α (*Ppargc*) in cerebral cortex and *Tfam* in both cerebral cortex and hippocampus of juvenile MIA offspring were reduced.

Conclusions: The observed changes in mitochondrial ultrastructure, function and gene expression of main proteins regulating mitochondrial dynamics/biogenesis and ETC subunits may help in understanding their role in synaptic stress. These findings may contribute to a potential point for novel therapeutic strategies for inflammation-related pathology in neurodevelopmental and neuropsychiatric disorders through the protection of synaptic transmission by targeting mitochondrial deficits. Future work will need to explore associations with behaviors, the impact of interventions, and the correlates in clinical populations.

Supported by the NCN Grant (2016/23/D/NZ4/03572)

217 **173.217** Altered Expression of Cadherins Suggests Their Potential Roles in Brain Development and Autism

***J. A. Frei**, R. F. Niescier, J. E. Nestor, M. W. Nestor, G. J. Blatt and Y. C. Lin, Hussman Institute for Autism, Baltimore, MD*

Background:
Multiple members of the cadherin superfamily have been strongly implicated in autism. The cadherin superfamily contains more than one hundred cell adhesion molecules. A genome wide association study identified the classical type II cadherin CDH8 and CDH11, the protocadherin PCDH9, and the atypical cadherin FAT1 as candidate risk genes. This suggests that cadherin signaling pathways could be disrupted and may display increased vulnerability in autism.

Objectives:

We first determined the expression of autism risk cadherins CDH8, CDH11, PCDH9 and FAT1 in iPSC-derived cortical neurons from control and autism individuals to evaluate whether cadherin levels are commonly altered in autism. We then investigated the expression patterns of cadherins in developing mouse brains and in primary neurons at the subcellular level. Functional effects of cadherins on dendrite arborization were further examined. This study provides novel insights into common and distinct functions of different cadherins in neural circuit formation and the implication in autism.

Methods:

Western blot analyses were performed to evaluate the protein expression of CDH8, CDH11, PCDH9 and FAT1 in iPSC-derived cortical neurons, the developing mouse tissues from different brain areas as well as primary neurons. Subcellular localization as well as enrichment of cadherins in synaptic plasma membrane and postsynaptic densities were further analyzed using a synaptic fractionation assay and immunocytochemical labeling with neuronal marker MAP2 or synaptic markers PSD95, Synapsin 1 and GAT1. Sholl analysis was performed to measure the effect of cadherin knockdown on the complexity of dendritic arbors.

Results:

We found altered cadherin expression levels in iPSC-derived cortical neurons with an increase of CDH8 and a decrease of CDH11. Similar findings were observed in brains of CDH11 knockout mice. Temporal expression analysis in the developing mouse brains revealed increased expression of all cadherins examined at P7 and P14. Analysis of specific brain areas showed that CDH8, CDH11 and PCDH9 were prominently expressed in the cortex, hippocampus and thalamus/striatum whereas FAT1 expression was restricted to the cerebellum. CDH8, CDH11 and FAT1 localized to MAP2-positive dendrites and were enriched in synaptic plasma membrane and post-synaptic density. Moreover, CDH8 and CDH11 were associated with excitatory and inhibitory synaptic markers. Sholl analysis of hippocampal neurons revealed opposing effects on dendrite arborization after loss of CDH8 and CDH11 compared to PCDH9.

Conclusions:

The present study suggests altered expression profiles of cadherins in autism brains, thus strengthening the hypothesis of a central role of cadherins in autism. The findings presented here highlight that cadherins of different subfamilies are expressed in a developmental time window and in vulnerable brain areas implicated in autism. Taken together, by focusing on cadherins across different subfamilies, this study elucidates the role of different cadherin classes in the neurodevelopment of autism, both in animal models and in individuals with the condition.

218 **173.218** Autism-Associated CHD8 Deficiency Impairs Axon Development and Migration of Cortical Neurons

***Q. Xu**[1], Y. Liu[2], C. Liu[3], X. Xu[4] and Y. H. Jiang[5], (1)Children's hospital of Fudan University, Shanghai, China, (2)Guangxi Medical University, Nanning, China, (3)Children's Hospital of Fudan University, Shanghai, China, (4)Children's Hospital of Fudan University, Shanghai, China, (5)Duke University, Durham, NC*

Background: Mutations in *CHD8*, chromodomain helicase DNA-binding protein 8, are among the most replicated and common findings in genetic studies of autism spectrum disorder (ASD). The CHD8 protein is believed to act as a transcriptional regulator by remodeling chromatin structure and recruiting histone H1 to target genes. The mechanism by which deficiency of CHD8 causes ASD has not been fully elucidated.
Objectives: To reveal the expression pattern and important roles of Chd8 in mouse developing brain.

Methods: We examined the expression of *CHD8* in human and mouse brains using both immunohistochemistry and RNA in situ hybridization. We performed in utero electroporation, neuronal culture, and biochemical analysis using RNAi to examine the functional consequences of *CHD8* deficiency.

Results: We discovered that CHD8 is expressed highly in neurons and at low levels in glia cells in both humans and mice. Specifically, CHD8 is localized predominately in the nucleus of both MAP2 and parvalbumin positive neurons. In the developing mouse brain, expression of *Chd8* peaks from E16 to E18 and then decreases significantly at P14 to adulthood. Knockdown of *Chd8* results in the reduction of axon and dendritic growth, disruption of axon projections to the contralateral cortex, and delayed neuronal migration at E18.5 which is recovered by P3 and P7.

Conclusions: Our findings indicate an important role for CHD8 in dendritic and axon development and neuronal migration, and thus offer novel insights to further dissect the underlying molecular and circuit mechanisms of ASD caused by CHD8 deficiency.

219 **173.219** Convergence of Causal Paths across Epigenetic Regulators in ASD

***C. P. Dotter** and G. Novarino, IST Austria, Klosterneuburg, Austria*

Background: Autism spectrum disorders (ASD) are a range of neurodevelopmental disorders affecting 1 in 59 children in the US. A large number of risk genes have been identified by whole exome sequencing studies of patients. Previous studies provided evidence for both common themes in idiopathic ASD as well as common pathways affected by ASD risk genes, giving rise to the concept of convergence across different genetic etiologies. This concept states that different causes, such as mutations at the DNA level converge onto similar changes along the causal path from mutation to phenotype, for example at the level of transcriptional regulation.
Objectives: The aim of this study is to provide evidence for convergence across multiple ASD risk genes associated with chromatin regulation, as this process has been implicated to play an important role in the pathogenesis of ASD. For this reason we study the molecular consequences for neurodevelopment of heterozygous mutations in these genes using cortical spheroids derived from genetically modified human embryonic stem

cells (hESCs) as an *in vitro* human model system.

Methods: Heterozygous mutant hESC lines were established by insertion of a GFP cassette on one allele using CRISPR/Cas9 and the use of a FACS based selection strategy. Multiple independent clones were generated per gene and verified by PCR and Southern Blot including off-target effects. We then used both wild type and mutant hESC to generate cortical spheroids and study the transcriptomic and epigenomic consequences through RNA- and ATAC-seq at different stages of development, starting with the stem cell state.

Results: We successfully generated and verified clones for five genes (KDM5B, SETD5, CHD8, KMT5B and ASH1L). Sequencing showed correct insertion and an intact wild type allele, Southern blot and PCR confirmed the absence of random integrations and off-target effects. Cortical spheroids were generated and showed the expected cell-types across differentiation. RNA-sequencing and ATAC-seq of hESC and cortical spheroids are ongoing at the time of abstract submission.

Conclusions: The genetic heterogeneity present in ASD hinders the progress in understanding the underlying pathogenic mechanisms. Convergence across causal paths in the pathogenesis of the disorder is a useful paradigm to narrow down the list of possible causative mechanisms. The focus on common downstream effects of mutations in different risk genes allows the delineation of the processes important for ASD pathogenesis from confounding coincidental effects. This might ultimately lead to a way to develop common treatments for patients with mutations in different genes.

220 **173.220** Exploring the Neurodevelopmental Bases of DDX3X Syndrome

D. Ung[1,2,3], *A. Boitnott*[1,2,3], *D. Mendonca*[1,2,3], *K. Niblo*[1,2] *and S. De Rubeis*[1,2,3], *(1)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (3)Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY*

Background:
DDX3X syndrome is a recently identified rare genetic disorder associated with autism spectrum disorder (ASD) and intellectual disability (ID). Affected individuals present with ID, behavioral problems including ASD, low body weight, movement disorder, hypotonia and brain anomalies such as cortical malformations. DDX3X syndrome is caused by mutations in the X-linked gene *DDX3X* and most patients are females with *de novo* mutations. DDX3X is a RNA helicase and it has been studied in non-neuronal cells, where it has been found to regulate mRNA translation. Local mRNA translation at synapses is essential for learning and memory and is altered in mouse models for ASD and/ID. To date, the exact functions of DDX3X in neurons and at synapses are poorly known.

Objectives: The objective of the study is to understanding the molecular and cellular functions of DDX3X during neurodevelopment, particularly corticogenesis and synaptogenesis.

Methods:

We have generated a novel conditional knockout mouse recapitulating DDX3X deficiency. To study the effect of DDX3X deficiency on corticogenesis, we study cortical lamination with layer-specific markers. To dissect the molecular complexes and mechanisms mediating DDX3X-dependent translation, we apply biochemical methods to purified synapses (synaptosomes) from mouse cortices.To study synaptogenesis, we use the novel mouse model we have generated to assess synapse morphology and density in single-embryo mouse neuronal cultures modeling the genetics of DDX3X syndrome.

Results: We found that *Ddx3x*null male mice (Ddx3x$^{-/y}$) die *in utero*, compatible with the dearth of boys affected by DDX3X syndrome. *Ddx3x*-deficient females (*Ddx3x*$^{+/-}$) are viable and have reduced DDX3X protein expression in the cortex compared to control littermate. DDX3X is expressed at synapses from cortex at a critical window for synaptogenesis and expression is sex-specific. DDX3X is also expressed in glutamatergic projection neurons in the developing cortex and we are beginning to characterize cortical connections in *Ddx3x*-deficient mice.

Conclusions:

We have generated a mouse model with construct validity for DDX3X syndrome that shows initial evidence for face validity. We are using this model to understand the molecular and cellular neurobiology underlying DDX3X syndrome.

221 **173.221** Gabaergic Interneuron Cell Loss in Mice Lacking Autism-Associated Gene Slit3

K. Menzel[1], *S. Edwards*[1,2], *C. Ensor*[1,2], *D. Sidibe*[1,2] *and* ***C. Plachez***[1], *(1)Hussman Institute for Autism, Baltimore, MD, (2)Baltimore City Community College, Baltimore, MD*

Background: Altered neuronal connectivity reported in Autism Spectrum Disorder (ASD) leads to alterations in brain function and multisensory integration. Human studies reported that SLIT3, an axon guidance molecule, may be associated with neurological conditions, such as major depressive disorder, schizophrenia and ASD. SLIT proteins bind to the receptor Roundabout (ROBO) and have a role in axon guidance, cell migration, cell proliferation and differentiation of various cell types during embryogenesis. Taken together, these findings suggest that Slit3 may be an attractive candidate to analyze altered neuronal connectivity in ASD.
Objectives: The purpose of the current study is to investigate how Slit3 mutation affects neuronal connectivity in ASD. Since SLIT3 is involved in cell migration, we hypothesized that during brain development the migration of GABAergic interneurons is affected by the loss of SLIT3 gene, leading to alterations in the Excitation/Inhibition (E/I) balance, as seen in ASD.

Methods: Slit3 mutant mice were crossed with either GAD (Glutamate decarboxylase) 65 or GAD67-GFP (Green Fibrillary Protein) mouse lines to study GABAergic interneurons in different key areas of the brain affected in ASD. Inserting these GAD knock-in mouse lines within the Slit3 knock-out mouse line allows for reliable tracking of specific cell populations to investigate the contribution of Slit3 toward GABAergic interneuron migration.

Results: Analysis of the Slit3 mutant mice crossed with either GAD65-GFP or GAD67-GFP mouse lines revealed a reduced number of GABAergic interneurons in the cortex, hippocampus, reticular thalamic nucleus and cerebellum in Slit3 knockout (KO) adult mice compared to SLIT3 wild type (WT) mice. This cell reduction in GABAergic interneurons was seen early during brain development suggesting that the loss of SLIT3 gene affects either the production, proliferation or migration of GABAergic interneurons. When we analyzed the different populations of GABAergic interneurons our results showed that Parvalbumin interneuron number was reduced in Slit3 KO mice cortex, hippocampus, reticular thalamic

nucleus and cerebellum (KO, n= 14, WT, n=15), whereas Calretinin and Calbindin interneurons were not affected, suggesting that SLIT3 gene loss affects only the fast spiking-PV population.

Conclusions: Interneurons are known to synchronize neuronal activity and this synchronization is essential for cortical network function. Our results show a loss of GABAergic interneurons, especially the fast spiking-PV population, in mice lacking autism-associated gene Slit3. These findings reveal the importance of Slit3, an axon guidance molecule, in the formation of GABAergic neuronal networks and provide insight into the molecular pathways that may lead to altered neuronal connectivity in ASD.

222 **173.222** Implication of the Oxytocin System in Shank3-Deficiency

H. Harony-Nicolas[1,2,3,4], *N. Burlant*[1,2], *K. T. Rajamani*[1,2], *K. Niblo*[1,2] *and J. Buxbaum*[1,2,3,4,5,6], *(1)Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (3)Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY, (4)The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY, (5)Fishberg Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY, (6)Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY*

Background:

Social deficits are a core symptom of autism spectrum disorder (ASD). To date, behavioral therapies are the first line of intervention for treating impaired social behaviors, whereas pharmacological treatments have been ineffective at addressing this symptom domain. To inform treatment targets, there is an urgent need to understand the pathophysiology underlying social deficits. The hypothalamic oxytocin system is a key modulator of social behavior that is well conserved across species. Despite the wealth of behavioral and pharmacological studies implicating oxytocin in social behavior, and the increased interest in oxytocin as a therapeutic in ASD, little is known about the effect of ASD-associated mutations, such as *SHANK3*, on the oxytocin system. Moreover, it is unclear whether impairments in the oxytocin system underlie social deficits in some forms of ASD. We have recently demonstrated attentional, social recognition memory, and synaptic plasticity deficits in a rat model carrying a S*hank3* mutation: the *Shank3*-deficient rat. We showed that both behavioral and synaptic plasticity deficits in this model are reversed by oxytocin. In this project, we study the effect of a *Shank3* mutation on the neural oxytocin system.

Objectives:

The objectives of our study are to understand if a *Shank3* mutation imposes a deleterious effect on (1) the hypothalamic oxytocin system in the paraventricular nucleus where oxytocin is produced and released and (2) the social recognition memory circuit that comprises brain regions targeted by the paraventricular nucleus. Further, we aim to examine the causality between alterations in the oxytocin system and the social recognition memory deficits that we have reported in the *Shank3*-deficient rat model.

Methods:

We are leveraging the *Shank3*-deficient rat model to explore the effect of the *Shank3* mutation on the neural oxytocin circuitry. Techniques include: immunohistochemistry to study the effect of the *Shank3* mutation on the morphology of oxytocin neurons, brain microdialysis to assess oxytocin levels during social behavior, fiber photometry to record neural activity of oxytocin neurons during social interaction, and chemogenetic tools to manipulate the oxytocin neural population in vivo and test the causality between social behavior deficits and alterations in the oxytocin system in *Shank3*-deficient rats.

Results:

Our preliminary findings show increased oxytocin immunoreactivity in oxytocin neurons within the paraventricular nucleus of *Shank3*-deficient rats, suggesting an accumulation of the oxytocin peptide due to impaired secretion. Furthermore, we observe diminished photometry signals in the PVN during social interaction, suggesting impaired neural activity of PVN neurons.

Conclusions:

Our findings suggest that *Shank3* mutations impact the oxytocin system by altering neural activity of oxytocin neurons and the release and oxytocin. These variations may underlie the social recognition memory deficits that we have previously reported in the *Shank3*-deficient rat model.

223 **173.223** Investigating the Role of NRXN1 in Autism Using iPSC-Derived Neurons

A. T. Massrali[1], *A. Paul*[2], *L. Dutan Polit*[3], *S. Baron-Cohen*[4], *M. R. Kotter*[5] *and N. J. Gatford*[6], *(1)Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (2)Department of Psychiatry, Autism Research Centre, Cambridge, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (5)Department of Clinical Neurosciences, Wellcome Trust-MRC Stem Cell Institute, University of Cambridge, Cambridge, United Kingdom, (6)Department of Basic and Clinical Neuroscience, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom*

Background: Hundreds of genes contribute to autism likelihood. Of particular interest are mutations in genes encoding trans-synaptic signalling molecules, such as neurexins and their binding partners which have been implicated in autism. The Neurexin-1 gene (NRXN1) encodes for the presynaptic adhesion molecule neurexin-1, which binds to postsynaptic cell-adhesion molecules. While the role of NRXN1 has been established in regulating typical synaptic function and physiology, the role of its different isoforms and their contribution to the aetiology of autism is only now emerging and our knowledge remains patchy.

Objectives: Introduce the optimised inducible transgene (NGN2) over-expression for forward programming patient derived-iPSC lines and isogenic NRXN1-KO lines to investigate neuronal phenotypes, synaptic and functional changes caused by NRXN1 mutations

Methods: We generated iPSC-lines derived from individuals with autism carrying mutations in *NRXN1*-α (n= 2, 1 male, 1 female) and healthy controls (n=2, 1 male, 1 female (carrier))and 2 isogenic pair of iPSCs using eSpCAS9 to create NRXN1 knock-out via non-homologous end-joining. We aimed to target exon 4-5 (for NRXN1-α / KO) and exon 19 (shared by both isoforms). We systematically optimised inducible transgene over-expression (OPTi-OX) in the generated lines using a dual genomic safe harbour gene-targeting strategy to overcome silencing of transgenes and allow forward programming of iPSCs into mature functional neurons. We then examined the effect of those mutations on gene expression levels and protein using synaptic genes-specific primers and western blot antibodies. We also investigated neuron morphology using a combination of

live cell imagine and immunocytochemistry for synaptic protein markers. Neuronal synaptic activity was recorded using multi-electrode array (MEA) as well as calcium imaging.

Results: The neurons reprogrammed from the generated patient-derived lines as well as the isogenic pair showed high expression of MAP2, SYN1, VGLUT1 and other neuronal markers. Q-PCR show varied expression levels of NRXN and NRXN associated genes in the autism and control lines:while the mutation lies in the NRXN1-α it not only affected this isoform, but also affected NRXN1-bas well as CASK. The neurons were then tested for electrophysiological properties using multi-electrode array.

Conclusions: We have successfully developed a highly consistent and efficient human cell model to study NRXN1 defects in the induced neurons. This model shows accelerated generation of excitatory neurons that express pan-neuronal and glutamatergic markers. The multielectrode array recordings show that those neurons are electrophysiologically functional with synchronised firing starting at Day 21 as compared to Day 100 using traditional differentiation methods.

174 - Neuroimaging
11:30 AM - 1:30 PM - Room: 710

224 **174.224** Early (3–4 years) Brain Markers of Autism and Application of Machine Learning to Predict Future Diagnosis: A Feasibility Study Using Clinical Data

*G. J. Katuwal[1,2], S. M. Myers[3], S. A. Baum[2,4] and **A. M. Michael**[1,2,5], (1)Geisinger Health System, Lewisburg, PA, (2)Rochester Institute of Technology, Rochester, NY, (3)Geisinger Autism & Developmental Medicine Institute, Lewisburg, PA, (4)University of Manitoba, Winnipeg, MB, Canada, (5)Duke University, Durham, NC*

Background: Most previous brain imaging studies in autism spectrum disorder (ASD) are based on children older than 6 years, well after the median age of ASD diagnosis (~52 months)[1]. The few studies that have used subjects less than age four years have investigated only a small subset of brain features[2]-[5]. As such, there is a significant knowledge gap of early ASD brain alterations. A comprehensive investigation of early brain markers is critical to identify the neuroanatomical underpinnings of ASD and may ultimately aid earlier diagnosis. Carrying out a prospective study to characterize early brain markers of ASD would be inordinately expensive. However, clinical brain images of patients who are later diagnosed with ASD are available in hospitals.
Objectives: We aim to identify pre-diagnosis brain alterations of ASD from images acquired as part of clinical care. We apply machine learning on brain morphometric features to predict future ASD diagnosis.

Methods: Brain MRI of 15 ASD male subjects of age three to four years and 18 age- and sex-matched non-ASD subjects were obtained from Geisinger Health System. ASD diagnosis status was based on ICD codes found on electronic health records. A comprehensive set of 687 brain morphometric features were extracted using Freesurfer[6]. ASD versus non-ASD prediction was performed using Random Forest[7]. Prediction accuracy and feature importance were evaluated using 5-fold cross-validation.

Results: Significant ($p<0.05$, uncorrected) ASD versus non-ASD brain differences are presented in Figure 1. We find that although total intracranial volume (TIV) in ASD was 5.5% larger, volumes of many brain areas (as a percentage of TIV) were smaller in ASD and can be partly attributed to larger (>10%) ventricles in ASD. TIV in ASD was correlated to surface area and cortical folding but not to cortical thickness. The correlation between total ventricular CSF and average cortical folding was 0.56 ($p=0.02$) for ASD, but was -0.13 ($p=0.6$) for non-ASD. Folding indices of 58 out of 68 cortices were higher in ASD in the frontal, temporal, cingulate, postcentral, and precuneus regions. White matter regions in ASD had less image intensity (predominantly in the frontal and temporal regions) suggesting myelination deficit.

We achieved 95% AUC for ASD vs. non-ASD prediction using all brain features. When prediction was performed separately for each brain feature type, image intensity yielded the highest predictive power (95% AUC), followed by cortical folding index (69%). The important prediction features for each feature types that yielded high AUCs are presented in Figure 2. The most important feature for prediction was white matter intensity surrounding the rostral middle frontal gyrus and was lower in ASD.

Conclusions: In addition to replicating previous findings, we report several novel brain morphometry differences in early ASD. The high degree of prediction success indicates that the application of machine learning methods on brain features holds promise for earlier identification of ASD, but this pilot study result needs to be replicated with a larger sample. To our knowledge this is the first study to leverage a clinical imaging archive to investigate early brain markers in ASD.

225 **174.225** Early Social Perception in Infants at Risk for ASD Using Functional Near-Infrared Spectroscopy (fNIRS)

***F. Zhang** and H. Roeyers, Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium*

Background: Converging evidence is implying that individuals with autism spectrum disorder (ASD) show atypical brain response to social stimuli at an early stage. However, the neural processing during early infancy in ASD has not been fully characterized. Studies of infants who are at substantially higher risk to develop ASD than the general population (HR), have the potential to clarify early functional manifestations of the brain for individuals with ASD.
Objectives: In this study, our aim was to find out whether cortical response to socially stimuli in HR infants differs from low risk (LR) controls by using fNIRS.

Methods: Until now, twenty 5-months-old infants participated in the fNIRS study; 4 of them were excluded because they failed to complete the whole study or made too much head movements.Finally, sixteen 5-months-old infants (n=8 for HR, n=8 for LR) were included for further analysis. Infants in the HR group had an older sibling with an ASD diagnosis or feeding problem or were premature babies. All subjects passively listened to a set of human vocal sounds (e.g., coughing and laughing) and familiar environmental sounds (e.g., rattles and car moving). fNIRS measurements were made using the NIRScout (NIRX, Germany/USA) device.

Results: The cortical activation by human sounds (i.e., the social task) relative to environmental sounds (i.e., the non-social task) was first

measured by paired-sample t-tests within each group, primarily using the changes of oxy-hemoglobin (HbO). For the LR group, we found a greater hemodynamic response to the social task (compared to the non-social task) in the bilateral temporal cortex, mainly located in the left posterior temporal region (channel 32: t (7) = - 3.26, p < 0.05, d = 1.36; channel 34: t (7) = - 2.67, p < 0.05,d = 1.06), and the right temporal region (channel 53: t (7) = - 3.32, p < 0.05, d = 1.37). By contrast, no channels showed significant activation for the social task compared to the non-social task in the high-risk group (p > 0.05 for all tests) after Bonferroni correction. To further investigate whether patterns of activation were different in the two groups, we carried out a 2*2 (groups: HR, LR; tasks: social, non-social) mixed ANOVA analysis in the left regions (Ch.32 and Ch.34)and right regions (Ch.53) separately. We observed a significant interaction effect between groups and tasks in the right hemisphere (F (1,15) = 5.04, p = 0.04, ηp^2 = 0.14) but not in the left hemisphere. For the social task, HR infants showed lower activation (t (7) = - 2.58, p = 0.02, d = 0.98) in the right hemisphere than LR infants. For the non-social task, no group differences were found.

Conclusions: Our initial results demonstrate that HR infants show different neural activation to social stimuli in the temporal regions compared to LR infants. This suggests that social development may already be impaired in the first year of life for (some of the) infants in the HR group. Data collection is still ongoing. At the meeting we expect to present results of at least 50 infants.

226 **174.226** Endogenous Bold Signal Complexity of Ventromedial Prefrontal Cortex Is Different in Autistic Men Versus Women and Differentially Associated with Compensatory Behavioral Camouflaging

S. Trakoshis[1], *W. You*[2], *S. Baron-Cohen*[3], *B. Chakrabarti*[4], *A. N. Ruigrok*[5], *E. Bullmore*[5], *J. Suckling*[6], *M. C. Lai*[7] *and M. V. Lombardo*[5], *(1)Department of Psychology, University of Cyprus, Nicosia, Cyprus, (2)Diagnostic imaging and radiology, Children's National Medical Center, Washington, D.C, WA, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (4)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (5)University of Cambridge, Cambridge, United Kingdom, (6)University of Cambridge, Cambridge, United Kingdom of Great Britain and Northern Ireland, (7)The Hospital for Sick Children, Toronto, ON, Canada*

Background: Longstanding theories suggest that there may be an imbalance of excitation versus inhibition (E/I) in the autistic brain. E/I imbalance can result in increased neural noise with long-range dependence and this may be represented in the 1/f signal of non-invasive in-vivo measurements of brain function such as resting state fMRI (rsfMRI). The 1/f signal has been characterised with the Hurst exponent (H), indicating the temporally persistent behaviour (long memory) and stationarity of the signal when 0.5<H<1. However, rsfMRI BOLD signal exhibits non-stationary behaviour that also needs to be quantified. Thus we have utilised a novel approach for estimating H based on the fractionally integrated process (FIP) model to allow H>1, as a non-stationarity index. Using H as a metric of endogenous BOLD signal complexity, we examined how H may differ between males versus females with autism, by expanding on previous work on adult males (Lai et al., 2010). Here, we assess if H exhibits sex-by-diagnosis interaction effects when examined in a 2x2 design.
Objectives: To assess sex-by-diagnosis interactions in H and assess any sex-differential associations with clinical measures of behavioural camouflaging.

Methods: Age-matched male and female adults with ASD (males n=23; females n=25) and a typically developing (TD) group (males n=29; females n=33) were scanned with rsfMRI (3T, TR=1302 ms, 620 volumes) while awake with eyes closed. Data were preprocessed using a standard pipeline in AFNI, along with motion regression, CSF regression and wavelet despiking. Mean time-series from 180 parcels from the HCP parcellation (Glasser et al., 2016) were used to estimate H based on the FIP model. For each region, a linear model was constructed to examine main effects of sex and diagnosis along with the sex-by-diagnosis interaction, after covarying for mean framewise displacement and full-scale IQ. Multiple comparison correction was implemented with FDR q<0.05. A behavioural camouflaging index was computed identical to past work (Lai et al., 2017) and was utilised in correlation analyses with H, stratified by sex within autistic individuals.

Results: A region in ventromedial prefrontal cortex (vMPFC) showed evidence of a sex-by-diagnosis interaction (F=15.134, p=1.76e-4, partial η^2=0.12) with a TD>Autism effect in males (d=1.30) but no strong effect in females (d=-0.27). Increasing vMPFC H was significantly associated with increasing behavioural camouflaging in females (r=0.60, p=0.0015), whereas no association was present in males (r=-0.10, p=0.63). The strength of these vMPFC H-camouflaging correlations was different between males versus females with autism (z=2.58, p=0.0098).

Conclusions: These results suggest that an important node of the 'social brain', vMPFC, shows lower H in men but not women with autism, compared to same-sex TD controls. Lower H could indicate enhanced neural noise and may impact several key functions of vMPFC involved in social and self-referential cognition, particularly in males with autism. This marker also explains variance in clinically relevant phenomena such as camouflaging, in a sex-differential manner, suggesting that the less neural noise present in vMPFC of females with autism may be related to enhanced ability to camouflage impairments in the social-communicative domain.

227 **174.227** Factors Contributing to Success and Failure in MRI Assessment in Individuals with Low-Functioning Autism

H. Y. Lin[1], *Y. C. Liu*[2], *M. Y. Hsu*[3], *H. C. Ni*[4], *J. C. Chang*[5], *E. N. Tu*[6], *Y. Y. Wu*[3] *and S. S. F. Gau*[1], *(1)Department of Psychiatry, National Taiwan University Hospital & College of Medicine, Taipei, Taiwan, (2)Department of Psychiatry, National Taiwan University Hospital, Taipei, Taiwan, (3)YuNing Psychiatry Clinic, Taipei, Taiwan, (4)Chang Gung Memorial Hospital- Linkou Medical Center, Taipei, Taiwan, (5)Department of Psychiatry, National Taiwan University Hospital. Yun-Lin Branch, Yunlin, Taiwan, (6)Department of Psychiatry, Keelung Chang Gung Memorial Hospital,, Keelung, Taiwan*

Background: Although accumulating evidence indicates altered brain phenotypes in autism spectrum disorder (ASD), the majority of neuroimaging research has focused on individuals with relatively intact cognitive and language function (i.e., 'high-functioning'). Those having more severe phenotypes (i.e., 'low-functioning', including minimally verbal and intellectually disabled individuals, are generally understudied and overlooked. This dearth of the knowledge hinders unraveling the etiologies underlying the heterogeneity in phenotypic expressions.
Objectives: We aimed to identify the factors and individual features which contribute to the success and failure in MRI assessment.

Methods: To answer this specific question and further investigate the expression of brain phenotypes in this understudied population, minimally verbal individuals and those with intellectual disabilities were recruited. These individuals were intentionally grouped in the 'low-functioning' group considering the sample size and dimensional features of verbal language expression levels, and were contrasted with the 'high-functioning' individuals with ASD (full-IQ>70), and neurotypical group. All participants received comprehensive assessment of clinical presentations (including the ADI-R, ADOS, and a myriad of parent-rated questionnaires measuring autistic features, adaptive functioning, and co-occurring

behavioral/emotional problems), cognitive abilities (Wechsler and Leiter scales), and MRI (T1w, resting-state and task MRI, and diffusion imaging). Failure to complete MRI assessment was defined as inadequate quality (notable motion artifacts after several runs) of 6-minute T1w image, participants' active cancellation of scans, or inability to be compliant.

Results: The sample (age 7-30 years) consisted of 33 high-functioning, 27 low-functioning participants with ASD (17 fulfilled the stringent criteria of minimally verbal status), and 27 neurotypical controls. Among them, 32 (97%) high-functioning, 20 (74%) low-functioning individuals (12 minimally verbal), and all neurotypical controls successfully completed MRI assessments. All low-functioning individuals had practiced to lie still before scans, and were accompanied by the parents or therapists during scans. 20 (all low-functioning, including all unsuccessful cases) had received the mock scan before the official assessment; 3 of them failed to comply with mock scans. All participants who failed to complete scans, alongside 3 individuals in the low-functioning group having tolerable quality of image data, had several runs of T1w scans. Overall, low-functioning, relative to high-functioning individuals, had higher autistic severity based on the ADI-R and ADOS. These two patient groups did not differ in ratio of sex, or psychiatrist-diagnosed comorbidity, or most of parents-rated questionnaires, except higher internalizing and externalizing problems in high-functioning individuals. Benchmarking against the low-functioning individuals successfully completing MRI assessment (N=20), those who failed (N=7) had younger age (10±1.5 vs. 19±4.9 years). These two subgroups on the low-functioning spectrum did not differ in the severity of autistic or ADHD symptoms (regardless of the raters), or intellectual function.

Conclusions: Our preliminary findings suggest that younger age lead to higher failures in completing MRI assessment. Company by the family members or therapists, and several scan attempts may facilitate higher successful rates for scans. The mock practice could help the low-functioning individuals better accustom to the scan environment, and also helps the researchers to decide which participants might have higher chances to finish MRI scans.

228 **174.228** Hyperconnectivity of Social Perception, Language Processing, and Face Recognition Areas Associated with Greater Deficits in Social Cognition in Autism Spectrum Disorder

***D. Cochran**, S. M. Hodge, J. Frazier and D. Kennedy, Psychiatry, UMass Medical School, Worcester, MA*

Background: The right posterior superior temporal gyrus (rpSTG) is involved in language processing and social perception, particularly the perception of biological motion, and has been found repeatedly to be one of the core neuroanatomical areas with observed differences between individuals with autism spectrum disorders (ASD) and typically developing controls (TD). Functional connectivity studies have found both hyper- and hypoconnectivity of rpSTG in ASD with various brain regions associated with social cognition.
Objectives: We sought to determine whether the functional connectivity of rpSTG with other brain regions was associated with quantitative measures of social cognition in adolescent males with and without ASD.

Methods: We used resting-state functional connectivity (rsFC) data from males age 13-17 with verbal IQ in range of 85 to 115 included in the Autism Brain Imaging Data Exchange repository. We focused on male gender and narrow age and IQ range to limit the confounding effects of these variables on the resting state results. We limited our analysis to those subjects with documented total scores on the Social Responsiveness Scale. The final dataset included 29 subjects with ASD [Mean Age(SD) = 15.4 (1.5); Mean VIQ(SD)=100.7(9.5)] and 27 TD subjects [Mean Age(SD)=15.6(1.3); Mean VIQ(SD)=102.5(8.6)]. Seed-to-voxel rsFC analyses were performed using the CONN-fMRI toolbox v18a and SPM12 with the rpSTG as defined by the FSL Harvard-Oxford atlas used as the seed. SRS scores were used as regressors in the analysis, controlling for age. A peak voxel threshold of $p<0.001$ and a cluster extent threshold of $p<0.05$ were set for positive and negative associations of connectivity, with significance defined as surviving Family-Wise Error correction at $p<0.05$.

Results: Greater impairment in social cognition was associated with increased connectivity between the rpSTG and a single cluster centered in the right temporal occipital fusiform cortex, in the region associated with distinguishing faces from other objects. Using this cluster in exploratory analysis as a seed for analysis, the increased connectivity extended to a region including the right planum temporale along with the rpSTG, involving regions associated with auditory processing.

Conclusions: There is evidence for association between greater impairment in social cognition and increased connectivity between regions involved with social perception, language processing, and recognition of faces, functions that are impacted by the core symptoms of ASD.

229 **174.229** Intranasal Oxytocin Differentially Affects Functional Connectivity in Women with and without Autism

***T. L. Procyshyn**[1], M. V. Lombardo[1,2], M. C. Lai[1,3,4], B. Auyeung[1,5], S. Crockford[1,6], J. B. Deakin[7,8], S. Soubramanian[7,9], A. Sule[7], P. Kundu[10,11], S. Baron-Cohen[1] and R. A. Bethlehem[1], (1)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (2)University of Cyprus, Nicosia, Cyprus, (3)The Hospital for Sick Children, Toronto, ON, Canada, (4)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (5)University of Edinburgh, Edinburgh, United Kingdom, (6)University of Cambridge, Cambridge, United Kingdom, (7)Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (8)Cambridgeshire and Peterborough NHS Foundation Trust, Cambridge, United Kingdom, (9)Behavioural and Clinical Neuroscience Institute, University of Cambridge, Cambrideg, United Kingdom, (10)Brain Imaging Center, Icahn Institute of Medicine at Mt. Sinai, New York, NY, (11)Translational and Molecular Imaging Institute, Icahn Institute of Medicine at Mt. Sinai, New York, NY*

Background: Oxytocin, which is known to influence social behaviour and cognition, may be of therapeutic value for enhancing social functioning in individuals with autism spectrum conditions (ASC). We previously reported that intranasal oxytocin increased resting state connectivity across subcortical and cortical networks in neurotypical women and that this effect correlated positively with autistic-like traits [1]. Thus, we predicted strong oxytocin-induced increases in functional connectivity in the same corticostriatal circuit in women with ASC.
Objectives: To test whether the same effect of oxytocin on resting state connectivity observed in neurotypical women is present in autistic women.

Methods: To extend this study, 16 age- and IQ-matched women with a diagnosis of high-functioning autism or Asperger syndrome participated in the same double-blind placebo-controlled crossover experiment. Resting-state functional magnetic resonance imaging (fMRI) data were collected after intranasal administration of 24 IU oxytocin (Syntocinon, Novartis) or placebo. A total of 270 resting-state functional volumes (eyes-open, with fixation cross) were acquired using a multi-echo sequence and online reconstruction (TR = 2300 ms; field-of-view = 240 mm; 33 oblique slices, alternating slice acquisition, slice thickness = 3.8 mm, 11% slice gap; 3 echoes at TE = 12, 29, and 46 ms, flip angle 80°). Independent components

analysis was applied to examine connectivity between networks. Correlation matrices for all independent component (IC) pairs were computed with corrections for multiple comparisons.

Results: Mirroring our previous finding, we identified components involved in reward, emotion, social communication, language, and pain processing. Three IC pairs showed significant changes in activation between the oxytocin and placebo conditions in autistic women, although the effect sizes were small (≤0.80, Cohen's d). The independent component pair (IC11-IC21) previously found to show the greatest oxytocin-induced connectivity increase in neurotypical women did not show a significant connectivity change between placebo and oxytocin conditions in autistic women. While all neurotypical women showed significantly increased connectivity in this IC pair under oxytocin relative to placebo, several autistic women showed a substantial decrease in connectivity under the oxytocin condition (Figure 1). Overall, oxytocin-induced connectivity changes were more heterogeneous in autistic women compared to neurotypical women.

Conclusions: These findings are suggestive that response to exogenous oxytocin between autistic and neurotypical women. Within the autism group, individual differences in response to oxytocin may arise from differences in the oxytocinergic system or interactions between oxytocin and other hormones. In future work, we plan we explore this possibility by combining fMRI data and salivary hormone level data.

230 **174.230** Longitudinal Sex Differences in Early Brain Growth in Autism Spectrum Disorder

J. K. Lee[1], *D. S. Andrews*[1], *A. L. Hechtman*[2], *M. Solomon*[3], *S. Rogers*[1], *S. Ozonoff*[2], *D. G. Amaral*[1] *and C. W. Nordahl*[1], *(1)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (3)Department of Psychiatry & Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, University of California, Davis, Sacramento, CA*

Background: Atypical growth patterns of total brain volume during childhood have been reported in ASD. However, longitudinal studies are lacking, and most existing studies reflect the male bias of ASD. Thus, sex differences in early brain enlargement and growth trajectories have not been fully explored.

Objectives: This longitudinal research examines sex differences in the growth of total cerebral volume (TCV) from early to middle childhood in ASD relative to age- and sex-matched typically developing (TD) controls.

Methods: The longitudinal sample comprised three annual time points spanning early childhood with 237 ASD (77 female) and 115 TD (52 female) participants at Time 1 (T1; *M*=38.4 months), 134 ASD (41 female) and 76 TD (32 female) participants at T2 (*M*=51.5months), 85 ASD (27 female) and 59 TD (24 female) at participants T3 (*M*=64.3 months), and one additional time point during middle childhood with 52 ASD (11 female) and 42 TD (17 female) participants at T4 (*M*=136.1 months). Due to existing evidence that disproportionate megalencephaly may represent a distinct neurophenotype in ASD, current sample and analyses did not include participants with disproportionate megalencephaly. TCV was estimated using template-based registration of T1-weighted MR images (1mm^3 resolution). Primary analyses examined within-person growth in TCV during early childhood (T1-T3) using mixed level modeling; future planned analysis will examine growth of TCV into middle childhood (T1-T4). Age was separated into a within-person covariate (change in age since T1) and a between-subject covariate (starting age at T1). Mixed level models were conducted in R using lme4. Model comparisons were conducted testing interactions between sex, diagnosis, change in age. Tests of parameter estimates used Satterthwaite's degrees of freedom, as implemented in the lmerTest package.

Results: At T1, TCV was significantly enlarged in males with ASD compared to males with TD (b=+32.5cm^3, *t*=2.78, *p*=.0059), but not significantly enlarged in females with ASD compared to females with TD (b=+15.6 cm^3, *t*=1.18, *p*=.24). However, a significant sex by diagnosis interaction was not observed at T1 (*p*=.43). All groups exhibited substantial positive growth in TCV over time (Figure 1; *p*s ≤ 2e-16), however the rates of that growth differed by sex and diagnosis, as indicated by significant two- and three-way interactions with change in age (two-way: χ^2=36.1, df=2, *p*=1.5e-8; three-way: χ^2=4.26, df=1, *p*=.039). Compared to sex-matched TD controls, the rate of change in TCV was slower in ASD in both males (b=-.34 cm^3/month, *t*=-2.49, *p*=.014) and females (b=-.79 cm^3/month, *t*=-4.38, *p*=2.6e-5). However, the rate of growth was slowest in females with ASD (rate relative to males with ASD: b=-.69 cm^3/month, *t*=-4.59, *p*=7.9e-6).

Conclusions: Brain enlargement during early childhood is not as prominent in females with ASD as in males with ASD. Moreover, females with ASD have a slower rate of TCV growth during early childhood. Future analyses will examine TCV trajectories into middle-childhood.

231 **174.231** Machine Learning Analysis of White Matter Connectome Edge Density: A Path Towards Imaging Biomarkers for Autism Spectrum Disorders

E. J. Marco[1,2], *S. Payabvash*[3], *E. M. Palacios*[4], *J. P. Owen*[5], *M. B. Wang*[6], *T. Tavassoli*[7], *M. R. Gerdes*[2], *A. Brandes-Aitken*[8] *and P. Mukherjee*[4], *(1)Cortica Healthcare, San Diego, CA, (2)Neurology, University of California San Francisco, San Francisco, CA, (3)Yale University, New Haven, CT, (4)Radiology, UCSF, San Francisco, CA, (5)University of Washington, Seattle, WA, (6)University of Pittsburgh, Pittsburgh, PA, (7)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom, (8)New York University, New York, NY*

Background:

Neuroimaging studies, using Diffusion tensor imaging (DTI) and fiber tractography have found white matter network underconnectivity in many children with the social communication challenges indicative of Autism Spectrum Disorders (ASD). Thus, the structural connectome, representing the whole-brain network of macro-scale white matter connectivity, has emerged during the past decade as a powerful formalism for the study of neurological and psychiatric diseases, including ASD. However, to date there are no studies of ASD examining regional connectomic properties within the white matter. Edge Density Imaging (EDI) has recently been introduced as a framework to represent the anatomic embedding of these white matter connectome edges. In EDI, the edges or links of the white matter connectome – from probabilistic tractography – are constrained to network nodes based on standard atlas parcellation of the cortical and deep gray matter nuclei. Machine learning analyses are also gaining popularity for pattern recognition and development of classification (or regression) models based on multidimensional data. These algorithms seem particularly suitable for devising classifiers based on multitude of variables extracted from diffusion and connectivity maps.

Objectives:

In this study, we compared the white matter connectome and microstructure between children with ASD and typically developing children (TDC)

using voxel-wise analysis. Then, we applied different machine-learning algorithms for identification of ASD based on the white matter tract-based average Edge Density (ED) and conventional DTI metrics to determine the differences that were most associated with the clinical condition.

Methods:

We examined the structural connectome of children with (n=14) and without ASD (n=33) using tractography-based Edge Density Imaging (EDI); and then applied machine leaning algorithms to identify boys (8-12 years) with ASD based on EDI patterns. The Edge Density (ED) maps were computed from probabilistic streamline tractography applied to high angular resolution diffusion imaging (HARDI). Tract-Based Spatial Statistics (TBSS) was used for voxel-wise comparison and coregistration of ED maps in addition to conventional DTI metrics of Fractional Anisotropy (FA), Mean Diffusivity (MD), and Radial Diffusivity (RD). Tract-based average DTI/connectome metrics were calculated and used as input for different machine learning models: naïve Bayes, random forest, support vector machines (SVM), neural networks. For these models, cross-validation was performed with stratified random sampling (×1000) of the cohort into training and validation datasets. The average accuracy among validation samples was calculated.

Results:

In voxel-wise analysis, the body and splenium of corpus callosum, bilateral superior and posterior corona radiata, and left superior longitudinal fasciculus showed significantly lower ED in children with ASD. Overall, machine-learning models using tract-based EDI metrics had better performance in identification of children with ASD compared to those using FA, MD, and RD. The EDI-based random forest models had greater average accuracy (75.3%), specificity (97.0%), and positive predictive value (81.5%), whereas EDI-based polynomial SVM had greater sensitivity (51.4%), and negative predictive values (77.7%).

Conclusions:

In conclusion, we found reduced number of connectome edges in the posterior white matter tracts of children with ASD; and demonstrated the feasibility of connectome-based machine-learning algorithms in identification of children with ASD.

232 **174.232** Malleability of Neural Activity in Response to Treatment: Examining fMRI Biomarkers of Social Behavior and Anxiety Among Autistic Adolescents across the PEERS® Intervention

A. J. McVey[1], *J. D. Herrington*[2], *H. K. Schiltz*[1], *B. Dolan*[3], *A. Barrington*[4], *A. Arias*[1], *A. D. Haendel*[5], *K. Willar*[6] *and A. V. Van Hecke*[7], *(1)Marquette University, Milwaukee, WI, (2)Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA, (3)Medical College of Wisconsin, Milwaukee, WI, (4)Biomedical Engineering, Marquette University, Milwaukee, WI, (5)Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI, (6)Stanford University, Stanford, CA, (7)Psychology, Marquette University, Milwaukee, WI*

Background: Autistic adolescents frequently experience clinical levels of anxiety that exacerbate social difficulties (van Steensel, Bögels, & Perrin, 2011). Improvements in both social behavior (Gates, Kang, & Lerner, 2017) and anxiety (e.g., Corbett, Blain, Ioannou, & Balser, 2017; Lei, Sukhodolsky, Abdullahi, Braconnier, & Ventola, 2017; McVey et al., 2016; Schohl et al., 2014) have been previously documented after receiving a social skills intervention. Recent literature highlights the importance of using neurobiological markers to assess for intervention response (Stavropoulos, 2017). No study to date, however, has examined changes in neural activity via fMRI and links with social behavior and anxiety across a well-validated social behavioral intervention for autistic adolescents.

Objectives: The present study will begin to address this gap by evaluating changes in neural activity (fMRI), 1) social behavior, 2) amygdala activity relative to anxiety subsequent to an evidence-based social skills intervention, the Program for the Education and Enrichment of Relational Skills (PEERS®).

Methods: Sixty-one adolescents (48 autistic, 13 typically developing) ages 11-16 were recruited for the present study. In this randomized controlled trial, autistic adolescents were randomly assigned to an experimental or a waitlist control group. All adolescents underwent fMRI at two timepoints – before and after the PEERS® intervention for the experimental group. Self- and caregiver-report measures of social behavior (Social Skills Improvement System, SSIS; Social Responsiveness Scale, SRS; and Test of Adolescent Social Skills Knowledge, TASSK) and anxiety were collected before and after intervention. Measures of anxiety (Child Behavior Checklist, CBCL and NIMH Diagnostic Interview Schedule for Children, Social Phobia, DISC) will be used to further classify the autistic groups as having or not having clinically-significant anxiety and social anxiety.

Results: Although the groups differed in their Ethnic identity (Table 1), neural differences are not expected based on this variable. Nonetheless, analyses will be conducted to examine potential effects based on Ethnicity due to the group difference. No other demographic differences were found (see Table 1). Preliminary results indicated that the intervention functioned as expected (paired sample *t* test of TASSK for the experimental group: $t(21) = -10.85$, $p < .001$; waitlist and typical group showed no change over time $p > .05$). Data analyses to be conducted include: two mixed model ANCOVAs to examine changes in amygdala activity over time and the moderating role of anxiety (Group*Time*Anxiety; Group*Time*Social Anxiety).

Conclusions: It is hypothesized that autistic adolescents in the experimental group with high levels of anxiety and social anxiety prior to the intervention will show decreased amygdala activity in response to the intervention, coinciding with improvements in social behavior and secondary effects on anxiety. Those with low levels of anxiety to start, on the other hand, will show increased amygdala activity, coinciding with improvements in social behavior (and no change in anxiety). The waitlist control and typically developing groups are expected to show no significant changes in neural amygdala activity over time. This study will be the first of its kind to examine effects of PEERS® on brain function via fMRI among autistic adolescents.

233 **174.233** Mapping Superficial White Matter Anomaly in Autism Spectrum Disorder: Effects on Functional Networks and Behavior

S. J. Hong[1,2], *B. Hyung*[1], *C. Paquola*[1] *and B. Bernhardt*[1], *(1)Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, QC, Canada, (2)Center for the Developing Brain, Child Mind Institute, New York, NY*

Background:

Autism spectrum disorders (ASD) are life-long developmental conditions characterized by atypical social cognition, communication, and repetitive behaviors/interests [1]. Multiple neuroimaging studies have shown alterations in cortical morphology in this syndrome [2]. White matter changes remain less well understood, particularly their association to cortical structure and function.

Objectives:

We focused on the superficial white matter (SWM), a compartment that has gained only little attention so far in ASD neuroimaging. In addition to its role in genesis and maturation of the folded cortex [3, 4], its spatial proximity to the cortical ribbon ensures intrinsic correspondence, making it an ideal candidate for integrative studies on cortical grey matter morphology, function, and white matter organization in ASD.

Methods:

From the Autism Brain Imaging Data Exchange repository, we selected three sites that contained: *i)* males and females, *ii)* children and adults, and *iii)* diffusion MRI and T1-weighted MRI data. Following cortical surface extraction and its QC, our sample included 53 ASD and 57 controls. To examine the SWM, we generated a surface 2mm below the cortex by following a Laplacian potential field towards the ventricles (**Fig 1A**). Surface-wide statistics mapped alterations in fractional anisotropy (FA), mean diffusivity (MD), and a multivariate aggregate of both in ASD compared to controls, controlling for age, sex, and site. We carried out seed based functional connectivity analyses from significant clusters to evaluate pathological structure-function coupling. Finally, we examined associations to behavioral symptoms of ASD by correlating inter-individual differences in SWM measures with ADOS scores, and built path analytical models, evaluating the role of functional connectivity on the relation between diffusion anomalies and ADOS scores. Multiple comparisons were corrected using random-field theory at $p_{FWE}<0.05$.

Results:

Multivariate analysis mapped SWM diffusion anomalies in ASD compared to controls (**Fig 1B**) in bilateral precuneus and posterior cingulate (PCU/PCC) and the right temporo-parietal cortex. Effects were consistent in children and adults and across sites. Notably, functional connectivity analysis from these regions revealed decreased intrinsic connectivity in ASD compared to controls, with right PCC/PCU being disconnected from adjacent cuneus and with the right temporo-parietal cortex from insular and superior parietal cortex (**Fig 2A-C**). Again, connectivity reductions were similar across sites (**Fig 2D**). Notably, in the ASD group, inter-individual differences in SWM anomalies in both right hemispheric clusters correlated with degrees of functional connectivity reductions (SWM_{TPJ}: r=-0.38, p<0.0025; $SWM_{PCC/PCU}$: r=-0.25, p<0.037, **Fig 2E**). SWM anomalies were also correlated to more severe ASD symptoms, as indexed by total ADOS (r=0.27, p<0.04). Finally, associations between SWM anomalies and total ADOS scores were found to be partially mediated by reduced functional connectivity (z=1.93, p<0.06), suggesting a disease-related path between SWM alterations, functional connectivity, and behavioral symptoms (**Fig 2F**).

Conclusions:

Our study targeting the SWM in ASD offers a novel perspective on the interplay between white matter anomalies and atypical functional networks, providing a potential window to better understand the complex biological factors contributing to its diverse behavioral symptoms.

234 **174.234** Multimodal Stratification of ASD with the Help of DTI, MEG, and MRS

***J. I. Berman**, L. Bloy, L. Blaskey, E. S. Kuschner, M. Ku, M. DiPiero, L. D. Gaetz, J. C. Edgar and T. P. Roberts, Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Efficient white matter and synapses are both necessary for accurate and rapid encoding of auditory sensory information. In autism spectrum disorder (ASD), slow auditory response latencies may contribute to abnormal auditory processing and, ultimately, language impairment. A structure-function relationship between M50 latency and diffusion MR indices of white matter maturation has been shown in typically developing children. However, the M50 latencies observed in ASD are heterogeneous and not well explained by white matter microstructure. GABA is an inhibitory neurotransmitter and abnormally low auditory system GABA has been observed in ASD. This study hypothesizes that M50 is dominantly modulated by white matter microstructure (indexed by dMRI) in one subgroup of ASD and is modulated by synaptic transmission function (indexed by GABA MRS) in a separate biologically-distinct subgroup.

Objectives: This multimodal study uses dMRI, GABA MRS and magnetoencephalography (MEG) to identify the multiple physiological mechanisms which underlie auditory processing efficiency in ASD and to potentially stratify children according to differing biological etiologies.

Methods: Participants included 46 children with ASD (mean age = 11.5±2.3) and 27 typically developing (TD) children (mean age = 10.9±2.1) with evaluable DTI, MRS and MEG data. DTI was acquired at 3T with 30 gradient directions at b=1000s/mm^2 and voxel size 2x2x2mm. The MNI template was used to measure DTI parameters including FA from Heschl's gyrus. MRS was performed using a single voxel macromolecule-suppressed, edited MEGAPRESS sequence (TR=1500ms, TE=80ms, 128 transient pairs, acq. time ~6min) with voxels (4x3x2cm) placed in left and right superior temporal gyrus and expressed relative to the reference creatine. The M50 response component to auditory stimulus tones was measured with MEG and identified as the first source localized post stimulus peak in the interval 50-150ms.

Results: A mixed model of M50 with hemisphere, diagnosis, GABA level, and cross terms revealed a main effect of FA (p<0.02) and an interaction between GABA and diagnosis (p<0.01). Analyzed separately in controls alone, increasing FA (p<0.05) and decreasing GABA (p<0.01) were correlated with shorter (faster) M50. In the ASD group, the relationship between FA, GABA and M50 was uncoupled. A subgroup of ASD subjects was identified with long (slow) M50 latencies relative to the typically developing M50 vs GABA curve (>95th percentile). Outlier group FA (0.287±0.004) was lower than FA among non-outliers (0.296±0.002, p<0.05), suggesting latency was prolonged in this subgroup compared to the "typical for their GABA level" value, perhaps through immature white matter, with commensurately slow conduction velocity.

Conclusions: This study observed higher GABA levels were associated with slower M50 responses in typically developing children. This relationship is possibly related to the inhibitory role of GABA in cortico-cortical circuitry mediating the M50 response, after the initial thalamocortical volley. Uncoupling of GABA to M50 as well as diffusion MR to M50 was observed overall in ASD, suggesting heterogeneous subpopulations. This study suggests stratification of ASD subjects may be performed based on which physiological factors dominantly modulate or limit the speed of sensory input. Stratification based on such mechanistic etiology can potentially pave the way for tailored/personalized therapy.

235 **174.235** Neural Responsivity to Social Rewards in Girls with Autism Spectrum Disorder

***K. E. Lawrence**[1], L. M. Hernandez[1], S. Y. Bookheimer[2] and M. Dapretto[2], (1)University of California, Los Angeles, Los Angeles, CA, (2)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA*

Background: The social motivation hypothesis of autism spectrum disorder (ASD) posits that ASD is driven by a diminished sensitivity to the inherently rewarding nature of social stimuli, which contributes to reduced opportunities for social learning and thereby leads to the social challenges observed in ASD. Previous functional magnetic resonance (fMRI) studies have indicated that males with ASD do indeed display reduced neural activity to social rewards, but it is unknown whether this finding extends to females with ASD, particularly as behavioral evidence suggests that affected girls may not exhibit the same reduction in social motivation as their male counterparts.
Objectives: We aimed to test whether neural evidence supports the social motivation hypothesis among girls with ASD by investigating how social reward processing may differ between girls and boys with ASD, as well as between girls with ASD and typically developing (TD) girls.

Methods: As part of an NIH-funded multi-site network, fMRI data was collected during an implicit-learning socially-rewarded task from a total of 154 youths with ASD and TD controls. An approximately equal number of girls and boys contributed data to each group, and participants were between the ages of 8 and 17 years old. Prior to starting the fMRI scan, participants were told that a number of abstract fractal-like images would be presented multiple times over the course of the task, and each time an image appeared they should guess via button press whether it belonged to "Team 1" or "Team 2", after which they would receive feedback on their response. If the participant guessed correctly, feedback consisted of a smiling male or female face with the text "That's right!"; if the subject's response was incorrect, a sad male or female face was instead displayed along with the text "That's wrong."

Results: Our group-level analyses focused on the contrast Correct > Incorrect (i.e., happy face > sad face). We used both a whole-brain approach and a region of interest (ROI) approach where we focused on the nucleus accumbens due to its known importance in reward processing. Groups were matched on implicit learning rate. Girls with ASD displayed increased activity to socially rewarding stimuli, including greater activity in the nucleus accumbens relative to boys with ASD, as well as greater activity in the lateral orbitofrontal cortex, the ventrolateral prefrontal cortex and the anterior insula compared to typically developing girls.

Conclusions: These results demonstrate for the first time that girls with ASD do not exhibit the same reduction in social reward sensitivity as boys with ASD. Instead, girls with ASD display increased neural activation to such stimuli in areas related to reward processing and salience detection. This heightened neural sensitivity to social rewards may be a protective biological mechanism underlying the reduced prevalence of ASD among females and the sex differences in friendship patterns among youth with ASD. Importantly, our findings suggest that the social motivation hypothesis may not generalize to affected females and highlight the importance of studying potential sex differences in ASD.

236 **174.236** Neurobiological Correlates Associated with Clinical Improvement in an Open Label Trial Assessing Autologous Umbilical Cord Blood for Treatment of Young Children with Autism

K. L. Carpenter[1], *E. Glenn*[2], *S. Major*[1], *C. Tallman*[3], *L. Chen*[3], *L. Franz*[1], *J. Sun*[3], *C. W. Nordahl*[4], *D. G. Amaral*[4], *J. Kurtzberg*[3], *A. Song*[3] *and G. Dawson*[5], *(1)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (2)Duke Center for Autism and Brain Development, Durham, NC, (3)Duke University, Durham, NC, (4)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (5)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC*

Background: While the exact mechanism underlying neural differences in autism (ASD) remains unknown, a number of studies have linked altered immune responses to brain overgrowth and altered white matter connectivity. As such, immune modulating therapeutic interventions have the potential of impacting neurodevelopment and clinical outcomes in ASD. In support of this, we have previously reported significant improvement following treatment with a single infusion of autologous cord blood
Objectives: The current study explored whether behavioral improvements were associated with differences in total cerebral volume (TCV) at baseline and changes in brain white-matter connectivity following treatment.

Methods: Twenty-five children participated in a phase I, open-label trial to assess the feasibility and safety of a single infusion of autologous cord blood in 2-6 year old children with ASD. Clinical improvement was measured through change in scores from baseline to 6 months on the Vineland Adaptive Behavior Scales-II Socialization subscale (VABS-SS) and the Expressive One-Word Picture Vocabulary Test-4 (EOW), as well as the Clinical Global Impression-Improvement Scale (CGI-I) score at 6 months. Brain volume and white-matter connectivity were measured at baseline and 6-months in a subset of 19 children. TCV was calculated from the baseline MRI using an automated template-based method to mask out brainstem and cerebellum. Changes in white-matter connectivity from baseline to 6 months were calculated from 25-direction Diffusion Tensor Imaging (DTI). DTI data were analyzed using deterministic tractography, the Connectome Mapping ToolKit (CMTK), and *a priori* defined nodes from a pediatric gray matter atlas. The relationships between TCV or white-matter connectivity and behavioral improvement were assessed with Spearmen correlations to account for non-normal distribution of clinical variables.

Results: Correcting for age, higher baseline TCV was associated with greater improvement on the EOW ($r=0.52$, $p=0.02$) and CGI-I ($r=-0.44$, $p=0.04$), and trend level improvement on the VABS-SS ($r=0.4$, $p=0.07$). Improvement across all 3 behavioral outcome measures was correlated with increased connectivity between the right frontal pole and the globus pallidus (GP; all $p\leq0.04$) and between the left fusiform and superior temporal cortex (STC; all $p=0.04$). Improvement on the VABS-SS and the EOW was associated with increased connectivity between the left STC and putamen (both $p=0.03$). Improvement on the VABS-SS and the CGI-I was associated with increased connectivity between the left inferior temporal cortex and STC, the thalamus and the hippocampus, and the temporal pole and the GP (all $p\leq0.04$). Finally, improvement on the EOW and the CGI-I, was associated with increased connectivity between the right frontal and temporal pole, the STC and GP, and the rostral middle frontal cortex and GP, as well as between the left fusiform and middle temporal cortex (all $p\leq0.04$).

Conclusions: Significant improvements in behavior in children with ASD were seen in a phase I, open label study after autologous cord blood infusion. The current results suggest that children with larger TCV at baseline showed the greatest levels of improvement. Furthermore, behavioral improvements were associated with increased white-matter connectivity in brain regions previously linked to social, communication, and language abilities.

237 **174.237** Perception of Art in High Functioning Autism

A. R. Charlebois[1], *B. Wicker*[2], *E. Roy*[3], *L. Giroux*[4] *and L. Giroux*[4], *(1)Psychology Department, Université de Montréal, Montreal, QC, Canada, (2)neurosciences, Université Aix-Marseille, Marseille, France, (3)Psychology, Université de Montréal, Montreal, QC, Canada, (4)Museum of Fine Arts of Montréal, Montreal, QC, Canada*

Background:
Art exploration is a complex process conditioned by factors that include both basic visual principles and complex cognitive factors. It has often been reported that people with autism spectrum disorders (ASD) possess a different capacity for visual apprehension and artistic expression, explaining their artistic talent, particularly their holistic visual processing. However, no empirical study has explored if people with ASD had a different perception of art in a qualitative way. Conversely, several therapies based on art perception and artistic creativity have been designed to help deal with their socio-emotional deficits. The use of creative art therapy has been put forth to promote adequate emotional state regulation.

Objectives:

The general objective of this project was to investigate, with an eye-tracking technique, the visual explorative behavior of ASD participants. We expected to observe significant differences in the eye-tracking patterns of neurotypical versus ASD participants. A secondary aim was to study if exposure to creative art sessions modify gaze behavior patterns.

Methods:

13 participants with ASD and 11 neurotypical controls (18 to 49 years old) participated were recruited. In a dark and quiet room, participants sat in front of computer screen displaying photographs of 12 paintings taken from the Montreal Museum of Fine Arts (MMFA). Paintings were shown sequentially for 15 seconds each. Eye-tracking data were collected and analyzed using an Eye-Tribe camera and the Ogama software. All participants then attended 7 creative arts sessions at the MMFA. These sessions included visits of the museum with a guide explaining the paintings displayed, and creative workshops where participants could create their own art. A second session of eye tracking data acquisition was then performed, where participants viewed the paintings a second time.

Results:

Areas of interest (AOI) were selected on each painting, based on the focus of attention of the neurotypical group. Complete fixation time in the AOIs was calculated for each painting and compared between groups. We first compared the gaze behaviour during the first session of data acquisition. The salience analysis revealed that while neurotypical participants display a very homogenous gaze fixations behaviour which followed some general common principles (e.g., being attracted to saliency regions), a large variability was observed in ASD participants, who did not show the same attraction to salient regions, especially in the case of figurative paintings with social or emotional value. We then explored how the art therapy sessions influenced the gaze behaviour of ASD participants. Results show that gaze behaviour was different from the first session for all subjects, suggesting that art therapy-like workshops had an influence on the way ASD participants look at paintings.

Conclusions:

These preliminary results highlight a peculiarity in gaze behaviour in ASD when observing art paintings. This suggests a different way to perceive information in an art-related context, particularly in social dimensions. This could be due to a diminished influence of top-down processes on painting perception in ASD. We further show that art therapy sessions have an impact on how participants look at paintings.

238 **174.238** Pre-Scan Preparation in fMRI Research for Children with Autism: A Scoping Review

***D. Tajik-Parvinchi**, K. R. Black and J. A. Weiss, Psychology, York University, Toronto, ON, Canada*

Background: Functional magnetic resonance imaging (fMRI) plays a vital role in advancing our understanding of typical and atypical brain development, including for youth with autism. Progress in this field can be hampered by practical requirements of scanning, as successful image acquisition requires participants to remain still and tolerate the noise and confinement of the fMRI scanner bore. The common cognitive, emotional, and behavioral challenges associated with autism compound acquisition difficulties. Many non-pharmacological strategies are available to prepare children with autism for the fMRI environment and there is a need to understand the kinds of approaches that researchers can employ to have successful data acquisition.
Objectives: The current scoping review of the recent literature aimed to identify the pre-scan approaches used to prepare children and adolescents (3-21 years) with autism for the fMRI environment.

Methods: A review protocol was developed and refined further using the recommendations for scoping review reports. A search of scientific databases between the January of 2014 – February 2018 period uncovered 270 articles, of which 128 met inclusion criteria. Information on diagnosis, sample size, age-range, pre-scan preparation methods, and scanning success rate (Number of participants recruited/Number of participants who completed the fMRI session with acceptable quality scans) was extracted and charted.

Results: Out of the 38 articles reporting the use of a preparation protocol, 42% reported using a mock scanner, 16% using a mock scanner with additional behavioural, visual, and technological training strategies, 26% using sedation, 11% using natural sleep, and 5% others. The data acquisition success rate of studies reporting pre-scan preparation methods was on average, considerably better than previously reported (93% vs. 66%). Sedation led to the highest rate of success (99%), followed by natural sleep (95%), mock scanner (92%), and mock scanner with additional training and/or others (87%). Sedation and natural sleep methods were primarily implemented in studies of children with autism under 6 years of age, or with autism and ID. Five articles reported detailed descriptions of their pre-scan preparation protocols. Common strategies described within the mock scanner protocol included gradual exposure to MRI noise (simulated within the mock scanner bore); practice sessions often occurred the same day with varying durations (20 – 120 minutes). Studies implementing training in addition to the mock scanner described empirically supported behavioural strategies and technology-aided instruction.

Conclusions:

Results suggest that researchers who intend to begin a neuroimaging study with children with autism without intellectual disability may greatly increase their scanning success rate by implementing a pre-scan protocol with a single mock scanner session. Additional strategies such as picture schedules, video demonstrations, and inclusion of a preferred movie are other important strategies to consider. For younger children with autism and those with co-occurring ID, scanning during natural sleep or via inclusion of intensive behavioural strategies in addition to a mock scan protocol have been used with success. Documenting pre-scan preparation methods, success rates, and reasons for dropouts are important steps to standardizing the processes in future work.

239 **174.239** Rapamycin Effects on the Brains of C57BL/6 Mouse Models

***H. Li**, Medical Biophysics, University of Toronto, Toronto, ON, Canada*

Background: Rapamycin is a specific inhibitor of mTOR (Mammalian Target of Rapamycin), which regulates multiple biological activities. There have been some researchers looking into rapamycin efficacy against Autism and other neurological diseases, and it has been verified multiple times that rapamycin does have the ability to ameliorate those diseases, but meanwhile, some data also implied that rapamycin could have potential toxicity towards brains.
Objectives: To apply rapamycin on wild type C57BL/6 mouse models and use MR imaging to examine change on whole brain regions, and any reversal change after ceasing the application of drug. Based on the ROIs (regions of interest), more behavioral tests and histology tests will be conducted to verify any correlations between brain volume change and potential adverse effect

Methods: To investigate the potential influence of rapamycin on the brain, we use 6 weeks/10 weeks old wild type C57BL/6 mouse models as subjects or vehicles. Rapamycin was dissolved in 0.25% polyethylene glycol and 0.25% tween prior to usage, and subjects were administered 6 mg/kg every Monday, Wednesday, and Friday by intraperitoneal injections for 4 weeks, while vehicles were administered with the same solution without rapamycin of the same amount and frequency. The drug application ceased from week 5 and all mice are still examined for another 6 weeks for potential reverse symptoms. All mice were examined by 7.0 Tesla MRI scanner at the end of each week, with contrast agent (MnCl2 Solution) applied a day in prior to scanning. All data retrieved by MRI scanner was processed by python and R.

Results: The outcomes of experiment were quite different between subjects of 6 weeks old and 10 weeks old. Upon the initiation of the drug application, subjects (of either 6 weeks old or 10) were experiencing a slower drop of brain volumes, followed by a fast drop from week 3. 10-week subjects' brain volume dropped to the lowest (3.43%) at the end of week 4 and an almost immediate recovery began when stopping using the drug starting from week 5. The volume went all way back to nearly the initial level after 4 weeks and stay steady since. From the t-statistics produced based on the MR images, only a few areas located mainly at cerebral cortex showed high significance of atrophy (0.1 FDR). However, 6-week subjects were experiencing a larger and faster decrease in brain volume and continued to drop after the cessation of drug (as low as 6.44%). T-statistics showed atrophy across the whole brain (0.1 FDR), especially in visual, auditory, motor, and somatosensory cortex regions. The recovery process also took much longer than 10-week subjects, and had only recovered less than 1% at the end of week 8.

Conclusions: The results showed that rapamycin does have the ability to cause brain atrophy and the younger the subjects are, the worse the possible influences seem to be. The adverse effect on the brain is partially recoverable according to the results, and possible influence on the subjects are still examined by detailed behaviour tests and histology tests.

240 **174.240** Reduced Beta Connectivity during a Music Familiarity Task in Children with Autism

C. P. De Barros Freitas[1], *S. M. Wong*[2,3], *L. Ristic*[4], *S. Fragiadakis*[5], *S. Chow*[4], *A. Iaboni*[5], *B. Dunkley*[6], *M. J. Taylor*[7], *J. P. Lerch*[8] *and E. Anagnostou*[5], *(1)Holland Bloorview Research Institute, Autism Research Centre, Toronto, ON, Canada, (2)Division of Neurosurgery, Hospital for Sick Children, Toronto, ON, Canada, (3)Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada, (4)Bloorview Research Institute, Toronto, ON, Canada, (5)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (6)Diagnostic Imaging, Hospital for Sickkids, Toronto, ON, Canada, (7)The Hospital for Sick Children, Toronto, ON, Canada, (8)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada*

Background:
Background: Emerging evidence suggests autism is a disorder of brain connectivity and atypical reward processing has been proposed as an explanation for social deficits in ASD. Music is a valuable tool to study human cognition, emotion and reward networks and it is also an auditory stimulus that interests and motivates children with ASD.

Objectives: To examine both whole brain and seed analysis functional connectivity in the reward networks associated with familiarity and liking of music listening in children with ASD compared to typical controls.

Methods: 23 children with autism (ASD) and 23 typically developing children (TDC) children, between 7 to 14 years old, matched on age and sex were recruited. Magnetoencephalography (MEG) was used to measure brain activation and neural synchrony, while listening to different types of music (familiar liked, familiar disliked, unfamiliar liked and unfamiliar disliked). These music selections were chosen by the children and then matched with unfamiliar songs (of the same genre, tempo and mode) for presentation in the MEG.

Results: 23 ASD (mean age 10.09 ± 1.41) and 23 TDC (mean age 10.26 ± 1.85) of IQ>70 have been recruited. Findings revealed a network of reduced beta-band amplitude synchronization in the unfamiliar disliked music in children with ASD compared to controls (p=0.004, corrected). Also, we found increased low gamma amplitude synchronization in the familiar disliked music condition in children with ASD (p=0.003, corrected). Seed analysis of the reward networks are currently underway.

Conclusions: These findings reinforce theories suggesting that beta-band connectivity is important for establishing long-range communication among brain regions and reduced beta synchronization in the ASD group could reflect inadequate processing in task-dependent networks. On the other hand, gamma-band (30 to 80 Hz) abnormalities have been reported in many studies of ASD and are associated with impaired perceptual and cognitive functions.

241 **174.241** Reduced Regional Gray Matter Volume in the Frontal Lobe May be the Neural Basis Underlying Atypical Sensory Processing in Autism Spectrum Disorder

Y. Matsubara[1], *M. Takahashi*[2], *S. Ono*[3] *and K. Nakamura*[4], *(1)Hirosaki University Graduate School of Medicine, Hirosaki, Japan, (2)Research Center for Child Mental Development, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (3)Department of Radiology, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (4)Graduate School of Medicine, Hirosaki University, Hirosaki, Japan*

Background: Atypical sensory processing, such as sensory hypersensitivity and hypoesthesia, exists in individuals with autism spectrum disorder (ASD), and affects social functioning. Although many studies have shown that sensory processing is an important feature for understanding ASD, the neural substrates underlying abnormal sensory processing in ASD individuals remain unknown. Current studies in typically developing subjects (TD) have suggested that atypical sensory processing is associated with reduced gray matter volume in the precentral gyrus; however, no studies have reported on reduced gray matter volume in the precentral gyrus in ASD individuals. Therefore, we hypothesize that a different neural basis contributes to atypical sensory processing in ASD.
Objectives: The present study aimed to investigate the structural abnormality that may be involved in atypical sensory processing in ASD.

Methods: We acquired structural MRI data using a 3T scanner and assessed individual differences in sensory processing using the Adolescent/Adult Sensory Profile questionnaire in adults with ASD (n = 11) without intellectual disabilities and psychotropic medications, and in sex, handedness-, and intelligence- matched TD subjects (n = 14). We used MRI Cloud to analyze structural MRI, which is a cloud-based tool for calculating the regional brain volume with a multi-atlas template. We used intracranial volume as a covariate in comparisons of regional gray matter volume and correlational analyses.

Results: ASD adults had significantly higher scores for low registrations (t = 4.969, p <0.001), sensory sensitivity (t = 4.554, p < 0.001), and sensory avoidance (t = 6.288, p < 0.001) than did TD subjects. The regional gray matter volume was lower in the ASD than in the TD adults in several brain regions, including the right middle frontal gyrus (F = 6.564, p = 0.018). Correlational analyses, revealed a negative relationship between gray matter volumes in the right middle frontal gyrus and hypersensitivity (r = −0.504, p = 0.012), thus indicating that reduced right middle frontal gyrus may be the neural basis underlying atypical sensory processing in ASD. Additionally, reduced gray matter volume in the right middle frontal gyrus was also associated with a more severe autism symptom measured using the Social Responsiveness Scale-2. (r = −0.427, p = 0.020), thus suggesting that reduced gray matter volume in the right middle frontal gyrus may be a common feature of atypical sensory processing and other ASD symptoms.

Conclusions: Current studies reveal that the right middle frontal gyrus is involved in reorienting attention from an exogenous stimulus. Our results suggest that reduced gray matter volume in MFG represents the neural underpinnings of sensory processing in ASD. Therefore, we propose that defective function in attention control may also be closely associated with hypersensitivity in ASD individuals. Additionally, reduced gray matter volume in the right frontal gyrus is a common neural basis underlying atypical sensory processing and other ASD symptoms such as social impairment and repetitive restricted behavior.

242 **174.242** Resting State fMRI and Attachment Difficulties in Children

E. J. Choi[1], *M. M. Vandewouw*[2] *and M. J. Taylor*[1], *(1)The Hospital for Sick Children, Toronto, ON, Canada, (2)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada*

Background: Autism spectrum disorder (ASD) can be a risk factor for developing secure attachment. Correspondingly, attachment problems also disturb social development in the typically developing population, and in severe cases, attachment deprivation in a critical period can lead to autistic symptoms, having life-long effects on the individual's mental health. Although the etiology of ASD is more strongly associated with genetics, children with ASD and children with attachment problems may present with some overlapping difficulties in building social relationships. Despite the extensive neuroimaging studies on neural correlates underlying ASD, little is known about the neural correlates of attachment disturbance.

Objectives: In the present study, we compared DMN functional connectivity between secure and insecure attachment in typically developing children and correlated connectivity strength with neuropsychological measures to determine if attachment problems affect DMN function.

Methods: Resting-state fMRI data on a Siemens 3T MRI using 32 channel head coil was collected in typically developing 9-10-year-old boys (N=80, Mean age/SD = 9.62/0.69). Of these children, 46 were assessed as secure attachment and 34 as insecure according to the semi-structured attachment interview, The Separation Anxiety Test (Resnick, 1993). Subject's data were slice-time and motion corrected, smoothed, intensity normalized. Signal from the white matter and CSF were regressed out. The default-mode network (DMN) connectivity, which represents a relaxed mental state, stimulus-independent thoughts or self-referential processing, was investigated between secure and insecure attachment children using seed-based analysis for five core DMN seeds (pC, precuneus; PCC, posterior cingulate cortex; vACC, ventral anterior cingulate cortex; mPFC, medical prefrontal cortex; vmPFC, ventromedial prefrontal cortex), using FSL's FEAT program. Statistical images were thresholded using clusters determined by Z >2.3 and a corrected cluster significance threshold of p = 0.05.

Results: We found significantly increased functional connectivity among core regions of DMN in children with insecure attachment such that the vACC, vmPFC and PCC. Increased vmPFC connectivity was also found in dorsomedial prefrontal and hippocampal regions, which are known as parts of two subsystems of DMN, in children with insecure attachment. In addition, the increased functional connectivity in DMN was negatively correlated with the children's emotional openness scores (vACC connectivity with PCC: r=-0.44, p=0.00).

Conclusions: Our results are the first to show that early attachment experience contributes to the shaping of core DMN functional connectivity in typically developing children, implicating the importance of early experience. Given that atypical DMN functional connectivity has often been reported in ASD, our results may offer one model as to why some behavioural manifestations may overlap between these two conditions.

243 **174.243** Sensory Seeking and Salience Network Functional Connectivity in Females and Males with Autism Spectrum Disorder

K. K. Cummings[1], *K. E. Lawrence*[1], *L. M. Hernandez*[1], *S. Y. Bookheimer*[2], *M. Dapretto*[2], *S. A. Green*[2] *and G. Consortium*[1], *(1)University of California, Los Angeles, Los Angeles, CA, (2)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA*

Background: Individuals with an autism spectrum disorder (ASD) are significantly more likely to experience atypical sensory sensitivities and seeking behaviors compared to their typically developing (TD) peers (Liss et al., 2006). Prior work in our lab has found that sensory over-responsivity (SOR) in autism is related to atypical resting-state functional connectivity in the salience network (SN), an intrinsic brain network thought to be related to where the brain directs attention (Green et al., 2016). However, most studies examining the neurological basis of sensory processing have been done with primarily male samples, so little is known about how ASD females process sensory information. Additionally, little is known about the neurobiological basis of sensory seeking (compared to SOR) though we hypothesize that seeking is also related to atypical attribution of salience to sensory stimuli.

Objectives: To examine SN functional connectivity underlying sensory seeking in males and females with ASD and to determine whether atypical seeking-related connectivity confers resilience in the form of better executive functioning.

Methods: The relationship between sensory seeking and SN functional connectivity was compared between ASD males and females in two samples of youth aged 7-18 years. In Study 1, resting-state fMRI was conducted on 78 ASD (43F) and 103 TD (55F) participants. The anterior insula (AI), thought to be the hub of the SN (Seeley, 2007), was used as the seed in whole-brain analyses. Seeking behaviors, determined through self-report on the Short Sensory Profile (SSP; Dunn, 1999), were correlated with AI connectivity. Because youth with ASD have been shown to be poor reporters of their own internal sensations (Shalom, 2006), we replicated the analysis in a second sample of 44 ASD (11F) and 31 TD (10F)

participants that had parent reports of sensory seeking on the SSP. Whole-brain analyses were thresholded at Z>2.3 and corrected for multiple comparisons at p<.05 for both studies. Executive functioning was measured with the BRIEF (Gioia et al., 2000).

Results: In both studies, there were no sex differences in seeking. In Study 1, ASD females with more abnormal sensory seeking behaviors showed greater AI connectivity with medial prefrontal cortex (mPFC) compared to their male counterparts. In Study 2, sensory seeking related to greater positive connectivity between the SN and mPFC across males and females with ASD. Better executive functioning was correlated with both more sensory seeking and greater SN connectivity with mPFC in both males and females.

Conclusions: Sensory seeking may potentially be used as a regulatory mechanism for ASD adolescents, as shown through correlations with prefrontal connectivity and executive functioning. This process appears to only have sex group differences when sensory seeking behaviors are self-reported, perhaps providing insight into the ways males and females with autism are able to report on their internal states. Results of mediation analysis will be discussed to determine whether seeking might mediate the relation between medial prefrontal connectivity and executive functioning.

244 **174.244** Sex Differences in Hemispheric Asymmetry in Autism

D. L. Floris[1], *T. Wolfers*[1], *M. Zwiers*[1], *J. K. Buitelaar*[2], *L. G. EU-AIMS*[3] *and C. B. Beckmann*[1,4,5], *(1)Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, Netherlands, (2)Karakter Child and Adolescent Psychiatry University Centre, Nijmegen, Netherlands, (3)EU-AIMS Organization, London, United Kingdom, (4)Centre for Functional MRI of the Brain (FMRIB), University of Oxford, Oxford, United Kingdom, (5)Radboud University Medical Center Nijmegen, Donders Institute for Brain, Cognition and Behaviour, Department of Cognitive Neuroscience, Nijmegen, Netherlands*

Background: Autism spectrum disorder (ASD) is characterized by a striking male preponderance with three times more males being affected than females. While neuroimaging studies have started to pick up on studying sex differences in ASD, none has addressed the question of sex differences with respect to hemispheric specialization. ASD is characterized by a disruption of specialization in the brain with findings pointing to atypical hemispheric asymmetry across hemispheres (Herbert et al., 2002; Floris et al., 2016). Sex differences in hemispheric specialization have frequently been reported in neurotypical (NT) individuals with males showing more pronounced patterns of lateralization than females, however, no study has addressed this question in ASD.

Objectives: We aimed to explore sex differences in hemispheric lateralization across individuals with ASD and NT controls.

Methods: We selected high quality structural T1-weighted MRI data from the Longitudinal European Autism Project dataset including 94 females with ASD aged 6-30 years, 260 IQ-and age-matched males with ASD as well as 166 age-matched NT males and 90 NT females. T1-weighted images were preprocessed using SPM12 and the CAT12 toolbox. Specific preprocessing steps were adopted to meet requirements for the analysis of asymmetry: 1) images were segmented using a symmetric tissue probability map; 2) segmented images were flipped along the x-axis; 3) original (OI) and flipped images (FI) were used to create a symmetric DARTEL template and subsequently registered to it; 4) laterality indices was calculated at each voxel by the formula:(OI–FI)/(OI+FI)*2. Laterality images were restricted to the right hemisphere (RH) and smoothed with a 4mm FWHM kernel. Main effects and interactions were tested by regression of a GLM at each voxel with group and sex as fixed factors and age and scanning sites as nuisance covariates. Significance levels for clusters were set at a voxel-level cluster-forming $p<0.001$ and by their number of expected voxels (spatial extent threshold) according to Gaussian Random Field theory. Statistical outcomes were corrected for multiple comparisons at the cluster-level by controlling the topological false discovery rate (FDR) at $q<0.05$. Significant results were correlated with symptom measures such as the ADOS and ADI.

Results: Voxel-wise analysis of laterality in the RH revealed significant group-by-sex-interactions in the posterior cingulate cortex and the pars trinagularis. Males with ASD showed reduced leftward asymmetry compared to NT males, while ASD females showed increased leftward asymmetry compared to NT females. The opposite pattern was evident in the angular gyrus and supplementary motor area with ASD females showing reversed rightward asymmetry compared to NT females and ASD males showing reversed leftward asymmetry compared to NT males. Results remained the same when including handedness and FIQ as nuisance covariates. Correlation analyses with ADI- and ADOS-subscales did not yield any significant results.

Conclusions: Males and females with ASD exhibit differential patterns of structural hemispheric lateralisation compared to NT controls in language processing regions and default network hubs. While males with ASD show patterns that resemble those in NT females, females with ASD exhibit neural masculinization suggesting that models of 'gender-incoherence' of ASD also apply to atypical hemispheric lateralization.

245 **174.245** Sleep Problems, Brain Development, and ASD Risk in the First Two Years of Life

A. Estes[1], *K. E. MacDuffie*[2], *M. D. Shen*[3], *S. R. Dager*[1], *T. St. John*[1], *M. Styner*[4], *J. Wolff*[5], *J. Pandey*[6], *H. C. Hazlett*[3], *K. Botteron*[7], *R. T. Schultz*[6] *and J. Piven*[4], *(1)University of Washington, Seattle, WA, (2)Speech and Hearing Sciences, University of Washington, Seattle, WA, (3)University of North Carolina, Chapel Hill, NC, (4)*Co-Senior Authors, IBIS Network, University of North Carolina, Chapel Hill, NC, (5)University of Minnesota, Minneapolis, MN, (6)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (7)Washington University School of Medicine, St. Louis, MO*

Background: Children with ASD experience sleep problems at 2-3 times the rate of typically developing (TD) children (Liu, 2006; Maskey, 2013). Sleep problems in ASD may emerge as early as 30 months, and persist through adulthood (Humphreys, 2014; Croen, 2015); however, little is known about sleep patterns in infants at high familial risk for ASD or about possible effects of inadequate sleep on early brain development (Graven, 2008).

Objectives: Using data from a multi-site, longitudinal neuroimaging study of a large cohort (N=440) of infants at high risk for ASD (HR; with an older sibling with ASD) and low risk (LR; with a TD older sibling and no family hx of ASD), we examined parent-reported sleep problems from 3-12 months of age in relation to brain structure from 6-24 months of age.

Methods: Participants were assessed for ASD by expert clinicians at 24 months and underwent MRI (high-resolution 3T T1 & T2-weighted imaging data; $1mm^3$ voxels) at 6, 12, and 24 months. An automated segmentation algorithm derived hippocampal volume (HCV), total cerebral volume (TCV), caudate and amygdala volumes (Fig. 1). Children were grouped according to diagnostic outcome at 24 months (HR-ASD=72, HR-NonASD=241, and LR=127). Sleep problems were characterized from 3-12 months of age with the Infant Behavior Questionnaire (IBQ), a measure of infant temperament with 5 items related to sleep initiation and maintenance. IBQ sleep scores demonstrated adequate validity when compared with

scores from the Brief Infant Sleep Questionnaire, available for a subgroup of the sample (n=98; Fig. 2). Linear mixed models were used to predict HPC, amygdala, and caudate volumes (individual intercepts included as a random effect; outcome group, sleep score, age, quadratic effect of age, and group interactions with each included as fixed effects; TCV and scan site included as covariates).

Results: Infant sleep scores differed across the groups ($F(2,397)= 4.7$, $p<.01$); *post hoc* testing revealed greater sleep problems for HR-ASD vs TD and a non-significant trend for HR-ASD > HR-NonASD infants. Group moderated the relationship between sleep problems and hippocampal volume in infancy. Worse sleep in infancy was related to increased hippocampal volume from 6-24 months only for HR siblings who went on to develop ASD (HR-ASD; $\beta=57.16$; $t=3.15$, $p=.002$; Fig. 1). No relationship between poor sleep and hippocampal volume was found in the HR-NonASD and LR groups. The IBQ-HPC relationship was unique to the IBQ sleep items; no other IBQ subscales predicted HPC volume, and no significant sleep-amygdala or sleep-caudate relationships were found.

Conclusions: Sleep in the first 12 months of life may be related to hippocampal development in HR infants who go on to develop ASD. In contrast to prior studies with typically-developing older children and sleep-deprived animals (Taki, 2012; Guzman-Marin, 2003), sleep problems in HR-ASD infants were associated with increased (rather than decreased) HPC volume. The relationship between sleep and HPC volume is likely to be dynamic across development and this relationship may begin to differ early in the course of ASD in HR infants.

246 **174.246** The CO-Occurrence of MRI Findings and Autism Spectrum Disorders:What Is the Importance of Pineal Cyst???

A. Mira Coelho[1] *and F. Gouveia*[2]*, (1)Psychiatry, Hospital S.Joao, Port, Portugal, (2)hospital s.Joao, Porto, Portugal*

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder, with persistent impairment in reciprocal social communication and social interaction, and restricted, repetitive patterns of behaviour, interests or activities.There are different findings on Magnetic Resonance Imaging(MRI) and their high prevalence may be an important tool in clinical assessment as is suggested in many studies. Pineal cysts, arachnoid cysts, choroid plexus cysts, enlarged perivascular spaces, *cavum septum pellucidum*, asymmetrical ventricles are some of the MRI incidental findings discovered in children with ASD.

Objectives: Evaluate the simultaneous occurrence between magnetic resonance imaging findings, namely pineal cysts which shows a high prevalence in this group, and children diagnosed with autism spectrum disorders.

Methods: Retrospective case-control study carried out on 161 children: 93 cases diagnosed with autism spectrum disorder (38 with level 1 severity and 55 with level 2 severity) were compared with 68 controls (non-autistic patients). All participants had done a magnetic resonance image and were patients of the paediatric psychiatry appointments.

Results: This study shows that the prevalence of pineal cysts is higher in autistic children comparing with non-autistic children (84.6% vs 15.4%, $p=0.041$). If the level of severity of the autism is discriminated into level 1 and 2, there is also a significant difference between the groups (15.4% vs 84.6% vs 0.0% in non-autistic, level 1 and level 2 ASD, respectively, $p<0.001$). The latter association was analysed calculating the odds of the presence of pineal cyst and having level 1 autism which was increased but with a wide variability (OR, 95%CI 13.75, [2.38 – 79.38]).

Conclusions: There is a possible association between pineal cysts and autism spectrum disorders as shown in this study. This association is stronger in the children diagnosed with level 1 autism, since it is the group with the highest prevalence of pineal cysts (11.8%). It would be interesting to further explore the factors underlying this correlation by extending the study to a larger sample.

247 **174.247** The Development of Frontal Cortex of the Adolescent with Autism Spectrum Disorders (ASD) and Its Relationship with Working Memory

W. Cao[1]*, H. Zhu*[2]*, Y. Li*[2]*, Y. Wang*[2]*, H. Guo*[3]*, Y. Zhang*[2] *and X. Zou*[4]*, (1)South China Academy of Advanced Optoelectronics, South China Normal University, Guangzhou, China, (2)Child Developmental & Behavioral Center, Third Affiliated Hospital of SUN YAT-SEN University, Guangzhou, China, (3)School of Psychology, South China Normal University, Guangzhou, China, (4)Child Developmental & Behavioral Center, The Third Affiliated Hospital,Sun Yat-Sen University, Guangzhou, China*

Background:

Working memory (WM) is one of the core components of executive function, which plays a central role in the pathology of Autism Spectrum Disorders (ASD). Although high-functioning autism (HFA) tend to have a normal range of IQ, WM is a main impact on the daily life. Adolescence is a period in which WM becomes increasingly important, but the supported brain regions like frontal cortex are still immature. Thus, the development of these brain regions and its relationship with WM ability, severity of adolescent HFA is extremely interesting.

Objectives:

This study aimed to investigate the development of the frontal cortex of the HFA. The resting-state connectivity and graph metrics were computed through the time course signals measured by an fNIRS device. The relationship between the neuroimaging results and the WM ability, severity of autism was also evaluated.

Methods:

In total, 12 typically developing (TD) children, 14 children with ASD and 18 adolescents with ASD were recruited. The IQ was measured by the Wechsler Intelligence Scale for Children (WISC-IV), and the diagnostic of ASD was confirmed by ADOS. All the participants were asked to close the eyes and sit still in a dark and quite room for 8 mins during the experiment. 13 emitters and 12 detectors were attached to the forehead forming 40 measuring channels, which covered the middle frontal gyrus (MFG), superior frontal gyrus (SFG), dorsolateral prefrontal cortex (DLPFC) and the supplementary motor cortex (SMA). The motion artifacts and physiological noise were first removed, and then the Pearson correlation coefficient r between DLPFC and all the other channels was calculated. the small worldness, network efficiency, betweenness centrality, degree was computed using a network sparsity threshold between 16% and 35% in increments of 1%. The area under the curve (AUC) was also obtained for each metric to avoid dependence on threshold levels.

Results:

Compared to children with ASD, adolescents with ASD showed lower connectivity between right SMA and bilateral DLPFC (p=0.022; p=0.021), and higher between left DLPFC and right SFG (p=0.012). The graph analysis revealed adolescents with ASD showed lower network efficiency than TD group (p=0.004) and children with ASD group (p=0.004). Moreover, the study found that the adolescents with ASD group showed lower

betweenness centrality, the degree and the nodal efficiency in channels within the DLPFC (p<0.05). Meanwhile the connectivity between bilateral DLPFC in the children with ASD group was significantly correlated with working memory index of WISC-IV (r=0.540, p=0.046), and the network efficiency of children with ASD group was correlated with the repetitive scores of ADOS (r=-0.681, p=0.010). The betweenness centrality of left DLPFC of adolescents with ASD group negatively correlated with working memory index (r=-0.493, p=0.038). The degree and nodal efficiency of left DLPFC of both ASD groups were negatively correlated with communication and reciprocal interaction of ADOS (p<0.05).

Conclusions: T

his atypical neural developmental trajectory of DLPFC related to the WM ability and severity of adolescent HFA. The DLPFC seemed to follow a "posterior to anterior" pattern in ASD, which was the opposite to that of TD.

248 **174.248** The Neurodevelopment of the Posterior Superior Temporal Sulcus As an Neuroendophenotype in Autism

A. Martinez Teruel[1,2,3], *S. Hotier*[1,2,3], *C. Laidi*[1,2,3], *M. A. D'albis*[1,2,3,4], *J. F. Mangin*[5], *A. Beggiato*[4,6,7], *F. Amsellem*[4,6,7], *A. Lefebvre*[7], *R. Toro*[6], *M. Leboyer*[2,3,4], *M. Elmaleh*[8], *T. Bourgeron*[9], *R. Delorme*[4,6,7] *and J. Houenou*[1,2,3,4], *(1)UNIACT, Psychiatry Team, NeuroSpin, I2BM, CEA Saclay, Gif-Sur-Yvette, France, (2)INSERM U955, Equipe 15 'Psychiatrie Translationnelle', IMRB, Université Paris Est, Créteil, France, (3)AP-HP, Mondor Hospital, DHU PePSY, Pôle de Psychiatrie, Créteil, France, (4)Fondamental Foundation, Créteil, France, (5)UNATI, Neuropin Neuroimaging platform, CEA Saclay, Gif-Sur-Yvette, France, (6)Pasteur Institute, Human Genetic and cognitive function, Paris, France, (7)AP-HP, Robert-Debré Hospital, Child and adolescent Psychiatry unit, Paris, France, (8)AP-HP, Robert-Debré Hospital Department of Pediatric imaging, Paris, France, (9)Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France*

Background:

In functional and morphological studies among people with Autism Spectrum Disorder (ASD) and their families (Boddaert et al. 2004; Baron-Cohen et al., 2006, Spencer et al., 2011), one region of the social brain has been constantly disturbed: the posterior part of the Superior Temporal Sulcus (pSTS). Following the definition of the endophenotype (Gottesman & Good, 2003), the pSTS should be a potential neuroendophenotype in autism.

Cortical folding patterns of the pSTS and its three caudal branches (the anterior caudal branch (cSTS1), the intermediate caudal branch (cSTS2) and the posterior caudal branch (cSTS3)) (Segal & Petrides, 2012) have been solely investigated in ASD. Two studies only have demonstrated a longer cSTS1, specifically in the right hemisphere among children and adults with ASD (Levitt et al., 2003; Hotier et al., 2017). In our best knowledge, no study has established that neurodevelopmental abnormalities in pSTS exist among unaffected relatives of individuals with ASD

Objectives:

To compare the length of the three branches of the pSTS between three groups; one with ASD, one with their direct and unaffected relatives, and one healthy control group.

Methods:

We included 20 individuals with ASD, 70 of their direct unaffected relatives and 31 controls with no family history of autism [respectively: Mean Total Intellectual Quotient(sd) = 98(19); 115(14); 115(11) (p<0.0004) - Mean age (sd)= 18 (11); 34(16); 29(13); (p<7.73 x10^{-5})- Males/ Females % = 58/42; 44/56; 36/64; (p<0.22)]. Using the toolbox Morphologist in Brainvisa software, on structural MRI, we manually labeled the branches of the pSTS and extracted their length.

Mixed linear models were used with length of each branch of the pSTS in each hemisphere as dependent variable, group as independent variable and age, sex, Total IQ as control variables.

Results:

Only a specific effect of the group on the length of the right cSTS1 was present. The cSTS1 was significantly longer in unaffected relatives (52.1 mm) compared with healthy controls (43.3 mm) (p=0.004) and patients with autism (44.1 mm) (0.04). The length of right cSTS1 in the probands with autism did not significantly differ from healthy controls (p=0.8). No effect of the group, age or sex was present on the length of other branches of the STS, in the right or left hemisphere (p<0.05).

Conclusions:

We show that specific morphological abnormalities in a key region of the social brain are also present among unaffected relatives with autism. The morphology of the pSTS could be a candidate neuroendophenotype for autism.

249 **174.249** The White Matter Microstructure of Basal Ganglia Related Atypical Sensory Processing in ASD

M. Takahashi[1], *Y. Matsubara*[2], *K. Nakamura*[3] *and S. Ono*[4], *(1)Research Center for Child Mental Development, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (2)Hirosaki University Graduate School of Medicine, Hirosaki, Japan, (3)Graduate School of Medicine, Hirosaki University, Hirosaki, Japan, (4)Department of Radiology, Graduate School of Medicine, Hirosaki University, Hirosaki, Japan*

Background: Atypical sensory processing exists in individuals with ASD and white matter (WM) microstructure abnormalities may contribute to this. However, the underlying mechanisms have not been fully elucidated. Furthermore, it has been reported that atypical sensory processing is closely associated with other ASD symptoms, such as social impairment and repetitive restricted behavior and hence, it is assumed that these impairments share a common neural basis with atypical sensory processing. However, these assumptions remain to be clarified.
Objectives: This study aimed to investigate the relationship between WM microstructure and atypical sensory processing in ASD and the common neural basis with other ASD symptoms using diffusion tensor imaging (DTI) in an attempt to reveal the neural pathology of ASD, which contributes to atypical sensory processing.

Methods: We used DTI with a 3T scanner and the adolescent adult sensory profile (AASP) to investigate WM microstructure and abnormalities in sensory processing, respectively. We used MRI Cloud to analyze DTI data and calculated the fractional isotropy (FA) in each ROI. These data were acquired from 11 ASD patients without intellectual disabilities (FSIQ ≥ 80) and 14 sex-, handedness-, and intelligence-matched neurotypical subjects (NT).

Results: ASD individuals showed a higher score for both hypersensitivity (p < 0.01, d = 2.42) and hyposensitivity (p < 0.01, d = 1.17) on the AASP than did NT. A comparison of sensory processing for each sensory modality, revealed that ASD individuals obtained higher scores for touch

hypersensitivity (p < 0.01, d = 1.66), activity hypersensitivity (p < 0.01, d = 2.39) and hyposensitivity (p < 0.01, d = 2.04), and auditory hypersensitivity (p < 0.01, d = 3.05) and hyposensitivity (p < 0.01, d = 1.48). In comparisons of FA, ASD had a significantly lower FA in the white matter of the left putamen (p = 0.03, d = 0.93) and right supramarginal gyrus (p = 0.03, d = 0.91) than did the NT. Correlational analyses demonstrated that FA in the left putamen was negatively correlated with activity hypersensitivity (r = −0.556, p < 0.01) and hyposensitivity (r = −0.538, p < 0.01), and auditory hypersensitivity (r = −0.449, p = 0.02) and hyposensitivity (r = −0.434, p = 0.03). Conversely, FA in the right supramarginal gyrus was not associated with any AASP scores (all p > 0.05). Moreover, FA in left putamen was negatively correlated with the total score on the Social Responsiveness Scale-2, indicating the decreased FA in the left putamen is associated with a more severe autism symptom (r = −0.457, p = 0.02). These results suggest that WM microstructure abnormalities in the left putamen are closely associated with ASD pathology.

Conclusions: Decreased FA in the left putamen is associated with atypical sensory processing of activity and auditory sense in ASD. Additionally, decreased FA in this area was also associated with more severe ASD symptoms. These results suggest that individuals with ASD have an abnormality in the WM microstructure in the left putamen, which is associated both with atypical sensory processing and other ASD symptoms.

250 **174.250** Tract-Based Cluster Analysis: DTI Group Differences in Autism

P. A. Luque Laguna[1,2], *R. A. Dallyn*[1,2], *D. G. Murphy*[1,2] *and F. dell'Acqua*[1,2], *(1)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:

Previous studies have reported white-matter differences associated with autism on a wide range of anatomical regions using different methods. However, with conventional voxel-wise analysis it is difficult to associate anatomical specificity to changes occurring on a large and spread group of voxels, while the direct use of few selected tractography reconstructions or brain regions may limit the actual interpretation of global changes within the brain.

To investigate difference in microstructural organisation and diffusion properties between ASD and TD subjects we adopted a novel imaging analysis technique. Tract-based cluster analysis (TBCA[1]) is a method of voxel-clustering analysis that improves the anatomical specificity and the sensitivity of existing methods without being restricted to specific regions. Specifically, TBCA uses the anatomical coherence between white-matter voxels and the connectivity information provided by tracts to inform the voxel-cluster analysis within a non-parametric statistical framework.In this study, we present results using the TBCA approach on diffusion dataset from a large cohort as part of the UK-AIMS consortium (n=122).

Objectives:

To investigate white-matter differences in autism using diffusion imaging data from the UK-AIMS datasets and a new data-driven method of image analysis (TBCA).

Methods:

MRI acquisition: 61 male subjects with autism and 61 matched controls aged 18 to 45 years. Diffusion-weighted MRI data collected with b-value=1300 s/mm2, 32 diffusion weighted directions and 4 b0s volumes and isotropic voxel size of 2.4mm.

Data pre-processing: motion and eddy-current distortion correction were performed using ExploreDTI[2]. Whole brain DTI maps of Fractional Anisotropy (FA) were computed for each subject. Each FA map was normalised to the FMRIB58FA 1mm template using flirt/fnirt[3].

Statistical analysis: non-parametric cluster-level inference analysis was performed on FA voxels defined within a white-matter mask. For comparison, two methods were tested. One approach was based on the traditional cluster-level inference as implemented in SnPM[4] to detect significant clusters formed only by adjacent voxels. Method-2, tract-based cluster analysis with TBCA was applied to detect significant clusters formed by voxels anatomically connected and related to each other according to a connectivity template provide connectivity information for each WM voxel (for more details see Luque-Laguna 2018).

Results:

Figure-1-top: SnPM detected a single cluster covering a region white-matter region around the genu and the anterior body of the corpus callosum. Figure-1-bottom: TBCA consistently detected multiple clusters of voxels belonging to distinct white-matter tracts such as the left arcuate (green), left uncinate (blue), the genu (red) and the anterior body of the corpus callosum (pink). These tracts are consistent and in line with previous studies showing white-matter changes in adults with ASD.

Conclusions:

The new TBCA results show clusters where the diffusion properties of white-matter differ between ASD and TD subjects. These results also show an increase anatomical specificity simplifying the interpretation of these results. Further research is now required to replicate these results on additional dataset and on other quantitative metrics.

251 **174.251** Typical Cortical Concentration of GABA and Glutamate in Young Adults with Autism Spectrum Disorder

T. Kolodny[1], *M. P. Schallmo*[2], *J. Gerdts*[3], *R. Bernier*[3] *and S. Murray*[1], *(1)Psychology, University of Washington, Seattle, WA, (2)Psychiatry and Behavioral Science, University of Minnesota, Minneapolis, MN, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA*

Background: An imbalance of excitation and inhibition (E/I) in neural circuits has been postulated as a key neurobiological characteristic of autism spectrum disorder (ASD). Various evidence from genetics, animal models and post-mortem analyses point to a central role of the

inhibitory transmitter GABA, yet evidence in humans is lacking. Magnetic resonance spectroscopy (MRS) provides a non-invasive technique to measure concentrations of GABA and other neurometabolites *in vivo*. Several recent MRS studies have found reduced GABA concentration in children with ASD, lending support to the E/I imbalance model. However, results are inconsistent across experimental procedures, regions of interest, and sample characteristics, including the potential confounding effects of psychotropic medication use.
Objectives: Since developmental changes may underlie the mixed results of GABA in cross-sectional studies in children, we aimed to test GABA levels in young adults with ASD, at the end point of the developmental trajectory, while controlling for effects of sex and medication use.

Methods: Participants included 30 adults with ASD (19 male) with diagnoses confirmed through ADOS, ADI and clinical judgment using DSM-5 criteria, and included 39 age-, sex- , and IQ- matched neurotypical controls (22 male). MRS scans were acquired with a 3T scanner using MEGA-PRESS editing, in 5 different volumes of interest (VOIs; Figure 1A): medial occipital cortex, left temporal cortex, parietal cortex opposite to the participant's dominant hand, and in right and left lateral occipital cortex (functionally-defined human MT complex). GABA+ (GABA plus co-edited macromolecules) and Glx (glutamate plus glutamine) concentrations were quantified in each VOI using the Gannet GABA Analysis Toolkit, and scaled to water (Figure 1B). Measurements in the occipital VOI were repeated in two separate scanning sessions to assess test-retest reliability.

Results: There were no differences in GABA+ levels (Figure 2A), Glx levels (Figure 2B), or their ratio, between individuals with ASD and neurotypicals, in any of the VOIs (all t's<1.55). The same pattern of results was obtained when excluding participants treated with selective serotonin reuptake inhibitor drugs (SSRIs; NT: n=1; ASD: n=8), and when excluding participants treated with any psychotropic medications (NT: n=2; ASD: n=14). There were no sex differences in any of the MRS measures and no correlations with age. GABA+ and Glx concentrations did not correlate with ADOS, SRS, or Sensory Scale scores. Likewise, GABA+ and Glx did not correlate with behavioral measures of visual perception (motion discrimination thresholds or contrast detection thresholds, measured with psychophysical tasks). Test-retest repeatability analysis of the occipital VOI measurements revealed low coefficients of variation across sessions (GABA+: CV=4%; Glx: CV=6%) but poor intraclass correlations (GABA+: ICC=.24; Glx: ICC=.35; Figure 2C-D).

Conclusions: The current study provides a comprehensive set of measurements in 5 different VOIs in adults with ASD and found typical levels of both GABA+ and Glx concentrations in ASD, yielding no support for brain-wide alteration of E/I imbalance. We suggest that low test-retest reliability might limit the power to detect small group differences, and that better signal-to-noise is required in future studies.

252 **174.252** White Matter Microstructure of Autism Spectrum Disorder (ASD) and Attention Deficit Hyperactivity Disorder (ADHD)

ABSTRACT WITHDRAWN

Background: Previous researches have shown high rate of comorbidity (30-50%) between attention deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD). Several studies reported that impaired structural brain connectivity was related to the core features of ASD and ADHD. However, only a few studies directly compared the white matter microstructure between ASD and ADHD. Sensory hypersensitivity is often existed in both individuals with ASD and those with ADHD, however little is known about the brain substrates related to sensory sensitivity in the two neurodevelopmental disabilities.
Objectives: The aim of the present study is to reveal the commonality and difference of white matter microstructure between adults with ASD and those with ADHD, especially concerning sensory sensitivity, using Diffusion Tenor Imaging (DTI).

Methods: A total of 218 adults participated in this study; 58 Normal Controls (NC), 105 ASD, 55 ADHD. Two medical specialists diagnosed ASD and ADHD according to DSM-5 criteria. ADOS-2 was conducted on 83 out of 105 ASDs. DTI data were processed using programs in the FMRIB Software Library (FSL) version 5.0. Automatic quality control was conducted with DTIprep. TOPUP was performed to correct susceptibility induced distortions. TBSS was used for voxelwise statistical analysis. Simple regression analysis using individual scores for sensory hypersensitivity was applied to FA values within clusters showing significant main effect of diagnosis on FA. The statistical threshold was defined at $p < 0.05$ (corrected for multiple comparisons). Age, gender and head motion were included as covariates.

Results: FA values of 7 clusters differed in FA across diagnostic groups. These clusters were located at genu, body, and splenium corpus callosum (CC) and posterior cocona radiata in right hemisphere. Post hoc analyses revealed both ASD and ADHD had lower FA compared to TD in 5 clusters. Two small clusters at genu of CC, voxel size 5 and 3, indicated reduced FA in ADHD compared to ASD and TD. Significant interaction effects of FA and sensory sensitivity were identified between Developmental Disabilities (DD) and NC in the cluster located at body of CC in right hemisphere.

Conclusions: Altered white matter microstructures in CC and posterior corona radiata were observed in both ASD and ADHD. Different effect of sensory hypersensitivity on FA was identified in CC between developmental disabilities and NC. This study suggested the similar alternation of white matter microstructure, including regarding sensory hypersensitivity, between ASD and ADHD. However, further studies are required to investigate the disorder-specific alternations since group differences in FA were observed between the two DDs in small regions.

253 **174.253** Shared Dynamic Emotional Face Processing in Children with ASD, OCD and ADHD and Controls: Data from the Pond Network

M. M. Vandewouw[1], *E. J. Choi*[2], *C. Hammill*[3], *J. P. Lerch*[4], *E. Anagnostou*[2] *and M. J. Taylor*[3], *(1)Neuroscience & Mental Health Program, The Hospital for Sick Children Research Institute, Toronto, ON, Canada, (2)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)The Hospital for Sick Children, Toronto, ON, Canada, (4)Mouse Imaging Centre, Hospital for Sick Children, Toronto, ON, Canada*

Background: Autism spectrum disorder (ASD) is classically associated with poor face processing skills, yet increasing evidence suggest that those with obsessive compulsive disorder (OCD) and attention deficit hyperactivity disorder (ADHD) also have difficulties with understanding emotions. We contrasted fMRI measures of emotional face processing across these three clinical paediatric groups, compared with typically developing controls. We also investigated the developmental trajectories of face processing in these groups. As facial movements underlie facial expressions of emotion, we used dynamic faces, which have been shown to improve emotion identification.
Objectives: To determine a) if the processing of emotional faces differs across three developmental disorders (NDD), and b) if the neural mechanisms underlying emotional face processing develop differently in these groups.

Methods: 223 high-functioning children aged 5-19yrs were included in the current study, 87 with ASD, 44 with ADHD, 42 with OCD, and 94 typically developing (TD) controls. The fMRI stimuli were dynamic (480ms-long) faces (neutral-to-happy, neutral-to-angry) and dynamic flowers (closed-to-open), presented in 18 pseudo-randomized blocks (6 each of happy, angry, flowers) of 13.5s on a Siemens 3T MRI using a 12-channel head coil.

Subjects' data were slice-time and motion corrected, smoothed, intensity normalized and motion scrubbed (>0.9mm framewise displacement (FD)). Signal from the white matter, CSF, whole-brain, and 6 motion parameters were regressed out, and data were bandpass filtered (0.1-0.2Hz) and de-noised with FSL's FIX. FSL's FEAT was used to obtain the brain response for each subject to the happy, angry and flower task conditions. FSL's FLAME was used to investigate group-by-age interactions and group differences between the TDs and NDDs, using F-tests to examine shared differences to TDs across the NDDs, in the task condition contrasts, with sex and mean FD as covariates. Statistical images were thresholded using clusters determined by Z > 2.3 and a corrected cluster significance threshold of p = 0.05.

Results: F-tests investigating shared differences in the NDD group compared to TDs when processing happy and angry faces compared to flowers revealed shared increased activation in the right fusiform, bilateral lingual gyri and other occipital regions in the NDDs compared to TDs, with post-hoc tests revealing that this effect was being driven by the ASDs and OCDs. These two NDDs were also driving a significant F-test investigating group-by-age interactions to increased activation when processing happy compared to angry faces in the superior frontal gyrus, with ASDs and OCDs exhibiting a positive relation with age, and TDs exhibiting a negative relation. Furthermore, all three NDDs exhibited shared increased activation in the right occipital regions to happy compared to angry faces.

Conclusions: We provided evidence that children with ASD, ADHD and OCD demonstrate shared amplified activity in dynamic face processing compared to TDs, both across age and in their developmental trajectories, relying more on posterior brain regions with increases in frontal social-cognitive areas with age.

Poster Session
175 - Sensory, Motor, and Repetitive Behaviors and Interests
11:30 AM - 1:30 PM - Room: 710

254 **175.254** Longitudinal Change Profiles of Repetitive Behaviours in ASD Children, Adolescents and Adults over Two Time Points

D. V. Crawley[1], *E. J. Jones*[2], *J. Tillmann*[3], *B. Oakley*[1], *J. Ahmad*[1], *C. Moessnang*[4], *H. L. Hayward*[5], *T. Charman*[6], *D. G. Murphy*[7] *and E. Loth*[1], *(1)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (3)King's College London, London, United Kingdom of Great Britain and Northern Ireland, (4)Department of Psychiatry and Psychotherapy, Central Institute of Mental Health, University of Heidelberg, Mannheim, Germany, (5)Institute of Psychiatry, Psychology and Neuroscience, King's College London, King's College London, London, United Kingdom, (6)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

Background:
Restricted, repetitive behaviours and interests (RRB) are core features of autism spectrum disorder (ASD), some of which cause significant impairment and disrupt daily life (learning/socialisation). RRB are multi-faceted, ranging from self-injurious behaviour to circumscribed interests. Some evidence suggests that RRB symptoms decrease with age. Besides this, little is known about prognostic markers of RRB change, particularly outside toddlerhood. Here we test whether anxiety, sensory processing and/or executive function play a role.

Objectives:

To examine stability/change in RRB, in total and across different subdomains, and investigate factors that may predict change.

Methods:

164 children, adolescents and adults with ASD aged 6-30 years (M=15.55, SD=5.54) from the EU-AIMS Longitudinal European Project were included. RRB were assessed at two time points (T1, T2; time between: M=19.67 months, SD=3.37) using the Repetitive Behaviour Scale-Revised (RBS-R). Both total and subscale scores were examined. Anxiety was measured using the SDQ 'Emotional symptoms' score, sensory processing with the Short Sensory Profile. EF was indexed by cognitive flexibility (reversal learning: perseverative errors) and response inhibition (go/no-go: commission errors). Change scores were computed such that higher values indicate improvement. Change groups ('improve', 'no change', 'worsen') were calculated using +/-0.5 interquartile range of T1 median, due to skewness (1.49) – common on the RBS-R. We report effect sizes for Wilcoxon signed-rank test (*r*) and Spearman's correlations (r_s). Predictors of change were examined using linear regression.

Results:

At the group level, only the total and Stereotyped Behaviour subscale decreased significantly from T1 to T2 (total: effect size *r*=-0.15, *p*=0.006; stereotyped: effect size *r*=-0.16, *p*=0.004). Whilst total RRB severity was significantly negatively related to age cross-sectionally (T1:r_s*=-0.31,* T2:r_s=-0.26, *p*'s<0.001), degree of change did not vary with age (r_s=-0.08, *p*=0.29). *Change groups*: 18.3% of individuals showed improvement in total RRB, 69.5% showed no change and 12.2% worsened (Fig1). RRB subdomains showed similar profiles; 15.2-21.3% improved while 7.9-13.4% worsened. Change groups did not differ on age or IQ, however, there was a higher proportion of females in the 'worsen' group and a higher proportion of males in the 'improve' group (Fig2; X_2=6.49, *p*=0.03, φ=0.20). No differences were found between change groups in anxiety or sensory processing at T1. At T2, the 'worsen' group had significantly greater anxiety (X^2=11.19, *p*=0.004) and sensory symptoms (X^2=7.50, *p*=0.02) than both other groups. Change in sensory symptoms significantly predicted change in RRB (F(3,103)=5.358, p=0.002, R^2=0.24; sensory: p=0.004). Comparatively, change in anxiety significantly predicted RRB total at T2 (F(3,103)=4.285, p=0.007, R^2=0.22; anxiety: p=0.001). Groups did not differ on EF measures at T1 or T2, nor did performance changes between time points predict RRB change or T2 RRB total.

Conclusions:

We found RRB stability was considerably more frequent than change, though there was some evidence for overall RRB reduction over time. Males were over-represented in those who 'improved', whilst females were over-represented in those who 'worsened'. Findings support the close links between RRB, anxiety and sensory symptoms, but do not provide evidence for an EF role. Future research should further consider the mechanisms by which RRB symptoms ameliorate or deteriorate.

255 **175.255** Measuring Imitation Ability in Autism Using Dynamic Time Warping Applied to a Dance Videogame Task

R. N. Rochowiak[1], *C. Pacheco*[2], *R. Nicholas*[3], *E. Mavroudi*[2], *S. Rengarajan*[4], *G. Miller*[4], *B. Messenger*[4], *A. S. Pillai*[4], *R. Vidal*[2], *S. H. Mostofsky*[5] *and B.*

Tuncgenc[6], (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Johns Hopkins University, Baltimore, MD, (3)University of Nottingham, Nottingham, United Kingdom, (4)Kennedy Krieger Institute, Baltimore, MD, (5)Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD, (6)Neurology, Johns Hopkins University, Baltimore, MD

Background:

Impaired motor imitation is commonly reported in individuals with autism spectrum disorder (ASD) and is thought to contribute to impaired development of reciprocal-social skills. To date, most imitation studies have relied on human observer coding (HOC) to detect presence/absence of certain elements based on behavioral coding schemes. The reliance on HOC is time-consuming, introduces coder bias and reliability issues, and limits assessment to predetermined elements delineated in coding schemes. Using a computer-based technique would eliminate coder bias, reduce time spent, allow for reliable comparisons across sites, and provide more complete assessment of movement dynamics. Further, most studies have examined imitation of single, discreet movements performed in unrealistic settings. Using a videogame task to assess motor imitation ability would allow for assessment across a range of realistic contexts.

Objectives:

This study aims to develop and validate the novel use of a machine learning algorithm, dynamic time warping (DTW), to investigate imitation ability in typically-developing (TD) children and children with ASD during performance of a dance videogame task.

Methods:

Thirty-six children aged 8-12 years (22 ASD; 3 females per group) participated. Children imitated a video avatar performing a 1-minute dance sequence comprised of 18 novel whole-body movements. Children's movements were recorded using two Kinect Xbox depth cameras at 30 frames-per-second, placed in front of and behind the child (Figure 1a). The x-y-z coordinates of 20 joints were extracted from the depth recordings using iPi Motion Capture Software.

HOC was used to assess imitation performance and to validate the accuracy of DTW. For each move, elements describing key changes in limb locations were defined (Figure 1a). Children received a score of 1 for each element performed; as such, higher HOC scores indicate better imitation accuracy (Figure 1b).

DTW temporally aligns the child's time-course to the avatar's time-course by minimizing the Euclidean distance between them. DTW distances of the 18 moves were averaged to make up the child's total DTW distance (Figure 1c). Higher DTW distances indicate greater difference between the child and the avatar, and hence poorer imitation. Preprocessing performed included positioning the hip as point of reference, normalizing the children's limb length to the avatar's skeleton, and adjusting the children's rotation to match the avatar's at the beginning of the activity.

Results:

HOC scores were reliability-coded by two hypothesis-blind coders (κ= .915, p< .001). HOC scores and DTW distances were significantly correlated ($r(35)$= -.77, p< .001) and this correlation held equally strong within the ASD ($r(22)$= -.77, p< .001) and TD ($r(14)$= -.74, p< .001; Figure 2) groups. Furthermore, DTW distances revealed significantly better imitation in TD than in ASD group (p= .02), and HOC scores confirmed this trend with near-significant values (p= .09; Figure 2).

Conclusions:

The present study provides evidence for the use of a computer-based algorithm (DTW) to investigate autism-associated differences in motor imitation during a naturalistic dance videogame task. This approach for assessing motor imitation could prove useful in establishing biomarkers for assessing diagnosis and response to intervention.

256 **175.256** Motor Skills in Children and Adolescents with Autism Spectrum Disorder

***L. Turriziani**, F. La Fauci Belponer, F. Cucinotta, A. Ricciardello, M. Boncoddo, F. Bellomo, M. Briguglio, D. Dicanio and A. M. Persico, Interdepartmental Program "Autism 0-90", "G. Martino" University Hospital, University of Messina, Messina, Italy*

Background: Children and adolescents with autism spectrum disorder (ASD) frequently display deficits in gross and fine motor skills, motor coordination, static and dynamic balance. These deficits, in turn, impair daily living tasks, such as feeding, handwriting, and buttoning, as well as motor performance in jumping, running, throwing, and sport-related activities. Subjects with ASD also present difficulties in integrating sensory input and motor output, particularly in anticipatory control and action planning.

Objectives: (1) To assess the prevalence, features and severity of motor deficits in ASD; (2) To define the clinical and patient history variables most differentiating ASD individuals with and without motor deficits; (3) To evaluate the applicability of the Movement Assessment Battery for Children-2 (Movement ABC-2) to test motor skills in ASD.

Methods: We performed a retrospective study on 100 ASD patients and a prospective study on 103 patients consecutively recruited at the Interdepartmental Program "Autism 0-90" of the "G. Martino" University Hospital in Messina (Italy). All patients were assessed using ADOS-2, ADI-R, Leiter-3, WPPSI-III, GDMS, PEP-3,VABS-II. Patients recruited for the prospective study were also assessed using the Movement ABC-2. All patients with neuroanatomical abnormalities at the MRI, history of seizures or severe EEG abnormalities, were excluded from the prospective study and data have been to this date analyzed for 55 patients (2-17 y.o., M:F=47:8).

Results:

Retrospective study - Motor deficits were detected by neurological examination in 60/100 (60%) ASD patients. Parents reported moderate-to-severe motor deficits in 57/100 (57%) for gross motor skills, 56/100 (56%) for fine-motor skills; 66/100 (66%) for visuo-motor coordination, 65/100 (65%) in bimanual coordination.

Prospective study – the Movement-ABC2 battery was completed by 26/55 (47.3%) patients. Motor deficits, either involving coordination, visuo-motor skills or balance, were recorded in 17/26 (65.4%) completers, confirming the estimates produced by our retrospective study. Non-completion of the Movement ABC-2 battery is significantly more frequent among patients with: (a) moderate or severe ASD (26/29, 89.7%, P=0.005); (b) co-morbid Intellectual Disability (27/29, 93.1%, P<0.00001); (c) deficits in receptive language with limited understanding of the instructions (22/29, 75.9%, P=0.007).

Conclusions: Moderate-to-severe deficits in motor skills have been recorded in 60-65% of ASD children and adolescents in our sample. The assessment of motor deficits in ASD is deeply influenced by autism severity, cognitive level and receptive language skills. The Movement ABC-2 battery is thus of limited use in ASD, because it can be reliably applied only to autistic subjects either high-functioning or at least endowed with

sufficiently developed receptive language. These limitations spur interest in new technologies applied to ASD children in naturalistic contexts. Addressing motor deficits in a personalized treatment plan may foster improvement not only in motor performance and self-esteem, but also in social cognition and executive functions.

257 **175.257** Multisensory Integration in Children and Adolescents with ASD: Susceptibility to the Flash-Beep Illusion

***S. Scholes**, K. Ainsworth and A. Bertone, McGill University, Montreal, QC, Canada*

Background: Atypical sensory processing is a key characteristic of Autism Spectrum Disorder (ASD; APA, 2013). One specific sensory process, which allows individuals to experience the world as a coherent whole, involves the ability to efficiently integrate stimuli from multiple sensory modalities, or multisensory integration (MSI). Research suggests that altered MSI may partially underlie sensory-related behaviours in ASD (Iarocci & McDonald, 2006; Zhou et al., 2018). There has been mixed evidence as to whether the MSI of non-social information (e.g. information void of social content) is altered in individuals with ASD (e.g. Stevenson et al. 2014; Bao et al. 2017). Additionally, little is known about the development of MSI across age.

Objectives: The goal of the study is to investigate the MSI of non-social information in individuals with ASD at different periods of development using the flash-beep illusion task (Shams et al. 2002).

Methods: Thirty-one individuals with ASD (27 males, 4 females) and 57 typically developing (TD) individuals (32 males, 25 females), aged between 6 and 18 years, completed a sound induced flash illusion task. On every trial, participants were presented with either one (1F) or two flashes (2F) with either zero (0B), one (1B), or two beeps (2B) congruently in time, resulting in six different audiovisual conditions; 1F/0B, 1F/1B, 1F/2B, 2F/0B, 2F/1B, and 2F/2B. The *fission* illusion trial is the 1F/2B combination, and the *fusion* illusion trial is the 2F/1B combination. Participants were asked to indicate if they viewed 'one' or 'two' flashes on the screen. In parallel to the task, participants completed the Wechsler Abbreviated Scale of Intelligence 2nd Edition (WASI-II) and the Sensory Profile Questionnaire.

Results: Participants were separated into four groups: ASD child (n=17; age <=12), ASD adolescent (n=14; age > 12), TD child (n=31; age <=12) and TD adolescent (n=26; age > 12). A 4 x 6 ANOVA (group x task condition) revealed a significant effect of condition ($p<.001$); a post-hoc Bonferroni comparison indicated that illusion trials were less accurate than non-illusion trials (suggesting participants were susceptible to the illusion). However, a significant group effect was also found ($p<.001$), with Bonferroni post-hoc analyses revealing a significant jump in accuracy between ASD children and ASD adolescents ($p<.001$), while there was no significant difference between TD children and TD adolescents ($p=.547$). This suggests a shift to being less susceptible to the illusion with age for ASD individuals but not TD individuals, specifically for the fusion illusion.

Conclusions: Our results revealed that TD individuals are susceptible to both illusions and this appears to be consistent across development. In comparison, adolescents with ASD were less susceptible to the fusion illusion than children with ASD, suggestive of less automatic MSI processes with age. Future research looking at MSI abilities, in ASD, for non-social information should do so within a developmental context.

258 **175.258** Predicting Self-Injurious Behavior at Age Three Among High-Risk Infant Siblings

***A. F. Dimian**[1], B. Pennington[2], K. Botteron[3], S. R. Dager[4], A. Estes[4], H. C. Hazlett[5], R. T. Schultz[6], J. Piven[7], J. Wolff[1] and .. The IBIS Network[5], (1)University of Minnesota, Minneapolis, MN, (2)University of Minnesota Twin Cities, Minneapolis, MN, (3)Washington University School of Medicine, St. Louis, MO, (4)University of Washington, Seattle, WA, (5)University of North Carolina, Chapel Hill, NC, (6)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (7)*Co-Senior Authors, IBIS Network, University of North Carolina, Chapel Hill, NC*

Background: Existing research suggests that self-injurious behavior (SIB) is a relatively common behavior disorder that can occur across the lifespan of individuals with autism spectrum disorder (ASD). Repetitive behavior is also a core diagnostic feature of ASD, but few empirical longitudinal studies have examined SIB specifically in the early years of life. We previously reported potential risk factors for SIB using psychosocial variables from 12 months of age to predict SIB at 24 months among a preschool sample of children at high familial risk for ASD (Dimian et al., 2017). In the present study, we extend these findings and examine SIB occurrence and associated potential risk factors at 36 months.

Objectives: 1) Extend our previous models on early potential risk factors with 12 months predictors of SIB occurrence at 24 months to predicting SIB occurrence at 36 months among toddlers at high familial risk for ASD; 2) investigate if sensory experiences and subtypes at 12 months of age predict SIB occurrence at 36 months, and 3) explore how topographies of SIB and stereotypy change across 12, 24 and 36 months of age.

Methods: Participants were from a longitudinal study of infants at familial risk for ASD. The present sample included 149 high-risk infants (65.8% male) who completed the following assessments at ages 12, 24, and 36 months: MSEL, Vineland-II, Sensory Experiences Questionnaire, and Repetitive Behavior Scales-Revised (RBS-R). The RBS-R was used to identify SIB and stereotypy. Descriptive analyses and binary logistic regression models were utilized to examine 12 month predictors for SIB at 36 months.

*Results***:** SIB was reported for 22% of participants at age 36 months and the risk of engaging in SIB was 3.36 times higher among children who received a diagnosis of ASD compared to children with no diagnosis. The first logistic regression model replicated Dimian et al. and included sex, MSEL and Vineland composite scores, and SIB and stereotypy from the RBS-R at 12 months. The overall model significantly predicted 36 month SIB ($\chi^2 = 29.7$, $p < .001$, $R^2_{pseudo} = 0.29$). Of individual predictors, Mullen composite score and stereotypy at 12 months were significantly predictive of SIB at age 36 months. A second model including Sensory subtype scores was evaluated. The overall model was significant ($\chi^2 = 38.9$, $p < .001$, $R^2_{pseudo} = 0.41$). Topographies of SIB and stereotypy changed in overall frequency over time and most children tended to engaged in hitting self against a surface.

*Conclusions***:** SIB was more prevalent among those children who received a diagnosis of ASD. Logistic regression results were mixed but the best fitting model indicated that presence of SIB, stereotypy, hyper and hypo responsivity, and lower intellectual functioning at age 12 months significantly predicted the occurrence of SIB at 36 months. These findings have implications for potential early intervention targets that could help inform prevention programming in the future, but more research is warranted.

259 **175.259** Predictive Motor Abilities in Children with Autism Spectrum Disorder: Evidence from Kinematics and Muscle Activity

***S. W. Park**[1,2], A. Cardinaux[2], D. Guo[1], S. Ben-Ami[3], L. Denna[2], K. Chan[2], S. Diamond[2], M. Kjelgaard[4], P. Sinha[2] and D. Sternad[5], (1)Northeastern University, Boston, MA, (2)Massachusetts Institute of Technology, Cambridge, MA, (3)Brain and cognitive science, Massachusetts Institute of*

Technology, Cambridge, MA, (4)Marymount Manhattan College, New York, NY, (5)Biology, Electrical & Computer Engineering, and Physics, Northeastern University, Boston, MA

Background: Motor clumsiness has often been reported in individuals with autism spectrum disorder (ASD). However, as findings highly depend on the testbeds and inclusion/exclusion criteria, no common denominators or causal underpinnings of motor impairments in ASD have been identified. A recent theoretical framework from our group suggests that the seemingly distinct manifestations of ASD in multiple domains may share a common core: an impaired ability to make predictions. Difficulties in language, cognition, social interactions, repetitive behaviors, and motor coordination may all result from the same underlying impairment, albeit at different time scales. This study thus examined motor impairments through the lens of predictive control.

Objectives: We tested the hypothesis that individuals with ASD show reduced motor coordination when interacting with moving objects, specifically when performing actions that involve prediction. We examined whether impairments depended on the degree of prediction challenges in ASD.

Methods: Sixteen children with ASD (aged 7-12 years) and 26 age- and IQ-matched neurotypical (NT) children participated in a series of motor tasks involving catching in both naturalistic and virtual environments. While performing naturalistic ball catching, 3D joint kinematics and muscular activities in participants' arm, leg, and trunk were recorded to quantify predictive motor behaviors. A set of control tasks assessed postural balance, reaction time and movement speeds when reaching to a static ball. The same individuals performed virtual interception tasks that simplified the coordination challenges and also afforded manipulating the time window for prediction. Catching accuracy was evaluated by temporal and spatial errors. A control virtual task was designed to be analogous to the experimental tasks when assessing reactive action.

Results: In naturalistic ball catching, ASDs showed a lower percentage of successful catches compared to NTs ($p=0.01$). While NTs approached the ball with a relatively stable profile of hand velocity, ASDs exhibited a collision-like motion at ball contact, suggesting insufficient prediction. Reduced predictive control in ASD was also evident in the muscles; ASDs showed peak muscular activity in trunk muscles at catching moment while NTs showed preparatory muscle activation prior to catching ($p=0.02$). Further, ASDs exhibited more pronounced co-activation of biceps and triceps, consistent with abrupt ball interception ($p=0.01$). In contrast, postural sway during quiet standing and reaction and movement time during the control tasks did not show difference between ASDs and NTs ($p>0.3$). In the virtual interception tasks, ASDs' accuracy in catching indicated significantly worse performance, especially when occlusion of the ball trajectory enhanced the predictive challenge ($p=0.02$). In a control test of reaction time, ASDs did not differ from NTs, neither in reaction nor movement time ($p>0.5$).

Conclusions: Results from a suite of prediction-based tasks revealed that ASD children manifest reduced predictive motor control. Further, the impairment depended on the degree of predictive challenge. These findings suggest that the ability to predict may be a unified mechanism explaining phenotypic variations across ASD individuals. With this theoretical context, the results have implications beyond motor skills towards a more encompassing understanding of autism.

260 **175.260** Prescribing Yoked Prism Lenses- Examiner Agreement Using the Kaplan Nonverbal Battery

R. A. Coulter[1], *A. Bade*[2], *E. Jenewein*[3] *and Y. C. Tea*[4], *(1)College of Optometry, Nova Southeastern University, Ft Lauderdale, FL, (2)Optometry, Nova Southeastern University, Fort Lauderdale, FL, (3)College of Optometry, Salus University, Elkins Park, PA, (4)College of Optometry, Nova Southeastern University, Fort Lauderdale, FL*

Background:

Autism Spectrum Disorder (ASD) is marked by deficits in social communication and behavior, and difficulties in sensorimotor function, including visual processing.[1,2] Yoked prism lenses, an optometric intervention, target dysfunctions in the ambient vision system. ASD individuals wearing yoked prism lenses have demonstrated improvements in posture, spatial awareness, and behavior in double blind studies[3,4] Though results support clinical application, prescribing studies have been limited to one single investigator team [5,6] This study evaluates the clinical method for determining yoked prism prescriptions for ASD individuals using the Kaplan Nonverbal Battery (KNB). The KNB is a series of nine tasks that do not require verbal response from patients; it is scored using a 5-point scale focusing on 39 facets of the tasks.[7]

Objectives:

To determine inter-examiner agreement between two masked examiners evaluating yoked prism prescription using the KNB by live and video presentation.

To determine intra-examiner agreement between two masked examiners evaluating habitual correction using the KNB by live and video presentation.

Methods:

Ten nonverbal, or minimally verbal, ASD subjects between 9 and 17 years old were enrolled and completed a comprehensive eye examination. All subjects adapted to spectacles by wearing their refractive correction, or plano lenses if emmetropic, for four weeks. Subjects then completed two videotaped study visits; at each visit, they completed the KNB wearing their habitual spectacle correction and then wearing yoked prism lenses of five-prism diopters base up or down. Two examiners assessed subjects' performance on the KNB live. Two other examiners assessed the subjects' performance via video recordings. Examiners were masked to the prescription of the yoked prism lenses and other examiner responses. Agreement between and within examiners was computed using the weighted version of Cohen's kappa.

Results:

Nine out of ten subjects completed both study visits and all nine tasks of the KNB. Inter-examiner and intra-examiner agreement were calculated for both the live and video presentations. Both inter-examiner and intra-examiner agreement were markedly better when examiners scored results using video presentation. In the yoked prism lenses evaluation, overall inter-examiner agreement for live presentation was 0.726 (visit 1) and 0.357 (visit 2), but on video presentation increased to 0.702 (visit 1) and 0.678 (visit 2). In evaluation of the habitual correction, intra-examiner agreement on live presentation was 0.451 for examiner 1 and 0.579 for examiner 2, but increased to 0.861 for examiner 3 and 0.875 for examiner 4.

Conclusions:

Masked examiners using the KNB to determine the yoked prism prescription for nonverbal or minimally verbal ASD children showed good inter-examiner agreement when evaluating videotaped presentation, but not by live presentation. Intra-examiner agreement in assessing KNB when the subject wore their habitual correction also was very good. Clinicians and investigators using the KNB to determine yoked prism prescription

show good agreement when evaluating videotaped performance.

261 **175.261** Prevalence of Motor Impairment in Autism Spectrum Disorder: Analysis of a Population-Based Cohort

M. K. Licari[1], *G. A. Alvares*[2], *K. J. Varcin*[2], *K. Evans*[2,3], *D. B. Cleary*[4], *S. Reid*[5], *E. J. Glasson*[2], *K. Bebbington*[2], *J. Wray*[6] *and A. J. Whitehouse*[2], *(1)Autism Research, Telethon Kids Institute, Nedlands, Australia, (2)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (3)School of Occupational Therapy, Social Work and Speech Pathology, Curtin University, Bentley, Australia, (4)Telethon Kids Institute, Nedlands, Australia, (5)School of Human Science, Sport and Exercise Science, University of Western Australia, Crawley, Australia, (6)State Child Development Service, Western Australia Department of Health, Perth, Western Australia, Australia*

Background: There is mounting evidence to support motor impairment as a key clinical feature of Autism Spectrum Disorders (ASD). With prevalence reports as high as 79%, and delays in motor milestones preceding other clinical features, motor impairment appears to be an important clinical feature that may be overlooked in the diagnostic process.

Objectives: The present study examined the prevalence of motor impairment at time of diagnosis in a large cohort of children with ASD, and to investigate the relationship between motor impairment and core features of the ASD phenotype.

Methods: Vineland Adaptive Behavior Scale (VABS) motor scores were examined in a sub-cohort of children aged ≤ 6 years from the Western Australian Autism Register (N = 2084; 81.2% males, 18.8% females). Motor scores were compared to other domains within the VABS (communication, daily living socialization), across DSM criteria, intellectual level, age and gender.

Results: A total of 35.4% of children scored in the low range on the motor skill subdomain of the VABS, and a further 43.7% in the moderately low range (combined total of 79.1%). This frequency was slightly lower than the other VABS subdomains, with 79.1% scoring in the low and 17.7% in the moderately low ranges for social skills (combined total of 96.8%), 62.3% scoring in the low and 29.3% in the moderately low ranges for daily living (combined total of 91.6%), and 65.7% scoring in the low and 24.9% moderately low ranges for communication (combined total of 90.6%). Whilst the prevalence of poor motor scores was high, motor impairment was only reported as a comorbid condition by diagnosing clinicians in 1.34% of the sample. Motor scores were lower in children diagnosed with ASD at a later age ($p<0.001$), and children with intellectual impairment (37.7% of the sample) had motor scores lower than those without ($p<0.001$). Examination of motor scores based on diagnostic criteria from the DSM revealed that those cases meeting the diagnostic criteria for impairments in non-verbal behaviour (i.e., body postures and gestures) and restricted and repetitive behaviours (i.e., motor stereotypies) displayed lower motor scores than those without.

Conclusions: The prevalence of motor impairment found in this large cohort was at least as common as one current diagnostic specifier. This highlights the need for further consideration of motor impairment within diagnostic evaluation for ASD.

262 **175.262** Sensory Reactivity Symptoms Are Related to Specific Anxiety Symptomology in Autistic Children

K. MacLennan[1], *T. Tavassoli*[2], *L. Roach*[1], *F. Englezou*[1] *and C. R. Daniels*[1], *(1)University of Reading, Reading, United Kingdom, (2)Centre for Autism, School of Psychology & Clinical Language Sciences, University of Reading, Reading, United Kingdom*

Background:

Sensory reactivity symptoms are reported in around 60-90% of autistic individuals, such as being hyperreactive (e.g. over-sensitive to sounds), hyporeactive (e.g. under-responsive to touch), or sensory seeking (e.g. fascinated by lights). Additionally, over half of autistic children experience co-morbid anxiety disorders, which can impact learning, social inclusion, and future prospects. Sensory hyperreactivity can be distressing and has previously been linked to anxiety in autistic children. However, hyporeactivity and seeking behaviours are often neglected in research. Therefore, it is unclear if different sensory reactivity constructs relate to anxiety generally, as well as specific anxiety symptomology, such as generalised anxiety disorder (GAD) or obsessive-compulsive disorder (OCD).

Objectives:

This study aimed to elucidate the relationships between sensory reactivity sub-types (i.e. sensory hyperreactivity, hyporeactivity and seeking behaviour), and specific anxiety symptomology in autistic children.

Methods:

Sensory reactivity and anxiety were assessed for 40 autistic children (age 4 – 14 years, 11 females, 29 males) using a multidisciplinary approach, combining caregiver questionnaires, direct observation and self-report.

Caregiver reported sensory reactivity was measured by the Sensory Profile 2 (SP2) and Sensory Processing Scale Inventory (SPSI). Observed and caregiver-reported sensory reactivity was measured by the Sensory Assessment for Neurodevelopmental Disorders (SAND). Composite scores were derived from these measures for sensory hyperreactivity, hyporeactivity, and seeking behaviour.

Caregiver-reported anxiety was measured by the Spence Children's Anxiety Scale (SCAS), the Preschool Anxiety Scale (PAS), which provide a score for total anxiety symptoms, and sub-scores for symptoms of panic attack/agoraphobia, separation anxiety (SAD), physical injury fears, social phobia, OCD, and GAD. Self-reported anxiety was measured using the Dominic Interactive computer game, which provides scores indicative of GAD, SAD, and specific phobia.

The relationship between sensory reactivity sub-types and specific anxiety symptoms were analysed using a bivariate correlation analysis, and a partial correlation analysis controlling for age. Significant multicollinear relationships were then analysed using hierarchical regression to explore predictive relationships.

Results:

Bivariate correlation analysis revealed principal correlations between sensory hyperreactivity and specific anxiety symptoms; total anxiety symptoms ($r = .54$, $p = .002$), SAD ($r = .48$, $p = .005$), physical injury fears ($r = .48$, $p = .005$) and GAD ($r = .42$, $p = .03$). OCD related to sensory hyperreactivity ($r = .44$, $p = .01$), hyporeactivity ($r = .58$, $p = .001$) and seeking behaviour ($r = .37$, $p = .04$). Hierarchical regression analyses established that hyporeactivity and hyperreactivity explained 39% of the variance in OCD, $F(2,32) = 6.3$, $p = .002$.

Conclusions:

The results suggest that sensory hyperreactivity is primarily related to specific anxiety symptomology and predicts total anxiety symptoms, and that sensory hyporeactivity could be a key predictor of OCD in autistic children. Understanding the role of sensory reactivity symptoms in anxiety

is important for developing early clinical interventions, aimed at improving mental health outcomes. Future directions should determine the developmental relationship of sensory reactivity symptoms and specific anxiety symptomology, and further define the role of sensory hyporeactivity and seeking behaviour in the development and maintenance of anxiety symptoms in autistic children.

263 **175.263** Relations Among Repetitive Behaviors and Language in Toddlers at Familial Risk for Autism

B. Pennington[1], *A. F. Dimian*[2], *K. Botteron*[3], *S. R. Dager*[4], *A. Estes*[4], *H. C. Hazlett*[5], *R. T. Schultz*[6], *J. Piven*[7] *and J. Wolff*[2], *(1)University of Minnesota Twin Cities, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN, (3)Washington University School of Medicine, St. Louis, MO, (4)University of Washington, Seattle, WA, (5)University of North Carolina, Chapel Hill, NC, (6)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (7)*Co-Senior Authors, IBIS Network, University of North Carolina, Chapel Hill, NC*

Background:
Previous studies have shown that restricted and repetitive behaviors (RRBs) are negatively associated with communication ability among school-aged children and adolescents with ASD (e.g., Dominick et al, 2017). However, the relationship between RRBs and communication during early childhood has not been well-characterized, and existing findings are mixed. Most previous work has examined communication as a single construct rather than decomposing communication into components of expressive, receptive, and social communication. Understanding whether RRB differentially relates to expressive, receptive, and social communication could shed light on previous disparate findings and inform intervention.

Objectives:

The purpose of this study was to examine relations among receptive and expressive language, socialization, and RRBs for 24-month-olds at high familial risk of ASD. A secondary purpose was to evaluate whether relations differ between children who did versus did not meet diagnostic criteria for ASD.

Methods:

Participants included n=426 toddlers at high familial risk for ASD. Of these, n=113 met criteria for ASD classification at age 24 months (HR-ASD) and n=313 did not (HR-Neg). We measured using the Restricted Behavior Scale-Revised (RBS-R, Bodfish et al. 2000), and represented RRB using a three-factor model with lower-order RRB, higher-order RRB, and SIB factors (Mirenda et al., 2010). We measured receptive and expressive language using the relevant subscales from the Mullen Scales of Early Learning, Macarthur-Bates Communication Development Inventory, and the Vineland Adaptive Behavior Scales (MSEL; Mullen, 1995; MCDI, Fenson et al., 1993; and VABS-II; Sparrow, Balla, & Cicchetti, 2005), and we measured socialization with the VABS-II. We used structural equation modeling to compare the extent to which data fit five models testing different relations among receptive and expressive language, socialization, lower-order RRB, higher-order RRB, and self-injurious behavior (SIB). Models controlled for sex and diagnostic status. The measurement model was confirmed using confirmatory factor analysis prior to running the full model, and all factors showed acceptable fit. We next compared model fit for groups on the basis of ASD classification (HR-ASD vs. HR-Neg).

Results:

The best-fitting model included receptive and expressive language predicting lower-order RRB, higher-order RRB, and SIB. This model had acceptable global fit with significant direct paths from receptive language to all RRB factors. No direct paths from expressive language to RRB were statistically significant. Global model fit was also acceptable for the separate groups of HR-ASD and HR-Neg. Factor loadings and covariances were similar between groups. When considering subgroups, the only significant direct path was from receptive language to lower-order RRB among the ASD group.

Conclusions:

These findings inform an understanding of early relations of RRB to communication by showing evidence of an association between receptive language and RRB for toddlers at high risk for ASD. Additionally, these findings suggest that associations among language and RRB differ minimally between children at high familial risk with and without an ASD classification.

264 **175.264** Repetitive and Stereotyped Behaviors in Autism: A Longitudinal Exploration of the Repetitive Behavior Scale-Revised throughout Childhood

V. Courchesne[1], *R. Tesfaye*[2], *P. Mirenda*[3], *W. J. Ungar*[4], *C. M. Kerns*[3], *E. Duku*[5], *T. Bennett*[6], *S. Georgiades*[5], *I. M. Smith*[7], *P. Szatmari*[8], *T. Vaillancourt*[9], *J. Volden*[10], *C. Waddell*[11], *A. Zaidman-Zait*[12], *L. Zwaigenbaum*[10] *and M. Elsabbagh*[13], *(1)McGill University, Montreal, QC, Canada, (2)Neuroscience, McGill University, Montreal, QC, Canada, (3)University of British Columbia, Vancouver, BC, Canada, (4)University of Toronto / The Hospital for Sick Children, Toronto, ON, Canada, (5)McMaster University, Hamilton, ON, Canada, (6)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (7)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (8)The Hospital for Sick Children, Toronto, ON, Canada, (9)University of Ottawa, Ottawa, ON, Canada, (10)University of Alberta, Edmonton, AB, Canada, (11)Simon Fraser University, Vancouver, BC, Canada, (12)Tel-Aviv University, Tel-Aviv, Israel, (13)McGill University, Montreal, PQ, Canada*

Background: Repetitive and stereotyped behaviors are a core domain of autism spectrum disorder (ASD); however, little is known about how these behaviors co-occur and evolve with time, and how they correlate with other developmental outcomes. Previous study results tend to differ depending on what measure is used. To date, the Repetitive and Behavior Scale –Revised (RBS-R; Bodfish et al., 2000) is the most frequently used in the literature. Mirenda et al. (2010) validated the use of this parent-report questionnaire in a large cohort of young children with ASD using confirmatory factor analysis based on models proposed in the literature. They reported that a three-factor model yielded the most parsimonious results and that the three factors correlated negatively with adaptive behaviors, while none correlated with IQ.
Objectives: The goal of this study was to explore the evolution of repetitive and stereotyped behaviors exhibited throughout childhood using the Mirenda et al. (2010) sample and to document the associations between the trajectories identified and developmental outcomes.

Methods: Data were drawn from the Pathways in ASD cohort (N=421). Participants were assessed using the Repetitive Behavior Scale-Revised at the time of diagnosis(T1), 6 months(T2) and 12 months(T3) later, and followed-up at ages 6 years(T4), 9 years(T5), and 11 years(T6). Assessments of developmental outcomes (Vineland Adaptive Behavior Scales for adaptive functioning, the Perceptual Reasoning Index of the WISC-IV for non-verbal IQ, and the Core Language score of the Clinical Evaluation of Language Fundamentals for language) were completed at T5 or T6 (only the most recent assessment was considered). To create a measure of the number of different behaviours exhibited that was independent of severity,

43 items on the RBS-R were recoded into dichotomous variables and summed. Scores 1-3 were assigned a 1 (exhibits behaviour), while items with a score of 0 remained (does not exhibit behaviour). Group based trajectory modeling analysis was then performed to describe children's RBS-R trajectories using these summed scores. One way ANOVAs were used to examine whether trajectory groups were associated with developmental outcomes.

Results: A five-group trajectory model was determined the best fit. Trajectory 1(11.5%) had the lowest numbers of RBS-R exhibited behaviours throughout the time period, followed by trajectory 2(28.2%). They both tended to decrease gradually with time. Trajectories 3(19.5%) and 4(24.8%) had higher numbers of exhibited behaviours at T1, but trajectory 3 decreased considerably from T2 to T4 whereas trajectory 4 slowly increased during the time period. Trajectory 5(16.1%) had the highest numbers of exhibited behaviours at all time points and tended to decrease with time. Children in trajectories 4(increasing) and 5(highest) had lower adaptive functioning (p<.001). Children in trajectory 4 also had lower language levels (p<.05). Non-verbal IQ did not differ between groups.

Conclusions: These results are a first step toward a better understanding of how the numbers of exhibited repetitive and stereotyped behaviors change over time in autism. Such longitudinal approaches can be useful in understanding how this domain of symptomatology is linked to development. Further insight involving the role of behaviour severity, in addition to its appearance, is also warranted.

265 **175.265** Restricted Repetitive Behaviors Related to Increased Activity at Ends of the Power Spectrum: Results from the ABC-CT Interim Analysis

D. Stahl[1], *A. Naples*[1], *T. McAllister*[1], *C. Carlos*[1], *S. J. Webb*[2], *F. Shic*[3,4], *C. Sugar*[5], *M. Murias*[6], *J. Dziura*[7], *C. Brandt*[7], *K. Chawarska*[1], *G. Dawson*[8], *C. A. Nelson*[9], *R. Bernier*[2], *S. Jeste*[5] *and J. McPartland*[1], *(1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (4)Pediatrics, University of Washington School of Medicine, Seattle, WA, (5)University of California, Los Angeles, Los Angeles, CA, (6)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (7)Yale University, New Haven, CT, (8)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (9)Boston Children's Hospital, Boston, MA*

Background: Individuals with autism spectrum disorder (ASD) exhibit high variability across symptom domains. To better understand the neural mechanisms behind clinical heterogeneity, it is important to investigate whether symptoms are associated with specific facets of brain activity. While there have been many studies assessing brain function in ASD, relatively few have examined how brain activity correlates with specific symptoms of ASD independent of a task. Previous research has found that increased behavioral rigidity, a common symptom in ASD, is correlated with increased alpha power in typically developing individuals. However, this relationship has not been directly investigated in individuals with ASD.

Objectives: To investigate whether a relationship exists between behavioral rigidity and alpha power in a sample including individuals with ASD.

Methods: 215 children between the ages of 6 and 11 years 7 months were recruited. 152 met criteria for ASD and 63 were typically developing (TD). EEG data was recorded using an EGI 128 channel net at a sampling rate of 1000Hz for three minutes while participants viewed an abstract screensaver (changing colors). Restricted repetitive behaviors (RRBs) were measured using subscales of the Autism Diagnostic Observation Schedule 2 (ADOS-2) and the Social Responsiveness Scale (SRS).

Results: T-tests were run comparing power bands of the EEG frequency spectrum; delta (1 to 3Hz), theta (4 to 7 Hz), alpha (8 to 12 Hz) beta (13 to 35 Hz) and gamma (>35 Hz) bands between diagnostic groups. No group differences were found (p>0.05). However, RRB symptoms as measured by the ADOS-2 and SRS were correlated with the EEG measures. Increased ADOS-2 RRB symptoms were significantly associated with greater absolute delta power (r=0.12,p=0.019), absolute theta power (r=0.12,p=0.017), absolute beta power (r = 0.11, p=0.024) and absolute gamma power (r=0.18, p=0.00032) but not absolute alpha power (r=0.066,p=0.19). Correlations with the SRS measure of behavioral rigidity were likewise significant for delta (r=0.11, p=0.030), theta (r=0.11, p=0.029), beta (r=0.12, p=0.014), and gamma (r=0.18, p=0.00050) bands but not for the alpha band.

Conclusions: Compared to findings from prior research in TD adults, in this study, increased activity at the ends of the power spectrum (delta, theta, gamma, and beta bands), but not in alpha, were associated with RRBs in participants with ASD. Other studies that have found that the extremes of the power spectrum are increased in ASD while alpha power is reduced, and postulate that this difference is partially related to abnormal GABAergic inhibitory tone in ASD (Wang et al 2013). Our results suggest that RRBs are a behavioral correlate of this phenomenon. GABA is thought to reduce power in the extremes of the spectrum and increase power in the alpha band (Gabard-Durnham et al 2012). Increased RRBs may indicate increased dysregulation in GABA tone in individuals with ASD. These results are a step towards specific linkages between cortical mechanisms and clinical symptomology.

266 **175.266** Sensitivity to Sounds and Touch and Sleep Concerns in Children with ASD

A. Bennett[1], *A. R. Marvin*[2], *D. Coury*[3], *B. A. Malow*[4], *J. K. Law*[2] *and P. H. Lipkin*[2], *(1)Children's Hospital of Philadelphia, Philadelphia, PA, (2)Medical Informatics, Kennedy Krieger Institute, Baltimore, MD, (3)Nationwide Children's Hospital, Columbus, OH, (4)Sleep Disorders Division, Department of Neurology, Vanderbilt University Medical Center, Nashville, TN*

Background: Sleep problems are commonly reported in children with ASD. Hyper or hypo-reactivity to sensory input is one of the diagnostic criteria for ASD, and may play a role in severity of sleep problems.

Objectives: To examine the relationship of sensitivity to sounds and touch with sleep problems in children and adolescents with ASD as measured by the Composite Sleep Disturbance Index (CSDI).

Methods: U.S.-based primary caregivers of children with ASD were recruited from a validated and verified national autism registry. Parents completed an online survey on co-occurring conditions that incorporated family and child demographic information including the CSDI, a validated tool that scores the frequency and duration of six sleep habits (scored 0-2) over the previous month; total score range=0-12; score≥4 indicates a severe sleep problem. Parents were asked to rate their child's sensitivity to sounds and to touch on a scale from 0 to 3 with 0 = absent and 3 representing most severe. Descriptive statistics, Pearson chi-square, and logistic regression were performed.

Results: 604 parent/child dyads with responses about both sound sensitivity and touch sensitivity were analyzed. Responding parents were the primary caregiver, primarily female (94%), white (89%), and non-Hispanic (92%); mean age of 43.35 (SD 7.26; range 25-65) years. Children were

primarily male (81%), white (83%), and non-Hispanic (88%); mean age of 12.1 (SD 3.61; range 3-17) years. Median household income was $70,000-$79,000. On the CSDI, parents rated their child's sleep problems as Severe (score≥4)=374 (61.9%) vs. Not Severe (score<4)=230 (38.1%). Caregivers of children with severe sleep problems reported a higher rate of sound sensitivity ($\chi2(3)= 35.112$, $p=0.000$) or touch sensitivity ($\chi2(3)= 27.8749$, $p=0.000$) when compared with children without severe sleep problems (see Figures 1 and 2). Children with severe sleep problems had higher rates of moderate or severe sound and touch sensitivity when compared with children without severe sleep problems - Severe vs. Not Severe Sleep Problems: Moderate Sound-Touch Sensitivities 46% vs. 31%, Severe 14% vs 7% ($\chi2(3)= 42.8942$, $p=0.000$). Sound-Touch Sensitivity were highly correlated ($r=0.488$, $p=0.000$). Being female (OR 1.64, $p=0.036$) and younger age (OR 0.94, $p=0.020$) were weakly predictive of having combined sound-touch sensitivity.

Conclusions: The prevalence of reported severe sleep problems increases as parents report severity of either sound sensitivity or touch sensitivity indicating that sleep problems and touch/sound hypersensitivities are associated. Sleep problems are known to be associated with increased behavioral problems and can have negative impact on both child and family functioning. Further study is needed to determine causality, namely, if sleep problems exacerbate sensitivity to sound or touch, or if sound or touch sensitivity exacerbate sleep problems. The presence of parent reported sound or touch sensitivity in their child with ASD should prompt screening for other comorbid conditions such as sleep problems.

267 **175.267** Sensorimotor Deficits in Individuals with Autism Spectrum Disorder and Their Unaffected Biological Parents

E. Bojanek[1], *L. M. Schmitt*[2], *J. A. Sweeney*[3] *and M. W. Mosconi*[4], *(1)University of Kansas, Lawrence, KS, (2)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Division of Developmental Behavioral and Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS*

Background: Sensorimotor impairments are highly prevalent in individuals with autism spectrum disorder (ASD), and reduced precision of eye movements in unaffected parents and siblings of individuals with ASD also has been documented. The degrees to which sensorimotor impairments are present across oculomotor and manual motor systems in unaffected parents and are familial have not yet been determined. Objectives: 1) To examine the precision of eye movements and manual force in individuals with ASD and their biological parents, and 2) to determine whether sensorimotor abilities are inter-correlated among individuals with ASD and their parents.

Methods: We studied 48 probands with ASD and 102 parents of individuals with ASD (ASD parents). Among the probands and parents, 34 family trios were studied (i.e., proband and each biological parent). Thirty-three typically developing (TD) controls were matched with probands on age (range: 4-27 years), gender ratio, and nonverbal IQ. An additional 47 TD controls were matched with ASD parents on age, sex and IQ. Participants completed a visually-guided saccade (VGS) task in which they fixated on a central cue, and made rapid eye movements (i.e., saccades) to peripheral targets presented at ± 12 and 24 degrees from center. Participants also completed a sustained precision grip force task in which they pressed opposing load cells with their thumb and index finger while they viewed a static red/green target bar and a white force bar that moved upwards with increased force. They were instructed to press when the target bar turned green so that the white bar reached the level of the target bar and hold it there as steadily as possible for 8 seconds. Participants completed the precision force task at 15%, 45%, and 85% of their maximum force.

Results: During the VGS task, probands showed reduced saccade accuracy compared to controls at 24 deg. ASD parents showed greater saccade error variability compared to controls at 24 deg. During precision gripping, probands' force was less accurate than controls during their initial pressing and when they sustained their force during the trial. ASD parents also were less accurate than controls during their initial pressing. Data collection is complete, and analysis of the familiality of sensorimotor issues in ASD is ongoing.

Conclusions: Our findings indicate that reductions in the precision of eye movements and manual motor behaviors previously documented in individuals with ASD also are present in unaffected biological parents suggesting that these deficits may be familial. Importantly, these deficits include reduced precision of both rapid movements controlled by predictive motor control processes as well as sustained motor behaviors guided by sensory feedback processes. These studies implicate multiple distinct sensorimotor control processes in the pathophysiology of ASD that may be important new targets for family genetic studies.

268 **175.268** Sensorimotor Integration in Autism Spectrum Disorders: A Behavioural Meta-Analysis

S. M. Coll[1,2], *N. Foster*[2,3], *A. J. Meilleur*[1,2], *S. Brambati*[2,4] *and K. L. Hyde*[2,3], *(1)BRAMS - International Laboratory for Brain, Music and Sound Research, Montreal, QC, Canada, (2)Psychology, University of Montreal, Montreal, QC, Canada, (3)International Laboratory of Brain, Music and Sound Research (BRAMS), University of Montreal, Montreal, QC, Canada, (4)Centre de Recherche de l'Institut Universitaire de Gériatrie de Montréal, Montreal, QC, Canada*

Background: Sensorimotor skills are often reported as atypical in individuals with autism spectrum disorders (ASD). Daily motor behaviours as diverse as grasping an object or regulating walking gait require the integration of sensory information. While intact sensorimotor integration is essential to navigate our everyday world, little is known about how atypical sensorimotor skills in ASD may vary across development and with clinical symptom severity.

Objectives: The main objective of this study was to conduct a comprehensive quantitative meta-analysis of sensorimotor skills in ASD. The specific aims were: to assess the consistency of atypical gross and fine sensorimotor behaviors in ASD, to examine the relationship between sensorimotor skills and ASD symptom severity, and to examine the effect of age on sensorimotor skills in ASD.

Methods: An exhaustive search was conducted in Psycnet, PubMed, Web of Science and Cochrane Database to identify studies in ASD from 1980 to 2018 that involved quantitative evaluations of motor coordination, motor impairments, arm movement, gait, postural stability, visuomotor or auditory motor integration. A total of 232 studies were identified, reviewed and coded. The Comprehensive Meta-Analysis software 2.0 (Borenstein, Hedges, Higgins, & Rothstein, 2005) was used to calculate study effect sizes (Hedges' g) and analyze overall effect size using random effects models. The I2 index was used to examine heterogeneity across studies (Higgins et al., 2003). Visual inspection of funnel plots and a trim-and-fill procedure were used to assess the presence of publication bias (Duval & Tweedie, 2000).

Results: Results strongly support the presence of deficits in overall sensorimotor abilities in ASD (n=127, g=1.25, SE = 0.08; p< 0.001, CI=1.10-1.40). More specifically, these atypicalities extended to both fine motor abilities (n=76, g=1.16, SE = 0.1; p < 0.001, CI=0.96 -1.36) and gross motor abilities

(n=67, g=1.31, SE= 0.11; p < 0.001, CI=1.10-1.52). However, clinical severity did not show a significant relationship with sensorimotor behaviors in available studies (n=19, r= -0.15; p= 0.21, CI=-0.37-0.08). Finally, a smaller analysis found an association between increasing age and improved sensorimotor behaviors in ASD (n=5, r=0.37; p< 0.001, CI=0.19-0.52). Heterogeneity of variance for all analyses was moderate to large (34-86%, except 0% for age), supporting the use of a random-effects approach. No evidence of publication bias was found.

Conclusions: These meta-analyses strongly support the presence of sensorimotor impairments that extend to both fine and gross motor skills in ASD. Deficits decrease with age, but do not appear to covary with social/communication symptom severity. This work provides a novel contribution to the field by quantitatively examining relationships between sensorimotor skills, development, and clinical symptom severity in ASD. The ultimate mission of this research is to set a theoretical groundwork for future sensorimotor-based interventions (e.g., music and dance) in ASD. By better understanding differences in sensorimotor deficits in ASD, it is hoped that interventions can be better designed to target these deficits.

269 **175.269** Sensory Correlates of Autism Risk in the First Year of Life: A Multi-Cohort Study

A. E. Lane[1], *M. Van Aswegen*[2], *M. Turner-Presker*[2], *J. J. Tait*[2], *F. Karayanidis*[3], *A. J. Woolard*[4], *C. A. Mallise*[5], *O. Whalen*[4], *J. Mattes*[2], *P. Gibson*[2], *L. Korostenski*[6], *S. J. Lane*[7], *V. Murphy*[8] *and L. E. Campbell*[9], *(1)University of Newcastle, Callaghan, Australia, (2)University of Newcastle, Callaghan, NSW, Australia, (3)Psychology, University of Newcastle, Australia, Callaghan, Australia, (4)University of Newcastle, Australia, Callaghan, Australia, (5)The University of Newcastle, Callaghan, Australia, (6)John Hunter Children's Hospital, Newcastle, Australia, (7)Occupational Therapy, University of Newcastle, Newcastle, Australia, (8)Medicine and Public Health, University of Newcastle, Australia, Callaghan, Australia, (9)School of Psychology, University of Newcastle, Newcastle, Australia*

Background: There are reports that sensory features in the first year of life may be linked to early signs of Autism Spectrum Disorder (ASD). Sensory features refer to atypical responses to daily sensory stimuli in the environment. Responses can be described as hyper-reactive (sensitive or avoiding), hypo-reactive (poor registration) and/or as unusual sensory interests (seeking). Parents of children with ASD often report concerns regarding their child's development in the first year of life although diagnosis does not typically occur until 3-4 years. Sensory features are observable in young children in infancy. To date, however, there are few studies investigating which sensory features in the first year of life may indicate risk for ASD.

Objectives: This study examines the relationship of sensory features to ASD risk in 12-month-old infants from varying risk cohorts.

Methods: Infant participants were members of one of three baby cohorts – babies born to mothers with asthma (asthma; n=69; mean age=12.7 months), babies born preterm (preterm; n=30; mean corrected age=12.19 months) and general population controls (controls; n=50; mean age=12.3 months). All infants attended a study visit where developmental (Bayley-III), sensory (Toddler Sensory Profile 2/TSP2; Test of Sensory Function in Infants/TSFI) and ASD risk (First Year Inventory; FYI) measures were administered. Spearman rho correlation analyses were conducted by cohort examining the relationship of sensory features with ASD risk. Preliminary stepwise regression analysis was then used to identify the most salient sensory features predictive of increased ASD risk across all three baby cohorts. Cognitive function was included in all analyses as a co-variate.

Results: FYI Total Risk score was negatively associated with Bayley Cognitive Composite score in asthma and control baby cohorts (asthma r_s=-0.35, p=0.003; controls r_s=-0.35, p=0.02) but not the preterm group (r_s=0.27, p=0.16). In the asthma group, FYI Total Risk was further associated with TSP2 sensory sensitivity (r_s=0.41, p=0.001), sensory avoiding (r_s=0.26, p=0.03) and poor sensory registration (r_s=0.31, p=0.01). In the preterm group, there were no significant associations between FYI Total Risk and any of the sensory measures. In the control group, FYI Total Risk was associated with TSP2 sensory avoiding (r_s=0.33, p=0.02). No significant associations were observed between the TSFI total score and FYI Total Risk. Preliminary stepwise regression analysis revealed TSP2 sensory sensitivity as the best predictor of FYI Total Risk across all three cohorts (R^2=0.26, F=35.02, p=0.001).

Conclusions: The relationship of sensory features to ASD risk at 12 months of age varied by infant cohort. Sensory sensitivity, however, was identified as a moderate level predictor of ASD risk at 12 months of age independent of cognitive function and cohort membership. These findings suggest that early sensory sensitivity may be a common variant in infants with risk for ASD. Further elucidation of the variance in sensory features across infant cohorts, however, may assist in identifying distinct sensory phenotypes associated with early autism risk.

270 **175.270** Sensory Processing As a Transdiagnostic Mechanism for Behavioural Outcomes in ASD and ADHD

S. E. Schulz[1], *K. M. Parks*[2], *E. Anagnostou*[3], *R. Nicolson*[4], *E. Kelley*[5], *S. Georgiades*[6], *J. Crosbie*[7], *R. Schachar*[8], *X. Liu*[9] *and R. A. Stevenson*[1], *(1)Western University, London, ON, Canada, (2)The University of Western Ontario, London, ON, Canada, (3)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)University of Western Ontario, London, ON, Canada, (5)Queen's University, Kingston, ON, Canada, (6)McMaster University, Hamilton, ON, Canada, (7)Psychology, The Hospital for Sick Children, Toronto, ON, Canada, (8)Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (9)Genomics, Queen's Genomics Lab at Ongwanada, Kingston, ON, Canada*

Background:

The most commonly reported symptoms in autism spectrum disorder (ASD) are sensory processing issues. Atypical sensory processing has been found to contribute to specific aspects of autistic symptomatology, including decreases in speech perception and restricted interests and repetitive behaviours. The extent of the cascading influence that sensory issues have has yet to be determined. Furthermore, atypical sensory processing is not unique to ASD, and it is unknown whether the impact of sensory processing issues is unique to ASD. This project addresses these two outstanding research questions.

Objectives:

This project aims to examine the pathway from sensory processing issues to higher-order symptoms in ASD and compare this symptom trajectory between ASD and attention-deficit/hyperactivity disorder (ADHD) and their typically-developing (TD) peers.

Methods:

Data were collected from 2388 participants through a large-scale, multisite data collection project. 519 participants with ASD (N=202), ADHD (N=181), or TD (N=120) completed the measures of interest on adaptive functioning (Childhood Behaviours Checklist; CBCL) and sensory processing (Short Sensory Profile; SSP) and thus, were included in this study. Differences in functioning and sensory processing were assessed using an ANOVA, and linear regressions were utilized to predict overall functioning based on sensory processing in each group. Finally, a single hierarchical

regression with all clinical participants was used to assess whether sensory scores predicted CBCL scores above and beyond clinical diagnosis by entering diagnosis into the first model step and sensory processing scores into a second model step.

Results:

ANOVA results displayed significant group differences in sensory processing and adaptive functioning (Figure 1; all p-values<0.001). Post-hoc tests showed ASD and ADHD groups exhibited greater sensory-processing and behavioural issues than the TD group (all p-values<0.001). Compared to the ADHD group, the ASD group displayed significantly fewer behavioural issues (p=0.004). However, the ASD group presented with significantly greater sensory-processing issues in every subscale of the SSP (all p-values<0.004) except *Auditory Filtering,* where ADHD was greater than ASD (p=0.012), and *Underresponsive/Seeks Sensation,* where there was no difference (p=0.873).

Notably, in every group, sensory processing issues predicted total CBCL scores. In ASD and ADHD, CBCL scores were significantly driven by *Tactile Sensitivity*, *Underresponsiveness*, and *Auditory Filtering,* whereas the relationship in the TD group was driven by *Tactile Sensitivity, Auditory Filtering,* and *Movement Sensitivity* (see Table 1). The final hierarchical regression including all clinical participants found that sensory processing abilities predicted CBCL total scores above and beyond what was predicted by diagnostic group (Step1(Diagnosis): R^2=0.021, F-Change$_{(1,382)}$=8.373, p=0.004; Step2(SSP): R^2=0.417, F-Change$_{(7,375)}$=36.320, p<0.001).

Conclusions:

Individuals with ASD have unique behavioural and sensory processing issues relative to TD individuals and individuals with ADHD. Interestingly, sensory processing issues predict functional abilities in ASD as well as the other diagnostic groups. Despite unique sensory profiles between ASD and ADHD, the manner with which sensory issues relate to behavioural outcomes appears to be quite similar between ASD and ADHD. Therefore, although ASD and ADHD have their own distinct sensory symptom profile, sensory processing may act as a transdiagnostic mechanism that predicts outcome severity in various diagnostic groups.

271 **175.271** Sensory Processing in ASD and ADHD: A Multi-Groups Approach

R. A. Stevenson[1], *K. M. Parks*[2], *S. E. Schulz*[1], *M. Segers*[3], *E. Anagnostou*[4], *R. Nicolson*[5], *E. Kelley*[6], *S. Georgiades*[7], *J. Crosbie*[8], *R. Schachar*[9] *and X. Liu*[10], *(1)Western University, London, ON, Canada, (2)The University of Western Ontario, London, ON, Canada, (3)York University, Toronto, ON, Canada, (4)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)University of Western Ontario, London, ON, Canada, (6)Queen's University, Kingston, ON, Canada, (7)McMaster University, Hamilton, ON, Canada, (8)Psychology, The Hospital for Sick Children, Toronto, ON, Canada, (9)Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (10)Genomics, Queen's Genomics Lab at Ongwanada, Kingston, ON, Canada*

Background: Though the *DSM-5* diagnostic criteria for autism spectrum disorder (ASD) and attention/deficit-hyperactivity disorder (ADHD) show little overlap between the two disorders, studies have shown that children with ASD and ADHD have many overlapping issues, including sensory issues. Sensory processing impairments occur in several modalities including touch, taste, smell, and sound and can impact how a child perceives and responds to everyday events. In turn, these impairments have significant implications for a child's social communication, academic achievement, and quality of interpersonal relationships. Despite this, few researchers have directly compared sensory processing patterns in ASD and ADHD. Thus, while it is known that children with ASD and ADHD both exhibit atypical sensory processing, the extent to which these patterns operate similarly across groups remains unclear.
Objectives:

- To compare sensory processing across ASD and ADHD using the Short Sensory Profile (SSP);
- To evaluate the validity of the current seven-factor model in describing sensory processing patterns in ASD and ADHD using the SSP;
- To compare factor structures between ASD and ADHD.

Methods: Participants included 571 children and young adults (*Age range*=1.88-21.89 years, *Mean age*=10.01±3.98), with ASD (*n*=361) and ADHD (*n*=210) without any comorbidities. Parents completed a well-established questionnaire assessing sensory processing (SSP). Subscale scores on the SSP were compared across groups. Confirmatory factor analyses were performed using individual items comprising the SSP on each group separately to determine whether a seven-factor model to describe sensory processing holds the same meaning and measurement properties across ASD and ADHD groups. The seven latent variables were defined based on the original creation of the SSP where each item loaded onto the corresponding sensory system to which it belongs.

Results: Direct comparisons across diagnoses revealed that the ASD group showed greater impairment in tactile, taste/smell, movement, low energy, and visual/auditory (all p-values<.001), but not sensory seeking (p=.634) domains and the ADHD group showed greater impairment in the auditory filtering domain (Figure 1). For both ASD and ADHD models, all items on the SSP loaded onto the originally proposed latent variables well (>.40; Table 1), fit indices indicated acceptable overall fit (Table 1), and correlations among latent variables were low (<.85), indicating that these variables are tapping into distinct constructs in describing sensory processing patterns. Thus, despite significant differences in sensory processing between diagnostic groups, the factor structures still capture the same underlying latent variables for both groups.

Conclusions: Our results demonstrate that although there are differences in the way individuals with ASD and ADHD process sensory information, a single inventory of sensory processing can be reliably used to describe sensory processing *patterns* in both groups. The SSP measures components of basic sensory processing without referencing social or affective responses to sensory events, providing a good measure of sensory processing without tapping into other diagnostic features. These findings provide a useful next step for those interested in understanding the underlying structure of sensory processing in diagnostic groups who exhibit similar sensory processing patterns as those with ASD and ADHD.

272 **175.272** Sensory Processing in Relation to Sleep Disturbances in Young Children with Autism Spectrum Disorder and Fragile X Syndrome with and without Comorbid Autism Spectrum Disorder

C. E. Knott*, E. A. Will and J. E. Roberts, Psychology, University of South Carolina, Columbia, SC*

Background: Autism Spectrum Disorder (ASD) and fragile X syndrome (FXS) are highly comorbid, with approximately 60% of children with FXS also having ASD (Hagerman, Rivera, & Hagerman, 2008). Children with ASD or FXS are at increased risk for a variety of other challenges, including sensory processing abnormalities and sleep difficulties (Gagnon, & Godbout, 2018). Despite high prevalence of sensory and sleep difficulties in these populations, little is known about how these difficulties may impact one another. Previous studies have linked sensory hyperresponsiveness to sleep difficulties in the typical population (Shochat, Tzischinsky, & Engel-Yeger, 2009); however, this relationship is vastly understudied in those with neurodevelopmental disorders. Given the elevated prevalence of sensory and sleep challenges in these children, examining the association between sensory response patterns and sleep disturbances will shed light on the functional impact of these challenges in those with ASD, FXS and comorbid FXS and ASD.

Objectives: The present study characterizes sensory response patterns across three groups of young children: ASD, FXS-only and FXS comorbid with ASD. This study also investigates the effect of sensory response patterns on sleep disturbances across groups.

Methods: Participants included 18 children with non-syndromic ASD (i.e., nsASD; not associated with a specific syndrome), 16 preschoolers with FXS-only and 11 preschoolers with FXS+ASD between the ages of 36-72 months of age (*M* = 46.07, *SD* = 11.48). Clinical best estimate procedures were used to determine presence of comorbid ASD in the FXS+ASD group. Participants' parents completed the Sensory Experiences Questionnaire (SEQ; Baranek, 1999) as a measure of sensory processing, as well as the Children's Sleep Habits Questionnaire (CSHQ; Owens, Spirito, & McGuinn, 2000) as a measure of sleep.

Results: Results indicated significant group differences on sensory processing across domains ($F(1, 42)=10.61$; $p<.001$), such that the FXS-only group was significantly lower (i.e., better processing) across all sensory domains than both the nsASD and FXS+ASD groups (see Figure 1). Within group bivariate correlations revealed no significant associations between sensory response patterns and sleep scores in any of the groups ($p>.05$).

Conclusions: Findings suggest that children with nsASD and FXS+ASD experience similar levels of elevated sensory processing difficulties compared to those with FXS-only. Thus, elevated sensory impairments appear to be a shared feature across ASD independent of etiology. Despite group differences in sensory difficulties, no clear association between sensory difficulties and sleep were apparent in any of the groups. Given sample sizes, this may be due to issues with statistical power, or it may be that there are additional underlying mechanisms contributing to sleep difficulties in these populations. The similarities between the nsASD and FXS+ASD groups in their sensory response patterns enhance our understanding of a unique profile between FXS+ASD and FXS-only. These similarities indicate those with FXS+ASD may experience a greater impact on functional outcomes as a result of their elevated sensory processing challenges, and therefore require targeted intervention.

273 **175.273** Sensory Profile of TIP-TOE Behavior ASD Subjects

G. Valagussa[1,2], *A. Nale*[2], *R. Pirovano*[2] *and E. Grossi*[2], *(1)School of Medicine and Surgery, University of Milan-Bicocca, Milano, Italy, (2)Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy*

Background: In a previous study we have validated the use of the Short Sensory Profile (SSP) scale in Italy confirming the existence of sensory impairments in ASD subjects that is related to ASD severity, particularly expressed as under-responsiveness or seeking stimuli and an increased or decreased response to auditory stimuli.

Since tip toe behavior (TTB) is likely to be related to sensorial disorders, it is interesting to assess how the sensorial pattern is different in ASD subjects with and without TTB, for which we developed a standardized protocol of the assessment.

Objectives: The aim of this study is to explore the sensory pattern of Severe ASD Subjects with or without TTB through a validated cross-cultural Italian adaptation of the SSP.

Methods: We administered the Short Sensory Profile in a sample of 50 Italian ASD children (7 females; 43 males; mean age 13.9 years). We chose capable special education teachers who carefully and thoroughly reported the children's behaviors. The ASD diagnosis was done using the DSM V criteria and was confirmed using the ADOS 2. The presence of Tip-Toe Behavior (TTB) was assessed using both direct observation as well as a structured checklist completed during the day by the main caregiver living with the subject through a standardized protocol.

Results: The SSP mean total score of the sample was 149.22 (range 119-182) evidencing the presence of sensory function impairment in our study group (the expected value ranges between 155 and 190). We also found a negative correlation values between ADOS CSS score and total SSP score ($r= -0.38$). The SSP mean total score of the TTB subgroup was 144.06 (median 142) while the SSP mean total score of the NON-TTB subgroup was 151.65 (median 152): both the TTB and NON-TTB subgroups mean total score ranged in the "probable difference" score. The mean total score values of the two subgroups were not significantly different according to the Mann-Whitney test.Comparing the mean score of SSP subscales between TTB and NON-TTB subgroups using a Mann-Whitney test we found a significant lower score of TTB subgroup only in the "Under-responsive/Seeks sensation" section ($p=0.027$). Instead the "tactile sensitivity" section was in the "probable difference" score for both TTB and NON-TTB without significant subgroups difference . We also evidenced a significant inverse relationship between toe walking severity and "Under-responsive/Seeks sensation" score ($r= -0.31$).

Conclusions: We confirm the existence of sensory impairment in ASD subjects related to ASD severity. TTB ASD subjects show a sensory function impairment when compared with normative values and a more severe sensory impairment in the "Under-responsive/Seeks sensation" section when compared with NON-TTB ASD subjects. This finding seems suggest that TTB subjects show this behavior as an high need of sensations instead of a tactile oversensitivity.

274 **175.274** Quantitative Assessment of TIP-TOE Behavior in Autism Spectrum Disorder: A Prospective Cohort Study

G. Valagussa[1,2], *V. Balatti*[2] *and E. Grossi*[2], *(1)School of Medicine and Surgery, University of Milan-Bicocca, Milano, Italy, (2)Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy*

Background: About 20-30% of ASD individuals display toe-walking to some degree. Previously, using a qualitative structured assessment, we described three mutually exclusive clinical functional classes: tip-toe behavior (TTB) during running (TTB1), TTB during walking and running (TTB2) and TTB during standing, walking and running (TTB3). In another study, we also found a positive relationship between the presence and severity of TTB and the Achilles's tendon shortening in ASD subjects. To our knowledge, no prospective quantitative TTB study is currently available.

Objectives: The aim of this prospective cohort study is to describe the natural history of TTB and NO-TTB ASD subjects at short-medium term using a quantitative standardized method.

Methods: We included 37 consecutive subjects (32 males; mean age: 12.32 years – SD 4.36) with ASD diagnosed according to the DSM V criteria, and then confirmed with ADOS–2. According to the qualitative assessment, 21 ASD subjects resulted NO-TTB, 2 resulted in TTB1 subgroup, 7 in TTB2 subgroup and 7 in TTB3 subgroup. The intensity of TTB expression during static and dynamic tests was quantified as a percentage of time spent on the tip toes and as a percentage of toe steps, respectively, through a standardized method previously described. The second assessment was repeated 11 to 38 months (mean: 21.41 months – SD 6.82; median: 23 months) after the first observation.

Results: The overall ADOS CCS was 6,67 (1,43 SD) in NO-TTB, 10 (SD 0) in TTB1, 7,57 (2.07 SD) in TTB2 and 8,29 (1,25 SD) in TTB3 (p = 0.014 between groups). The mean percentage time spent on the tip-toes (TSTT) during the static quantitative test in NO-TTB group, TTB1 TTB2, TTB3 was 0.1% (0.3 SD) , 0.5% (0.71 SD), 4.86% (6.36 SD), 29% (25.15 SD) respectively. The values of TSTT registered in No-TTB group and in TTB1 group remained substantially unchanged at follow up. Five subjects of TTB2 group decreased and two increased their TSTT respectively. The same happened in TTB3 group. The mean percentage of toe steps (PTS) during the dynamic quantitative test in NO-TTB group, TTB1 TTB2, TTB3 was 0.91% (2.36 SD), 3.5% (4.95 SD), 18.71% (6.36 SD), 48.71% (33.74 SD) respectively. The PTS registered in No-TTB group and in TTB1 group remained substantially unchanged at follow up. Five subjects of TTB2 group decreased and two increased their PTS respectively while four subjects of TTB3 group decreased and three subjects increased their PTS in TTB3 group.

Conclusions: This is the first study that used a quantitative structured assessment to describe change over time in TTB of ASD subjects. NO-TTB and TTB1 subgroups substantially maintained their condition at follow up. TTB2 and TTB3 subgroups showed a more variable behavior: some subjects decreasing TTB over time as commonly known, but some increasing TTB. This finding underlies the importance of a TTB sub-classification and a close monitoring with quantitative standardized protocols of TTB phenomenon.

275 **175.275** Sex Differences and the Neural Substrates of Repetitive Behavior and Restricted Interests

D. W. Evans[1], *M. Uljarevic*[2], *E. Loth*[3], *A. N. Ruigrok*[4] *and A. M. Michael*[5], *(1)Department of Psychology, Bucknell University, Lewisburg, PA, (2)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (3)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)University of Cambridge, Cambridge, United Kingdom, (5)Geisinger Health System, Lewisburg, PA*

Background: Repetitive behaviors and restricted interests (RBRI) are a broad and heterogeneous set of behaviors and thoughts that include stereotypic motor movements, compulsions, tics, self-injury, as well as obsessions, circumscribed interest patterns, perseverative thought and speech. RBRI are defining features of a range of neurodevelopmental and neuropsychiatric disorders (NDD/NPD), including autism, obsessive-compulsive disorders (OCD), tic disorders, intellectual and developmental conditions. In addition to their clinical significance, RBRI are also common in typically-developing children. Across NDD/NPD RBRI have established links to cortical-striatal-thalamo-cortical pathways, however the degree to which typical and atypical RBRI are subserved by common neural mechanisms is unclear. Structural sex differences in these pathways have also been observed which may indicate a mechanism for the male preponderance of many neurodevelopmental conditions involving repetitive behaviour, such as autism.

Objectives: To examine sex differences in RBRI and gray matter (GM) volume of cortical and subcortical brain regions that have been implicated in the pathogenesis of disorders characterized by RBRI.

Methods: Thirty-three children aged 6 to 15 years (17 females) underwent a 3T structural T1 magnetic resonance imaging scan. GM classification was performed using the Voxel Based Morphometry in SPM8 (Ashburner & Friston, 2000). SPM combines spatial information from the tissue probability map (TPM) of a standard template and the intensity information of the subject image to construct the segmented GM TPM of the individual. The value at a GM TPM voxel represents the percentage of GM content in that voxel (corrected for overall GM volume). GM TPMs were further segmented into 116 AAL atlas regions (Tzourio-Mazoyer, et al, 2002). We then calculated the average GM content in the following bilateral brain regions: supplementary motor area, cingulate cortex, caudate nucleus, putamen, globus pallidus, and amygdala. Parents completed the Childhood Routines Inventory-Revised (Evans et al., 2017). This is a 62-item measure of RBRI that was normed nationally, and reflects a two-factor structure: Repetitive Motor Behaviors/Compulsions (RMBC) and Rigidity/Insistence on Sameness (RIS).

Results: For males, the RMBC factor was significantly and positively linked to GM volumes of the left supplementary motor area, the left inferior frontal gyrus (pars triangularis) and the left cingulum. The anterior cingulum is further divided into anterior, middle, and posterior regions. For males, RMBC correlated with the left ($r(16)=.82$, $p=0.00009$) and right ($r(16)=.84$, $p=0.00008$) middle , and with the left ($r=.52$, $p=.04$) and right ($r=.54$, $p=.04$) anterior cingulum, but not the posterior cingulum.

For female participants, a distinctly different pattern emerged. The RMBC factor was significantly, and negatively associated with both the left and right caudate nucleus, and the left putamen, and left amygdala (see Table 1).

Conclusions: This preliminary study suggests that there are sex differences in key brain regions implicated in RBRI. These findings have potentially important implications for understanding the brain-behavior links that underlie neurodevelopmental conditions. Our future research will conduct similar analyses on a larger sample comprising both typically-developing individuals and a well-characterized cohort of probands with autism.

276 **175.276** Sex Differences in Repetitive and Restricted Behavior Using the Repetitive Behavior Scale-Revised

C. M. Harkins[1], *M. O. Mazurek*[2] *and R. Grimm*[2], *(1)Curry School of Education, University of Virginia, Charlottesville, VA, (2)University of Virginia, Charlottesville, VA*

Background: Repetitive and restricted behaviors (RRBs) are a core symptom of autism spectrum disorder (ASD). Some studies have found that RRBs occur at lower rates in females, particularly in those with higher IQ. Additionally, females are reported to have more socially accepted interests than males, while males with ASD often present with more atypical motor behaviors, restricted interests, and repetitive use of objects. The association between RRBs and developmental level is well established, and when controlling for age and IQ, these differences are found less consistently. The presence of potential sex differences in presentation and frequency of RRBs may have important implications for early detection and diagnosis of ASD. It is possible that if females present with fewer or different RRBs this could lead to delayed diagnosis or misdiagnosis, negatively affecting their access to appropriate intervention and treatment.

Objectives: To examine potential sex differences in the type and frequency of RRBs after accounting for the effects of age and IQ.

Methods: Participants included 391 children and adolescents with ASD ages 2-14 (319 males, 72 females) participating in a larger research study. As

part of the measurement battery, parents completed the Repetitive Behavior Scale-Revised (RBS-R), and IQ was assessed using the Mullen Scales of Early Learning or the Differential Ability Scales-2nd Edition. A one-way analysis of Covariance (ANCOVA) was performed to evaluate differences between males and females on the RBS-R total score, controlling for age and IQ. A one-way multivariate analysis of covariance (MANCOVA) was conducted to examine potential sex differences on the various subscales of the RBS-R, while controlling for age and IQ.

Results: RBS-R total score was significantly correlated with both age (r=-.006, p=.91) and IQ (r=-.124, p=.049). The ANCOVA revealed a significant difference $F(1, 388)=3.90$, p=.049, with females obtaining higher RBS-R total scores (M=33.69, SD=22.35) than males (M=28.90, SD=18.12) after controlling for age and IQ. A MANCOVA was conducted with sex as the independent variable and RBS-R subscale scores as dependent variables, and age and IQ as covariates. Females had significantly higher scores than males on the self-injurious behavior subscale, $F(1,93.19)= 6.30$, p =.013, h^2=.016, and the sameness behavior subscale, $F(1, 229.27)=6.01$, p=.015, h^2=.015, but not on any other subscale. However, after taking a more conservative approach and performing a Bonferroni correction (a=.0083), no significant differences in scores were found for any subscale.

Conclusions: The results reveal that there may be differences in type and frequency of RRBs displayed by males and females with ASD. Although sex differences were observed in overall RRB score and two subscales after controlling for age and IQ, these differences did not remain statistically significant after correcting for multiple comparisons. The effect of IQ remained significant following the correction, however, further demonstrating how IQ may account for the previously reported differences in RRBs between males and females with ASD.

277 **175.277** Smart Tablet-Based Gameplay Identification of Preschool Children with Autism: A Replication Study with Machine Learning Data Analytics Improvements

*K. Sobota[1], A. Anzulewicz[1], D. Zaremba[2] and **J. Delafield-Butt**[3], (1)Harimata Sp. z.o.o., Kraków, Poland, (2)Harimata, Krakow, Poland, (3)Laboratory for Innovation in Autism, University of Strathclyde, Glasgow, United Kingdom*

Background: It has been proposed that one of the early markers of autism spectrum disorder (ASD) is a disruption in intentional movement evident from early childhood. Evidence suggests disruption to motor timing and integration may underpin the disorder, providing a new potential marker for its identification. In earlier work, we demonstrated machine learning analysis of children's movement patterns during smart tablet gameplay identified ASD with 83% sensitivity and 85% specificity (Anzulewicz, Sobota and Delafield-Butt, 2016).
Objectives: In this study, we sought to test the original performance accuracy with more generalised, new data. And we sought an iterative improvement on the machine learning data analytics to simplify and further generalise the models. Overall we aimed to achieve an accessible, computational identification of ASD in young children by smart tablet gameplay.

Methods: The original study of 37 children 3-6 years old with ASD and 45 children typically developing (TD) was augmented with a new dataset of 118 children with ASD and 420 TD children. In addition, 26 children 3-6 with another neurodevelopmental disorder that was not ASD was included. Feature selection was reduced by recursive feature selection and removal of low variance and high within-group correlations. New machine learning algorithms were trained on the new dataset (n=564), and these models applied to the original dataset (n=82) to test for generalisation.

Results: Dimensionality was reduced from 262 kinematic and descriptive metric features of children's gameplay patterns to 49 features. Ten repetitions of a ten-fold cross-validation procedure performed on the new dataset (n=564) identified children with ASD from their TD counterparts with 87% sensitivity and 85% specificity. Differentiation of OND from their TD counterparts was comparable, but with low confidence. Finally, we tested the models produced on the original study dataset (n=82). The model performed 83% sensitivity and 82% specificity accuracy, replicating the original finding.

Conclusions: This study produced new machine learning models for the identification of ASD from TD children on a large dataset with comparable performance to the first study, and with reduced feature selection. Moreover, we replicated the findings of our previous study with these new algorithmic models, tested on those original data and without prior training on those data. We consider this strong verification of the principle of machine learning data analytics in the successful, and potentially clinically useful early identification of ASD in young children. The basis of these features on calculations of motor kinematics supports the view movement differences are a fundamental feature of ASD that may be subtle to the eye, but significantly associated computationally.

278 **175.278** Temporal Processing in Autism Spectrum Disorder: A Systematic Review and Meta-Analysis

A. J. Meilleur[1,2], *N. Foster*[1,3], *S. M. Coll*[1,2], *S. Brambati*[1,4] *and K. L. Hyde*[1,3], *(1)Psychology, University of Montreal, Montreal, QC, Canada, (2)BRAMS - International Laboratory for Brain, Music and Sound Research, Montreal, QC, Canada, (3)International Laboratory of Brain, Music and Sound Research (BRAMS), University of Montreal, Montreal, QC, Canada, (4)Centre de Recherche de l'Institut Universitaire de Gériatrie de Montréal, Montreal, QC, Canada*

Background: Studies of autism spectrum disorders (ASD) have reported deficits in processing rapidly timed unisensory information, as well as integrating sensory information from different sensory modalities (Zhou et al., 2018). Failure to temporally integrate sensory cues can lead to deficits in higher-order communication and social skills (Stevenson et al., 2014). However, it is unclear whether atypical processing of unisensory and multisensory temporal information is a consistent feature in ASD.
Objectives: This study used quantitative meta-analyses to examine two standard tests of temporal processing, the temporal order judgment (TOJ) and simultaneity judgment (SJ) tasks in ASD. The aims were to 1) determine if temporal processing shows consistent deficits in ASD, 2) assess whether atypical temporal processing exists in ASD for both unisensory processing and multisensory processing, and 3) compare the TOJ and SJ tasks to evaluate whether these two types of temporal judgment show similar effects in ASD.

Methods: An exhaustive search for ASD studies using TOJ and SJ tasks from 1980 to 2018 was conducted in five online databases (Proquest, PsycInfo, Pubmed, Scopus, and Web of Science). Data from 18 different studies (Nasd=369, Ntd=408) were retrieved and coded. A synthesis and analysis of the set of ASD studies was performed following the PRISMA guidelines (Moher et al., 2009). Analyses were performed on study effects (Hedges' g) using random-effects models, and heterogeneity of variance was measured using the I2 measure (Higgins et al., 2003). Visual inspection of funnel plots and a trim-and-fill procedure were used to assess the presence of publication bias (Duval & Tweedie, 2000).

Results: Individuals with ASD showed lower temporal acuity in simultaneity and order judgments compared to typically developing (TD) controls (n=18, g=0.444, SE=0.119, p<.001, CI= 0.210-0.677). Separate analyses of unisensory and multisensory studies provided stronger evidence for deficits in multisensory temporal processing (n=12, g=0.484, SE=0.121, p<.001, CI= 0.248-0.720), as the analysis of unisensory studies failed to reach

significance (n=7, g=0.463, SE=0.252, p=.066, CI= -0.031-0.957). Lastly, temporal acuity in ASD appears to be more impacted in SJ tasks (n=8, g=0.585, SE=0.147, p<.001, CI= 0.296-0.873), versus TOJ (n=10, g=0.321, SE=0.168, p=.057, CI=-0.009-0.650). Heterogeneity of variance for all analyses fell between low and moderate (4%-40%), and no evidence of publication bias was found.

Conclusions: ASD shows lower temporal acuity than TD, as assessed by two relative timing tasks. Poorer multisensory processing was found, but unisensory processing did not differ between ASD and TD. Finally, overall temporal processing differences are larger when considering only the SJ task, which involves a judgement about simultaneity rather than order of events, a task considered to be easier than TOJ. Future work will address the association between multisensory temporal processing in ASD and symptom severity, as well as whether performance on different tasks can identify individual differences in temporal processing.

279 **175.279** The Impact of Restricted and Repetitive Behaviours on Social Emotional Learning and Executive Functioning in Adolescents with Autism Spectrum Disorder

C. Rimmer[1], *H. Dahary*[1] *and E. M. Quintin*[2], *(1)McGill University, Montreal, QC, Canada, (2)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada*

Background: Autism spectrum disorder (ASD) is defined as a broad category with two symptom dimensions: social communication deficits and restricted/repetitive behaviours (RRBs) (APA, 2013) RRBs may be presented as stereotyped motor movements, adherence to non-functional rituals, or circumscribed interests (Richler et al., 2010), and can be the most disabling feature of the disorder (Bishop et al., 2007). Further, RRBs compete with social interactions and impact communication (LaGasse & Hardy, 2013). Moreover, research has found that RRBs could be a result of abnormal frontal lobe functioning (Pierce & Courchesne, 2001), a brain region involved in executive functioning. Results of studies examining RRBs in relation to executive functioning find that RRBs are associated with deficits in cognitive flexibility and planning (Lopez et al, 2005).
Objectives: The purpose of this study is to examine the relationships between RRBs and the social emotional learning and executive functioning profiles of youth with ASD, using measures commonly used in research with this population.

Methods: A total of 45 youth with ASD between 12 and 18 years old participated in this study. Social communication was measured using the *Social Responsiveness Scale* (SRS-2; Constantino, 2012), social emotional learning using the *Social Skills Improvement System – Social Emotional Learning Edition* (SSIS-SEL; Gresham & Elliot, 2017), executive functioning using the *Behaviour Rating Inventory of Executive Functions* (BRIEF-2, Gioia et al., 2015) and cognitive abilities using the Wechsler Intelligence Scale for Children (WISC-V; Wechsler, 2014). Participants were grouped into low RRB and high RRB severity groups using a median split of the SRS-2 restricted interests and repetitive behaviour subscale (RRB = 65).

Results: Low RRB and high RRB severity groups were compared on the SRS-2, SSIS-SEL, BRIEF-2, and WISC-V. MANOVAs revealed a significant difference ($p < .05$) on four subscales of the SRS-2 (social awareness, social cognition, social communication, and social motivation) and on four subscales of the SSIS-SEL (self-management, social awareness, relationship skills, and responsible decision making) demonstrating that youths with higher severity of RRBs have greater difficulties in these areas. Further, results revealed a significant difference ($p<.05$) on six subscales of the BRIEF-2 (inhibition, self-monitoring, shift, emotional control, initiate, and working memory) indicating that participants with higher severity in RRBs have more difficulty with these components of executive functioning. High and low RRB severity groups did not differ in their scores on the WISC-V ($p > .05$), demonstrating similar cognitive abilities.

Conclusions: Results contribute to the literature in identifying specific social emotional learning and executive processes related to RRBs. Additionally, our results support previous ASD research showing a relationship between executive functions and RRBs, specifically, to inhibitory control (Mosconi et al, 2009; South et al, 2007) and working memory (Lopez et al, 2005). Findings also highlight the negative impact that RRBs have on the social and executive profiles of adolescents with ASD and support interventions targeting these behaviours, as studies show that participation in peer-initiation interventions (Lee et al, 2007) and multi-component social skills interventions (Loftin et al., 2008) lead to decreases in RRBs and increases in social engagement.

280 **175.280** The Influence of Restricted Repetitive Behaviors on the Relationship between Autism Symptom Severity and Sleep Problems in Children

M. R. Ledoux[1], *L. A. Alba*[2], *K. K. Stavropoulos*[2] *and J. Blacher*[2], *(1)Graduate School of Education, University of California, Riverside, Riverside, CA, (2)Graduate School of Education, University of California Riverside, Riverside, CA*

Background:
Many studies have documented increased sleep problems in children with autism spectrum disorder (ASD) when compared to their typically developing peers[4]. Research has reported mixed results in terms of the correlation between ASD symptom severity and increased sleep problems[3]. Specifically, some studies found that ASD severity was positively correlated with sleep problems; while others did not find this correlation[2,4]. This study examined the role of restricted, repetitive behaviors (RRBs) as a possible mediator of the relationship between sleep problems and ASD symptomatology.

Objectives:

1. Is there a difference on reported sleep problems between children with high versus low ASD severity?
2. Is there a relationship between RRBs, ASD severity, and sleep problems in children with autism? If so, do RRBs mediate the association between ASD severity and sleep problems?

Methods:

Participants included children who were screened for ASD at a university research center in the Inland Southern California. From this sample, 148 children with ASD under the age of five (M= 3.91, SD= 1.04, range 1.60-5.80) were included. Intelligence quotient (IQ) had a mean of 69.15 (17.90) with a range of 41-120. Most children were male (30 female) and 48.6% were Hispanic (23.6% Caucasian; 21.6% other; 4.1% African American; .7% Asian, 1.4% declined).

Data were collected from the following measures: Autism Diagnostic Observation Schedule—Second Edition (ADOS-2), Child Behavior CheckList (CBCL), and Social Responsiveness Scale (SRS). Sleep problems scores were derived from the CBCL t-scores. ASD calibrated severity scores (CSS)

were derived from the ADOS-2 comparison score. Participants with a CSS of 4 or 5 were considered low severity and those with a CSS of 6 to 10 were considered moderate/high severity. RRBs were determined by the Autistic mannerisms/RRBs subscale t-score of the SRS.

Results:

Correlations were conducted to examine the differences in sleep problems between participants with high and low CSS. A negative correlation was found between CSS and sleep problems (p = .04). Correlations were also conducted for RRBs, ASD severity, and sleep problems. Positive correlations were found between RRBs and sleep problems (p < .01). No correlations were found between RRBs and CSS.

To examine the possible impact of RRBs (*M*) on the relationship between CSS scores (*X*) and sleep problems (*Y*), while for controlling for IQ, internalizing and externalizing problems, a mediation Model 4 was conducted using the SPSS PROCESS plug in[1]. The indirect effect was not significant, (95% CI = [-1.33, 2.58]), such that RRBs do not mediate the relationship between CSS and sleep problems.

Conclusions:

Findings from this study add to the existing literature on sleeping difficulties in children with ASD. In particular, this study provides insight into the relationship between RRBs, sleep problems, and ASD severity. Although RRBs did not mediate the relationship between CSS and sleep problems, both RRBs and CSS were correlated with sleep problems. Moreover, this also underscores the need to consider RRBs in interventions targeting sleep problems.

281 **175.281** The Movements of Children with Autism Can be Faster or Slower Than Their Typically Developing Counterparts, Depending on the Task

S. C. Lu[1], *P. Rowe*[1,2], *C. Tachtatzis*[1,3], *I. Andonovic*[1,3], *A. Anzulewicz*[4], *K. Sobota*[4] *and J. Delafield-Butt*[1], *(1)Laboratory for Innovation in Autism, University of Strathclyde, Glasgow, United Kingdom, (2)Department of Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom, (3)Department of Electronic and Electrical Engineering, University of Strathclyde, Glasgow, United Kingdom, (4)Harimata Sp. z.o.o., Kraków, Poland*

Background: Atypical movement patterns in autism spectrum disorders (ASD) have been reported. Compared with typical developing (TD) children, children with ASD took more time to complete a point-to-point movement (Dowd et al., 2012), but adults with ASD performed faster horizontal arm swings than their typical counterparts (Cook et al., 2013). Incongruent kinematic results are common in the literature, which may imply that the kinematic features in ASD are task-dependent, but this is yet not well understood. Smart tablet gameplay has been proposed as a new paradigm to measure the movement features of ASD in young children (Anzulewicz et al., 2016). In this study, smart tablet games were employed to test for kinematic differences in autism, and the effect of the task.

Objectives: The study aims to compute the swipe kinematics during smart tablet gameplay, and to compare these characteristic movements between ASD and TD children within different gameplay contexts.

Methods: 37 ASD children (mean age: 4.5 years) and 45 age-matched TD children were recruited in the study. The children were shown two smart tablet games: “sharing” and “creativity” games. In the sharing game, the children were tasked to share the food pieces to four characters; in the creativity game, the children were tasked to select an object, trace the lines, and colour the object. Their touch trajectories on the smart tablet (iPad mini, Apple Inc.) were recorded during gameplay. The food-to-target swipes in the sharing game and the swipe gestures in the creativity game were identified using a customized MATLAB script. The travelled distance, duration, and speed of each swipe were calculated. For the sharing game, the difference between the travelled distance and the optimal distance (i.e. the straight line) was also calculated. Mann-Whitney U tests were used to determine kinematic differences between ASD and TD groups.

Results: A total of 4785 food-to-target swipes were identified in the sharing game (ASD: 1585 swipes; TD: 3200 swipes) while 6178 swipes were identified in the creativity game (ASD: 2793 swipes; TD: 3385 swipes). Significant differences between ASD and TD were observed in the sharing game that ASD demonstrated slower food-to-target swipes than TD (median of 50.12 mm/s vs. 58.84 mm/s), and that they deviated from the optimal distance more than TD (median of 3.9 mm vs. 2.59 mm). There was no significant difference in the optimal distance. By contrast, ASD showed significantly faster gestures than TD (median of 81.77 mm/s vs. 60 mm/s) in the creativity game.

Conclusions: The study compared the swipe kinematics between ASD and TD children in two smart tablet gameplay contexts. ASD demonstrated slower movement than TD in a goal-oriented food-to-target task, deviating more from the optimal trajectory. In contrast, ASD performed faster swipe gestures than TD in a relatively unconstrained creativity game. These data are the foundations to allow an understanding of how movement is controlled in autism within different contexts. Further, characterising movement features in ASD during smart tablet gameplay supports the development of algorithms that enable the early identification of ASD in serious game paradigms.

282 **175.282** The Role of the Corpus Callosum in Sensory Hyporesponsiveness of Children with Autism Spectrum Disorder

B. G. Travers[1,2], *O. J. Surgent*[1,3], *K. K. Ausderau*[2,4], *D. C. Dean*[1], *O. I. Dadalko*[1] *and A. L. Alexander*[1], *(1)University of Wisconsin - Madison, Madison, WI, (2)Occupational Therapy Program in the Department of Kinesiology, University of Wisconsin - Madison, Madison, WI, (3)Neuroscience Training Program, Univeristy of Wisconsin-Madison, Madison, WI, (4)University of Wisconsin-Madison, Madison, WI*

Background: Atypical experience of sensory stimuli is commonly reported in individuals with Autism Spectrum Disorder (ASD) (Baranek et al., 2006) and in those without ASD who have higher autism-like traits (Robertson & Simmons, 2013). However the neurobiological basis of these sensory features is unclear. The white matter integrity of the corpus callosum (CC) is a viable candidate for the neurobiological basis of atypical sensory experience as it has common reports of group differences related to ASD (Travers et al., 2012), and has been shown to have an atypical developmental trajectory in children with ASD (Travers et al., 2015). Importantly, the corpus callosum is critical for the facilitation of hemispheric synchrony, which has demonstrated a role in typical sensory experience (Ouimet et al., 2010). Therefore, the white matter integrity of the CC may potentially correspond to individual differences in sensory features both within and beyond an ASD group.

Objectives: To characterize the relationship between CC white matter integrity and degree of sensory hyper- and hypo-responsiveness in children with ASD, children with typical development (TD), and children at higher genetic risk for ASD (ASD-Related).

Methods: Seventy-four children (6-10 years old) completed a diffusion-weighted imaging (DWI) scan and sensory measures (32 children with ASD, 26 children with TD, and 16 ASD-Related children). The ASD-Related group included children with an ADHD diagnosis and children with a first-degree relative with ASD, major depressive disorder, bipolar disorder, or schizophrenia. Groups were well-matched on age (p =.30). Hyper- and

hypo-responsiveness were assessed using the parent-reported Sensory Experience Questionnaire Version 3 (Baranek, David, Poe, Stone, & Watson, 2006). Multi-shell DWI was performed on a 3T GE Scanner with a 32-channel head coil with protocol: 63 encoding directions: b=0 (6); b=350 (9); b=800 (18); b=2000 (36) s/mm^2; isotropic 1.8mm voxels: 3.6 mm thick slices with 1.8 mm overlap. Median fractional anisotropy (FA) in each of ten CC sub-regions (Genu: G1, G2, G3; Body: B1, B2, B3; Isthmus; Splenium: S1, S2, S3) was used for correlational analyses. False discovery rate (fdr) was used for multiple comparisons.

Results: Hyporesponsivity was significantly correlated in the Autism group with FA in G2 (r=.46, p=.01 [fdr]), G3 (r=.47, p=.01 [fdr]), B1 (r=.61, p<0.001 [fdr]) (Figure 1). These CC sub-regions primarily connect to the frontal lobe. In contrast, hyperresponsivity was not correlated with any sub-region in any diagnostic group.

Conclusions: More severe hyporesponsivity symptoms were associated with greater white matter integrity in the CC genu and body, although no area of the CC was associated with hyperresponsivity. These results suggest that potential overconnectivity between the left and right frontal lobes may be associated with more severe hyporesponsivity. However, follow-up analyses will examine other DWI metrics to see if these hyporesponsivity associations are consistent with greater axonal packing, myelination differences, or both. Intriguingly, the present data suggest that hypo and hyper-responsivity may have different neurobiological substrates, although this will need to be corroborated by future research.

283 **175.283** Understanding ASD Traits from a Sensory Sensitivity and Habituation Perspective

*T. Y. Podoly[1] and **A. Ben-Sasson**[2], (1)Faculty of Social Welfare & Health Sciences, University of Haifa, Haifa, Israel, (2)University of Haifa, Haifa, Israel*

Background:
Sensory symptoms, including unusual sensory seeking, over-responsivity (SOR) and under-responsivity, are recognized as core features of Autistic Spectrum Disorder (ASD). However, their interplay with other facets of the ASD phenotype (i.e., social-communication and cognitive) is yet to be understood. The Empathizing- Systemizing theory views the autistic drive to analyze and construct systems as closely related to the unique sensory perception of individuals with ASD. Sensory evidence relies mostly upon the Sensory Profile questionnaire, which inquires about the affective response to daily stimuli with some overlap with social-communication features of ASD. Our study utilized sensory questionnaires aimed to isolate different perceptual aspects of sensory symptoms and bypass overlap with other clinical features. SOR may reflect an increased reaction towards a stimulus and/or a relatively slow sensory habituation, an overlooked aspect. Lack of Sensory habituation may contribute to the functional impairment of individuals with ASD. We hypothesize that both sensitivity and habituation play an important part in explaining specific ASD traits.

Objectives: To (1) examine the relationship between different ASD traits and sensory symptoms; and (2) determine the contribution of sensory sensitivity versus slow habituation to specific ASD traits.

Methods: Eighty typical adults rated their sensory symptoms with the Adolescent/Adult Sensory Profile (AASP), Sensory Perception Quotient (SPQ) and the Sensory Habituation Questionnaire (S-Hab-Q). Autistic traits including: social skills, communication, imagination, attention to details and attention switching, were reported via the Autism Spectrum Quotient (AQ).

Results: The AQ score showed a significant moderate correlation with the AASP/SOR score (r=.36, p=.001), with the SPQ sensitivity score (r = 0.33, p = 0.003), and S-Hab-Q score (r=.45, p=.002). Among the AQ subscales, attention to details stood out by correlating with the S-Hab-Q (r=.34, p=.024) and SPQ (r=.48, p=.001), while not with the AASP/SOR scores. Interestingly, the AQ communication and imagination subscales correlated with AASP sensory under-responsivity (*r=.33, p=0.31*) and seeking scores (r=*-.33, p=.0.31*) while not with any of the SOR scores in this study (*p* ≥.49). None of the sensory scores associated with the social AQ scores (*p* >.68).

Conclusions: Our findings significantly add to the "systemizing theory" which views SOR as the underlying cause of over-focused attention. Although "attention to details" would seem to be more associated with increased sensitivity, we found that habituation and sensitivity contributed equally. When scrutinizing other sensory aspects, we found that seeking and under responsivity correlate distinctively with communication and imagination ASD traits. These sensory symptoms may tap into developmental level rather than perceptual atypicalities. This study shows the importance of using sensory tools which measure perceptual aspects of SOR. Examining these correlations in a clinical sample of ASD and combining knowledge about sensory symptoms from questionnaire and physiological data is needed to further understand these correlations.

284 **175.284** Using Sensory Processing Behaviors to Differentiate ASD and ADHD Diagnoses

K. M. Parks[1], *S. E. Schulz[2], M. Segers[3], E. Anagnostou[4], R. Nicolson[5], E. Kelley[6], S. Georgiades[7], J. Crosbie[8], R. Schachar[9], X. Liu[10] and R. A. Stevenson[2], (1)The University of Western Ontario, London, ON, Canada, (2)Western University, London, ON, Canada, (3)York University, Toronto, ON, Canada, (4)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)University of Western Ontario, London, ON, Canada, (6)Queen's University, Kingston, ON, Canada, (7)McMaster University, Hamilton, ON, Canada, (8)Psychology, The Hospital for Sick Children, Toronto, ON, Canada, (9)Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (10)Genomics, Queen's Genomics Lab at Ongwanada, Kingston, ON, Canada*

Background: Children with autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD) have overlapping issues with social communication difficulties. Social communication issues can include excessive talking, poor turn-taking during conversation, maintaining appropriate physical proximity, and poorly organized expressive language, all of which have been observed in children with ASD and ADHD. These commonalities can often impact the ability to provide accurate differential diagnoses. In addition to impairments associated with social communication, both groups show atypical sensory processing relating to difficulties in detecting, modulating, and interpreting incoming stimuli. However, the extent to which these sensory issues can inform diagnostic classifications remains unclear.
Objectives: To test whether the considerations of sensory behaviours in addition to social communication measures can improve differential diagnoses between ASD and ADHD.

Methods: Participants included children (N=207) with ASD (*n*=116, *mean age*=9.06±2.00) and ADHD (*n*=91, *mean age*=9.25±1.93) without comorbid diagnoses. Parents completed two well-established questionnaires evaluating social-communication abilities (Social Communication Questionnaire; SCQ) and sensory processing (Short Sensory Profile; SSP). Logistical regressions assessed the diagnostic predictability of each measure's individual subscales, and a follow-up hierarchical logistic regression determined if sensory processing scores improved diagnostic

prediction over and above the SCQ

Results: The SCQ significantly predicted diagnosis, with *Social Interaction* and *Restricted and Repetitive Behaviors* (*RRB)* subscales being individually predictive (see Table 1 for detailed statistics). The SSP also significantly predicted diagnosis, with *Auditory Filtering, Low Energy,* and *Visual/Auditory* subscales being individually predictive (Table 1). The first model of the follow-up hierarchical logistic regression including individually-predictive subscales of the SCQ, with SSP subscales added in the second model. Adding in sensory measures significantly improved our ability to delineate between ASD and ADHD diagnoses. There was a small increase in ***sensitivity***, with ASD diagnostic accuracy increasing from 82% to 85%, and a more substantial increase in ***specificity***, with ADHD diagnoses without ASD increasing by 11% (from 73% to 84%). This was particularly driven by the *Auditory Filtering* and *Visual/Auditory* subscales of the SSP where auditory filtering was more impaired in ADHD, and visual/auditory components of sensory processing were more impaired in ASD.

Conclusions:

Our results demonstrate that the inclusion of sensory processing measures, particularly *Auditory Filtering* and *Visual/Auditory* subscales significantly increased the ability to differentiate between ASD and ADHD diagnoses in childhood. Items on the auditory filtering subscale of the SSP measure distraction and attention, while those on the visual/auditory subscale measure sensitivities to loud sounds and bright lights, relating to hypersensitivity, a core symptom of ASD. Thus, these subscales likely tap into core features of each disorder, allowing clinicians to use scores on these subscales to differentiate between the two disorders. Our findings provide useful diagnostic information for clinicians, suggesting that only certain aspects of social communication abilities contribute to the accurate delineation of ASD or ADHD diagnoses in children, and that the inclusion of sensory measures has potential to increase diagnostic specificity.

285 **175.285** "Keep Calm and Use Context Clues": An Investigation into Interoceptive Awareness in Teens with Autism

C. Lucas[1], *K. Mahler*[2] *and C. Tierney-Aves*[2], *(1)Penn State Hershey College of Medicine, Hershey, PA, (2)Penn State Hershey Medical Center, Hershey, PA*

Background: Interoceptive Awareness (IA) refers to the level in which one notices internal physiological signals (i.e., interoceptive sensations) and shapes our emotional experience. IA underlies the ability to clearly interpret emotions such as anger, calmness, distractibility, and fear (i.e., specific affective emotions) as well as hunger, thirst, and body temperature (i.e., specific homeostatic emotions). Given that autistic teens are often reported to have difficulty with emotional regulation, and the underlying reasons for this are poorly understood, it is possible that IA is a key factor. Our hypothesis was that autistic teens will report differences in IA as compared to neurotypical controls.
Objectives: The purpose of our study was to develop a novel approach to understanding IA in teens with and without ASD in order to facilitate targeted, effective interventions for emotional regulation.

Methods: Our study consisted of a 55-item Likert Scale survey administered to autistic and neurotypical teens, assessing general IA (12 questions), specific homeostatic emotions (14 questions), and specific affective emotions (19 questions). Possible responses for all questions were never, sometimes, and frequently/always. All questions were compared between groups using a Fisher's Exact Test. A Bonferroni correction determined statistical significance, i.e., p-values <0.0009 were deemed significant.

Results: The study included 143 teens, 59 teens (41%) with ASD and 84 teens (79%) without. Autistic teens had a mean age of 14.5 years, and 75% were male. Teens without ASD had a mean age of 13.2 years, and 46% were male. Ten of the 12 items assessing general IA (83%), 4 of the 24 (17%) assessing specific homeostatic emotions, and 6 of the 19 (32%) items assessing specific affective emotions were significantly different between groups. Responses to questions assessing general IA were more likely to significantly differ between autistic teens and controls. For example, for the item, "Figuring out how I feel can be tricky," 39% of teens with ASD endorsed "frequently/always" as compared to 6% of teens without ASD ($p<0.0001$). Responses to questions assessing specific homeostatic and specific affective emotions were less likely to significantly differ between groups. To illustrate, there were no significant differences between group responses for the two items: (1)"I can wear shorts or no jacket outside … on a chilly winter day and not feel cold" ($p = 0.070$), i.e., assessing awareness of body temperature and (2)"I can feel changes in my muscles when I am angry" ($p = 0.347$), i.e., assessing awareness of anger. Open-ended and more abstract experiences appear to be challenging for teens with ASD to interpret as compared to the interpretation of IA when provided with context clues, perhaps making the experience more specific, detailed, and concrete.

Conclusions: Overall, autistic teens report differences in IA affecting interpretation of broad emotional states. This may play a key role in the emotional regulation challenges this population frequently experiences. In order to develop more robust IA, autistic teens may benefit from targeting the skills necessary to scaffold concrete details from their daily experiences onto more abstract emotional concepts, where inference and subtext analysis are required.

286 **175.286** Circumscribed Interests in Autism: Are There Sex Differences?

S. W. Nowell[1], *C. Harrop*[2] *and D. R. Jones*[3], *(1)University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)University of Texas at Dallas, Richardson, TX*

Background:
Turner-Brown et al. (2011) found that circumscribed interests (CI) in ASD were more nonsocial, less age-appropriate, less functional than the interests of typically developing (TD) peers; yet, their sample was only 5% female. Sex differences in CI may contribute to delayed diagnosis or misdiagnosis for females on the spectrum. Therefore, it is important to characterize sex differences in CI to determine if differential approaches to assessment and intervention are warranted for females and males with ASD.

Objectives:

This study aimed to replicate and extend the findings of Turner-Brown et al. (2011) by examining sex differences in parent-reported quantity, content, and functional impairment of children's interests.

Methods:

Parent responses to the Interests Scale (Bodfish, 2003) were analyzed using ANOVAs to determine diagnostic (ASD vs. TD) and sex differences between 4 groups of children ages 6-10 years: ASD Males (n=27), ASD Females (n=27), TD Males (n=16), TD Females (n=17).

The Interests Scale (Bodfish, 2003) is a parent-report measure of children's CIs. Parents indicate whether or not their child is currently or has ever

been interested in 39 common categories of interests. Then, parents write down their child's primary interest and answer seven questions about the amount of functional impairment associated with that interest. Higher ratings on these items indicate greater severity of functional impairment. Cronbach's alpha for this sample was .81 for items measuring functional impairment of the child's primary interest. Individual item internal consistency ranged from .74-.82.

Results:

Groups were comparable on the quantity of interests reported on the Interests Scale $F(1,86) = .44$, $p \leq .51$, $\eta 2 = .00$. Children with ASD demonstrated significantly more nonsocial interests $F(1,86) = 7.87$, $p \leq .01$, $\eta 2 = .08$ and had significantly greater functional impairment associated with their interests on all seven parent ratings than TD children (see Table and Figure). A significant diagnosis*sex effect was found for the number of interests in the traditionally female category of Folk Psychology with TD females having the greatest number of Folk Psychology Interests compared to the other groups ($F(1,86) = 5.20$, $p \leq .03$, $\eta 2 = .05$), followed by TD males and ASD males. ASD females had the fewest current interests in Folk Psychology and were more similar to ASD males and TD males than their TD female peers.

Conclusions:

These findings replicated the results of Turner-Brown et al. (2011) in a sample that was balanced by biological sex (51% female compared to 5%), indicating that some aspects of the content and functional impairment of CI are characteristic of the autism phenotype regardless of sex. Even if the interests themselves may be different across sexes, the impact on daily life for children and their families is the same. Regarding sex differences, there was a significant diagnosis by sex effect for the number of current Folk Psychology interests. Females with ASD demonstrated the fewest interests in this category and their interests were more closely aligned to males with ASD than to TD males or TD females supporting the "Extreme Male Brain Theory" of autism (Baron-Cohen, 2010).

287 **175.287** Deconstructing the Repetitive Behavior Phenotype in Autism Spectrum Disorder through a Whole-of-Population Analysis

M. Uljarevic[1], *M. N. Cooper*[2], *K. Bebbington*[3], *E. J. Glasson*[3], *M. T. Maybery*[4], *K. J. Varcin*[3], *G. A. Alvares*[3], *J. Wray*[5], *S. R. Leekam*[6] *and A. O. Whitehouse*[2], *(1)Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, CA, (2)Telethon Kids Institute, The University of Western Australia, Perth, Western Australia, Australia, Perth, Australia, (3)Telethon Kids Institute, University of Western Australia, Perth, Western Australia, Australia, (4)School of Psychological Science, University of Western Australia, Perth, Australia, (5)State Child Development Service, Western Australia Department of Health, Perth, Western Australia, Australia, (6)School of Psychology, Cardiff University, Cardiff, NSW, United Kingdom*

Background: Restricted and repetitive pattern of behaviors (RRB) are a cardinal feature of autism spectrum disorder (ASD), but there remains uncertainty about how these diverse behaviors vary according to individual characteristics. Firm findings in large, well characterized, heterogeneous cohorts are essential in order to advance the ASD research agenda. Therefore, the current study aimed to enhance our understanding of RRB by utilizing a unique repository of clinical data from the Western Australian (WA) Register for Autism Spectrum Disorders-a long-term prospective, population-based register of newly diagnosed cases of ASD.

Objectives: To characterize the nature of the relationship between Repetitive Motor Behaviours (RMB), Rigidity/Insistence on Sameness (IS) and Circumscribed Interests (CI) with other individual characteristics in newly diagnosed individuals with ASD

Methods: Participants (N= 2668; 18.1% females; Mage= 7.2 years [SD= 4.8]) were part of the Western Australian (WA) Register for ASD, an independent, prospective collection of demographic and diagnostic data (diagnosticians rate each of the DSM-IV-TR criteria on a 4-point Likert severity scale) of newly diagnosed cases of ASD in WA.

Results: The associations between RRB domains, indexed by Kendall's Tau, were weak, ranging from 0.00 for both CI and IS to 0.20 for IS and RMB. An older age at ASD diagnosis was associated with a lower rating for CI (OR 0.97; 95% CI 0.95,0.98) but a higher rating for IS (OR 1.05; 95% CI 1.03,1.07) and RMB (OR 1.07; 95% CI 1.05,1.09). Higher IQ was associated with lower CI (OR -3.88; 95% CI -5.26,-2.50) but higher IS (OR 3.52; 95% CI 2.13,4.91) and RMB (OR 0.55 95% CI 0.4 0.74). Male gender was associated higher RMB but not IS or CI. Higher social impairments were a significant predictor of higher severity of all three RRB domains; communication severity was a significant predictor only for CI.

Conclusions: The pattern of associations identified in this study provides suggestive evidence for the distinctiveness of RMB, IS, and CI, suggesting the potential utility of RRB domains for stratifying the larger ASD population into smaller, more phenotypically homogenous subgroups that can help to facilitate efforts to understand diverse ASD etiology and inform design of future interventions.

Poster Session
176 - Service Delivery/Systems of Care
11:30 AM - 1:30 PM - Room: 710

288 **176.288** An Ethnographic Study of the Experience of Patients with Autism Spectrum Disorder during Outpatient Encounters

S. King, *Developmental and Behavioral Pediatrics, Boston Medical Center, Boston, MA*

Background: Autism spectrum disorder (ASD) is often associated with increased rates of other comorbidities, with over 95% of patients with ASD displaying co-occurring conditions or symptoms such as gastrointestinal issues, attention-deficit/hyperactivity disorder, and sleep disturbances. The complexity of these cases often require regular treatment from a wide range of medical specialties, resulting in children with ASD utilizing a wider range of medical services with greater frequency compared to children in general. It has been reported that patients with ASD face additional barriers when accessing health care that result in many individual needs remaining unmet. In particular, over-stimulating environments, disruptive patient behaviors, and difficulties in communication between providers and patients have been cited as contributing to poor outcomes for patients with autism.

Objectives: The purpose of this study was to identify and describe barriers and facilitators to care for patients with ASD when receiving outpatient treatment in a hospital setting.

Methods: We used ethnographic methods to understand the experiences of patients with ASD and their families. Researchers followed 23 patients

and their families for the duration of their outpatient visit to Boston Medical Center, an urban safety-net hospital. All patients had a documented ASD diagnosis and were attending a regularly scheduled outpatient appointment. Extensive ethnographic fieldnotes were taken to capture all relevant features of medical visits and transcripts of these notes were coded to identify key themes and recurring patterns during patient visits.

Results:

There were 752 occurrences of barriers to care across all transcripts, representing 85 unique events or interactions. Barriers to care were distributed relatively evenly across thematic categories of Patient Behavior (29.4%), Other Hospital Factors (28.2%), Environment (27.1%), and Communication (15.3%). A majority of barriers to care occurred in the exam room (55.3%), with the distraction of caregivers or providers due to patient behavior representing a major issue (11.8% of cases). In addition to these barriers to care, 45 unique events or interactions were identified as facilitators. Most facilitators were related to Communication (42.2%) and Environment (36.4%) rather than Patient Behavior (4.4%) or Other Hospital Factors (4.4%). Like barriers, most facilitators were identified in the exam room (46.7%), with the bulk of facilitating events being patient-directed communication (28.9%) and direct caregiver participation (17.8%), including caregiver input on specific needs related to ASD (4.4%).

Conclusions:

These results suggest that the barriers to care for children with autism are diverse, spanning patient behavior, the hospital environment, communication between families and providers, and other hospital factors such as long wait times. To address these barriers, hospitals may want to focus on enhancing facilitators of care such as a sensory-friendly environment with age-appropriate toys and provider training that emphasizes patient-directed communication and attention to specific ASD-related needs. We hope that further discussion of these results will inform best practices for the outpatient treatment of individuals with ASD and guide future research in the area.

289 **176.289** A Quality Improvement Approach to Reducing Throughput Time for Pediatric Patients Presenting with a Chief Complaint of Mental Health to the Emergency Department

***A. Jhonsa**, Children's Hospital of Philadelphia, Philadelphia, PA*

Background:

Emergency department encounters for mental health concerns have been steadily rising over the past decade. Children with autism spectrum disorders have higher rates of ED utilization compared to neuro-typical peers, and of those encounters, thirteen percent were for psychiatric problems for children with ASD, compared to two percent for children without ASD (Kalb, 2012). In September of 2017, the crisis center in Philadelphia was closed, and there was a corresponding increase in volume of encounters for children with a chief complaint of mental health at the Children's Hospital of Philadelphia.

Objectives:

To demonstrate improvement in the system of care, specifically decreased length of stay in the emergency room of a large pediatric emergency department for patients being seen for a chief complaint related to mental health.

Methods: In collaboration with the triage team, the primary medical team, and social work, the psychiatry emergency department consult group undertook a quality improvement effort to identify redundant efforts and to streamline the process of care. The team identified the baseline process of triaging patients and requesting social work and psychiatry consults. Utilizing PDSA cycles, interventions for reducing the time to consult, and discharge were identified.

Results: Baseline data from 2017 showed an average length of time from triage to discharge of 391 minutes per patient presenting with a chief complaint of mental health among a total of 1,599 patient encounters. Based on the quality improvement efforts, the team identified duplication of efforts during the admitting process- patients were being seen by the triage team, the primary medical team, the social work team, and the psychiatry team. The psychiatry team was also duplicating efforts of the social work team in documentation. The team developed a mental health track board through which members of the social work team and psychiatry team could immediately be notified when a patient presented with a chief complaint of mental health, and could begin the evaluation process immediately. A process for streamlining documentation was also implemented to reduce duplication of efforts between the psychiatrist and social worker. These changes resulted in a 21% reduction in average time to discharge from 391 minutes in 2017 to an average of 308 minutes among 2,753 patient encounters in 2018. The reduction in median time was 30%, from a median time of 354 minutes per encounter to 250 minutes per encounter.

Conclusions:

Close collaboration among ED clinicians that reduce redundant processes can significantly decrease the time to discharge for patients presenting to the ED with mental health needs. This is particularly important for patients with ASD who are presenting more frequently to the ED, and are presenting more frequently for psychiatric emergencies, and for whom ED encounters are particularly challenging and stressful.

290 **176.290** Implementation of "Patient Behavioral Debriefings" in a Medical Behavioral Unit to Improve Care for Behaviorally Complex Patients, Including Patients with Autism Spectrum Disorders

***D. DeBrocco**, Children's Hospital of Philadelphia, Philadelphia, PA*

Background: Post-event debriefings are a foundational behavior of high performing clinical teams (Sawyer T et al, J Perinatology, 2016). A solid literature base supports the utility of such facilitated discussions of significant clinical events for educational and quality improvement purposes. Debriefing as a post-experience analytic process of learning has a well-documented impact on bettering patient care, improving teamwork, elevating communication efforts, upgrading organizational systems, equipment and resources, supporting emotional processing of participants, and educating providers. As adult learning theory highlights that educational efforts are most effective when a topic is both relevant and carries emotional impact (Edelson DP, Arch Intern Med 2008; Fanning RM, Simul Healthcare, 2017), serious, unexpected, traumatic, and ineffective patient care events are important learning opportunities.

Objectives: To implement post-event debriefings in a Medical Behavioral Unit (MBU), a 10-bed inpatient medical unit at Children's Hospital of Philadelphia (CHOP), to enable iterative improvements to patient care.

Methods: The Medical Behavioral Unit provides care and support to behaviorally complex patients with medical needs. To develop a systematic approach to debriefing behavioral events, the CHOP debriefing tool for medical events was adapted to identify a consistent process and approach

to debriefings after patient behavioral events. This tool for debriefings, was implemented in February 2017 focusing on setting a collaborative tone and clear format for interdisciplinary discussion and improvement in patient care.
Results: The multi-disciplinary team, which includes Psychiatrist/ Psychiatric Nurse Practitioner, General Pediatric Hospitalist, Pediatric Acute Care Advanced Practice Provider, Nurses, Psychologist, Social Workers, Case Management, Child Life, Board Certified Behavior Analysts, Senior Nurse Aide, and Psychiatric technicians, now regularly debrief patient behavioral incidents in the MBU. This has led to rapid and highly individualized changes to care plans for MBU patients, whether a change in medication, or a team-wide change in how to approach the patient. The debriefings have enabled the entire team to more accurately understand patient needs and triggers and to adapt to those needs across disciplines. The debriefings have also led to more general changes in practice, for example the establishment of weekly scheduled meetings to discuss the ongoing care plans for long length of stay patients, and the development of consistent daily schedules to support patients with scaffolding and managing expectations. The consistency of schedule and the ongoing adjustments to care plans have been particularly helpful in supporting patients with autism spectrum disorders who benefit from structured routine, and have highly individualized behavioral triggers and needs. To date there have been 35 debriefings completed on the MBU since February 2017 on 23 unique patients.
Conclusions: The new model of debriefing in the Medical Behavior Unit where post-event inter-professional discussion leads to immediate changes in plans of care related to behavioral support, provides a mechanism for continuous review of unit processes and best practices, and has led to improved patient outcomes for children with ASD and other behavioral needs.

291 **176.291** The Medical Home and Its Predictors in Children with Autism Spectrum Disorder, Other Developmental Disabilities, and in the General Population

ABSTRACT WITHDRAWN

Background: The American Academy of Pediatrics recommends care in a medical home as the model for pediatric care. Receiving care in a medical home is associated with less delayed care and few unmet health care needs. While previous studies report that children with autism spectrum disorder (ASD) are less likely to receive care in a medical home than those without ASD, further study is needed to understand the predictors of having a medical home in children with and without ASD.
Objectives: We used data from the Study to Explore Early Development phase 2, a US multi-site case-control study of children 3-5 years old, to compare the percentages and assess predictors of having a medical home among children with ASD (n=769), other non-ASD developmental disabilities (DD, n=806), and the general population (POP, n=750).

Methods: Data on children's health and service utilization were collected via a maternal-reported form, which included information on five medical home components: 1) child has a usual place for care, 2) child has one or more personal doctors/nurses, 3) receipt of family-centered care (based on mother's experience with providers), 4) obtaining referrals for specialty services if needed, and 5) receiving help for child's care coordination if needed. A child was classified as having a medical home if the mother endorsed all applicable medical home components for that child (e.g., some children did not need referrals or care coordination). We compared odds of medical home between the three study groups adjusting for sociodemograhics, child health and developmental characteristics, and maternal health conditions using logistic regression. We also assessed predictors of having a medical home in logistic regression models stratified by study group.

Results: The percentage of children with a medical home was 46.3%, 52.0%, and 69.5% for ASD, DD, and POP, respectively. Compared to POP, the odds of having a medical home were lower in children with ASD (adjusted odds ratio [aOR]=0.65 [95% CI: 0.48-0.89]) and DD (aOR=0.65 [0.51-0.83]). These differences between ASD, DD versus POP were mostly attributable to three medical home components: referrals; care coordination; and family-centered care. Among the POP group, older maternal age and non-Hispanic white race were positively associated with medical home, while child cognitive score <70, sleep problems, and internalizing behaviors were inversely associated with medical home. In the ASD group, non-U.S. maternal birthplace and child internalizing behaviors were inversely associated with medical home. In the DD group, low family income, child internalizing behaviors, and mother diagnosed with ADHD were inversely associated with medical home.

Conclusions: Children with ASD or DD were less likely to receive care in a medical home than POP children. The predictors of having a medical home varied between study groups. Moreover, despite assessment of numerous child and maternal characteristics, we found only a few associations between medical home and individual-level variables in children with ASD or DD. These results suggest that additional research on other factors, including those related to the healthcare system globally, could inform ways to improve medical home access in children with ASD or DD.

292 **176.292** Service Use in Preschool Children with Autism Spectrum Disorder and Associations with Insurance Status

E. Rubenstein[1], *L. A. Croen*[2], *L. C. Lee*[3], *E. Moody*[4], *L. Schieve*[5], *G. N. Soke*[5], *K. Thomas*[6], *L. Wiggins*[5] *and J. Daniels*[7], *(1)Waisman Center at UW Madison, Madison, WI, (2)Division of Research, Kaiser Permanente, Oakland, CA, (3)Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)University of Colorado, Denver, Aurora, CO, (5)Centers for Disease Control and Prevention, Atlanta, GA, (6)University of North Carolina Chapel Hill, Asheville, NC, (7)University of North Carolina at Chapel Hill, Chapel Hill, NC*

Background:
ASD-related services can improve outcomes for young children with ASD but little is known about patterns of service receipt in young children. Further, insurance type may effect which services are received outside of school settings. Children may be on federally funded insurance programs ('public'), employer or personally paid for insurance ('private') or through specific service waiver be enrolled in both programs ('both'). Insurance may cover speech therapy, occupational therapy, behavior therapy, medication, social skills training, respite care, physical therapy, and some complementary and alternative medicines and treatments.

Objectives: To describe amount and type of services used among children age 3-5 years with autism spectrum disorder (ASD) and examine differences across health insurance status (public, private or both).

Methods: We used data on children with past ASD diagnosis in the Study to Explore Early Development, a US community-based study of neurodevelopment conducted between 2012-2016. Mothers reported child insurance status and service use at study entry. We estimated prevalence ratios for cumulative service use and odds ratios for each service type overall and by insurance status for out-of-school and both in- and out-of-school services combined using log-Poisson regression. In adjusted analyses we included maternal education, family income, number

of children in the household, and child year of birth to control for confounding.

Results: Of 803 children with past diagnosis of ASD, nearly 40% of children were not receiving out-of-school services at time of study entry. The most common out-of-school services were speech therapy and occupational therapy. In the sample, 34.7% were on public insurance, 50.6% were on private insurance, and 13.3% had both insurances. Children with public insurance had less total services than children with private or both insurances; however, after adjustment for socioeconomic and demographic confounders, children with private insurance alone received fewer out-of-school services than children with public insurance alone (prevalence ratio: 0.83, 95% confidence interval: 0.71, 0.97). Children with public insurance alone were least likely to receive out-of-school behavioral therapy and most likely to receive psychotropic medication compared to other insurance status. Total number and type of service use was similar between insurance statuses for combined in- and out-of-school services.

Conclusions: We found that while most preschool age children received at least one ASD-related service, many did not receive out-of-school services, especially behavioral therapy. Children on public insurance only were more likely to receive medication and less likely to receive behavioral therapy compared to children with any private insurance. Because receiving adequate service is important for young children with ASD to receive optimal outcomes, targeting policy and practice to improve the availability of evidence-based services to children in all types of insurance programs may improve service use and lead to improved outcomes.

293 **176.293** Shortage of Community Mental Health Clinicians Trained to Treat Autistic Adults

B. B. Maddox[1]*, S. R. Crabbe*[1] *and D. S. Mandell*[2]*, (1)University of Pennsylvania, Philadelphia, PA, (2)Center for Mental Health, University of Pennsylvania, Philadelphia, PA*

Background: Autistic adults with co-occurring psychiatric conditions often do not have access to quality mental health services in their communities, in large part because few community mental health clinicians are trained to work with autistic adults. Improving access to quality mental health services will require increasing clinicians' knowledge about and confidence in adapting their clinical practice for this population. Little is known about how to best train community mental health clinicians to effectively treat autistic adults with co-occurring psychiatric conditions.

Objectives: To gather information about community mental health clinicians' knowledge of, skills in, and confidence in treating autistic adults, in order to inform a training program for clinicians working with this population.

Methods: One hundred community mental health clinicians who work with adults in an urban setting completed an online survey (see Table 1 for demographic information). The survey was described as designed to elicit clinicians' opinions of outpatient therapy methods, without specific mention of autism, in hopes that clinicians with a wide range of experiences with autistic clients (i.e., even those with little to no experience) would participate. Participants answered questions about their clinical experience with autistic adults and their prior autism training. Participants also completed a measure of their confidence in working with autistic adults, using an adapted version of the Therapist Confidence Scale-Intellectual Disabilities (TCS-ID).

Results: Most respondents (70%) indicated that they had no autistic adults on their current caseload, although 60% reported some experience providing mental health services to an autistic adult. Most participants (76%) had not received any formal training (e.g., CE workshop, graduate school coursework) in working with autistic adults. Almost all (96%) respondents indicated that they would likely attend such a training if it were offered through their agency. On average, clinicians reported feeling only "slightly knowledgeable" about treating autistic adults. On a scale ranging from 1 (not at all confident) to 5 (extremely confident), clinicians reported significantly less confidence treating autistic adults (M = 2.65, SD = 1.00), than treating adults without autism (M = 3.71, SD = .76), $t(99) = -9.98$, $p < .001$.

Conclusions: This study highlights the need for training to increase community mental health clinicians' knowledge and confidence related to working with autistic adults. Better understanding the current landscape of community mental health services for autistic adults is crucial for future development of provider training programs. Most clinicians expressed a desire for more training in mental health interventions for autistic adults. However, one challenge is that most clinicians do not currently have an autistic adult on their caseload, which could limit the real-time practice of skills learned in a training program.

294 **176.294** The Impact of Intellectual Disability on the Health Service Utilization of Middle Aged and Older Adults on the Autism Spectrum

L. Bishop-Fitzpatrick[1] *and E. Rubenstein*[2]*, (1)University of Wisconsin - Madison, Madison, WI, (2)Waisman Center at UW Madison, Madison, WI*

Background: Preliminary evidence suggests that autistic adults live shorter lives and have more physical and mental health problems compared to the general population. Since so little is known about the larger population of middle aged and older adults on the autism spectrum, it is imperative to leverage existing population-level data to characterize their health service utilization to inform individual and systems-level prevention efforts that can help people on the autism spectrum live long, healthy, and self-determined lives in their communities.
Objectives: This study describes the health service utilization of a unique sample of all middle aged and older Wisconsin Medicaid beneficiaries with an identified autism spectrum disorder diagnosis and tests differences between those autistic adults with and without co-occurring intellectual disability (ID).

Methods: Participants were 143 middle aged and older autistic adults aged 40-88 with two or more Medicaid claims for an ICD-9 code corresponding to an autism spectrum disorder on two different days with (N=64) and without ID (N=79). We examined service claims from all providers (inpatient, outpatient, long-term care, home health, and dental) for service use and physical and mental health conditions between 2012-2015. We categorized service use based on service type and tested differences between autistic adults with and without ID in frequency and type of service use. We categorized physical and mental health conditions based on an established system for grouping ICD-9 codes (Croen et al., 2015) while also presenting prevalent individual conditions.

Results: Autistic adults had, on average, 176.4 (SD=220.6) claims during the four-year study period. In the full sample of autistic adults with and without ID, 66.4% had dental, 43.9% had outpatient, 32.9% had inpatient, 13.3% had home health, and 7.7% had long-term care claims. Findings indicate that autistic adults with ID were more likely to have dental (X^2=7.1, P=0.008) and home health (X^2=7.4, P=0.007) claims compared to adults without ID. Many physical and mental health problems, including immune (70.6%), cardiovascular (49.0%), sleep (85.3%), gastrointestinal (49.7%), neurologic (55.9%), and psychiatric (72.0%) conditions were highly prevalent in our full sample. When comparing odds of the categorized

conditions between those with and without ID, we saw increased but not statistically significant odds of neurologic and gastrointestinal conditions and decreased but not statistically significant odds for immune, cardiovascular, and psychiatric conditions in middle aged and older adults on the autism spectrum with co-occurring ID.

Conclusions: This is the first US study to use claims data to characterize the health and health service utilization of middle aged and older adults on the autism spectrum with and without intellectual disability. Our findings suggest that people on the autism spectrum have a high prevalence of health problems in midlife and old age, regardless of intellectual disability status. However, autistic adults with ID were more likely to have received dental and home health care. While more research is needed to confirm these findings and understand mechanisms, our results underscore the importance of prevention for high prevalence of physical and mental health problems in autism at the individual and systems level.

295 **176.295** A Novel Approach for Building Clinical Capacity of Pediatric Providers in Rural and Underserved Communities Predominantly Serving Native American Populations in the Southwest.

C. Burnette[1], *A. Curran*[2], *A. Del Fabbro*[1], *E. Geib*[1], *D. Daniels*[1], *L. King*[1] *and K. Sohl*[3], *(1)Pediatrics, Center for Development and Disability, University of New Mexico, Albuquerque, NM, (2)Thompson Center for Autism, Columbia, MO, (3)Thompson Center for Autism, University of Missouri - School of Medicine, Columbia, MO*

Background: ECHO Autism and ECHO Autism STAT are novel approaches for building provider capacity to treat patients with Autism Spectrum Disorder (ASD) in rural and underserved communities. Developed by clinicians and researchers at the University of Missouri Thompson Center, these approaches connect rural primary care providers (PCPs) to an interdisciplinary team of ASD experts at a university setting. Their impact has led to increases in PCP self-efficacy in managing patients with ASD and in early identification of symptoms using validated screening tools (Mazurek, et al., 2017; 2018). Through funding from the Autism Treatment Network (ATN)/Autism Research Intervention for Physical Health Network (AIR-P), both ECHO approaches have been implemented in New Mexico and Northern Arizona since January 2017.

Objectives: The objective of this project was to review the feasibility of and challenges associated with implementing the ECHO Autism and ECHO Autism STAT approaches with providers in rural and underserved areas of New Mexico and Northern Arizona.

Methods: The ECHO programs were designed for PCPs and included biweekly, 90-minute virtual clinics using zoom technology. Clinics focused on case presentations and included a standard, brief didactic curriculum about autism screening and identification, medical and behavioral management, and evidence-based intervention. ECHO Autism included training on the M-CHAT-R/F, while ECHO Autism STAT added a two-day training on the *Screening Tool for Autism in Toddlers (STAT*) and ECHO Autism STAT diagnostic model.

Results: Implementation of ECHO Autism and ECHO Autism STAT revealed challenges in three areas: recruitment, provider engagement, and operational efficiency. Recruitment was more time-intensive than anticipated. We contacted clinic managers, disseminated printed and electronic brochures, and presented at a local conference. The most effective method was in-person presentations at staff meetings by professionals of similar training background. Involvement of clinic administration was critical for provider engagement due to the potential impact on patient scheduling. The day, time, duration, and frequency of the clinic were chosen to minimize impact on scheduling and optimize provider availability. Clinician engagement was maximized when they presented their own cases and shared knowledge with participants experiencing similar challenges. Follow-up documentation of recommendations and resources provided targeted and concrete action items. Resource constraints limited implementation of some recommendations, such as access to community interventions. . Operationally, the efforts of the ECHO clinic coordinator proved invaluable for supporting operations and responsive communication between all parties. Centralizing information in an online platform offered consistent communication between everyone, as well as easy access to information discussed during the clinics. Due to the rural nature of several practices, we experienced difficulties with internet connectivity to utilize the online platform and video technology.

Conclusions: Implementation of ECHO Autism and ECHO Autism STAT proved feasible, but highlighted important considerations that will benefit others who are considering this model for their communities. These extra efforts, though substantial, can positively impact patient care within rural and underserved communities, and may be applicable to other communities who face similar challenges as those in New Mexico and Northern Arizona.

296 **176.296** Evaluating Feasibility and Acceptability of Echo Autism in India: A Telementoring Model to Build Physician Capacity in Diagnoses and Management of Pediatric ASD.

K. Sengupta[1], *L. Lobo*[2], *V. Krishnamurthy*[2] *and K. Sohl*[3], *(1)Ummeed Child Development Center, Mumbai, Maharashtra, INDIA, (2)Ummeed Child Development Center, Mumbai, Maharashtra, India, (3)Thompson Center for Autism, University of Missouri - School of Medicine, Columbia, MO*

Background:

A significant treatment gap exists in Low and Middle Income Countries (LMICs) for children with Autism Spectrum Disorder (ASD). Often, delayed age of diagnosis in LMICs (Samms-Vaughan,2014) translates into loss of access to intervention in the crucial early years. Potential contributors to delays in diagnoses include physician related factors- limited physician knowledge about ASD, incorrect beliefs about efficacy of therapy and long waiting lists. Additionally, both psychiatric (e.g. ADHD, Anxiety, OCD) and medical co-morbidities (e.g. constipation, sleep issues) are significantly over-represented in children with ASD requiring physician knowledge about addressing them simultaneously. Possible solutions include training professionals in diagnoses and management of ASD and co-morbidities.

Objectives: To evaluate the acceptability and feasibility of ECHO Autism-a tele-mentoring model to increase physician access to best-practise care for children with ASD, piloted in Mumbai, India.

Methods: The Extension for Community Healthcare Outcomes (ECHO) framework shown to be effective in improving self-efficacy and ASD specific practice parameters of primary care physicians in the U.S.A. (Mazurek,et al.,2017) was culturally modified and utilized for the current study. A “hub” team of multi-disciplinary experts at a child development center in Mumbai was connected by secure video-conferencing technology to the “spokes”- 27 primary care and developmental pediatricians, psychiatrists and neurologists working with children with ASD across India, Sri Lanka, Bangladesh, Nepal, Iran and Bahrain who chose to participate in the pilot. Baseline survey revealed that 87% of participating physicians “wanted to learn more about autism” and “81% “desired more confidence in ability to identify and manage ASD”. Over the course of 8 bi-weekly sessions, participants learnt through discussion of cases from their own practice, peer feedback and didactic modules. Content included best practice

methods in screening, early diagnoses of autism, principles of intervention, management of challenging behaviors, psychiatric and medical co-morbidities and involving families in care. Primary outcomes evaluated included participant acceptability of the content and delivery process. In addition, feasibility was evaluated by considering participant attendance, retention rates and changes in knowledge and self-efficacy.

Results:

Participants represented a broad geographic reach spread across 18 cities in 6 Asian countries.17 participants (63%) attended ≥ 75% of the sessions (7-8/8) with average attendance per session being 19.87 (Range 17-24). On a scale of 1-5, participants rated the course as highly satisfactory (*M*=4.34, SD =0.64). Participant knowledge increased on completion of the course (Pre-test *M*= 48.5, SD=12.89; post-test *M*=58.0, SD=12.71; *Z*= -2.56, p=0.01). Total self –efficacy scores as measured by a self-reported questionnaire (Mazurek,et al,2017) adapted to the Indian pilot improved significantly from the pre-test (*M*= 83.8, SD=22.87) to post-test (*M*=120.5, SD=25.59; *Z*= -3.86, p=0.0001) on a Wilcoxon Signed –Rank test. Qualitative feedback from participants emphasized need for videos and demonstration of live cases and information about intervention strategies.

Conclusions: The ECHO Autism model improved physician knowledge and self-efficacy in diagnoses and management of ASD in LMICs in Asia, potentially impacting many underserved communities across these sites. While acceptable and feasible in its current format, further context-specific adaptations to meet the unique needs of physicians practicing in low resource settings are explored.

297 **176.297** Extension for Community Health Outcome (ECHO) Autism - Uruguay: A Coordinated Strategy to Improve Access to Health Care for Children with Autism Spectrum Disorders.

G. Giachetto[1], *A. Casuriaga*[2], *A. Santoro*[2], *K. Sohl*[3], *V. Kanopa*[2] *and G. Garrido*[2], *(1)Pediatria, Universidad de la Republica, Montevideo, Uruguay, (2)Universidad de la República, Montevideo, Uruguay, (3)Thompson Center for Autism, University of Missouri - School of Medicine, Columbia, MO*

Background: Uruguay provides universal healthcare through an Integrated National Health System with public and private providers. Although in recent years this system has contributed to improving the health of children, the special care required for children with neurodevelopmental disorders presents difficulties including delays in early diagnosis and lack of access to autism specialists and rehabilitation services. Children with developmental concerns and/or autism often have long waits to see a specialist and receive services. In 2014, the Universidad de la República partnered with Project ECHO at University of New Mexico Health Sciences Center (UNMHSC) to use this model to increase capacity to evidence based medicine in Uruguay. Project ECHO is an innovate framework that uses multipoint video-conferencing to support community physicians and practitioners through case based learning via an "all teach, all learn" approach. ECHO is a cost effective mechanism to improve access to health care for conditions like autism. A multidisciplinary team including pediatricians, neuro-pediatricians and child psychiatrists started the ECHO Autism program in Uruguay in 2015. The goals of ECHO Autism Uruguay include increasing community physician knowledge about identification of symptoms of autism and treatment of autism in the community.

Objectives: To share the experience of the ECHO Autism program in Uruguay during the first three years of implementation, including analysis of case presentations and participates self-perception of skills and knowledge gained.

Methods: Analysis of ECHO Autism clinics from June 12, 2015 to June 8, 2018 including clinical cases presented and participant's self-perception of changes in skills and competences. The following skills and competencies were assessed: identifying developmental delay including autism before age 3, autism diagnosis, support family needs, comorbidity management, psychopharmacology, resource attainment and interprofessional communication.
